Evaluation: The evaluation of the automatic mapping was done by one of the authors (clinician LMR). The unmatched set of strings was analyzed to detect those that should have found a match and did not. Two mapping errors were found: ***"codeine"*** and ***"chlorpheniramine"*** mapped to two unrelated ingredient names with the highest score of 100. (These errors were reported to and corrected by the RxMix team). Overall, the method had a 0.99 precision, 0.97 recall and 0.98 F1-measure. The manual evaluation was performed by only one clinician.

Conclusions: The results demonstrate that simple NLP methods that use the existing free RxNorm API can be used to convert free text medications records into RxNorm concepts. Coded concepts offer researchers better data queries that can utilize drug class hierarchies and outperform the existing free-text search. The quality of the mapping using the automated string matching is excellent provided the total number of input strings with only two mapping errors (employing also the above score filters). Although the approximate matching function of RxMix was primarily developed to support matching of clinical drug names, not ingredients alone, we found it useful in the context of this experiment where our input data had various degrees of specification.

Implementation of a mobile communication application to enable secure electronic access and exchange of patient health information.

Taisha Y. Roman, MD, MPH, Allen Hsiao, MD, FAAP
Yale School of Medicine, New Haven, CT

Introduction

Alphanumeric pagers are the preferred mode of communication in many institutions because they allow providers to communicate pertinent patient information quickly over a secure hospital network.[1] However, these pagers do not satisfy current security recommendations for mobile devices used to transmit personal health information (PHI). The current recommendations call for the use of data encryption, user authentication, and remote disabling features.[2] Studies have also shown that the use of pagers can lead to medical errors if relayed lab results are erroneously reported.[3] In an attempt to ensure accurate and secure exchange of personal health information, we have piloted a mobile communication application that enables efficient communication between physicians and allows mobile access to important patient information such as lab results.

Methods

A secure mobile communication application (Mobile Heartbeat,™ Woburn, MA) was implemented in the pediatric and adult emergency rooms. The application was placed on preprogrammed mobile phones with passcode protection, remote disabling capability, and two-way encryption at rest and in transit. Shared devices were placed in a common area in each department. Providers were assigned a device at the start of their shift and returned it when the shift was completed. Anonymous pre and post implementation surveys were used to evaluate the application.

Results

A total of 60 providers completed pre and post implementation surveys. The implementation of Mobile Heartbeat decreased the use of unsecure modes of communication. Pager use during shifts decreased from 53% to 38% and the use of personal cellphones decreased from 22% to 10%. The application also improved communication, making it easier to contact providers within the department (24% found it easy prior to implementation vs 75% post implementation) and outside of the department (16% found it easy prior to implementation vs 45% post implementation). The device was well received by providers; 77% of users believed that mobile heartbeat improved workflow and 77% believed that it improved patient safety.

Discussion

Although alphanumeric paging is an efficient means of communication between physicians, studies have shown that it can pose a risk to patient privacy and patient safety.[3] Current mobile technology enables secure, efficient exchange of personal health information without compromising patient care. Our institution implemented a secure mobile communication application in the pediatric and adult emergency departments in order to reduce unsecure exchange of PHI and improve communication among providers. This application decreased the use of unsecure methods of communication such as personal cell phones and alphanumeric pagers. There was also a perceived improvement in communication, workflow, and patient safety. The results of our pilot show that secure mobile communication technology is a viable alternative to the alphanumeric pagers currently being used in most healthcare institutions.

Lessons Learned Bringing Public Health into the Primary Care Clinic through an EHR-based Application

Caryn Roth, MPH[1], Randi E. Foraker, PhD[2], Marcelo A. Lopetegui, MD, MS[1], Philip R.O Payne, PhD[1]

[1]Department of Biomedical Informatics, College of Medicine [2]Division of Epidemiology, College of Public Health, The Ohio State University Columbus, OH

Abstract

We developed an application embedded in the EHR to incorporate prevention guidelines into primary care clinics. The dynamic visualization facilitates patient-provider communication and motivates behavior change to improve health. We discuss the development and usability challenges involved in deploying such a tool, as well as strategies to overcome these issues.

Introduction

Chronic diseases disproportionally burden the healthcare system, and in order to tackle them successfully, we must shift our focus to disease prevention, rather than treatment. We aimed to develop and validate a personalized and interactive health visualization module in order to enhance communication between healthcare providers and patients to promote cardiovascular health (CVH) and prevent or manage cardiovascular disease.

Methods

By leveraging data visualizations and relying on tight integration with our commercial electronic health record (EHR), we designed SPHERE (**S**troke **P**revention in **H**ealthcare Delivery **E**nvi**R**onm**E**nts), a data-driven risk assessment instrument that enables seamless point-of-care interactive risk profiling for primary care physicians and their patients. We employed a composite CVH score, modified from the AHA's *Life's Simple 7*™ prevention campaign, and designed an interactive visualization tool to engage patients and improve patient-clinician communication. We piloted SPHERE among academic medical center primary care providers serving an urban, low socio-economic status patient population and catalogued strategies and solutions to successfully deploy such a tool.

Results

The final tool met all the specified requirements: we created an EHR-integrated application that leverages existing clinical data to provide a real-time representation of the patient's CVH status, and promotes discussion between healthcare providers and patients. Moreover, the interactivity feature provides immediate feedback about the impact of individual behavior changes on CVH.

Discussion

Automating health profiling and displaying visual cues to patients and physicians within the EHR may promote behavior change and improve cardiovascular health across our entire patient population. The informatics and public health lessons we uncovered while evaluating and refining SPHERE are critical to the success of such interventions. In addition to modifying the tool to be clinically relevant for our physicians, we uncovered issues relating to data capture in the EHR, technical differences across our academic medical center, and usability and workflow obstacles. While challenging, harmonizing clinical practice, public health, and information systems for such purposes can truly impact healthcare delivery and patient outcomes. Our tool is one example of how we can harness the power of the EHR to bring evidence-based public health interventions into primary care clinics, reduce risk for chronic disease and conserve valuable healthcare resources.

The Use of Multiple Emergency Department Reports per Visit for Improving the Accuracy of Influenza Case Detection

Victor M. Ruiz, BS[1], Ye Ye, MS[1], Amie J. Draper, BS[1], Fuchiang (Rich) Tsui, PhD[1]
[1]Real-time Outbreak and Disease Surveillance Laboratory, Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA

Abstract*: This study assessed the diagnostic accuracy of probabilistic Bayesian models that detect influenza from one or multiple emergency department (ED) reports per visit. We extracted clinical findings from ED reports using two natural language processing (NLP) tools. We measured and compared the area under the ROC (AUROC) curve of existing models applied to single and multiple ED reports per visit respectively, and found that using multiple reports per visit increased the detection performance significantly (p<0.01).*

Introduction: ED reports document the care received by patients in the ED, and contain clinically relevant information including medical history, medications, clinical findings, and ED course. Recent studies demonstrated that ED reports improve influenza detection performance over chief complaints.[1] Those studies used one ED report per visit. However, in ED practice, multiple reports exist for one visit due to multiple clinicians (e.g., residents, attending physicians) seeing one patient and/or one clinician dictating/writing multiple (supplemental) reports. To the best of our knowledge, no previous research studied the impact of using single vs multiple ED reports per visit on the performance of influenza detection. We hypothesize that the use of multiple ED reports per visit improves the accuracy of influenza detection through the collection of more clinical findings across multiple reports over time.

Methods: We used the Topaz[2] and MedLEE[3] NLP tools to extract 31 clinical findings from free-text ED reports, retrieved from electronic health records of 11 hospitals in Allegheny County, Pennsylvania. Those findings were selected by board-certified physicians as relevant for the diagnosis of influenza, and served as input to existing Bayesian network (BN) models for influenza detection.[4] These models share a static, expert-defined structure and were trained using one report per visit. They differ in the NLP tool used to extract clinical findings from training data.

When incorporating data from multiple ED reports per visit, it is possible to find contradicting mentions of clinical findings. We used two rules to resolve conflicts and evaluated the performance of the BN models for each rule. First, we assigned a 'True' value to findings with at least one positive mention. Alternatively, we used the value of the most recent mention of each finding.

To assess the contribution of using multiple ED reports per visit for the detection of influenza, we compared the AUROC of the BN models using the first available ED report for each visit to the AUROC of the same models using multiple reports. The testing dataset included 131 polymerase chain reaction (PCR)-confirmed influenza cases and 1179 randomly selected controls, from January 1, 2011 to June 30, 2013.

Results: BN models achieved the highest accuracy using the most recent finding values as conflict resolution rule, independently of the selection of NLP for finding extraction. With MedLEE, the AUROC increased to 0.90 (95% CI 0.87-0.93) from 0.86 (95% CI 0.83-0.90) when using multiple vs single ED reports per visit ($p < 0.01$). With Topaz, The AUROC increased to 0.91(95% CI 89-0.93) from 0.88 (95% CI 0.85-0.91), with $p < 0.01$.

Conclusion: The contribution of using multiple ED reports per visit to the diagnostic accuracy of influenza detection models was statistically significant. This indicates that updating the influenza probability estimation with the latest data can improve the accuracy of case detection systems (CDSs). Future work will assess if diagnostic accuracy can be further improved by using additional findings.

Background:

Adoption of Computerized provider order entry (CPOE) with embedded clinical decision support (CDS) has been a promising vehicle to improve quality and consistency of care, better cognitive workload, reduce errors, increase adherence to evidence-based knowledge guidelines. Clinical decision support (CDS) includes a group of computerized functions such as reminders, alerts that provide knowledge to clinicians to enhance health care. A mainstay of CPOE systems are order sets, a grouping of orders, related to a specific diagnosis or symptom, used by providers to create orders that are clinically related.

In our study, we chose to look at a unique CDS scenario that occurred in our Electronic Medical Record (EMR) system that allowed us to compare 2 types of CDS alerts ("hard" stop and "smart" stop alerts) in the same clinical workflow situation. As we went live with the EMR system, we embedded a Venous Thromboembolism (VTE) prophylaxis order set as a subset (VTE Subset) of ALL inpatient order sets in CPOE. In order to make sure a VTE order was selected, the system had a hard stop that required providers to order from the VTE Subset. Physicians could not proceed in their orders until they addressed VTE prophylaxis, even if documented previously, i.e. a provider might encounter several such hard stops, even if the patient had an active order for VTE Prophylaxis. At a later stage we changed the alert to a "smart" stop. The VTE Subset was still linked to all inpatient order sets, but no longer required a mandatory stop. It was based on a rule engine algorithm that only alerts providers of missing VTE prophylaxis on exiting an order set or on entry to the CPOE module. We hypothesized that the smart stop subset would influence prescribers to use order sets embedded in CPOE in greater numbers and in addition to gain better adherence to VTE prophylaxis guidelines as opposed to the hard stop subset.

Methods:

Study design and Locations: This is a retrospective, quasi experiment one group pre post study conducted on all inpatient admissions in two major tertiary hospitals in North Shore LIJ Health System: Long Island Jewish Hospital in Lake Success, New York and North Shore University Hospital in Manhasset, New York. Long Island Jewish Hospital: 63,000 admission With T1 (Hard stop VTE subset) from 04/11/2011 to 02/28/2012 and T2 (smart stop VTE subset) from 04/11/2012 to 02/28/2013; North Shore University Hospital:33,000 admissions With T1 (Hard stop VTE subset) from 10/15/2011 to 02/28/2012 and T2 (smart stop VTE subset) from 10/15/2012 to 02/28/2013.

Variable: The main outcome is to determine the difference in number of times VTE prophylaxis was utilized among all hospitalized patients in two tertiary hospitals using a smart stop VTE in comparison to a hard stop VTE subset. The secondary outcome was to measure the difference in number of times VTE prophylaxis was utilized using VTE diagnostic Order set or subset vs. individual orders from main order catalog among the same population in order to evaluate CPOE efficiency. Compliance criteria were met if at least one VTE prophylaxis item was addressed from the VTE list.

Data Collection and Statistical Analysis: Queries in inpatient database (Sunrise Clinical Manager) were performed and Data were exported to a spreadsheet and imported to SPSS for analysis. Chi square test was conducted to compare the differences to measure primary and secondary outcomes. Other variables were analyzed such as age, gender, medical unit, time from admission and time before discharge in addition to distinguishing type of VTE prophylaxis (mechanical vs. medication) and source of VTE utilization.

Results:

A total number of 63,000, 33,000 patients were assessed retrospectively in Long Island Jewish Hospital and North Shore University Hospital in two different time frames as mentioned in methodology. After implementing the smart stop VTE subset, over all adherence to VTE improved in LIJ and NSUH from 85.2 % to 94.9 % (odds ratio [OR], 3.17; 95% CI, 2.993-3.365; P<.001) and from 84.7 % to 96.6 % (odds ratio [OR], 5.17; 95% CI, 4.700-5.684; P<.001) respectively. Using Chi Square in both facilities, we proved that there is an association between implementing a smart VTE subset and increasing number of VTE orders for hospitalized patients prior to discharge. .X^2 (2, N = 62608) = 1781.556, p <0.05 in LIJ and X^2(2, N = 33148) = 1480.638, p <0.05 in NSUH. Furthermore, Patients in the Post group has statistically significant higher probability for VTE utilization via main order set as opposed to using individual VTE orders with Odds ratio >1.

Conclusion:

Using smart stop VTE subset is associated with increase compliance to VTE guidelines in comparison to using hard stop VTE subset. Also, that increase in VTE orders was associated with ordering from Order set catalog as opposed to individual catalog items and that association was statistically significant.

Feasibility of the SBAR Discharge Summary Format

Farrant H. Sakaguchi, MD, MS[1,2], Leslie A. Lenert, MD, MS[3]
[1]University of Utah, Salt Lake City, UT; [2]Intermountain Healthcare, Murray, UT; [3]Medical University of South Carolina, Charleston, SC

Abstract

To improve the clinical handover at hospital discharge, we have proposed reformatting the discharge summary using the SBAR mnemonic. We tested the feasibility of our template with five residents. They found the template relatively easy to use and agreed that the template helped focus on the clinical handoff.

Introduction

The ability of the discharge summary (DCS) to promote continuity in care may be limited by its structure of summarizing previous care without focusing on transmitting information needed for future care. Clinicians are frustrated by more extensive documentation for non-clinical purposes. The increasing prevalence and capabilities of electronic health records (EHRs) may facilitate the completeness and standardization of documentation but at the risk of losing the pithiest communication that clinicians often value; there are concerns that the expansion of electronic documentation may obfuscate clinical communication.

The Situation-Background-Assessment-Recommendation (SBAR) structure for handoff's is common in healthcare and has facilitated the sharing of clinical contexts, clarified roles and expectations, and increased critical thinking and analysis. We proposed reformatting the DCS using SBAR to shift the paradigm away from being a historical "Captain's Log" towards being a handoff document.[1]

Methods

We created an SBAR-DCS summary template (Figure 1) through an iterative process with a panel of five practicing physicians. The M icons refer to information specifically available in the EHR. Internal medicine residents were recruited to evaluate the feasibility of using a paper, pocket-sized SBAR-DCS template while dictating. After each dictation, they completed a brief questionnaire.

Results

Five residents created a total of 17 DCS using the SBAR-DCS template. They found the template relatively easy to use even though the template took 20 minutes to use instead of the estimated usual 10 minutes. However, in all discharges (17/17), they agreed that the template helped focus on the handoff. The template frequently reminded them of things otherwise likely forgotten (16/17 discharges), and emphasized the importance of lessons-learned for the follow-up provider (15/17 discharges).

Discussion

Outpatient physicians felt that several of the DCS based on the SBAR-DCS template were more useful than those they typically received. In one instance, an emergency room physician changed plans for readmitting a patient based on the insights available in the SBAR-DCS. Next steps will quantify the clarity of the handover from the recipient's perspective and the feasibility of an embedded, semi-automated SBAR-DCS template.

The Establishment of Health Informatics Laboratory for Specialized Wireless Remote Monitoring Training and R&D

Hasan Sapci, MD [1], Aylin Sapci, MD
1. Adelphi University, Garden City, NY

The American Board of Medical Specialties approved clinical informatics as a board certified subspecialty in 2011.[1] Academic institutions have been launching new medical informatics programs and adding new courses in their curriculum over the last decade and according to the Commission on Accreditation for Health Informatics and Information Management Education (CAHIIM), there are more than 100 accredited associated, baccalaureate and master level health/medical informatics programs in the United States.[2] American Telemedicine Association states that there are about 200 telemedicine networks in the United States and one million patients have been using remote monitoring devices. Considering the fact that this number reflects just one medical specialty which is cardiology, the importance of structured educational programs that provide hands-on remote patient monitoring and telemedicine skills is apparent.[3]

For a long time students, clinicians and information technology professionals have been trying to follow-up changing trends by themselves, either by forming special interest groups or traveling to other states in order to learn these specific skills from their colleagues' experience. Because health/medical informatics is a quite new field, professional organizations and institutions have been re-defining the core content recently. Competencies required to design and implementation of telemedicine systems, and to monitor, transfer and analyze data are still not listed in most health informatics programs' curricula.[4]

Traditional informatics training methods has various limitations and most students acquire these skills and knowledge from books or lectures only. They do not have access to data-driven healthcare applications, medical systems and devices. Practical hands-on skills are crucial to design, evaluate and implement state-of-the art telemedicine and remote monitoring systems.

We designed a new curriculum and established a health informatics laboratory with U.S. Department of Health's support in order to provide access to specific remote monitoring software and hardware such as medical scopes, exam cameras and vital sign monitors. The authors designed a replicable training model for academic institutions, received IRB approval and conducted pre and post training surveys on 60 graduate level health informatics students. This quantitative research compares traditional health informatics education with the proposed new problem-based learning model and focuses on different sophisticated modules that complement each other.

This presentation will describe a new methodology for the establishment of a health informatics laboratory, share the results of this research and propose a state-of-the art model for remote patient monitoring, and telemedicine training curriculum.

The role of HMG-CoA reductase inhibitors in the management of sepsis in a cohort study of adult intensive care unit patients

Raymond Francis Sarmiento, Paul Fontelo
Lister Hill National Center for Biomedical Communications, National Library of Medicine, National Institutes of Health, Bethesda, MD

Abstract
Recently, HMG-CoA reductase inhibitors, better known as statins, have been suggested as an element in the management of sepsis patients in the ICU because of its immunomodulating properties. We found in this study of the MIMIC-II database that statins are associated with reduced mortality in septic shock ICU patients but not in sepsis and severe sepsis.

Introduction
In the last 40 years, the number of sepsis cases has increased to 350% in the United States with 750,000 severe sepsis cases occurring annually.[1] Adjunct therapies have been found to modulate the marked inflammatory response found in sepsis patients.[2] Observational studies suggest that statins possess anti-inflammatory and antioxidant properties that may reduce the body's inflammatory response.[3] Previous statin use has also been suggested as protective against sepsis and stopping statins during severe sepsis might be deleterious for prior users. However, a multicenter randomized trial of atorvastatin therapy on severe sepsis patients in the ICU found that only prior, not *de novo*, statin use was associated with improved survival. Our objective in this study was to examine the relation between statin use and mortality among sepsis patients admitted into the ICU using the Multiparameter Intelligent Monitoring in Intensive Care (MIMIC-II) database.

Methods
To extract our dataset, we performed SQL queries on the MIMIC-II version 2.6 database, which contains 32,425 unique patients. We excluded 7,919 non-adult patients from the analyses and extracted cohort groups of sepsis, severe sepsis, and septic shock patients based on ICD-9 codes on the remaining 24,506 adult patients. We removed duplicate records, giving a final tally of 2,203 patients (477 sepsis only, 739 severe sepsis, and 987 septic shock patients). We analyzed the data by considering demographic as well as clinical covariates based on clinical knowledge and existing literature on sepsis and critically ill patients in the ICU.

Results
We developed models for analysis and ran the following covariates in our final logistic regression model: male gender, ethnicity, comorbidities (hypertension, diabetes, alcoholism, chronic kidney disease, COPD, and cancer), ICU interventions (dialysis, insulin, transfusion, total parenteral nutrition), and statin use. We found that even after adjusting for multiple potential risk factors, statin use seemed to have a beneficial effect on the survival of septic shock patients, but not on sepsis and severe sepsis. We found that septic shock patients had a lower mortality risk at 30 days and one year after ICU admission if given statins compared to sepsis only and severe sepsis patients.

Conclusion
This finding could provide more evidence on the role of statins in modulating the body's inflammatory response in extreme states of stress as in septic shock, although a similar response was not seen among sepsis only and severe sepsis patients. Further studies to investigate the effect of statins on acutely ill patients such as those in the ICU are warranted.

Customized Reference Ranges for Laboratory Values Decrease False Positive Alerts in Intensive Care Unit Patients

Christopher N. Schmickl, MD, MPH, Oguz Kilickaya MD, Ahmed Adil, MBBS, MSc, Juan Pulido, MD, James Onigkeit, MD, Kianoush Kashani, MD, Ognjen Gajic, MD MSc, Vitaly Herasevich, MD, PhD, Brian Pickering, MD
Multidisciplinary Epidemiology and Translational Research in Intensive Care (METRIC), Mayo Clinic, Rochester, MN

Abstract: Objective was to compare the accuracy of customized laboratory reference ranges (based on expert surveys) against standard reference ranges. Blinded to abnormal-value indicators, critical-care experts reviewed the laboratory results of 37 critically ill patients in the context of patients' problem list, judging about which of the values they would like to be alerted (gold standard). Customized reference ranges resulted in significantly less false positive results, thus possibly decreasing alert fatigue in health-care providers.

Background: Traditional electronic medical record (EMR) interfaces mark laboratory tests as abnormal based on standard reference ranges derived from healthy, middle-aged adults. This yields many false positive alerts with subsequent alert-fatigue when applied to complex populations like critically ill patients. Novel EMR interfaces using adjusted reference ranges customized for specific patient populations may ameliorate this problem. Our objective was to compare the accuracy of abnormal laboratory value indicators in a novel[1] vs traditional[2] EMR interface.

Methods: Laboratory data from intensive care unit (ICU) patients consecutively admitted during a two-day period were recorded. For each patient, available laboratory results and the problem list were sent to two mutually blinded board-certified critical care physicians, who marked the values about which they would like to be alerted. All disagreements were resolved by a third physician. Based on this gold standard, we calculated and compared the sensitivity, specificity, positive and negative predictive values (PPV, NPV) of customized vs traditional abnormal value indicators.

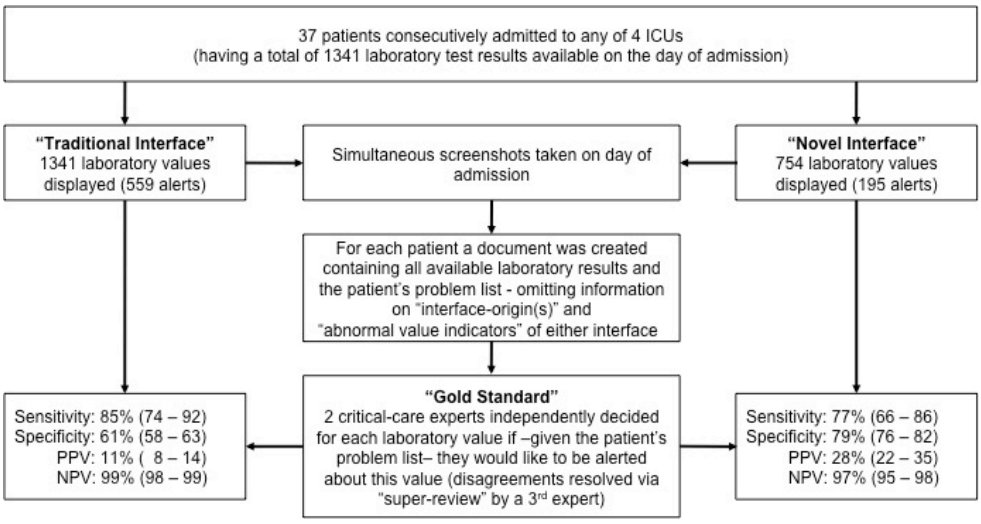

Figure 1. Studyflow. Results are displayed as estimate (95%-Confidence Interval).

Results: Thirty seven patients with a total of 1341 laboratory results were included (Figure 1).

Experts' agreement was fair (kappa=0.39). Compared to the traditional EMR, custom abnormal laboratory value indicators had similar sensitivity (77% vs 85%,P=0.22) and NPV (97.1% vs 98.6%,P=0.06) but higher specificity (79% vs 61%,P<0.001) and PPV (28% vs 11%,P<0.001).

Conclusions: Reference ranges for laboratory values customized for an ICU population decrease false positive alerts. Disagreement among clinicians about which laboratory values should be indicated as abnormal limits the development of customized reference ranges.

Reproducibility of Health Care Datasets

Daniel H Schneider[1], MS, Nathan D Sisterson[1], Luke V Rasmussen[1]
[1]Northwestern University, Chicago

Abstract
Healthcare data is being used in a wide array of statistical analyses and interpretations. Discrepancies in data points can lead an investigator to differing conclusions. We posit that in examining data collection methods by rerunning exact copies of executable data searches we will derive varying results which in some cases may be significant.

Introduction
With the growth of electronic health record data (EHR) available for institutional research as well as operations, reporting from these data has become routine. Since health care data is derived from many transactional systems this data is rarely static and has its own organic properties of modifications and alterations that occur over time. As a result, re-executing the same data searches over time will, intuitively, produce varying results. In addition, improvements made to data warehouses and integration efforts across systems can result in improved results.[1] The purpose of this study was to gain more understanding of both the magnitude and characteristics of such changes in results.

Methods
Ten previously defined datasets across multiple medical specialties were investigated to identify potential variation found within EHR data. In order to look back at the initial collection of these datasets we utilized an internal applications developed at the Northwestern Medicine Enterprise Data Warehouse (NMEDW.) This application (MyCohorts) allows a user to define and store patient identifiers to use for tracking subjects in a particular study. This allows us to reference a static snapshot of the dataset as existed when first created. These ten cohort definitions were then rerun to measure any difference in number of subjects meeting the eligibility criteria.

Results
The table shows that eight of ten queries did not produce stable results over time. In addition, the direction of change was not uniform, with both increases and decreases in patient counts over time. Three contributing factors were associated with a changing number of subjects identified. Poor query design, application updates, and source system data changes all contributed to the changing number of subjects. In one case, the placing of a date filter on an encounter date while failing to do so for a diagnosis date added subjects diagnosed after the query was initially run (cohort 1.) Deprecation of columns within a database as well as the removal of entire databases caused two of our queries to break completely (cohorts 2,9.) Examples of system data changing over time were also noted (cohorts 3,4,5,6,7,8,10.) Diagnoses were recoded, encounter types changed, and in some cases ages had been adjusted. All of these factors led to the changing number of subjects identified. The poster will examine the causes, and potential solutions for, these changes in more detail.

#	Cohort	Original Pt. Cnt.	New Pt. Cnt.	Difference
1	Outpatients with Meniere's Disease	341	495	154
2	Patients with Keloid Scar	386	0	-386
3	2009 Stem Cell or Bone Marrow Transplant Patients	231	231	0
4	All NMH Inpatients	121,056	104,958	-16,098
5	Patients with Aortic Stenosis and an Echo in 2010	390	389	-1
6	Patients with an HIT antibody test	1,310	1,291	-19
7	Spine Surgery Patients 2000-2010	2,598	2,598	0
8	NMH Patients with Hip or Knee Replacement	5,553	5,508	-45
9	Low Bone Mineral Density	247	0	-247
10	Sleep Study Patients	238	246	8

A Literature Review of Electronic Health Record Redesign for Optimization

Alissa A. Schultz, RN, MA, Albert M. Lai, PhD, Po-Yin Yen, RN, PhD
Department of Biomedical Informatics, The Ohio State University, Columbus, OH

Abstract

Meaningful Use has been a major driver behind most Electronic Health Record (EHR) implementations with mixed reviews of adoption and usability across disciplines, stakeholders and roles. Moving beyond initial installations, we wanted to learn how EHRs are being redesigned to optimize utilization for various performance outcomes given the Affordable Care Act and the healthcare reform. Our literature review revealed relatively few studies on the redesign of EHR systems that look at measurable outcomes of such initiatives.

Background

In 2009, the government offered monetary incentives for providers and institutions to implement Electronic Health Records (EHRs). Penalties and fines are being imposed when meaningful use requirements are not met. Most healthcare settings use EHRs to some extent, but perhaps not optimally. Much research exists on the usability and evaluation of EHRs, but a lack of standards within Health Information Technology make redesign difficult to study given the variability and dynamic nature of healthcare. Future focus will be on EHR optimization through redesign efforts that support patient centered evidence based care, continuous quality improvements, patient outcomes, and reducing overall health expenditures. The purpose of this study is to review the literature on EHR redesign efforts for optimization and measureable outcomes.

Methods

The literature search was performed primarily in two databases, PubMed and the ACM Digital Library. Search keywords included "(Electronic Medical Record OR Electronic Health Record OR EMR OR EHR) AND Redesign." Related MeSH terms were also used to search PubMed literature. Titles and abstracts were first screened for articles related to EHR redesign. Out of those included abstracts, we looked into full-text for further information.

Results

Searches in PubMed and the ACM Digital Library yielded 140 and 30 articles, respectively. In comparison, when swapping out the keyword "Evaluation" for "Redesign," there was approximately a 3000% increase in articles. Most studies identified through the literature review included a focus on process and environmental redesign (n=34), usability aspects (n=9), review or opinion based articles (n=54) and those that were not applicable (n=64). Only nine articles measured changes of an EHR redesign. Three studies measured patient outcomes, three focused on cost savings and three on clinical reminders incorporating evidence-based guidelines.

Discussion

EHR redesign opportunities exist and have the potential to facilitate significant impacts on the future of our healthcare system in terms of cost, quality, outcomes and accountability. Small changes in an EHR, such as unbundling lab orders for individual selection or adding one additional text box can drive significant cost savings. In addition, patient outcomes can be targeted for improvement by analyzing data to identify and prioritize efforts for improvement, such as redesigning order sets. Patient safety and quality of care should always be the first priority in EHR redesign efforts. The data used to identify redesign opportunities should also be utilized as outcome metrics to determine the success of redesign efforts.[1]

Conclusion

Relatively few redesign studies exist on EHRs. The focus must now change from EHR implementation to optimization via redesign efforts. Evidence based research is needed for guidelines and prioritization in respect to system enhancements. Limitations exist in conducting randomized controlled trials with an entire system.[2] However, individual redesigned system *features* within an EHR should be evaluated using randomized controlled trial study designs.[3]

Visualizing Design Trends by Mapping the Alzheimer's Disease Trial Space

Timothy Schultz, MS[1], Chaomei Chen, PhD[1]
[1]Drexel College of Computing and Informatics, Philadelphia, PA

Abstract

We propose to enable a system in which the massive space of clinical research itself can be mapped and queried from readily-available clinical data sources, through a scalable and distributed "Big Data" graph technology called Titan. By identifying the nature of and relationships between clustered areas of clinical research within and across therapeutic areas, it is proposed that future research trends can be extrapolated to further guide clinical trial design. We provide an example of these principles by modeling the Alzheimer's Disease clinical trial landscape.

Introduction

Disconcerting trends in clinical research have counter-intuitively shown that the failure to meet desired clinical trial endpoints has come at the cost of increased spending. This suggests the need for developing new ways in which clinical trials are designed, patients are recruited, and protocols are executed. One approach for addressing this issue is to provide research organizations a mechanism to proactively identify key clinical trial design patterns and trends within a therapeutic area through the utilization of novel visualization tools. At the heart of the clinical trial design lies the need to ensure appropriate selection of participants. The selection of patient attributes noted in inclusion/exclusion criteria, which aims at minimizing comorbid conditions that may confound treatment signals, can also be detrimental to the external validity of the study. By quantifying and qualifying thematic clinical trial design trends over time, we propose a framework for providing proactive guidance in designing more efficient clinical trials. For example, there is an interesting opportunity in Alzheimer's Disease research to visualize how our understanding of the amyloid cascade has evolved over time, and the many ways researchers have since proposed the best means to engage it.

Methodology

ClinicalTrials.gov remains the definitive source for information regarding the rationale and design of clinical trial around the world. Recently efforts have aimed to extend and augment its capabilities beyond plain-text and retrieval. For example, the Clinical Trial Transformation Initiative (CTTI) was established in 2007 to enable finer-grained database querying capabilities of ClinicalTrials.gov[1]. More recently it has been demonstrated that new insights can be gained by directly analyzing certain aspects of a protocol and imputing additional endpoints, such as similarity scores between trial entries[2]. Expressing similarity sets as a graph yields interesting applications. In 2009, researchers at Los Alamos Laboratory analyzed voluminous amounts of clickstream data across web-based scientific journal websites to construct a detailed "map of science"[3]. While only visual in nature, their work demonstrated the intuitive connectivity of scientific domains. It is proposed that by analyzing ClinicalTrials.gov data, a similar network can be constructed of the clinical research space. By semantically annotating clinical trial protocols with a modular set of publicly-available ontologies optimized for conceptual coverage, similarity scores between trial entries can be calculated. By expressing similarities as weighted time-dependent edges, a massive graph is constructed. Novel hierarchical clustering techniques are deployed at different granularities and summarized by their most distinct and descriptive ontological concepts. This establishes metadata outlining thematic levels of varying granularity. Numerical values/ranges are also extracted from the text and summarized at each level. As a result, we augment ClinicalTrials.gov allowing users to not only query attributes of clinical trials, but also their overarching structure, made accessible through Aurelius' Titan platform.

Conclusion

The initial development of a framework which allows researchers to directly interrogate a "map" of a clinical research space based on graph metrics has been demonstrated.

A Review of Clinical Decision Support Products in Dentistry

Kelsey M. Schwei[1], MS, Neel A. Shimpi[1], BDS, MM, Barbara Bartkowiak[2], MLIS, Zhan Ye[1], PhD, Ingrid Glurich[1], PhD, Amit Acharya[1], BDS, MS, PhD
[1]Marshfield Clinic Research Foundation, Marshfield, WI; [2]Marshfield Clinic, Marshfield, WI

Abstract

The adoption rate of health information technology is slow in dentistry and the implementation of clinical decision support (CDS) products in dentistry is even slower. This study aimed to identify CDS products that are used in dentistry and categorized the products' functionalities based off a literature review.

Introduction

With the implementation of electronic health records, the number of CDS systems is on the rise. CDS systems can help a dental clinician with patient-centered decision making as well as improve overall quality of care. Given the increasing importance of CDS in dentistry, this study evaluated the literature reviewed in a prior study[1] to identify and categorize functionalities of CDS products used in dentistry.

Method

Two informaticians reviewed the full text articles based on abstracts that were appraised in a previous study[1] to include CDS product review and classification of product functionalities. The articles were classified as relevant or non-relevant to CDS products in dentistry. Relevancy was defined based off of existing inclusion criteria[1]. The CDS products found within the articles were categorized as 'implemented and prototypical products' or 'conceptual ideas'. 'Implemented and prototypical products' were reviewed further. Each product discussed in the articles was included into a matrix. The matrix depicted the CDS products discussed in the literature on the y-axis and the CDS product functionalities on the x-axis. Product descriptions in the literature were used to determine functionality categories. The CDS products were classified as being developed in an academic or industry set-up. We also created a year of publication plot and used Google Citation to evaluate the number of citations on each article.

Results

Forty-one of the 49 articles from previous work[1] were identified to have discussions relevant to CDS products in dentistry. Implemented/prototypical (currently used or created and ready to use CDS products in dentistry) CDS products were discussed 63 times. Duplicate products were removed. Fifty-six unique CDS products were reviewed further for categorization into the functionality matrix. The frequencies of the functionalities of CDS products can be seen in Table 1. Based off of the frequencies of occurrence in the literature, the top CDS products were ORAD (frequency=3) and Logicon Caries Detector (frequency=3). Thirty-two CDS products had multiple functionalities. The top functionality was providing a diagnosis (frequency=40), followed by radiographic analysis (frequency=26). Ten CDS products were developed in academia, while 46 were developed in industry. Publication year for these 41 articles ranged from 1975-2012. The articles were cited 0-139 times in other publications.

Table 1: Frequencies of product functionalities from the articles. Products may have multiple functionalities.

Radiographic Analysis	Diagnosis	Practice Management	Prognosis	Treatment	Risk Assessment	Pathology	Database Management	Etiology	Total Products
26	40	1	4	20	1	1	1	1	56

Conclusion

This review has provided a functionality analysis of CDS products that are currently available in dentistry. The CDS products available could be useful in dental practice; however, there is always room for advancement on these CDS products. Furthermore, this review identified opportunities for further CDS development in other dental arenas, such as endodontics or oral cancer. As a next step, product reviews of the top identified CDS products will be conducted.

Automated Clinical Status and Treatment Prognosis tracking in Cancer Patients

Luis Selva PhD[1], Frank Meng PhD[1,2], Craig Morioka[2,3], Saiju Pyarajan PhD[1,4]
[1]MAVERIC, VA Boston Healthcare System, Boston, MA;; [2]UCLA Medical Imaging Informatics Group, Los Angeles, CA; [3]Greater Los Angeles VA Healthcare System, Los Angeles, CA, [4]Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Abstract
It has been estimated that in 2013 alone there were 1,660,290 new cases of cancer diagnosed in the United States with half a million cancer related deaths in the United States [1]. With technology advancements in the biomedical field and as treatment becomes more personalized and tailored to individual patients, tools will be needed that assist clinicians to determine the most effective treatment regimens based on all available data contained in the electronic medical record. We present a framework for clinical reports and image-based phenotyping using digital documents and medical images in order to give clinicians a rich representation of a patient's clinical condition.

Problem Description
There has been much recent progress in discovering and developing targeted therapy for cancer based on the genetic makeup of patients [2]. The Veterans Affairs (VA) Healthcare System is investing resources for developing clinical informatics infrastructures that support discovery of biomarkers for targeted therapy. The VA's Million Veteran Program (MVP) has a goal of collecting and analyzing consented bio-samples from a million veterans to build a large-scale genetic database that can be linked to the VA's electronic medical record (EMR) for enabling new discoveries. Treating patients with tailored therapies based on genetic information will require large data sets to successfully transition from general population-level medical care to targeted individualized care based on each patient's particular clinical and genetic characteristics. Precise and pertinent information on complex patient cases (e.g., cancer) is not always readily available to care providers. Here, we are building a framework to extract detailed information from unstructured imaging data and integrating with structured and unstructured clinical reports and notes that will give the physician the ability to determine a more precise clinical status using relevant health information in order to assist in optimizing treatment plans for individual patients.

Purpose and Methodology
In order to utilize targeted drugs for the treatment of cancer, clinicians must coalesce information from a multitude of sources, i.e., images, reports (pathology, radiology, molecular labs etc…) to design an effective treatment plan. Given enough information, care providers can also obtain detailed comparisons with other similar patients using historical clinical data to provide more accurate treatment response predictions [3]. We present a framework for deep phenotyping from the VA's extensive and voluminous EMR using clinical documents and integrating with radiology images to give clinicians a rich representation of patient status. Such a framework must not only scale to accommodate the extraction of large numbers of different phenotypes, it must also handle diverse data content and formats from the various regions of the VA network. Thus, the framework will have the following characteristics: 1) methods for rapid, large-scale development of phenotype extraction algorithms such as free text annotators and image feature extractors; 2) open, pluggable software architectures that enable the various algorithms to integrate seamlessly; 3) databases and warehouses that harmonize disparate data types along with provenance information that enables real-time querying and analysis (e.g., to determine discrepancies between care providers); and 4) continuous and scalable validation tools and techniques for evaluating system performance over time as changes occur both in the data as well as the system itself. Once a high quality structured database of phenotypes has been collected and curated, it can be combined with treatment outcomes data to support real-time querying by clinicians to retrieve specific characteristics of the patient or to gather groups of similar patients.

Scaling Information Technology in U.S. Health Care System Reform: An Interdisciplinary Perspective

Ann Séror, PhD, MBA
eResearch Collaboratory, Quebec City, QC, Canada

Introduction

Health care system reform efforts in the U.S. have long called for large scale development of interoperable EHRs and capabilities for health information exchange across geographical locations and health care stakeholders - patients, service providers and payers. On July 21, 2004, the U.S. Secretary of Health and Human Services issued a news release calling for a ten-year program to develop and implement a national health information infrastructure, the "Decade of Health Information Technology". This infrastructure was to include EHRs for all patients as well as a national network for health information exchange. In 2009 the Health Information Technology for Economic and Clinical Health Act (HITECH), part of the American Recovery and Reinvestment Act (ARRA), further mandated the Office of the National Coordinator for HIT (ONC) and pursuit of specific objectives including certification of EHR systems and Meaningful Use of HIT as formulated in the Federal Health IT Strategic Plan (2011-2015). While significant progress has been made in adoption of EHRs by health care providers across the U.S., policies to promote health information exchange have generally failed, both in developing standards for interoperability among EHR systems as well as creation of a nation-wide health information network.

Research Problem

At the time of launch of the "Decade of Health Information Technology" research on implementation of HIT projected substantial returns on prospective investments – 81 billion dollars annually saved by improved health care efficiency and safety.[1,2] Such returns have proven elusive, in part because the multi-payer market driven foundation of the system has remained in place. This review considers the literature on the promise of U.S. health care system-level savings resulting from implementation of health information technology in general (HIT) and electronic health records (EHR) in particular. Early evaluations of HIT implementation failed to produce accurate projections of financial return on HIT investments. While some interdisciplinary studies have suggested the relevance of socio-technical models and complexity theory, no research has focused on a holistic view of the system including business model design and payers as critical stakeholders. The U.S. application of HIT continues to focus at the individual transaction level, where clinical information is consistently tied to assessment of financial transactions to be intermediated by multiple payers. The administrative costs associated with information systems to support this multi-payer business model design are excluded from assessment of return on HIT investments. Recent studies have shown that HIT investments have contributed to growth in health care costs – both at the individual provider and at the system levels of analysis.[3,4] In the U.S. health care system, HIT and EHR systems support clinical decision making, but they are designed at the same time for complex claims and billing processes – as physicians transact on average with more than 20 payers according to the American Medical Association. This administrative burden increases costs associated with development of information systems focused on increasingly granular transactions, as in the transition from ICD 9 to ICD 10, a more than five-fold increase in the number of codes for accurate billing.

Recommendations: Future Research and Policy

Conclusions of this review suggest that HIT investments will yield positive returns only with the implementation of a single payer system in the U.S.. Future research and policy should focus on redesign of the health care system business model. Such reform would contribute to improve ranking of the U.S. health care system among western nations. ProcessAWARE: Patient Outcomes and Resource Utilization Changes following Implementing an Electronic Rounding Checklist in the Intensive Care Unit

Ronaldo A. Sevilla Berrios MD, Sumanjit Kaur MD, Aysen Erdogan MD, Lisbeth Y. Garcia Arguello MD, John C. O'Horo MD, Adil Ahmed MBBS, Vitaly Herasevich MD, PhD, Brian Pickering MBBCH, Ognjen Gajic MD
Multidisciplinary Epidemiology and Translational Research in Intensive Care (METRIC), Mayo Clinic, Rochester, MN

INTRODUCTION: Checklists have been proven to be an invaluable tool for standardizing processes in various industries including healthcare, and is now gaining evidence in the intensive care unit (ICU) environment. Checklists can improve adherence to best practice. This should translate to more rational resource utilization and improved patient outcomes. We have developed an electronic, context-sensitive rounding tool that algorithmically selects which relevant best practice goals to be addressed for each patient on a daily basis. This was integrated into a novel electronic platform, the Ambient Warning and Response Evaluation (AWARE) system. Checklist in AWARE was deployed in April 2013 with a prescribed rounding choreography termed ProcessAWARE. We sought to test the impact of this intervention on resource utilization in the ICU.

METHODS: All patients admitted to a medical ICU undergoing ProcessAWARE implementation in April 2013 were compared to admissions in the same unit in April 2011 (this period of time was chosen to minimize seasonal variation and as the last year where no components of ProcessAWARE were available). We investigated trends in length of stay, ventilator utilization, mortality, central line-days, urinary catheter-days and antibiotic days. Each was adjusted for APACHE-III score to correct for individual patient severity of illness.

RESULTS: At total of 183 patients were evaluated in April 2011 and 199 in April 2013. There was no difference on age (mean 62 vs 61, p=0.75) or gender (52% vs 58% male, p=0.26) when compare the 2011 vs 2013 groups, however the APACHE III score at 1 hour were 42 vs 55 p <0.01 respectively. Regarding to resource utilization, adjusted central line days were significantly reduced post-AWARE implementation (-0.87 days, 95% CI -0.84--0.91, p=0.04), and antibiotic use days trended towards a decrease as well (-0.87 days, 95% CI -0.01--0.88, p=0.06). Otherwise, resource utilization was similar in the two study periods. ICU length of stay was significantly reduced after AWARE implementation (-0.92 days, 95% CI -1.62-0.23, p<0.01), as was hospital length of stay (-2.53 days, 95% CI -4.19--0.87, p<0.01). ICU mortality was also reduced (Odds Ratio [OR] 0.32, 95% CI 0.11-0.85, p<0.01), without significant change in hospital mortality (OR 0.54, 95% CI 0.25-1.13).

CONCLUSIONS: Although these results are preliminaries, the initial implementation of ProcessAWARE was associated with decreased resource utilization in the medical ICU. These findings are limited by the retrospective nature of the study and further evaluations are required.

An Exercise Mapping MedDRA to ICD-10-CM

Amy Sheide, RN, BSN, MPH; 3M Health Information Systems Inc., Salt Lake City, UT

Introduction

To maintain compliance with Medicare Secondary Payer Mandatory Reporting Provisions in Section 111 of the Medicare, Medicaid, and SCHIP Extension Act (MMSEA) of 2007, pharmaceutical companies currently report the diagnoses of patients participating in their clinical trials using the International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM), to be replaced by ICD-10-CM starting no later than April 1, 2015[1]. Since the pharmaceutical companies collect their clinical trial data using the Medical Dictionary for Regulatory Activities (MedDRA), they are currently meeting the reporting requirement using a MedDRA to ICD-9-CM map. The shift from ICD-9-CM to ICD-10-CM requires a new mapping from MedDRA to ICD-10-CM. Differences in the specificity and structure of the code systems presents challenges in the mapping between them.

Methodology

The MedDRA PTs from version 16.1 (released September 2013) and the 2014 release of ICD-10-CM were evaluated in the mapping project. Each MedDRA PT is associated with one or more high level MedDRA grouping concepts called a System Organ Class (SOC). The file reviewed contained 28,424 MedDRA PTs and their associated System Organ Class (SOC). The file did not contain any rows from the Surgical and Medical Procedures SOC. SOC was used to provide context to the MedDRA PT and was not mapped at this time. A total of 18,361 distinct preferred terms were eligible for mapping.

The 3M Healthcare Data Dictionary (HDD) is a terminology server that was leveraged for this mapping project. It contains multiple standard and local terminologies, including ICD-10-CM and the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT®). It also contains mappings between terminologies, such as the SNOMED CT to ICD-10-CM map set provided by the US National Library of Medicine (NLM), which was used for this project, as a previous study has shown that 9,484 MedDRA PTs have a direct mapping to SNOMED CT[2].

Results

Of the 18,361 MedDRA PTs 1,032 distinct PTs resulted in an exact text string match for an ICD-10-CM code description (5.6%). The remaining unmatched terms (17,329) generated 1,717 exact text string matches to SNOMED CT concepts that exist as 1:1 mapping to ICD-10-CM in the NLM map set, providing an additional 9.3% of automated matching to ICD-10-CM codes. The remaining 15,612 PTs required tool-assisted "manual" mapping, as the goal is to find a single "best match" to the most specific ICD-10-CM code. Some of the considerations were:

- Level of specificity – the best match for a PT could be a higher level, less specific "parent" code in ICD-10-CM which is not a "billable" code. For example, 'Tibia Fracture' would map to S82.209 'Unspecified fracture of shaft of unspecified tibia' rather than one of the 16 "billable" codes under it, since MedDRA does not capture laterality, episode of care, healing status or classification for fractures.
- Laterality – MedDRA PTs do not capture laterality except in specific disease instances. In general, the only time the terms 'right' or 'left' appear within MedDRA PTs is in the instance of ventricular cardiac disease. One of the key features of ICD-10-CM is the presence of laterality. The differences between the code systems decrease the chances of an exact equivalent match between MedDRA PT and an ICD-10-CM code.
- Gender – MedDRA may capture diagnosis both as a pre coordinated term 'breast cancer female' or 'breast cancer male' but also the genderless 'breast cancer' which does not have an corresponding genderless match in ICD-10-CM. Therefore, for the PT 'breast cancer,' one must choose between C50-919 malignant neoplasm of unspecified site of unspecified female breast and C50.929 malignant neoplasm of unspecified site of unspecified male breast.

Conclusion

Both MedDRA and ICD-10-CM are needed within the pharmacology industry to meet different reporting requirements. The mapping between the two code systems is feasible but presents challenges around mapping multi-level of terms with varying levels of attributes. Mapping from MedDRA PTs to ICD-10-CM is valuable in this specific use case but may not present the same relevant benefits outside the scope.

Electronic Detection of Inpatient Diagnostic Error: A Scoping Review of Available "Triggers"

Edna C. Shenvi, MD, Robert El-Kareh, MD, MS, MPH
University of California San Diego, La Jolla, CA

Abstract

"Trigger" tools are specific criteria used to identify clinical records most likely to contain errors. We performed a scoping review of the literature to determine what such criteria may be used for automated detection of inpatient diagnostic error. Little automation or validation has been done specifically for this category of healthcare error.

Introduction

Diagnostic errors are a significant patient safety issue, but research into these errors is limited by difficulty in reliably measuring their incidence. While chart review remains the gold standard for detection, specific "triggers" may be useful screening tools to identify charts that are most likely to contain errors. Several established sets of criteria are designed to detect general adverse events, including nosocomial infections, adverse drug events, and procedural complications, and are not specific to diagnostic error. We sought to compile such explicit screening criteria that may indicate diagnostic error in hospitalized adult patients and are measurable in electronic health records, therefore making them amenable to automated detection.

Methods

Using a mixture of MeSH terms and keywords, we searched PubMed, Web of Science, and CINAHL databases and retrieved 8861 citations. After initial screening of titles and abstracts, we reviewed the full text of 146 articles. Citation tracking identified an additional five references to ultimately lead to 33 included articles that either developed or validated such tools. We extracted study setting, methods, and the criteria used, and we also examined for the presence of automation and if the study reported validation of criteria. We had developed a model of potential "signals" of outcomes of diagnostic error; some were specific to the patient status, such as death, whereas others were categorized as clinician assessment or management, like a care transfer. We determined which of the elements of our model were represented in actual studies.

Results

Several studies employed or validated variations of screening criteria developed in early studies on healthcare errors. Four of these criteria are associated with same-admission inpatient diagnostic error: transfer to a higher level of care, death, cardiac or respiratory arrest, and long length of stay. Subsequent trigger tools added four other clinical management indicators: calling multiple consults, change of physician in charge, change in procedure, and abrupt medication stop. Multiple studies used the trigger of calling a code or emergency response team, which often overlaps with cardiac or respiratory arrest.

Some studies reported validation metrics for their criteria such as positive predictive values or kappa coefficients for manual reviewers. However, only one study validated a specific criterion's performance in detecting diagnostic error. Only two studies used automated methods: comparing automated with traditional manual triggers and electronic screening of discharge summary text, although these did not report proportion of errors that were diagnostic in nature. Death, transfer to special or intensive care unit, and arrest or code team activation are the most widely used triggers to indicate error; however, none is specific for diagnostic error.

Discussion

Inpatient diagnostic errors may be more easily detected and studied using available electronic "triggers" to facilitate chart review. While this approach has been taken for adverse events in general, we did not find this approach applied specifically to diagnostic errors in the inpatient setting. Validation of these criteria is needed to identify those that are the most useful for these errors. Our preliminary model identified some additional criteria that may be useful for detecting diagnostic error, such as changes in primary diagnosis and multiple diagnostic procedures, which have not been used in either manual or automated methods for detecting error and may warrant future evaluation.

An Approach to Self-management of Metabolic Syndrome in Japan Using an Internet-Based System

Akiko Shibuya, RN, PHN, PhD[1], Tsuneo Yamada, MSc[2], Yukihiro Maeda[1], Yoshimasa Umesato, PhD[1], Yoshiaki Kondo, MD, PhD[1]
[1]Nihon University School of Medicine, Tokyo, Japan; [2]MEDIS, Tokyo, Japan

Abstract
We developed a healthcare monitoring and management system for individuals with metabolic syndrome (MetS) using an Internet-based system. Users can record health information, including daily blood pressure, waist circumference, and weight, in the system via a portal server at Tono City, Japan, and can obtain individually tailored advice and necessary medical information from healthcare professionals via their mobile phones or desktop computers. This system may have a significant impact on self-management for individuals with MetS.

Introduction
Metabolic syndrome (MetS) is linked to an increased risk of developing cardiovascular disease (CVD), type 2 diabetes mellitus (T2DM), and hypertension. Despite the potential to prevent T2DM and reduce CVD risk through lifestyle changes, individuals with MetS often have difficulty losing substantial weight and reducing waist circumference (WC) through self-management. In a previous study, poor decision making and a lack of both knowledge and tools for lifestyle interventions were considered important barriers for individuals with MetS[1, 2]. To help address these issues, we developed a healthcare monitoring and management system that can be accessed through mobile phones or desktop computers.

Methods and results
Figure 1 shows the architecture of our web-based healthcare monitoring and management system, which operates via the Internet. Users can record health information, including blood pressure, body weight, WC, and exercise, in the portal server and then view the data in graphical form on their mobile phones or desktop computers (Figure 2). Furthermore, through email or mobile phones, users are able to obtain personal health check-up data, including HbA1c, total cholesterol, and body mass index, as well as individually tailored advice from healthcare professionals regarding lifestyle factors such as diet, physical exercise, and other important medical information that can help reduce MetS risk factors.

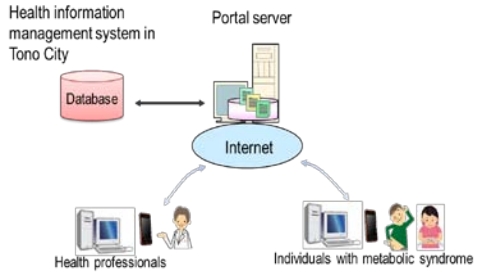

Figure 1. Overview of the system

Figure 2. The website as seen on a desktop computer monitor

To verify the efficacy of the system, 31 individuals (15 men, 16 women; mean [±SD] age, 56 ± 7.6 years) with MetS in Tono City, Japan, participated in this trial (response rate 81.6%). Participants first received lectures regarding the health site, after which they recorded their health status information and viewed the results in graphical form on their mobile phones or desktop computers. We then assessed their satisfaction and system usability using a questionnaire survey. Overall, 81% of the subjects rated the usefulness of the system as excellent or good. This indicates that the healthcare monitoring and management system for individuals with MetS was positively received. It is believed that this system may be useful for guiding behavior changes and lifestyle modifications for individuals with MetS.

Conclusion
The present study suggests that a healthcare monitoring and management system using mobile phones or desktop computers may help meet various support needs of individuals with MetS.

Developing an Electronic Health Record for Google Glass: Challenges and Use Cases

Karandeep Singh, MD[1,2]; Joseph V. Bonventre, MD, PhD[1,2]; Adam Wright, PhD[1,2]
[1]Brigham and Women's Hospital, Boston, MA; [2]Harvard Medical School, Boston, MA

Abstract

The mobile use of electronic health records (EHRs) has been primarily confined to smartphones and tablets, which require a user to hold the device. The Google Glass provides a unique platform by which a healthcare practitioner can access EHR data hands-free in real-time. This poster summarizes lessons learned during the development of a Google Glass-based EHR that interfaces with the Longitudinal Medical Record EHR at Brigham and Women's Hospital.

Introduction

There are several challenges that arise in designing an EHR for Glass, including but not limited to lack of a traditional input device, a fairly small display, a short battery life during activities requiring prolonged activation of the display or wireless connection, and absence of WPA2 enterprise wireless support. Though the Google Glass can be paired with a Bluetooth keyboard through the installation of the Android "Settings.apk" file using the Android Debug Bridge, the native input is confined to the touchpad, camera, accelerometer, and microphone. The touchpad is located on the right side of the Glass and can capture swipes and taps. Though this is effective for menu traversal and selection, it is quite slow for entering alphanumeric data. The camera is an effective way to capture secure information (such as a medical record number) using a QR code scanner, and it may also be an effective method to traverse menus through detection of hand gestures. The accelerometer is an effective way to tell to what extent the wearer is looking up or down and provides an effective way to scroll through free text data such as laboratories or clinical notes. Using speech recognition is an effective way to query the EHR but must be weighed against the noise pollution created by such voice commands. Another challenge to using the device in the exam room relates to the uncertain effect that the device may have on the patient-physician relationship: the display is not shared with the patient, the patient may feel their privacy violated due to the front-facing camera, and the novelty of the device itself may result in a feeling of unease. As such, initial use cases for interacting with the EHR must respect these social constraints.

Prototyped Use Cases

The following use cases have been prototyped in clinical scenarios using live patient data through the Glass EHR application. Additional proposed use cases include real-time critical results reporting, which could prove especially valuable in the emergency department, intensive care unit, and on inpatient hospitalist services.

1. Rapid Queries on Rounds: Using voice commands to ask for specific information (e.g. "what was the last creatinine?") on rounds may allow for faster information retrieval than traditional input-based methods. Secondly, for a supervising physician, having direct access to laboratory data on rounds while a trainee is presenting may allow for silent review of information that was not available prior to rounds.

2. A Second Screen for Clinic: While the use of a second screen has been associated with increased efficiency for many EHR-related tasks, using a Glass as a second screen has the added benefit of being always available, allowing a provider who is typing a patient note to have ready access to patient data for charting purposes without needing to occupy additional desk space through a second desktop monitor.

3. Glass as a Bluetooth Phone Accessory: The ability of Glass to make calls through a connected phone allow for voice commands and alerts to trigger the option to make a phone call (e.g. "call the primary care doctor").

Conclusion

Through the use of camera, speech, accelerometer, and touchpad-based inputs, traversing the EHR quickly and securely is technically feasible with Google Glass. Social barriers should be respected when designing a workflow in which Glass is used in clinical practice.

Using Data Mining as a Model for Behavior Change

Scott M. Sittig, MHI, RHIA[1], Amy Franklin, PhD[1]
[1]School of Biomedical Informatics, University of Texas Health Science Center at Houston, Houston, TX

Abstract
In order to manage mounting health care costs for chronic conditions such as diabetes, innovative solutions for wide spread behavior change are needed. One challenge is tracking the success of broadly implemented interventions. Medical claims databases may provide a novel solution to measuring the success of such projects. Linking changing data from diagnoses, medication adherence, lab tests ordered, and visits to physicians may provide a means to track the success of behavior change programs.

Introduction
Medical claims databases contain raw aggregate data linked to diagnoses, medication usage, types of lab tests ordered, types of physician visits and related information. If used carefully, with full assessment for completeness and appropriate statistical transformation, these data can inform the function of the larger health care system[1]. In this poster, we extract components of medical claims database to determine their potential for the development and evaluation of a diabetes behavior change program. This effort is part of a larger project to show the use of claims database data to reflect individual behaviors such as self-efficacy.

Methods
Using a combination of data mining and evidence based rules to extract data from a hospital medical claims database (01/01/2013 – 12/31/2013), standard SQL and proprietary queries were used to access and claims related to a subgroup of diabetic patients. Building from a diagnosis code of 250.00 – 250.9, 120 adults were selected and their claims queried for medication adherence based on prescription filling patterns with an 80% or greater possession ratio, dates for HbA1c and LDL reported tests along with screenings for diabetic retinopathy and diabetic nephropathy.

Results
Adherence ratios for the subgroup diabetic patients were categorized into three classifications: diabetes care patterns, disease management, and medication adherence. Aggregate data from diabetes care patterns (e.g. frequency of physician visits and appropriate testing) and medication adherence (e.g. proportion of on time medication refills) were identified as potential indicators of behavior change. Findings from the historical record of 2013 indicate, that contrary to the recommendation of bi-annual HbA1c[3], only 66% of our sample had a HbA1c within this time frame. Less than 27% met the requirement for two HbA1c tests in the last 12 months. Medication adherence was also found to be sub-optimal in three-medication classifications that fell below the 80% threshold for adherence. These classifications included thiazolidedione-containing medication (75%), sulfonylurea (74%) and exenatide (29%). These data provide points of evaluation by which a successful targeted behavior change program may be evaluated.

Conclusion
Aggregation of health information into very large data sets and repositories offers extremely valuable opportunities and benefits[2]. A medical claims database contains valuable aggregate data on behavior and diagnosis specific adherence ratios, which provides a baseline for establishing a behavior change program.

Clinical Decision Support Integrated in the Electronic Medical Record to Reduce Overuse of Blood Product Transfusion in the Cardiac Surgery ICU

Joseph H. Skalski, M.D., James R. Stubbs, M.D., Andrew A. Higgins, R.N., Lance A. Trewhella, R.N., Robert R. Bleimeyer, Kristy H. Doan, James M. Naessens, Sc.D., Pedro J. Caraballo, M.D., Mark H. Ereth, M.D.
Mayo Clinic, Rochester, MN

Abstract
Inappropriate transfusion of blood products has been associated with adverse clinical outcomes. Our institution implemented a comprehensive patient blood management program specifically for patients undergoing cardiac surgery. Clinical decision support rules mine patient data from the EMR including recent laboratory data and uses our transfusion algorithm to calculate recommended blood product needs individualized to the patient. We present preliminary data after a successful implementation.

Introduction
A conservative blood product transfusion strategy has been demonstrated to improve patient outcomes in multiple clinical settings. Cardiac surgery patients often have high blood transfusion requirements. A conservative transfusion strategy is not consistently followed by clinicians practicing in the cardiac surgery OR's and ICU resulting in overuse of blood products. Our institution has developed and implemented a comprehensive patient blood management program to guide transfusion for these patients by using a transfusion algorithm guided by coagulation tests. This program uses multiple interventions including education, CPOE-based clinical decision support (CDS) and reports. We present preliminary data showing provider compliance and initial impact of the CDS rules integrated in the medical record, specifically in the computerized physician order entry system (CPOE).

Methods
Our institution uses GE Centricity Enterprise as the main component of the electronic medical record (EMR) including the CPOE system. We used several CDS interventions to implement a previously published transfusion algorithm based on chest tube output and recent coagulation tests after cardiac surgery: 1) A new order set that simultaneously shows the orderable blood products (red blood cell, platelets, fresh frozen plasma, cryoprecipitate and granulocytes), and recent related lab orders and results (CBC with differential, prothrombin time, activated partial thromboplastin time, fibrinogen, and thromboelastogram maximum amplitude). 2) If a provider attempts to order a blood product for a cardiac surgery patient, but the patient lacks necessary recent test results, then the expert system displays an alert advising the order of clinically indicated tests before ordering the transfusion. 3) If a provider attempts to order a blood product and the required tests results are up-to-date, the expert system uses the transfusion algorithm on the EMR data to calculate recommended blood product needs individualized to the patient. It also displays a pop-up alert explaining the selection and advice to pursue based on clinical judgment. The provider has the option to change the preselected orders before finalizing. The system captures transactional data to support analytics.

Results
The CDS rules were implemented in 2011. The initial post-implementation acceptance rate of CDS rule recommendations was over 95%. Overall, blood product use for cardiac surgery has decreased approximately 40% since implementation without negative impact on clinical outcomes. However, the rule was implemented alongside multiple other interventions to encourage conservative blood product transfusion, so this reduction in blood product use cannot be attributed entirely to the CDS rules but the reduction is likely sustained over time.

Conclusion
Integrating CDS rules with individualized defaults into CPOE to tailor transfusion recommendations based on specific patient parameters is an effective intervention that is well accepted by providers. A comprehensive implementation program, including education and analytics, facilitates implementation of advanced CDS interventions. Additional evaluation of the long-term impact of these CDS interventions is underway.

The Financial Costs Associated with Implementing Electronic Health Records in U.K. Hospitals.

Sarah P. Slight MPharm, PhD, PGDip[1,2,3], Casey Quinn, PhD[4], Anthony J. Avery, MD, FRCGP[5], David W. Bates MD, MSc[1,6], Aziz Sheikh MD, MB, BS[1,3,6].

Abstract: *With increasing numbers of healthcare institutions considering implementation of electronic health record (EHR) systems, we sought to identify and categorize the costs associated with implementation and the factors that can influence these costs. We conducted 41 semi-structured interviews with members of implementation teams at 12 U.K. hospitals. The cost categories identified in this study can assist hospitals in the development of their business plans.*

Introduction: EHR systems hold the promise of improving the safety, quality and efficiency of health care.[1] U.K. hospitals have been slow to implement and adopt such systems, however, due in part to their costs and to uncertainties about whether they can achieve a return on investment. With more and more health care institutions considering implementation of EHR systems worldwide, this study aimed to categorize the costs associated with implementation and the factors that can influence these costs.

Methods: After obtaining the necessary ethical and institutional approvals, we conducted 41 semi-structured interviews between February 2009 and January 2011 with a diverse range of staff involved in the implementation of three different, centrally procured, EHRs at 12 U.K. hospitals. These hospitals were among the first to receive these systems as part of the National Programme for IT. Informed consent was obtained from all participants and interviews were audio-recorded with permission. We adopted an iterative approach to analysis, which enabled us to refine questions, investigate specific cost categories in greater depth, and pursue emerging themes and concepts during subsequent data gathering. A workable list of main- and sub-themes was developed inductively and applied systematically to these data with the aid of the computerized qualitative data analysis software QSR N-Vivo.[2]

Results: We identified four overarching cost categories associated with implementing EHR systems, namely: infrastructure (e.g., hardware and software), personnel (e.g., project management and training teams), estates or facilities (e.g., furniture and fittings), and other miscellaneous costs (e.g., consumables and training materials). A number of factors were felt to impact on these costs. The amount and type of infrastructure chosen by different hospitals appeared to be dependent on the stage of hardware maturity within the hospital; the requirements of the software application being implemented; the products currently available on the market; the budget (if predetermined); and the physical requirements of the wards or office rooms. The amount of resources spent on training clinicians and administrative staff to use the new EHR system depended on the number of users at each site; training methods employed; decision to backfill staff; and level of support provided to clinical users.

Conclusions: Healthcare organizations faced hard compromises relating to cost. For example, the infrastructure implemented often did not satisfy the demands of ward staff at peak times, but having more infrastructure was perceived as too expensive. With cost being one of the most significant barriers to EHR adoption worldwide, it is important for hospitals and governments to be clear from the outset as to the categories of costs involved and the factors that may impact on these costs, as well as the potential benefits which may result from the investments. The cost categories identified in this study can assist hospitals in the development of their business plans.

A Comprehensive Simulation Modeling Methodology to Reduce Health Care Process Redesign Risk

Rita Snyder, PhD, RN[1], Kevin Bennett, PhD[2], Bo Cai, PhD[3], Nathan Huynh, PhD[4], José Vidal, PhD[4], Bridgette Parsons, PhD(c)[4], Kolby Redd, MHA[1]
[1]College of Nursing; [2]School of Medicine; [3]Arnold School of Public Health; [4]College of Engineering & Computing; [1-5]University of South Carolina, Columbia, SC, USA

Problem. Redesign of high-risk health care processes can lead to unanticipated consequences. Ash, et al.[1-2] highlighted the significance of understanding clinical practice processes prior to implementation of CPOE systems. Others[3-4] have emphasized the need for better methods to assess EMR impact on clinician teamwork, and clinical communication processes. The persistent implementation failure of health information technology (HIT) innovations has escalated the need for better methods to assess pre-implementation workflow, and ongoing HIT implementation impact on workflow processes.[3-4] A comprehensive process redesign methodology is needed to examine the potential impact of process redesign interventions in advance of implementation.[4]

Methodology Description. A comprehensive three-phased health care process redesign methodology that integrates statistical and computer simulation modeling approaches is described (Figure 1). The goal of the methodology is to reduce process redesign risk in advance of actual intervention implementation. ***Phase 1*** supports multi-source contextual data collection. ***Phase 2*** uses Phase 1 data to iteratively model baseline workflow processes that are validated by subject matter experts until the most representative process model is identified. In ***Phase 3***, stakeholders examine the impact of simulated process redesign interventions on health care outcomes to determine the most feasible redesign intervention.

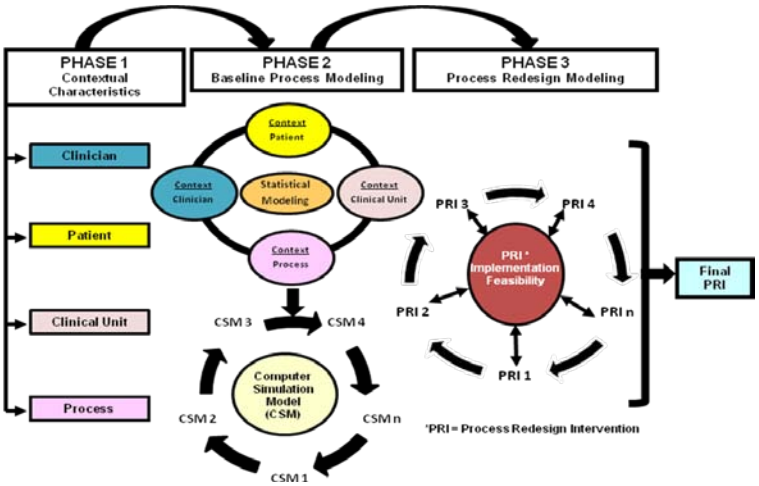

Figure 1. Comprehensive health care process redesign methodology.

Methodology Pilot Field Testing. Phases 1 and 2 were pilot tested on 2 comparable medical-surgical units using the medication administration process (MAP). Contextual data, consisting of RN characteristics, 305 RN MAP observations, and medication administration errors warnings corresponding to MAP observations, were examined using statistical and computer simulation modeling approaches. No statistically significant contextual differences were found between the 2 study units. Computer simulation modeling of MAP observations identified 2 types of RN MAP workflow patterns that corresponded to RN experience level, i.e., bundled=more experienced; unbundled=less experienced.

Conclusion. Field test findings supported Phase 1 and 2 data collection procedures, metrics, and statistical and computer simulation modeling approaches. Additional work is underway to field test expanded subject matter process model validation, and Phase 3 stakeholder redesign intervention feasibility assessments.

Exploration of Potential Drug Off-label Uses in Clinical Practice

Sunghwan Sohn, PhD[1], Hongfang Liu, PhD[1]
[1]Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN

Abstract

Off-label drug use is common in clinical practice but most of these off-label uses lack rigorous scientific evidences to support them. However, off-label drug use is legal and often useful. Analyzing actual clinical practice of off-label uses will be beneficial for patient treatments, patient safety, and quality improvements. In this study, we explored actual clinician-asserted drug uses from a large patient cohort in Mayo Clinic and compared them with the public drug usage database in order to investigate potential drug off-label uses.

Introduction

Off-label drug use is an intended drug use that is not approved by the FDA. It is very common in clinical practice. One in five prescribed medications in the U.S. is off-label. Although there are some public drug resources, they contain primarily labeled drug uses. A study that analyzed actual off-label drug uses in real clinical practice was limited. In this study, we compiled clinician-asserted drugs and their intended uses from clinical notes of 140K patients whose primary care is at Mayo Clinic and explored potential off-label uses.

Materials and Methods

We examined the Current Medication sections in clinical notes where most drugs reside and some of these drugs occur with clinician-asserted indications (i.e., drug uses) in a semi-structured way. We extracted the drugs using an open-source medication extraction and normalization system, MedXN (published in sourceforge) and indications using regular expressions. We then normalized the drug-indication pairs to standard terminologies—i.e., drugs to RxNorm ingredients and indications to SNOMED-CT concepts using RxNorm relation and MedTagger (published in sourceforge), respectively. Finally, we aggregated all indications along with their frequency for a given drug. These drug-indication pairs were compared with the public drug-indication resource, MEDI that is compiled from RxNorm, SIDER2, MedlinePlus, and Wikipedia. MEDI also contains a marker, 'possible label use,' which denotes whether a given indication is highly likely on-label or not.

Results

We investigated statistics at a different level based on the volume of patients who have a given drug indication. Mayo's drug-indication pairs match MEDI approximately 58% to 68% of the time, depending on patient volume. Figure 1 shows the portions of potential off-label candidates when $\log_2$(#patients) is >=5. Table 1 contains potential off-label uses.

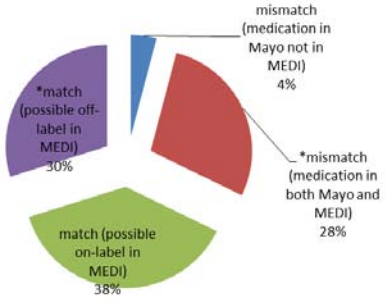

Figure 1. Off-label candidates (starts with *)

Table 1. Examples of potential off-label indications

Medication	Potential off-label
Brimonidine	photophobia
Bupropion	smoking cessation assistance
Albuterol	cough
Doxepin	allergies, hives
Azithromycin	traveler's diarrhea
Gabapentin	hot flashes
Trazodone	difficulty sleeping
Methylphenidate	depression

Discussion

Mayo's drug-indication pairs demonstrate that they have both off- and on-label medication uses. The ratio of potential off-label candidates, when restricted to candidate pairs that occurred in >=32 patients, is approximately 58%. However, it should be noted that this ratio in our results does not represent the actual off-label uses because we only investigated included indications. A well-managed database of actual off-label uses would likely prove beneficial to clinical practice. Our study may serve as a foundation for further investigation and the eventual development of such a database.

Google Glass for clinical procedures reference. Perception of optimal UI (user interface) and functionalities.

Yauheni Solad[1], MD; Nitu Kashyap[2], MD; Allen Hsiao[2], MD
[1]Yale University, Yale Center for Medical Informatics (300 George Street, Suite 501, New Haven CT); [2]Yale New-Haven Hospital (20 York Street, New Haven, CT 06510)

Background

Clinical procedures learning is one of the crucial steps in medical education. During residency, especially in small community hospitals, lack of required supervision can potentially limit the trainee's procedural exposure. Despite the abundance of reference material, not all references provide a quick procedure review, especially at the point of care. Wearable devices provide the opportunity to address this issue by providing crucial information at the point of care without clinical workflow interruption. Google Glass is an Android-powered wearable device with a consumer grade HUD (head-up display).

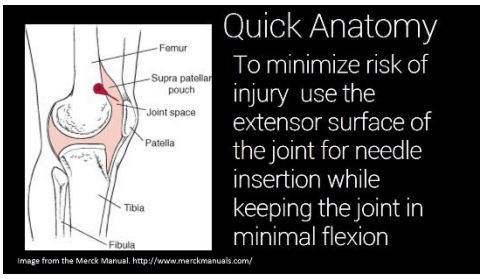
Goal

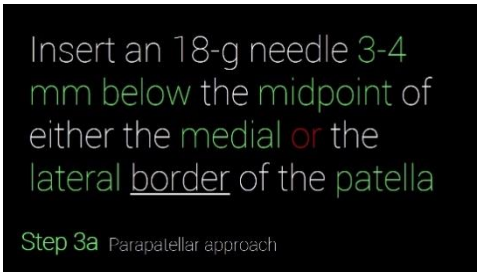
To evaluate perceptions of the different types of Google Glass user interfaces for clinical reference systems.

Methods

For demonstration purposes, we developed several versions of user interfaces (UI) for the Google Glass procedures reference system. Knee arthrocentesis was selected as a sample procedure and all versions utilized similar step-by-step procedural instructions. Demonstrated UI included one of the following: textual information, textual information and audio ("read aloud" function), graphic information, a combination of textual and graphic information, or video fragments.

To assess the UI perception, we surveyed medical students and residents at Yale New-Haven Hospital. After the demonstration, respondents answered a series of questions about the UI usability and potential applicability in clinical care. Examples of the Google Glass views:





Results

Preliminary data showed high levels of acceptance of the technology among medical students and residents. The combination of visual and auditory data in UI was found to be the most useful. Given the relatively small size and low-contrast level (especially in bright environments) of Google Glass display, textual information was found useful only in conjunction with audio ("read aloud"), especially if the view included significant amounts of text. Smaller video fragments, focused on every procedural step, got higher acceptance levels versus full procedural video. The majority of respondents supported the idea of potential live video procedure streaming to a supervisor. Many respondents liked the overall concept, but a significant number of questions were raised concerning patient privacy and degree of device acceptance in the patient population. Also technical limitations like: device security, heating problems and low battery time were found to be potential barriers to widespread device implementation.

Modeling Propensity for Readmissions with Claims Data

Gerardo Soto-Campos, PhD, MS,[1] Elisabeth L. Scheufele, MD, MS,[1,2] Aditya Sane, MS,[3] Santosh Narayanan,[1] Matvey B. Palchuk, MD, MS[1,2]
[1]ConvergeHealth by Deloitte, Deloitte Consulting LLP, Newton, MA; [2]Harvard Medical School, Boston, MA;
[3]Deloitte Advanced Analytics, San Jose, CA.

Abstract

We built a predictive model for hospital readmissions using claims data. The probability of hospital readmission was computed as a logit model. The coefficients for the logit model were trained with a Lasso regression on a set of 237,129 patients and tested on 70,465. The model's discriminative power evaluated via ROC was 0.813 and its calibration had p <0.05 assessed using the Hosmer-Lemeshow test.

Introduction

Health care organizations have been working to lower hospital readmission rates. Existing patient care models have been shown to improve readmission outcomes,[1] but solutions must be developed to help focus efforts on patients most amenable to readmission preventive management. Well validated predictive models offer a great alternative towards this solution. However, currently published readmission models report modest discriminative power (c-statistics varying between 0.55 and 0.75).[2] Hence we built a patient level predictive model for hospital readmissions with claims data using Lasso regression[3] which allows the inclusion of hundreds of covariates in a single model, thus taking advantage of the multitude of attributes available in patient data.

Methods

The probability for readmissions was obtained via a logit model with specific coefficients provided by the Lasso regression. MarketScan[4] data containing information on demographic, administrative, and some clinical data was used to build and validate the model. The model's discriminative power was estimated via a receiver operating characteristic (ROC) curve[3] and its calibration was evaluated with the Hosmer and Lemeshow's approach.[5]

Results

The original Lasso regression used 403 covariates. The model was trained with a random sample of 237,129 patients. The coefficients describing the probability of readmission in this model were applied to each patient of an independent testing set of 70,465 random cases. The ROC curves, with c-statistic and 95% CI and the Hosmer-Lemeshow p-values were computed (see Table 1).

Set	N	c-stat (95% CI)	Hosmer-Lemeshow p
Testing	70,465	0.813 [0.809 , 0.817]	<0.05
Training	237,129	0.820 [0.818 , 0.822]	<0.05

Table 1: Lasso Model of Readmission Propensity

Discussion

Our model has better c-statistic than most of the currently published readmission models. It separates readmission cases from non-readmission cases more than eighty percent of the time (c-statistic = 0.813). The low p-values found in the recalibration (Hosmer-Lemeshow, HL) may suggest that the predicted probabilities of readmission overestimate the actual observed readmission risks in the data. However, there is evidence[5] that for N larger than 50,000 a Hosmer-Lemeshow test with p-value smaller than 0.05 does not necessarily imply that the model's predictive capabilities are suspicious or that the goodness of fit is incorrect. Next steps include using different non-linear approaches taking into account variations in readmission risk as a result of geographic location and incorporating data from the clinical environment (e.g., labs, radiology results, etc.) into the model.

Specifying Initial Requirements and Architecture for the CUPID System

Karen Sousa, PhD[1], Blaine Reeder, PhD[1], Mustafa Ozkaynak, PhD[1], John Welton, PhD[1]
[1]University of Colorado College of Nursing, Aurora, CO

Abstract

There is a need for distributed data sharing networks that enable analysis of patient data aggregated from multiple hospitals to answer operational research questions, especially those related to nursing work and patient outcomes. The University of Colorado (CU) College of Nursing (CON) is leading the effort to develop such a system in collaboration with regional hospitals and other stakeholders. This poster describes our efforts to define requirements and architecture for the CUPID system.

Introduction

One of the primary goals of the Colorado Collaborative for Nursing Research (CCNR) at CU CON is to create a nursing data analysis center that enables near real-time nursing quality metrics from electronic health record data and delivers these metrics and trends back to hospitals for operational decision-making. This goal is being realized through the work of a CCNR technical team with efforts to design and develop the University of Colorado Patient Initiated Data (CUPID) system. The purpose of the CUPID system is to improve efficiency and effectiveness of quality patient care by changing the paradigm of how we use data to drive care processes.

Methods

The CCNR technical team has deep experience in nursing research, informatics and system design. Our current goal is to specify the requirements for CUPID and evaluate candidate systems that will meet these requirements. Through regular meetings we have specified data aggregation use cases that CUPID must support. Our design approach is informed by a reusable design philosophy[1] through which we seek to leverage existing systems and infrastructure to meet CUPID system goals. As part of this approach, we have initiated collaboration with CU Colorado informatics colleagues who recently completed the requirements and evaluation process for the Colorado Health Observations Regional Data Service (CHORDS)[2] project. Regular meetings of the CCNR team have resulted in a timeline for deliverables linked to requirements, a working list of use cases and candidate systems for evaluation.

Results

A partial list of use cases that CUPID must support includes: 30-day hospital readmissions; nursing work as it relates to patient outcomes; verification of patient symptom documentation by nurses; and workflow analysis through EHR documentation. In addition, we have created a general process flow for CUPID related to these use cases for data publishers and subscribers from participating organizations (Figure 1).While due diligence efforts to evaluate candidate systems must still be conducted, a comparison of CHORDS functional requirements with early CUPID requirements shows promise that CHORDS infrastructure aligns with system needs.

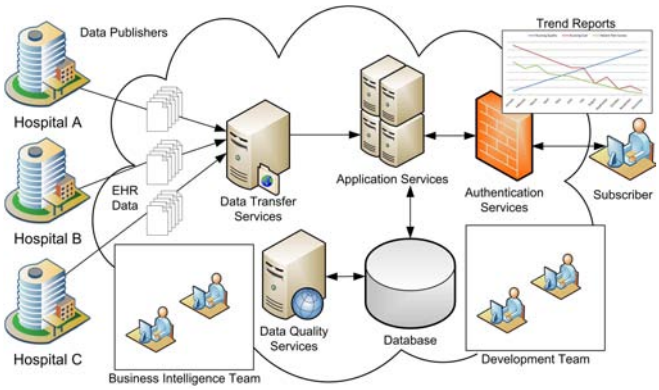

Figure 1. CUPID system process overview

Conclusion

Full CUPID requirements and results of evaluation efforts will be presented in addition to progress of the CUPID project at the AMIA Annual Symposium in November 2014.

A System Usability Study Assessing a Machine-Assisted Interactive Interface to Support Annotation of Protected Health Information in Clinical Texts

Brett R. South, MS[1,3], Danielle L. Mowery, MS[1,4], Jianwei Leng, MS[1,2]
Stéphane M. Meystre, MD, PhD[1,3] , Wendy Chapman, PhD[1,3]
[1]Salt Lake City VA Health Care System, Departments of [2]Internal Medicine & [3]Biomedical Informatics, University of Utah, Salt Lake City, UT; [4]Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA

Abstract: *Redaction of HIPAA-specified protected health information (PHI) from clinical texts remains an important research topic in the clinical NLP domain. Reducing the manual workload required to adequately de-identify clinical texts is one area that could benefit from machine-assisted annotation methods. Using a publicly available clinical corpus, we assessed usability of a machine-assisted approach that combined outputs from an existing de-identification system called BoB and outputs from an interactive interface called the "Oracle Module" from an annotation tool, extensible Human Oracle Suite of Tools (eHOST). From our annotation experiment, we report annotator perceptions from a self-reported questionnaire obtaining System Usability Score (SUS) ratings.*

Introduction: Generating a reference standard that identifies PHI types defined by HIPAA[1] is a challenging task. More efficient approaches to this task could be used to reduce the workload associated with manual review. We assess the usability of a machine-assisted approach that integrates pre-annotations from a de-identification system with outputs from an interactive annotation interface. The SUS developed by Brooke[2] is a simple, ten-item attitude Likert scale that provides a global view of subjective assessments of usability. System usability can be measured by taking into account the context of the system being used by those who use it for a specific task– in this case de-identification of clinical texts. Key dimensions of usability integrated with SUS include ***system effectiveness***, ***user satisfaction,*** and ***system efficiency*** which were assessed for this usability study.

Methods: We randomly sampled 1,535 unique texts from a sample of 2,330 clinical reports comprised of 40 subtypes from the publicly available MTSamples corpus (www.mtsamples.com). To generate pre-annotations, we applied a de-identification system called BoB - "Best of Breed" - originally developed in the Consortium for Healthcare Informatics Research (CHIR) De-identification project[3]. Seven reviewers independently annotated this subsample for all annotation types applying the CHIR annotation guidelines and schema. For the annotation experiment, we implemented a nonequivalent control group design with replication switching. Annotators alternated an experiment condition of reviewing document batches using the machine-assisted approach (BoB+eHOST Oracle) with a control condition of annotating raw documents (no BoB+eHOST Oracle).

Results: ***System effectiveness:*** Usability ratings obtained from SUS were slightly above average (69%). False positive annotations were introduced for <1% of eHOST Oracle annotations versus 67% introduced by BoB. ***User satisfaction***: Although annotators indicated they preferred using the eHOST Oracle module alone, eHOST Oracle only accounted for 640 (3.6%) out of 17,643 annotations generated by all 7 annotators. ***System efficiency:*** No statistically significant gains in efficiency were observed comparing the machine-assisted approach with the control.

Conclusion: Further research is required to assess under what conditions machine-assisted approaches result in above average usability ratings and efficiency gains.

A universal software-tool supporting proper continuity of care data handling

Basile Spyropoulos, PhD[1], Maria Botsivaly, Msc[1], Vasileios Pierros, Msc[2], Mamakou Vassiliki, MSc, MD[3], Aris Tzavaras, PhD[1]
[1]Technological Educational Institute (TEI) of Athens, Athens, Greece, [2]University of Athens, Athens, Greece, [3]Dromokaiteion Psychiatric Hospital, Athens, Greece

Abstract

It is the aim of this project to present the work progress of a multifunctional web-based framework, designed to support the continuity of health care information management, as the patient moves between different points of care. The system consists of a Patient Management module, a non-Hospital Scheduling and a non-Hospital Supervision module, serving proper continuity of care handling. It complies with E2369 (CCR)[1] and ISO 13606-1:2008[2] Standards and it combines symmetric and asymmetric cryptographic algorithms' data-protection.

Introduction

Healthcare provision will soon move towards outpatient, community and homecare schemata. This development is expected to provide for the upcoming demand for patient-centered care, while reducing at the same time the level of reimbursement for healthcare organizations and providers.

Methods and Resources

We have developed a complete platform, to ensure Continuity of Medical Care among Primary Health-care Agencies, Hospitals and Home Care, according to existing International and European regulations and standards, together with the emerging relevant Greek National ones. The platform is web-enabled and modular, consisting of three applications, the Patient Management, the Non Hospital Scheduling and the Non Hospital Supervision. The system utilises all the appropriate sets of clinical terminologies, coding systems and vocabularies[3]. It is also designed in such a way as to provide for both multilingual user interface and for the use of different terminology and coding systems as well, depending on the user's preferences. The system has some additional special features as it is the formation of CCRs according to different standards and the transmission of referral letters using a semantically annotated web service. The Non-Hospital Scheduling application offers a very flexible and easily adoptable module for the physician to schedule the homecare activities that are recommended for each particular patient, while the Non Hospital Supervision applications provides for both the surveillance and the monitoring of the homecare plan.

Results

The system in progress is currently being tested in our laboratory with anonymised data provided to us by the physician participating in our team. Both the services and the data bases are stored in our laboratory's server, which hosts a Windows 2008 Server System with IIS 6.0 (Internet Information Services). The various coding systems, clinical terminologies and vocabularies that are used in different countries have different annotations and hierarchical structures, making it difficult to create a unitary user interface, applicable to different countries. Semantic Web technology appears to be a feasible solution. Nevertheless, significant efforts still have to be made towards the realization of semantically reach distributed networks in healthcare domain. Such technologies require the development and adoption of well-structured and annotated vocabularies and the use of appropriately designed formal ontologies. The non-Hospital Supervision may be operated as a web-based and a stand-alone application, supporting a local database stored in home computer and allowing for the decision supporting services to be executed locally.

Conclusion

Regarding the system's architecture, we consider that the use of web-based techniques are appropriate for such applications, since web-based models allow for numerous distributed users; while reducing the maintenance task to a group of web servers at the same time.

Abstract: *The goal of an interdisciplinary, patient-centered plan of care is to actively engage patients, nurses, and physicians in meaningful collaboration. Currently, patients and family caregivers are not formally involved in developing their plan of care while recovering from acute illness in the hospital. Diagnoses, problems, goals, and safety measures are documented in several places across disciplines. To meaningfully engage patients in developing their plan of care through the use of bedside technology, information documented by nurses, physicians, physician assistants and sub-specialists must be reconciled. In this study, we describe our methodology for developing a web-based interdisciplinary, patient-centered plan of care.*

Introduction: Patients want easy access to meaningful medical information while in the hospital and ways to effectively communicate with their providers to engage in recovery. We previously identified a core set of information needs to engage patients in their plan of care using web-enabled devices at the bedside.[1] Our first prototype offered provider identification, medications, test results, and dietary information. However, a method of providing information such as medical problems, goals, and safety precautions to the patient at the bedside is not available due to current methods of documentation. Furthermore, there is limited ability to capture the patient's goals and concerns and communicate them back to the care team. In this study, we develop and test web-based interdisciplinary plan of care tools for providers and configure them to interact with the patient portal at the bedside.

Methods: We conducted observations in medical intensive care and oncology units at Brigham and Women's Hospital to identify workflow processes and methods for documenting the plan of care by nurses and physicians. We reviewed 17 nursing plan of care worksheets where problems and goals were documented. Subsequently, we conducted qualitative focus groups with healthcare providers facilitated by rapid prototype development of 10 + versions in PowerPoint and InfoPath to simulate electronic versions of the web-forms. Usability testing was performed on provider and patient facing tools.[2] Bedside interviews were conducted to obtain feedback on the patient facing tool with accessible plan of care content.

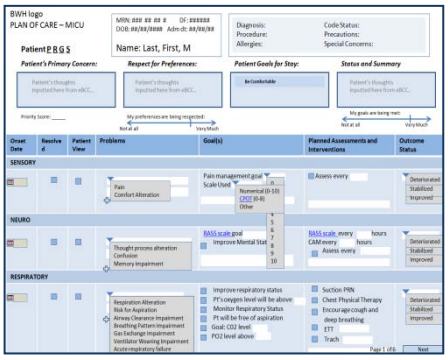

Figure 1- Prototype of a web-based interdisciplinary patient-centered plan of care. Patients' goals and preferences for care are displayed for clinician view and medical problems and goals are selected for patient view at bedside.

Results: Plan of care documentation methods and workflows such as morning rounds and family meetings were identified. Structured problems and goals were adopted from the Clinical Care Classification system and integrated into a web-based plan of care worksheet (Figure 1).[3] Tailored plan of care information was made available on the bedside devices with infobuttons linking to Medline Plus to provide patients self-managed education. A rounding checklist tool was developed to inform patients of safety precautions related to preventable harms and to provide clinicians with risk assessment data. The patient plan of care at the bedside was optimized for the iPad Air.

Conclusion: We developed innovative web-based tools that promise to facilitate development of an interdisciplinary, patient-centered plan of care. We plan to refine and implement these tools for patients, family caregivers, and providers to use in the medical intensive care and oncology units at Brigham and Women's Hospital.

Facilitating Reconciliation of Inter-Annotator Disagreements

Johann Stan, PhD, Dina Demner-Fushman, MD, PhD, Kin Wah Fung, MD, MS, Olivier Bodenreider, MD, PhD,
Lister Hill National Center for Biomedical Communications, U.S. National Library of Medicine, National Institutes of Health, DHHS, Bethesda, MD

Abstract

Development and evaluation of Natural Language Processing methods often requires text annotation. To gauge the difficulty of the task and increase the reliability and quality of annotations, researchers often recruit at least two annotators. The discrepancies in annotations by multiple annotators need to be identified and reconciled. We present a tool that identifies and helps reconciling and validating annotations in a widely used annotation tool Brat.

Introduction

In the process of annotating a corpus of drug package inserts for drug-drug interactions, we were faced with a problem of reconciling differences in fairly complex annotations of interactions between drugs, drug classes and substances. Our goal was to annotate interactions for training supervised machine learning (ML) algorithms and evaluating the results. Annotated corpora are most useful for training ML tools if they are consistent. To ensure consistency, two experts annotated the interactions and two senior annotators adjudicated the disagreements. To facilitate annotation, we used Brat[1] that is fairly convenient for annotation, but does not provide mechanisms for reconciliation of disagreements. Therefore we have developed functions that allow reconciling disagreements and ensure consistency of annotation across similar interactions mentioned multiple times in the drug package inserts.

Methods

The *Disagreement Reconciliation module* compares annotations by two annotators and uses line numbers in the files loaded to Brat for annotation to indicate the location of disagreements. The following details about the disagreements are printed to a text file: 1) absence of an annotation, for example, *"119 MISSING FROM FILE 1 Type: Drug Span: Amplodipine"* indicates that the first annotator did not highlight Amlodipine as drug in the 119th line of the package insert; 2) different labels assigned to the same span, for example, if one of the annotators labeled *alcohol* as substance, and the other one as drug. The *Sentence Validation module* identifies similar sentences and checks if they have been annotated consistently. Sometimes different package inserts for drugs in the same drug class or different sections of an insert contain almost identical sentences. These sentences can be used to quantify intra-annotator agreement over the entire annotation process, as well as consistency in reconciling disagreements. Sentence similarity was computed using an implementation of the *Jaccard* similarity measure (threshold 0.75). Annotated biomedical entities as well as those identified by Metamap were replaced with standard names, e.g. "drug" in order to capture similar syntactic constructions used for different representatives of drug classes with similar pharmacodynamic and pharmacokinetic properties.

Results

We tested the annotation reconciliation tools on 176 manually annotated package inserts (8081 biomedical entities and 4841 interactions). The tools identified 2584 discrepancies, of which 1200 were in entity annotation and 1384 in interaction annotations. 320 similar sentences were annotated inconsistently (e.g. different types attributed to same drugs or different interaction types).

Conclusion

The tools helped us improve annotation guidelines and detect and reconcile discrepancies. To the best of our knowledge, this is the first publicly available extension for assisting with discrepancies and assuring consistency of annotations using Brat. The toolkit can be downloaded from http://lhce-brat.nlm.nih.gov/disagreementAnalyzer.htm

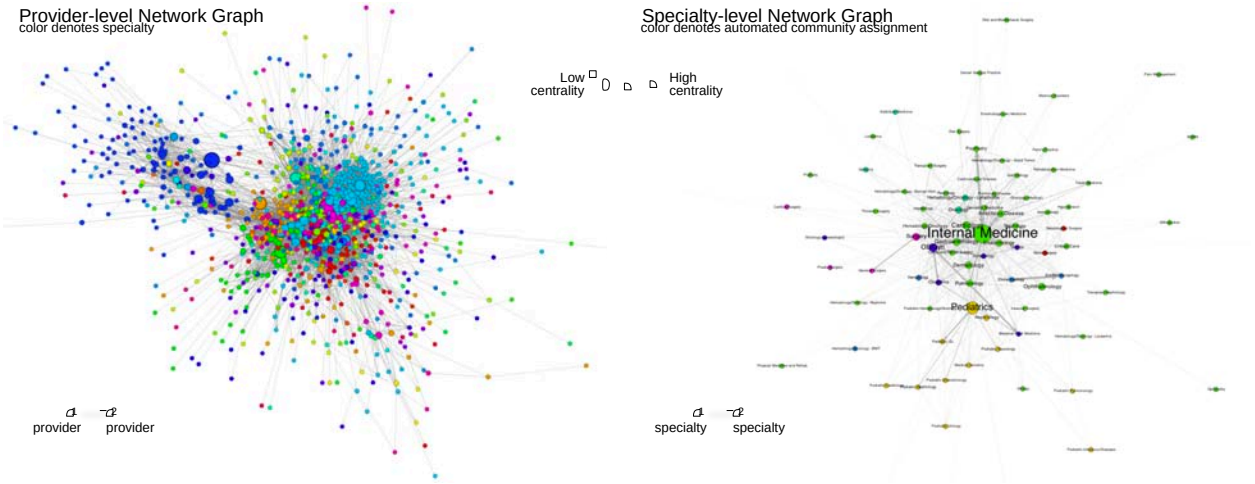
Social Network Analysis of EHR-Based Provider Communication

David E. Stark, MD[1], Zachary M. Grinspan, MD, MS[1,2], Daniel M. Stein, MD, PhD[2]
[1]Division of Pediatric Neurology, Department of Pediatrics and [2]Department of Healthcare Policy and Research, Weill Cornell Medical College, New York, NY

Introduction: Chronic illness drives a substantial percentage of national health expenditures. Effective care coordination is essential to longitudinal management of this population, and has been a key motivator driving large investments in health information and communications technology. Despite the substantial cost and uptake of communication tools to facilitate team-based collaborative care, their usage patterns remain relatively understudied.
Methods: We conducted a retrospective cross-sectional analysis of EHR-based communication within the ambulatory care network of a large academic medical center. We obtained all patient-linked provider-to-provider messages generated over an 8-month interval (8/2012-4/2013) and employed social network analysis to construct network graphs at the level of individual providers and provider specialties. In addition to performing an exploratory analysis of electronic communication patterns, we sought to determine the extent to which measurable differences in communication patterns might exist among primary care practices. In particular, we contrasted a hospital-based practice largely serving a public insurance population with hospital-affiliated practices caring predominantly for privately insured patients. Recognizing that these practices differ in many respects, we expected to measure quantifiable differences in communication patterns among the practices. Specifically, we hypothesized that within their respective networks, PCPs for privately insured patients would exhibit greater relative centrality as compared with PCPs for publically insured patients, reflecting a greater tendency for care management within the former group to conform to a 'hub-and-spoke' model in which the PCP (as the hub) communicates directly with specialists.
Results: We collected and analyzed 40,753 messages between 1,060 providers (89% MDs) regarding 12,393 patients. Providers exchanged on average 2.6 messages/week (range 0.06 – 73.9), typically during business hours (weekdays, 8a-5p). As in other domains, social network analysis recapitulated formal organizational structures and unveiled other informal communication patterns. Automated community detection (Walktrap algorithm) revealed four major clusters consisting of medical, surgical, pediatric, and OB/Gyn subspecialties. Further inspection also revealed interdisciplinary subnetworks; for example strong ties between specialists within internal medicine, infectious disease, and psychiatry involved in the care of HIV patients. As hypothesized, quantifiable differences emerged between public- versus private-insurance practices. Messages regarding private-insurance patients were more likely to be exchanged between a PCP and a specialist (47% of private-insurance messages versus 27% of public-insurance messages) and less likely to be between PCPs (35% private vs. 50% public) or between specialists (18% private vs. 23% public), X^2 (2, N = 14,036) = 526.37, $p < 0.001$. Network analysis at the provider level demonstrated that PCPs in the private-insurance network had substantially greater relative betweenness centrality than PCPs in the public-insurance network (4.0 versus 2.1, Wilcoxon rank sum test, W = 7694, $p = 0.003$). At the specialty level, overall graph centralization was greater for private- versus public-insurance patients (0.71 versus 0.64, respectively).
Conclusion: Social network analysis permits quantitative measurement of EHR-based provider communication. Our findings are foundational for ongoing work developing novel methods to quantify care coordination. Such measurements will support (1) research to identify factors associated with care coordination and (2) initiatives to develop more advanced social computing tools within EHRs for facilitating coordinated care.



Collaborative mHealth Tools for Diabetes Management

Bryan Steitz, Erika Poole PhD, Madhu Reddy PhD
College of Information Sciences and Technology
The Pennsylvania State University, University Park, PA

Mobile health interventions are an important part of the self-management of diabetes. The use of mobile technologies to support collaboration among stakeholders is important for effective self-management. We surveyed eighteen healthcare professionals in order to better understand the collaboration and data needs for the successful implementation of mobile health tools for diabetes self-management.

Background

It is estimated that 382 million people worldwide are living with diabetes.[1] Mobile health (mHealth) technologies are at the forefront of diabetes self-management and have shown promising results in the management of diabetes-related complications. Patients must undergo a lifetime of treatment and self-management, much of which can be assisted by the use of mHealth tools in collaboration with their care providers. Current applications offer a variety of self-management tools such as educational materials, nutrition tracking, activity monitoring, and blood glucose management. However, the extent to which collaboration is supported in such applications has been relatively unexplored.

Methods

We surveyed a cross-section of participants (industry and academia) of the National Science Foundation's Center for Health Organization Transformation's (CHOT) fall meeting to identify potential opportunities and barriers for using collaborative mHealth diabetes management applications. The brief survey included six open-ended questions dealing with collaboration or the use of such applications for collaborative management with external stakeholders. Eighteen surveys were distributed and twelve (66.7%) were completed. Survey results were compiled into an Excel spreadsheet and analyzed for common themes.

Results and Discussion

The majority of respondents indicated that collaboration between the patient, family, and physicians is most important for diabetes self-management tools. For the applications themselves, patient compliance with self-management interventions and medications is among the most important for the surveyed healthcare professionals, followed by the BG levels and results of other tests. When designing diabetes mHealth applications, they should be simple to use so that older patients can operate them. The development of diabetes self-management applications should focus on the collaboration between stakeholders, especially when dealing with adolescents and elderly users.[2, 3] The increased use of diabetes mHealth tools with a collaborative focus will provide additional benefits to all users and will allow the physician to provide higher quality and more accurate care.

Conclusion

The impact of specific features for diabetes self-management mHealth applications is not easily determined, but our findings support the need for additional collaboration. Present applications offer a variety of services for self-management, but without additional collaboration features mHealth will not reach its maximum potential.

Acknowledgement

This research was supported by a grant from Penn State University's Center for Integrated Healthcare Delivery Systems (CIHDs).

An Integrative Framework for Drug Target Prediction and Repurposing

Jingchun Sun, Ph.D[1], Cui Tao, Ph.D[1], Kevin Zhu, BMath[1], W. Jim Zheng, Ph.D[1], Junjie Chen, Ph.D[2], Hua Xu, Ph.D[1]
[1]School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX 77030, USA
[2]Department of Experimental Radiation Oncology, The University of Texas MD Anderson Cancer Center, Houston, Texas 77030, USA

Discovery of the safe and effective drugs and their targets play important roles to improve the health care. However, the process is very time-consuming and expensive, especially for complex diseases. Recently, computational approaches for target prediction and drug repurposing have become more common and effective compared to traditional observation-based drug discovery. However, since the data about underlying molecular mechanisms of drugs distribute among different knowledge domains and different databases, it is very challenging to design effective strategies to discover novel drug targets and propose successful drug repurposing. To alleviate this problem, we propose a computational framework to integrate complex relationship among different types of data and infer the potential drug targets by using the semantic web technology, and to improve performance through network neighborhood effect modeling. In this study, we utilize the colorectal cancer (CRC) as a proof-of-concept use case to evaluate the approach.

We collected the FDA-approved drugs to treat CRC from the NCI Cancer Drug Information website. Using these CRC drugs, we constructed a CRC ontology including drugs, diseases, genes, pathways, SNPs, and their relations from the database PharmGKB. From the CRC ontology, we inferred potential CRC drug targets using specified Web Ontology Language description logic rules. Starting from these potential targets, we first ranked them based on the fraction of CRC disease genes in their neighborhood at the first, second, and third shortest-path distances and then integrated the three sets of ranking using a robust rank aggregation (RRA) method. These CRC disease genes were collected from the Cancer Gene Census, the Online Mendelian Inheritance in Man (OMIM), and the Genetic Association database (GAD). Finally, from the significantly ranked genes, we inferred the drugs for CRC treatment based on the drug-target association from the DrugBank and the therapeutic target database (TTD).

Starting from eight FDA-approved CRC drugs and the CRC ontology, we inferred 113 potential CRC drug targets. The 113 genes were significantly enriched with CRC disease genes when compared to the 20,737 human protein-coding genes, which was more than expected by chance (Hypergeometric test *P*-value: 4.96×10^{-10}). Additionally, they were significantly enriched in the pathways related to drug metabolism by KEGG pathway enrichment analyses. Among the 113 genes, 15 were selected as the promising drug targets based on their neighborhood of CRC disease genes in the context of one human PPI network. For example, three of them encode known CRC drug targets (*EGFR*, *TOP1*, and *VEGFA*). Considering that the drugs targeting the promising CRC target genes could be used to treat CRC, we inferred 73 potential drugs for CRC treatment by mapping the 15 promising drug targets to drug-target association from the DrugBank and TTD data. We validated these drugs by comparing their overlap with the drugs studied in CRC clinical trials. We found that, among the 73 drugs, 18 have been investigated in at least one CRC clinical trial. For example, the drug celecoxib has been investigated in the 35 clinical trials for CRC either alone or in combination with other drugs. Celecoxib is an anti-inflammatory drug and a selective COX-2 inhibitor used for the treatment of osteoarthritis, rheumatoid arthritis, acute pain, painful menstruation, and menstrual symptoms. It has been regarded as a promising drug for the treatment of familial adenomatous polyposis (FAP), an inherited disorder characterized by cancer of the large intestine (colon) and rectum. The results indicate that our computational framework is promising for drug target prediction and drug repositioning.

Therefore, in this study, we developed a unique computational framework to integrate the ontology technology and network neighborhood modeling for drug target prediction and drug repurposing. The results demonstrate that this framework indeed identifies the novel targets and drug repurposing. Besides, we see many opportunities to improve upon the basic design of this integration, including integrating more relationship from multiple data sources during the ontology construction, application of score strategies in the ontology reference, and the combination of more network properties into the gene ranking.

Journaling and Journal Retrieval: An Information Management Tool to Assist Chronic Patients' Everyday Self-Management

Si Sun, MS
School of Communication and Information, Rutgers University, New Brunswick, NJ.

Abstract

An information management tool incorporating journaling and information retrieval features is designed to help people living with chronic diseases understand their health conditions and make health-related decisions. The study is carried out in two stages. In stage one, a prototype system is designed and five experienced type 2 diabetes patients provided feedback regarding the system during a semi-structured interview. In stage two, a smartphone application will be developed and its usability tested with 20 diabetes patients. This poster presents the results of stage one.

Introduction

Information management is a major barrier for the self-management of chronic conditions. Information overload, information fragmentation, and the ephemeral quality of daily information make it particularly difficult for patients to keep track of their health condition and act upon its development. In this circumstance, two methods – journaling and mapping tools – have attracted increased attention as important venues to help patients garner their daily health information. This study attempts to develop a tool with the combined advantages of both methods.

Background

Journaling that uses unstructured data and visualization of structured health information are two major methods that could promote healthful behaviors. For example, journaling can achieve this through increasing patients' awareness toward their health conditions[1]. Also, visualizing information can provide patients with health records for self-education[2]. However, both methods have issues that prevent them from reaching their potentials. For example, information overload is a common issue with journaling that make it hard for patients to recall the existence of useful information[3]. Also, a problem with structured health information is that it does not support the vast diversity of patient behaviors that can differ between individuals[3]. This study presents a smart phone based application that can potentially offer the benefits of both journaling and visualization and compensate for their respective issues by enabling the visualization of patients' health journals.

Methods

The initial prototype is a series of computer aided drawings on paper that feature the major functions of the app as they would appear on an actual smart phone. These features include (a) journaling, where patients can enter journals in free text; (b) browsing, where patients can review previous journals sorted by date and time; (c) searching, where patients can search for previous journals using keywords (fuzzy search) and dates; and (d) visualization, where the journal search results can be displayed in word usage frequency charts (when searching with keywords) or word cloud (when searching by date, using specialized thesaurus including AGROVOC for food and UMLS Metathesaurus for health-related terms). For each text box and button, a short floating text regarding their utilities is displayed.

Five diabetes patients were recruited from the author's personal network to participate in a semi-structured interview regarding the utility of the prototype and possible improvements. These patients all lived with diabetes for more than ten years and self-reported to manage diabetes information on a daily basis using electronic devices. Before the interview, patients reviewed the functions of the prototype system and watched the author's demonstration.

Preliminary Results and Discussions

An improved prototype system is developed based on patients' feedback. One of the major improvements is to include a planning module that utilized the journal retrieval function to persuade short-term behavior change. This new module enables patients to enter plans for the day. When this happens, the app retrieves and displays relevant previous journals based ranked by the number of words matched between the new entry and previous journals. This new module allows patients to easily reflect on their self-management records and make better informed decisions. Other suggestions including offering social sharing and a reputation system that would further engage patients through social support and peer pressure are also recorded for future developments. During the poster presentation, the author will demonstrate the improved prototype system on a poster with personas and user scenarios included.

This system could manifest patient experiences that are perhaps not easily visible in generic journal records, and help patients gain better understandings of their health conditions through engaging in a rich collection of their personal health records. Further, this system could provide a new basis for decision making and information sharing in both home and clinical settings.

Bridging the Gap in Transfusion Medicine: From Data to Decision

Nazanin Tabesh-Saleki, MS[1, 2], Mary E. Herwig, MBA[2], Julie F. DeLisle, MSN, RN[2], Nanci L. Fredrich, BSN, RN, MM[2], Sandra J. Butschli, BS[2], Timothy B. Patrick, PhD[1], Kathleen E. Puca, MD[2]

[1]Univerisity of Wisconsin-Milwaukee, Milwaukee, WI; [2]BloodCenter of Wisconsin, Milwaukee, WI

Abstract

Forty to sixty percent of blood transfusions are considered inappropriate[1], providing either no benefit, or heightened risk of complications, and increased cost of care. Addressing the variability in transfusion practice requires evidence-based guidelines, focused education, and meaningful presentation of information to drive appropriate decision-making and interventions. A focus on tight integration of the above elements bridges the gap that exists between knowledge and practice, and thereby can alter behavior.

Introduction: Historically, transfusion of two units of Red Blood Cells (RBC) has been the norm[2]. This traditional practice has come under intense scrutiny lately due to an increased awareness of the association of RBC transfusions with complications and worse outcomes, which are dose-dependent[3, 4]. Patient Blood Management (PBM) is a multidisciplinary, patient-centric, data driven approach designed to optimize utilization of blood products in patients who may require a transfusion in an effort to improve outcomes. Implementation of a robust hospital-wide PBM program is challenging; it requires leadership support, involvement of diverse groups of care providers, re-education of providers with ingrained transfusion practices, and standardization of blood utilization guidelines. Capturing relevant data plays a critical role in supporting the program, as derived information provides a baseline for current practice, both department and provider-specific, and can identify areas for improvement. For this study, efforts were focused on capturing data to reflect provider transfusion practices, specifically on ordering and transfusing one versus two units of RBC. **Methods:** Through a joint effort between transfusion medicine and information technology experts in collaboration with a local hospital, we have developed a set of PBM key performance indicators (KPI) to monitor transfusion practice. The development of PBM-focused KPIs included identification of data sets for extraction from the hospital's information systems. The data files were transferred to a central repository via a secure connection. Through use of third party software, we defined a unified metadata layer and mapped data elements for context sensitive views of information. The information was presented back to the hospital via a secure web-based dashboard, which depicted provider ordering practice at multiple levels including, by facility, service line, and provider. We coupled our efforts with provider education in the form of PBM newsletters and quarterly reports to department chairs highlighting RBC ordering practice. **Results:** Since our implementation of PBM the percent of one-unit RBC orders increased and simultaneously the percent of two-unit RBC orders decreased. Figure 1 represents the gradual divergence in provider ordering practice. In addition, an ongoing decline in total RBC unit transfused was noted. Using first quarter in 2013 (Q1-13) as the baseline, there has been a steady reduction in percent RBC units transfused – 3.99% (Q2-13); 8.31% (Q3-13); and 11.8% (Q4-13). **Conclusion:** Through capturing relevant data from disparate source systems and transforming it into meaningful information, we were able to effectively focus PBM strategies. The data from this one KPI along with focused education has resulted in lower RBC utilization. Our approach provided relevant metrics on provider RBC ordering practices and raised awareness around opportunities associated with PBM.

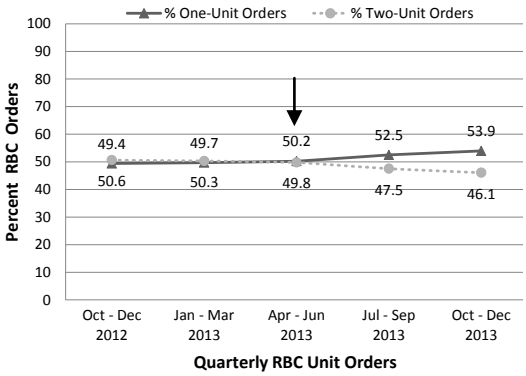

Figure 1. Trend in providers' ordering practice; representing normalized percent one-unit versus two-unit RBC orders. The arrow marks May and June 2013, when the first reports were distributed to hospital department chairs and the first PBM newsletter was disseminated to the providers, respectively.

Genetic Variant Databases: Current Practices for Development and Curation

Keeon Tabrizi, MEng[1], Robert Coopersmith, Ph.D.[1], David Hardison, Ph.D.[1], Elisabeth L. Scheufele MD, MS[1,2], Matvey B. Palchuk, MD, MS[1,2]
[1]ConvergeHEALTH by Deloitte, Deloitte Consulting LLP, Newton, MA; [2]Harvard Medical School, Boston, MA

Abstract
Disease-associated genetic variant databases play an important role in utilizing and interpreting variant data in a clinical context. We have performed an analysis to better understand best practices regarding evidence standards for variant classifications, curation practices, and to assess overall quality systems for gathering and maintaining high integrity data. The analysis included public locus specific databases (LSDB's), internal databases at commercial entities (clinical labs and biopharmaceutical companies), ClinVar at NCBI, and those at academic medical centers. A representative subset of databases was then chosen for structured interviews to obtain information that was not publically available. The interview was comprised of a series of questions developed from criteria to evaluate evidence quality and curation practices. Interviews were summarized respective to the evaluation criteria and an assessment was completed across the databases and against several highly-regarded and referenced databases.

Introduction
Rapid advances in genomics and informatics are augmenting the scope of personalized medicine to incorporate genomic data into medical decisions. By linking data obtained from next generation sequencing and other high throughput technologies with preclinical data, clinical outcomes, and other available patient information (clinical, demographics, etc.), it is possible to distinguish clinically actionable genetic variants from the larger collection of variants of unknown significance.[1] This process requires aggregation of good quality evidence from multiple sources. However, many of the ultra high-throughput genomic tests identify a significant number of variants where clinically meaningful phenotype or outcome has not been well-established. Thus, potential risk is introduced to patients if medical decisions are based on genomic information of unclear or ambiguous significance.[2]

Problem
Currently, issues with data quality and classification standards are not well-understood by the broader community of academic and commercial researchers, clinical laboratorians, physicians, patients, and regulators. These issues often limit the utility of databases when used to inform important decisions regarding medical practice. This need is underscored by research initiatives such as a recent $25 million NIH grant to bridge the various issues and develop a framework for evaluating variants relevant to patient care in disease.[3] While biomedical databases can collect data from a wide variety of sources and facilitate the capture and aggregation of information, the reliability of the data within any particular database relies on several factors, including the quality of the genomic data stored in the database, the amount and type of preclinical and clinical information associated with that data, and the curation practices instituted by that database.

Solution
We have conducted a study to survey the current landscape of disease variant databases and in particular to investigate curation practices and the use of evidence to classify variants. We included public LSDB's, internal databases at commercial entities (diagnostic and biopharmaceutical companies), and those at academic medical center diagnostic units. Information from publically available sources was used to develop criteria (Figure 1) for evaluating the evidence quality and curation practices. A representative subset of databases was then chosen for structured interviews based on a series of questions developed from the criteria. We found that parameters varied widely among databases, both across and within classes, while others were more consistent. Based on our review we propose a set of leading practices based on the examined database attributes.

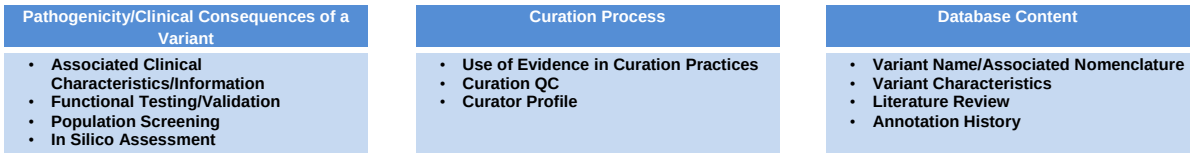

Figure 1: Evaluation Criteria

Information Use and Performance in an Accountable Care Organization

Douglas A. Talbert, PhD[1], Harold Chertok, DO[2], Kenneth R. Currie, PhD[1], Rebecca L. Turpin, MSN[1], Steve Talbert, PhD, RN[3]
[1]Tennessee Technological University, Cookeville, TN;
[2]Cumberland Center for Healthcare Innovation, Cookeville, TN;
[3]University of Central Florida, Orlando, FL

Introduction

An Accountable Care Organization (ACO) is a group of health care providers working together to coordinate care with the goal of delivering high quality, cost effective care.[1] When an ACO is able to satisfy the Medicare-defined quality standards at a cost lower than the threshold set by Medicare, the achieved savings are shared with the ACO.

Cumberland Center for Healthcare Innovation (CCHI) is an ACO consisting of 40 primary care physicians in 27 practices across the 14-county rural Upper Cumberland region of Tennessee, an area with documented higher health care costs and lower health care quality than the national average. CCHI's Medicare costs (per patient cost) and quality (percent of quality metrics satisfied) vary widely across member practices. Identifying the causes of these variations could help CCHI achieve the quality and costs needed to improve care and realize shared savings.

Methods

Studies[2] and national initiatives such as the HITECH Act[3] suggest that the availability and use of information in the clinical decision-making process influence health care cost and quality, but to the best of our knowledge, the connection between information use and performance across an ACO has not been studied. To improve our understanding of the extent to which information use explains the variation across the practices in CCHI, we surveyed the practices regarding their use of information in preparing for patient visits. Table 1 shows the high-level measures on which the survey and this study focused.

Table 1. Survey measures related to clinical information use.

A. Information captured during initial contact for a visit	D. Clinical info. updated by nurse or med. asst during initial patient review
B. Nature of the use of that initial info. for visit planning	E. Clinical info. reviewed by physician or physician extender prior to visit
C. Clinical info. reviewed by nurse or med. asst prior to visit	F. Does visit planning occur prior to or after patient arrival?

Of the 27 practices surveyed, four are new to the ACO and do not have Medicare-reported cost and quality metrics, five other practices did not return a complete survey, leaving 18 practices for which we had both cost and quality metrics and information-use metrics.

Results

We identified the most and least expensive practices as outliers. An analysis of the 16 remaining practices showed the correlation of measure *E* with *cost* (r = -.536) was significant (p = .023). Backward regression found that the model for *cost* that contained measures *D* (β = -.251) and *E* (β = -.470) was also significant (p = .049). The *quality* correlation matrix showed moderate but not significant correlation with measures *D*, *E*, and *F*, and while regression did not identify any independent predictors of *quality*, measure *E* had the highest standard coefficient (β = .537).

Discussion

With such a small sample size, it is not surprising that we found so few significant factors, but these initial findings suggest that, of the factors we examined, information use by the physician (or physician extender) in preparing for the visit had the most influence on cost and quality. We are continuing to study the impact of these and other factors (such as visits per day) on the cost and quality of health care.

A Time-and-motion Study of Clinical Trial Eligibility Screening in a Pediatric Emergency Department

Huaxiu Tang, MS, Melanie Hounchell, BA, CCRC, Judith W Dexheimer, PhD,
Stephanie Kennebeck, MD, Imre Solti, MD, PhD, MA Yizhao Ni, PhD
Cincinnati Children's Hospital Medical Center (CCHMC), Cincinnati, OH

Abstract

Determining patient eligibility is a major barrier to clinical trial enrollment. We conducted a time-and-motion study on the clinical trial eligibility screening workflow in a pediatric emergency department (ED). We observed the workflow activities and the major findings are presented. Most (50%) of the time is spent screening patients and performing procedures; the time spent walking and waiting suggests that rearranging work locations could save time.

Introduction

Eligibility screening (ES) is widely applied to determine the suitability of candidates for clinical trials. Time-and-motion has been used to evaluate efficiency of clinical activities[1]. The goal of this study is to investigate the workflow of clinical trial ES in a pediatric ED to identify inefficiencies that may be streamlined to improve workflow.

Methods

Fifteen 120-minute observations were conducted from 12/12/2013 to 1/3/2014, including 5 morning 5 afternoon and 5 evening observations. The workflow of eight research assistants (RA) was tracked. One RA was shadowed in each session and their activities were recorded in 30-second increments. The activity categories are listed in the table, with associated sub-categories. Time spent was summarized with mean and standard deviation (STD). The numbers of patients screened, approached and enrolled were also recorded.

Table. Time and percentage over all time spent on workflow activities.

Category	Subcategory	Minutes per Section	Percent
Patient Screening (31.62%)	Reading EHR content on screen	36.0 (±20.18)	29.4%
	Discussing patient's eligibility with clinical staff	2.67 (±2.01)	2.18%
Patient Contact (18.67%)	Ask patient to join in research	4.03 (±2.72)	3.30%
	Review/Confirm patient's eligibility	0.07 (±0.25)	0.05%
	Consent procedures	4.73 (±3.65)	3.87%
	Record data	8.67 (±11.29)	7.09%
	Waiting for patient to finish study procedure	3.83 (±5.13)	3.13%
	Other activities in patient contact	1.50 (±2.42)	1.23%
Performing Procedures (17.63%)	Performing procedures/ Documenting eligible patients	18.5 (±12.39)	15.2%
	Documenting ineligible patients	3.03 (±4.10)	2.48%
Physician Contact (1.09%)	Waiting for physician to finish study procedure	1.33 (±2.05)	1.09%
Other Activities (30.99%)	Task administration	14.2 (±7.46)	11.6%
	Emails/Web browsing	2.97 (±5.03)	2.43%
	Waiting	7.70 (±9.34)	6.30%
	Walking	12.6 (±5.87)	10.3%
	Personal time	0.47 (±1.50)	0.38%

Results

The *Patient Screening* and *Performing Procedures* activities (e.g. documenting eligible patients) occupied 50% of the RAs' time. The RAs spent 10.3% of their time *Walking* and 6.3% *Waiting*. The RAs approached 30 out of 197 screened patients and enrolled 20 subjects (enrollment 66.7%). Among the 10 cases in which patient declined enrollment, 8 occurred in evening, 1 in morning and 1 in afternoon. The decline rate for the evening is 57.1%, which is statistically significantly ($p<0.001$) different from 14.3% for the morning and 11.1% for the afternoon.

Discussion & Conclusion

Patient Screening and *Performing Procedures* occupy half of the RAs' time. This can be potentially reduced by computerized approaches such as automated ES and documenting. RAs spent a notable amount of time in *Walking* and *Waiting*, suggesting that relocating the workspace could be helpful. Patients declined more in evening shifts; the result may not be significant due to limited observation sections; future work will be to investigate the difference of decline rate. The findings suggest workflow improvement areas to increase the efficiency of clinical trial ES.

Reducing Readmissions and Intermountain Discover App: Stratification of Interventions based on Risk Assessment

David P. Taylor, PhD, Farrant H. Sakaguchi, MD, MS, Adam Kraft, MD, Kira Wagner, BS
Intermountain Healthcare, Salt Lake City, UT

Abstract

Hospital readmission reduction is a health policy priority. Interventions, such as ProjectRED, ProjectBOOST, Care Transitions Interventions, and Camden Health have shown efficacy at decreasing readmissions. However, these interventions would likely benefit from personalized risk assessments and stratifications of risk. We seek to marry risk prediction tools, such as LACE, HOSPITAL, and LACE + with current interventions through development of a web application and iPad app within our clinical environment. This application will improve flexibility to evaluate different algorithms, provide greater collaboration among care team members and highlight the most useful data.

Introduction

Reducing hospital readmissions is a national health policy goal with financial penalties for readmissions within 30 days. ProjectRED, BOOST, Care Transitions Interventions, and Camden's Care Management Program are interventions to decrease readmissions and have demonstrated promising results. However, tailoring the interventions to the individual risk and needs of each patient will likely be more effective. Tools such as LACE, HOSPITAL, and LACE+ have been developed to predict the risk for readmission. Stratification and tailoring of interventions based on personalized risk calculations are necessary to help manage constrained resources.

While the electronic health record (EHR) may be an ideal platform to standardize risk assessments and to present appropriate protocols, most current EHRs lack the flexibility to implement and rapidly evaluate different risk prediction tools, and intervention strategies and changes can be resource intensive. A flexible knowledge discovery tool where end-users can easily create questionnaires and checklists while pulling data from the EHR facilitates the comparison of different prediction tools and interventions.

Approach

The Homer Warner Center for Informatics Research (HWCIR) has developed Intermountain Discover, a HIPAA compliant form tool that can pull information from the EHR to prepopulate forms. The tool is available as both a web application and an iPad app, has dashboard capabilities and basic data visualizations. The interface can support workflows, guiding users through series of questions and acting as a dynamic checklist of appropriate interventions.

We have created a series of forms in Intermountain Discover to perform risk assessments based on LACE, HOSPITAL, an adapted LACE+, and Camden's Care Management Program. Services will extract data from the EHR as appropriate. We have tailored different interventions based on components of ProjectRED and BOOST to be based on predicted risk for readmission as well as specific risk factors. We will use the enterprise data warehouse to prospectively evaluate readmissions. We will evaluate which risk assessment tool has the greatest predictive value for our patients and which interventions have the greatest impact to reduce readmissions. We anticipate beginning to gather data for the hospitalist services at two local hospitals within the coming month.

Conclusion

Flexibility is needed to evaluate the performance of different risk stratification strategies and personalized interventions to reduce readmissions. Developing protocols to be implemented directly within the EHR poses potential disruption and user frustration. The use of a tool that can be viewed by all members of the care team is likely to provide greater collaboration and insight, while clarifying what data are most useful.

While the use of standard terminology services will be a part of future development, there is an immediate and great need for research tools that are able to pull data directly from the EHR and that facilitate flexible documentation.

A Qualitative Assessment of CPOE and Variation in Drug Name Display

Thu-Trang Thach, MPH[1], Alexandra Robertson[1], Arbor J. L. Quist[1], Lynn Volk, MHS[2], Adam Wright, PhD [1,2,3], Shobha Phansalkar RPh, PhD[1,3,5], Sarah Slight MPharm, PhD, PGDip[1,4], David W. Bates MD[1,5], Gordon D. Schiff MD[1, 5].

Abstract

Medication safety is an important goal of electronic health record (EHR) implementation. Refining the delivery and content of existing EHRs is a key regulatory initiative of the current US healthcare administration. This study aims to evaluate the impact of drug-name display on the potential for medication errors in computerized provider order entry (CPOE).

Background

Previous work suggests that prescribing errors account for the highest proportion of medication errors[1] and that 1 in every 4 reported in the U.S. can be linked to drug name confusion.[2] CPOE has been widely proposed, implemented, and shown to reduce errors associated with traditional, handwritten prescribing. Still, CPOE has not fully lived up to its predicted benefits, and many attribute these shortfalls to suboptimal system design. The FDA Brigham and Women's Hospital CPOE Medication Safety Project was funded by the FDA to assess drug name display issues and understand their potential to contribute to medication errors.

Methods

We assessed look-alike-sound-alike pairs, adjacency errors, font, and visual display in 10 CPOE systems at 6 U.S. medical centers via remote walk-throughs and on-site visits. We created a CPOE Assessment Tool incorporating medication ordering, review, and deletion scenarios to guide walk-throughs with a series of "regular" and "expert" users of these systems. Analysis of screen shots, video, and audio transcripts from these evaluations provided guidance for visits at each site to collect additional system information from medical leadership, IT experts, and CPOE users. Our examination of inter- and intra-system characteristics revealed patterns, themes, and variations.

Results

We identified a lack of standardization in the display of drug names in CPOE systems, which could contribute to medication errors. Issues and themes that emerged included: *(a) Brand versus generic name* – some systems limited search by brand or generic names, some systems displayed results either by either brand, generic or both names, and some system displays encouraged prescribing of preferred (typically generic) products. *(b) Combination products* – searches for combination drugs often yielded the brand name with the ingredients listed parenthetically and rarely provided explanations of ingredient strengths. In some systems, searching the brand name yielded only the brand name, without its generic ingredients. *(c) Drug-name modifiers* – drug name modifiers had some consistency, appearing primarily at the end of the drug name, in uppercase, and were rarely truncated but were often abbreviated (e.g. XR, DS). *(d) Extraneous additions to drug name fields* – we observed non-systematic population (jerry-rigging) of name fields with additional information ranging from drug indication to facility-specific availability. *(e) Font, text size, capitalization* – these varied widely with no standardized approaches seen either across or, often, within systems.

Conclusions

There is little consistency in the ways that CPOE systems search for and present drug names. This lack of standardization was seen both across and within systems. Brand vs. generic, combination products and drug name modifiers were particularly inconsistent, each presenting the potential for user frustration, confusion, and erroneous orders.

The impact of an automated response function in an electronic checklist on checklist accuracy: an observation from a simulation-based study

Charat Thongprayoon, MD; Andrew M Harrison, BS; John C O'Horo, MD, MPH; Ronaldo A Sevilla Berrios, MD; Brian W Pickering, MBBCh, Herasevich V, MD, PhD
Multidisciplinary Epidemiology and Translational Research in Intensive Care (METRIC), Mayo Clinic, Rochester, MN

Background:. With increasing prevalence of electronic medical record (EMR) systems, the utility of a checklist integrated into the EMR with decision support tools has been increasing apparent. The automated response function in a smart checklist is designed to individualize the checklist for each patient, which can potentially reduce the time to checklist completion. However, it may simultaneously increase checklist errors if providers are less engaged when using a smarter checklist. In a secondary analysis of a simulation-based study, we aimed to investigate the effect of the automated response function in an electronic checklist for checklist accuracy, as completed by intensive care unit (ICU) physicians.

Methods: We conducted a simulation-based study at an academic tertiary center. A total of 21 ICU physicians participated in this study. Each participant completed checklists for 3 ICU patients using an electronic checklist in a controlled usability lab setting with full access to the EMR system.. The automated response function was programmed with a detection algorithm using patients' real time data to select only applicable checklist items for participants to complete. Two independent clinician-reviewers served as the reference standard for checklist error calculation. The association between automated response errors and checklist errors per participant was assessed using the Chi-squared test.

Results: The number of checklist errors by ICU physicians and the number of automated response errors for each checklist item are summarized in Table 1. Although participants were advised to disregard the automated response, , the automated response errors in the "lung protective ventilation", "spontaneous breathing trial", and "adequate source control" items still resulted in an increased risk of checklist errors by participants.
Table 1. The number of checklist errors by ICU physicians and the number of automated response errors.

Checklist item	# of Checklist errors	# of Automated response errors	p-value*
Adequate source control	16	33	<0.001
Lung protective ventilation	9	15	<0.001
Spontaneous breathing trial	3	6	<0.001
Remove urinary catheter	15	3	0.07
Sedation break indicated	6	3	0.56
Continue vasoactive medication	5	9	0.70
Treat pain	1	2	0.86
Need for antimicrobial reviewed	1	1	0.90
Treat delirium	0	1	N/A
Remove vascular device	6	0	N/A
Head of bed elevated	0	6	N/A

*p-value from Chi-Squared test to assess association between checklist errors and automated response errors

The discrepancy in defining the applicability of checklist items between the detection algorithm and the reference standard was the main reason for checklist errors.

Conclusion: In previous studies, the electronic checklist was shown to significantly reduced provider workload and overall checklist errors However, the automated response function equipped in electronic checklist might inadvertently increase checklist errors in some items. Therefore, these automated response functions must be well validated and refined to achieve optimal accuracy before implementation in a real electronic checklist used in the ICU setting.

Value Set Management to Enable Interoperable Clinical Decision Support: Development, Use, and Initial Evaluation of the OpenCDS Value Set Manager

Tyler J. Tippetts[1], Phillip B. Warner, MS[1], David E. Shields[1], Salvador Rodriguez-Loya[2], Catherine J Staes, BSN, MPH, PhD[1], Kensaku Kawamoto, MD, PhD[1]
[1]University of Utah Department of Biomedical Informatics, Salt Lake City, UT;
[2]University of Sussex, School of Engineering & Informatics, East Sussex, United Kingdom

Abstract
To enable interoperable clinical decision support (CDS), clinical concepts referenced within CDS knowledge resources must be mapped to standard terminologies. While value sets from standard terminologies are increasingly becoming available, additional value sets are still required to support CDS. To address this problem, a Web-based Value Set Manager was developed by the OpenCDS initiative that leverages the Unified Medical Language System. Experience with implementing and using this resource, including challenges and future directions, is described.

Introduction
Value sets are lists of specific values derived from one or more standard terminologies to define concepts.[1] The definition of value sets is an essential requirement for a CDS knowledge resource to be semantically interoperable across institutions. Resources such as the National Library of Medicine's Value Set Authority Center (VSAC) [1] and the Public Health Information Network Vocabulary Access and Distribution System (PHIN VADS) [2] include value sets that can be used for CDS purposes. However, there is often a need to create additional value sets for CDS purposes. The objective of this effort was to develop an open-source, Web-based value set management tool that leveraged available terminology resources and enabled the efficient definition of value sets relevant for CDS.

Methods
This project was conducted within the context of the OpenCDS initiative (www.opencds.org), which is a multi-institutional collaborative effort to develop open-source, standards-based tools and resources for CDS. OpenCDS uses internally defined concepts which are then mapped to value sets. To facilitate the development of value sets for mapping to OpenCDS concepts, a Web-based Value Set Manager for CDS was developed using the Grails Web application development framework, the Google Web Toolkit user interface designer, and the National Library of Medicine's Unified Medical Language System (UMLS). System performance was evaluated for typical use scenarios.

Results
The UMLS database was instantiated locally. An application programming interface (API) was developed to allow various terminology operations on the UMLS, such as searching for codes within a code range (e.g., ICD9CM 250-250.99) and for codes subsumed by a parent concept (e.g., codes that are descendants of ICD9CM 250). Leveraging this API, the Web-based Value Set Manager enables value sets to be defined within a given code system (see Figure) and mapped to OpenCDS concepts. Identifying codes within a range is essentially instantaneous, and identifying codes subsumed by a parent concept typically takes less than five seconds to complete. Challenges included differences in how various terminologies are represented in the UMLS and the need for performance optimization for some terminology operations. Future directions include supporting multiple terminologies within a single value set and facilitating the editing of externally defined value sets.

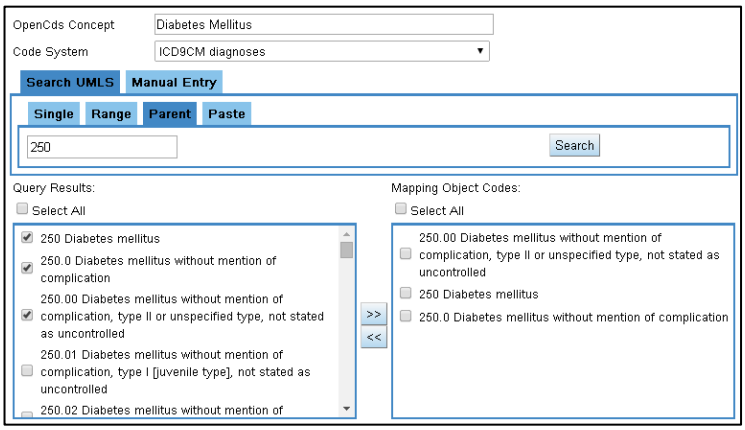

Figure. Screenshot of OpenCDS Value Set Manager

Conclusions
Specifying value sets with standard terms is essential to enabling interoperable CDS. The OpenCDS Value Set Manager fulfills this need efficiently and will be made freely available as a part of the OpenCDS initiative.

Contextualization of Comparative Assessment Reports and System-wide Decision Making for Drugs and Devices Reimbursement

Michele Tringali, MD[1], Silvia Vecchio, PhD[2], Emanuele Lettieri[3], Luca Romano[2]
[1]Regione Lombardia, Milano, Italy, MA; [2]ASL Pavia, Pavia, Italy; [3]School of Engineering, Milano, Italy

Abstract

Streamlining assessment and appraisal, for both emerging and established health care technologies, can be difficult and inconsistently applied within socialized systems like Italy's NHS as well as and by insurance-driven health care plans elsewhere. An information framework incorporating state of the art models from European HTA assessment reports and tools from the EVIDEM (Evidence and Values) Collaboration was successfully developed and used in Lombardy region for coverage decision on 13 health care technologies.

Background

Comparative Effectiveness Research (CER) and similar Health Technology Assessment (HTA) products for drugs, medical devices and other health care technologies require localization, i.e. adaptation of global information to contextual factors, in order to be used for informing reimbursement from payers. Real world processes of decision making are seldom formally modeled, and Multiple Criteria Decision Analysis (MCDA) approaches and tools can help legitimize robust appraisal practices and streamline communication to providers, doctors and patients.

Methods

Lombardy region's (10 million people) health care authority designed, tested and implemented an information framework with the aim to guide local experts in contextualizing national and European HTA reports prepared by AgeNaS (agency for medical devices) and EunetHTA[1] (the European Network of HTA that encompass all 27 Member States in the EU) to be efficiently used by a Priority (for emerging) and an Appropriateness (for diffusing or obsolete technologies) Committees to prepare value-based policy decisions, i.e. managed adoption or refusal and maintenance or delisting of drugs, devices, diagnostic and screening procedures. The EVIDEM Framework and set of MCDA tools[2] were implemented with minor modifications[3]. Data from four EUnetHTA Reports (Genomic tests for breast cancer adjuvant therapy, EndoBarrier for obesity, Renal cancer drugs, Renal denervation for drug resistant hypertension) were semi-automatically extracted using two templates (Model and Report files) and imported into an Access database, extracted in XML format then imported (FlexiC Import extension) into a Joomlaa 2.5 CMS organized around a hierarchical set of 9 Dimensions, 20 Criteria and a variable number of Subcriteria and Issues (example in Table 1). Domain experts revised and added content (epidemiology, financial impact, clinical practice, organizational issues areas).

Table 1. A sample Issue for Criteria *C08 - Improvement of efficacy/effectiveness* for the Dimension *D4 - Clinical effectiveness*.

D4 - Clinical effectiveness
C08 - Improvement of efficacy/effectiveness
S01 - Mortality and morbidity
D0002 - What is the expected beneficial effect on the disease-specific mortality?

The localized report was then used by the Appraisal Committee to structure complete decisions through MCDA methods (weights elicitation and discussion, scores and judgments collection, qualitative analysis of comments and elaboration of an Appropriate Use Index for each technology). A simplified version of the process, limited to an assessment of the first layer (dimensions) of the hyerarchy, was used by the Priority Committee with nine new and emerging technologies for which Horizon Scanning (HS) reports has been made available by Age.Na.S.

Results

The regional authority was able to elaborate contextually relevant coverage decisions on several health technologies with both initial (HS) or more complete (HTA) information.

Conclusion

An integrated information framework built around a 4-layers simple hierarchy of operational meanings for technical assessment, localization and decision analysis, adapted from established models for HTA and MCDA, can be applied to a wide range of health care technology coverage problems with consistency.

Mobile Education: Reaching Homeless PTSD Veterans

Stephanie R. Tucker, MS[1], Sriram Iyengar, PhD[1], Amy Franklin, PhD[1]
[1]University of Texas Health Science Center, Houston, TX

Abstract

Smart phone technology has immense potential for changing health education delivery. Mobile education has the ability to reach individuals outside traditional channels. This poster describes the application of smartphone-based instruction for PTSD training in homeless veterans. Such technology provides multimedia education, improves access, and may minimize social anxiety for this population. This project contributes evidence of the ways in which mobile education may increase the use of HIT and access to healthcare for underserved populations.

Introduction

Mobile devices are increasing dramatically in use. In the United States, cell phone ownership by adults exceeds 90%[1]. Mobile technology has many advantages over paper and computers for delivering health education content. It can be used without the connectivity often mandatory in streaming web-based systems, offers portability enabling anywhere/anytime use, provides a greater degree of privacy with the small screen than is available with large books, manuals, or computer screens, supports emotional engagement[2] and social cohesion[3], and delivers a high level of interactivity.

Methods

Here, we describe the benefits of mobile educational for homeless veterans with PTSD highlighting the gains from a mhealth platform. Presentation of materials to homeless veterans is often in to face-to-face verbal only exchanges. In such circumstances, multi-methods of learning are not available and situation factors such as crowding and social anxiety may overwhelm participants. Mobile education is highly adaptable to learning theories, and has the potential to present similar content making use of multiple adaptive forms of presentation including text, video, visual aids, and games.

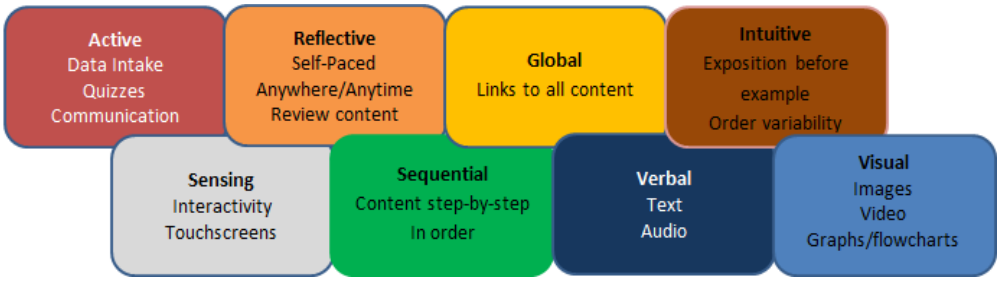

Figure 1 Model of mobile features adapted to Felder-Silverman Learning Style Theory[4]

Results

We believe that mobile education has the potential to reach populations currently unable or unwilling to access more traditional methods such as classrooms and office visits. In our example case study of homeless veterans, social, physical, mental, and even financial constraints may limit access to necessary care. We anticipate our intervention will achieve these aims and recognize potential drawbacks such as the difficulty of monitoring a homeless population, and charging mobile devices.

Conclusion

In an extension of telemedicine through mobile devices, we seek to explore ways in which education can be transformed. This study provides growing evidence of the ways in which mobile education may increase the use of HIT and access to healthcare for non-traditional populations.

Title: The State HIE Program Evaluation: A Typology of State HIE Approaches

Theme: Health Information Technology

Authors: Petry Ubri, Felicia LeClere, Sai Loganathan, Michael Latterner, Prashila Dullabh

Research Objective

The State Health Information Exchange (HIE) Cooperative Agreement Program ("the Program") was created by the American Recovery and Reinvestment Act of 2009 to expand the secure movement of electronic health information within the health care system. As part of a multi-year evaluation of the Program, we developed a method of organizing the strategies pursued by states to promote HIE services, a typology to help us determine 1) how states implemented the Program and 2) the methods by which states enabled exchange.

Study Design

Data was collected from all states and territories on various aspects of their program design to understand how these approaches vary by state and whether there are commonalities among state that accelerate the development of HIE. Contextual variables were assembled from secondary sources that characterize both the health care and economic climate of the state and the measures of HIE both before and after the initiation of the Program. The data analyses identify key program factors that may contribute to the viability of information exchange (e.g., legal and policy-related activities, governance structure, and technical aspects).

Principal Findings

This presentation will share descriptive statistics on trends in three areas: leadership and organization; technical approach; and legal/policy aspects of the program. Also discussed will be limitations in the typology and how these will be accounted for in the interpretation of key findings. Important trends include: Most states (70%) used a single technical entity for technical services, although many planned to build a network that might involve different vendors. Directed exchange is more commonly offered than query-based exchange (79% and 68%, respectively). Fifty-nine percent of states have enacted legislation supporting HIE or HIE and electronic health records, and many are bolstering its use with additional initiatives and financial incentives. Finally, a majority of states (68%) use an opt-out consent model.

Conclusions

The typology has allowed us to identify three primary categories and a core set of factors to best describe HIE implementation. While these factors are not necessarily associated with programmatic progress or lack therefore, there is a notable, clear trend towards certain implementation models and approaches.

Implications for Policy, Delivery or Practice

By assessing state progress and identifying national trends in HIE implementation strategies, we hope to contribute to the knowledge base guiding future HIE planning and implementation efforts.

Does size matter? A comparison of a large web corpus and a smaller focused corpus for medical term extraction.

Klaar Vanopstal, PhD[1], Els Lefever, PhD[1] and Véronique Hoste, PhD[1]
Ghent University, Belgium

Abstract

This paper investigates the cost-effectiveness a large corpus versus a smaller, more focused corpus for medical term extraction in English and Dutch. An error analysis will be presented, and we will study the extent to which these comparable – as opposed to parallel - corpora can be used in bilingual term extraction.

Introduction

Efficient acquisition and management of terminology has become increasingly challenging in the past few decades, as the explosion of information makes it difficult to keep term bases up-to-date. Although larger quantities of information are freely available, it is still difficult to find parallel texts for specialized domains, especially for underresourced languages. Automatic term extraction (ATE) is especially useful in the biomedical domain, which is highly productive when it comes to the creation of new terms. In this paper, we will investigate the cost-effectiveness of using a larger corpus versus a smaller, more dedicated corpus for ATE for English and Dutch, and their potential for use in bilingual term extraction from comparable texts in English and Dutch.

Description of corpora used

Large corpus of medical web data

The first corpus we used in this experiment was compiled using BootCat[1], a freely available web crawler which uses seed terms to automatically construct Google queries. We used the Wikipedia page for *heart failure* as a source for seed terms (n = 229). This resulted in a corpus of 2.5M words. The same procedure was followed for the Dutch web corpus, which contains 1.2M words.

Smaller, focused corpus of MEDLINE titles

The assumption here was that titles of scientific articles about a specific subject have a relatively high concentration of specialized terms. This smaller corpus was compiled using the PubMed interface to MEDLINE. We constructed a query for *heart failure* (*"Heart Failure"[MeSH Major Topic]) AND "heart failure"[Title/Abstract]*), which yielded about 45,000 results, from which we only retained the titles in our corpus. This resulted in a limited yet highly focused corpus of 613k words. The corresponding – smaller - Dutch corpus will be collected from the *Netherlands Journal of Medicine* and *Belgian Journal of Medicine.*

Gold standard

A gold standard was constructed by selecting the *heart failure*-related terms from MeSH. It consists of 172 concepts (and their Dutch translations as provided in the UMLS) and a total of 737 variant terms to express these concepts.

Results

Term extraction was performed on the larger and smaller corpora using TExSIS[2]. A total of 87,728 and 43,693 single and multiword terms were extracted from the English large web corpus, and the smaller corpus of titles, respectively. The web corpus contained 275 gold standard terms (37%), 234 of which were found by our term extraction system. The smaller corpus of MEDLINE titles contained 179 gold standard terms (24%), 138 of which were detected by TExSIS. In our poster, we will present a more detailed error analysis.

Conclusions

Although the difference in size between the two corpora was 75%, the difference in gold standard terms that were covered, was only 13%. This raises the assumption that titles (and by extension also abstracts) are an interesting and cost-effective source for terminology extraction. We will make the same comparison for a Dutch corpus of titles and a Dutch web corpus.

Disease/Disorder Semantic Template Filling – Information Extraction Challenge in the ShARe/CLEF eHealth Evaluation Lab 2014

Sumithra Velupillai, PhD[1], Danielle Mowery, MS[2], Lee Christensen, MS[3], Noemie Elhadad, PhD[4], Sameer Pradhan, PhD[5], Guergana Savova, PhD[5], Wendy W Chapman, PhD[3]
[1]Stockholm University, Sweden; [2]University of Pittsburgh, PA; [3]University of Utah, UT; [4]Columbia University, NY; [5]Childrens Hospital Boston and Harvard Medical School, MA

Abstract

We characterize data and describe the ShARe/CLEF eHealth 2014 challenge – Task 2.

Introduction

The meaning of disease/disorder (DD) mentions in the clinical narrative is often affected by semantic modifiers, such as negation. Such information is critical for accurate automated information extraction (IE). The ShARe/CLEF eHealth 2014 Task 2[1] is organized to advance the development of IE methods for detecting such DD semantic modifiers.

Methods and Challenge Corpus Characteristics

We released the extended ShARe corpus[2], a subset of clinical narratives from the MIMIC-II database[3], manually annotated by domain experts for DDs and 10 attribute/value semantic modifiers. Each DD is mapped to a SNOMED CT identifier from the UMLS (CUI), and each modifier has a normalized value:

Attributes Types	Example Sentence	Norm Slot Value	Cue Slot Value (span offset)
Negation Indicator (NI)	***Denies*** numbness	yes	*0-5*
Subject Class (SC)	***Son*** has schizophrenia.	family_member	*0-2*
Uncertainty Indicator (UI)	***Evaluation*** *of* MI.	yes	*0-9*
Course Class (CC)	The cough ***worsened*** over the next two weeks.	worsened	*11-18*
Severity Class (SV)	He noted a ***slight*** bleeding.	slight	*12-17*
Conditional Class (CO)	Return ***if*** fever.	true	*8-9*
Generic Class (GC)	pain ***while*** standing	true	*6-10*
Body Location (BL)	Patient has ***facial*** rash.	*C0015450: Face*	*13-18*
DocTime Class (DT)	Patient had tumor removed.	before	*--No cue annotated/no slot--*
Temporal Expression (TE)	The rash was present ***for 3 days***.	duration	*22-31*

In total, 433 clinical reports were released to task participants (300 training, 133 test). These are the richest semantic annotations of any previous clinical IE challenge. Results from participant submissions will strengthen the state of the art for deeper semantic IE from clinical reports.

Novel insights into disease interactions from Medicare claims data using Berg Interrogative Biology™ Informatics Suite

Vijetha Vemulapalli, Jiaqi Qu, Leonardo O. Rodrigues, Vivek K. Vishnudas, Rangaprasad Sarangarajan, Ely Benaim, Viatcheslav R. Akmaev, Niven R. Narain
Health Analytics Division, Berg, Boston, MA

There has been a quantum explosion in healthcare data availability since the drive to adopt electronic health records. This data can be leveraged to open up new avenues in advancing healthcare. Increased understanding of molecular and clinical interactions in patients that causes variation in outcomes is paramount to creation of precision models in medicine.

Big data efforts in healthcare have predominantly been focused on better management/curation of health care data and mining to test hypotheses. Though these types of big data efforts advance the field by improving access to data and speeding up research, they are limited by current knowledge and long-held biological or clinical phenotype hypotheses. Alternatively, knowledge discovery that is data-driven and unbiased by current knowledge will create a paradigm shift in healthcare by leading to discovery of new and often surprising trends in disease outcomes. Identification of non-obvious comorbidities, development of optimal treatment strategies and protocols will lead to practice-changing events that may mitigate side effects, thereby reducing healthcare costs.

Mathematical/statistical learning tools developed in Artificial Intelligence are well adapted to decipher complex interaction patterns in Big Data. The Berg Interrogative Biology™ Informatics Suite is a computational workflow for integration of varied data modalities and inference of causal effects in a data-driven manner using Artificial Intelligence (particularly Bayesian Networks (BN)). We propose that use of BNs in healthcare Big Data analytics has a significant impact on enhancing patient care and improving healthcare/hospital efficiency.

To demonstrate this idea here, we use low-resolution, publicly available data to make novel discoveries that directly inform care and lead to novel hypothesis. We built a data relationship network of DRG codes by applying Berg Informatics Suite to publically available billing data from CMS[1]. The data includes discharge counts for top 100 codes for 1600 providers in 2011. Data was prepared for AI model building using rigorous methods of filtering, normalization and missing data imputation. A cause-and-effect relationship network representing interactions between the numbers of discharges for DRG codes was built by using a BN learning algorithm.

Heart and renal failure sub-networks (**Error! Reference source not found.**) were chosen from the entire network for further exploration since these conditions rank high as leading causes of death. Most interactions identified in these sub-networks are recognized, hence serve as method validation. Identification of interaction between "bronchitis/asthma" and "renal failure" is new and unexpected based on current medical knowledge. Further exploration of this connection has resulted in a novel hypothesis where some treatment choices for bronchitis could have adverse effects on renal function. Testing of this hypothesis in a more granular dataset will potentially lead to findings that can directly be applied to improving patient care.

This analysis shows strong support for use of AI methods in hypothesis generation which on further exploration will result in clinically actionable information. Such network analysis strongly supports use of purely data-driven methodology on Big Data in healthcare to expedite medical research by providing unique insights unbiased by current knowledge.

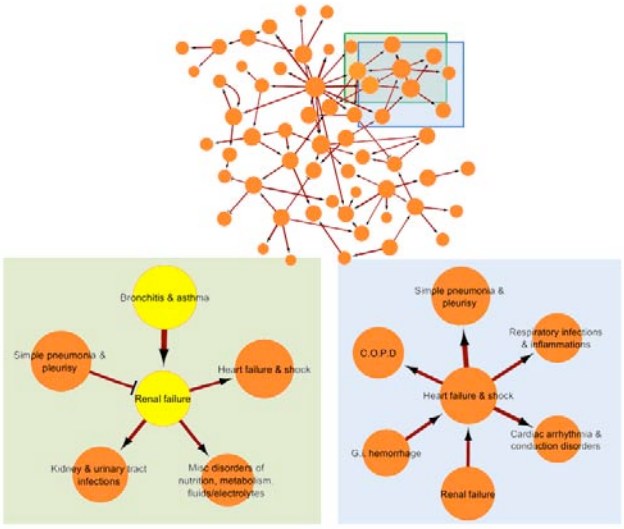

Figure 1: Heart and renal failure sub-network. Novel interaction is highlighted.

Feasibility of Improving Health Literacy Using an Internet Medication Application Implemented in a Diabetes Clinic in India

Jonathan S. Wald, MD, MPH[1,3], Madhu Shrestha, BS[1], Christine Poulos, Ph.D[1], N.S.Vishwanath, MBBS, MPH[2]

[1]Research Triangle Institute, Research Triangle Park, NC; [2]St. John's Research Institute, Koramangala, Bengaluru, India; [3]Harvard Medical School, Boston, MA

Abstract

Limited patient health literacy and barriers to provider-patient communication are common throughout the world and reduce the effective use of medications. The objective of this pilot study was to determine the feasibility of offering tailored printouts for diabetes medicines (Meducation®) to patients at a diabetes clinic in Kerala, India. Preliminary results showed that patients and medical staff found the medicine handouts to be useful and identified implementation challenges to address in future work.

Introduction

Non-adherence to medication contributes to poorer health outcomes and increased utilization of health resources[1]. Meducation® (Polyglot, Inc., Morrisville, NC) is a software product that provides tailored medication information to patients of all literacy levels using an easy-to-read format, pictograms, large font, basic reading level and 16 language choices. This preliminary report focuses on user acceptance and implementation challenges.

Methods

Diabetes medication name, dosage, and frequency were translated into Malayalam for use in the application. Patients newly presenting to the Diabetes Care Centre at the Medical Trust Hospital (MTH) in Kerala, India were recruited as participants, and completed multiple structured surveys between October 2014 and February 2015. Sixty-five participants assigned to an intervention group receiving medicine handouts and answered survey questions covering self-reported medication adherence, diabetes knowledge, self-care activities, and satisfaction with the Meducation® handouts. Semi-structured interviews of MTH staff were conducted. Approval was obtained from Institutional Review Boards at RTI and at MTH to perform this study.

Results

Survey data 4-6 weeks after the initial patient visit showed that most participants (a) found the handouts to be helpful and referred to them for information on their medicines(34/40, 85%); (b) said they would not be likely to view, download, or print the medicine information themselves (24/35, 69%); and (c) reported they would most prefer obtaining the handout from their physician (28/32, 86%). Challenges noted by staff included: (1) recurring internet slowdowns and power outages prevented access to the website at times; (2) interruptions to work flow; (3) that Malayalam translations sometimes lost the original meaning of the English text.

Discussion

While these results are preliminary, Meducation® handouts were generally viewed positively by participants, but they were not preferred in an electronic format or via self-service. Staff utilized workarounds, such as using pre-saved PDF files or having colleagues with a faster connection generate and email back handouts. Staff recommendations for improving implementation focused on utilizing the pharmacist to distribute the handouts and considering an approach that supported a "sometimes connected, sometimes powered" workflow.

Conclusion

Applications such as Meducation have the potential to change the way patients receive medication information, but more work is needed to match component applications with suitable health IT platforms in under-resourced settings.

Effective Strategies For Encouraging Provider Utilization of Mental Health Measurement-Based Care Software (COMMEND)

Dan Y. Wang, PhD[1], Justin G. Chambers[1], Sara J. Landes[1], Eve B. Carlson[1], Josef I. Ruzek[1], Steven E. Lindley, MD[1, 2]
[1]VA Palo Alto Health Care System, Palo Alto, CA; [2]Stanford University, Stanford, CA

Abstract
Adoption of measurement-based care software by mental health providers is not automatic nor common practice. For our system which is known as COMMEND, some success came with a modified interface enabling data to be saved in less than a minute and managerial acceptance and regular review of collected data.

Introduction
An integral part of delivering the best mental health care to returning veterans within the VA Health Care System (VA) is measuring outcomes and tracking outcomes against the types of evidence-based therapies and therapeutic drugs employed. We developed a software tool known as COMMEND which facilitates the saving of such data and their graphical display versus time for providers including psychiatrists and therapists. COMMEND works in synchrony with the VA's Computerized Patient Record System (CPRS), automatically displaying when a provider logs into CPRS. COMMEND's patient panel page shows most recent and baseline outcomes, most recent and next appointments, etc. to aid provider planning. At a click of the patient's name, the provider can also bring up graphs showing measured outcomes and therapies used and drugs prescribed versus time for the last 3 years. However, adoption by providers has not been enthusiastic. We describe some major barriers and initial strategies for overcoming some of these barriers.

Methods
Starting from March 1, 2013, about 25 providers were serially trained to use COMMEND over about 9 months. After training, each provider's use was monitored: all major user interactions with COMMEND were logged into a database. We also held many teleconferences with individual providers to discuss their concerns, many of which were addressed by modified features.

Results
The largest barrier to adoption stems from the fact that it is not standard practice for providers to use graphical outcome trends to guide or modify patient treatment. While outcomes are important for managers and administrators evaluating the performance of a facility with respect to the therapies employed, at the individual patient level there is considerable skepticism about the added value. The second barrier stems from providers' reluctance to do data recording tasks beyond the required writing of the session note.
After many rounds of iterative redesign, we achieved some success in provider adoption. The number of COMMEND notes written per week markedly increased in Aug-Sept. 2013. There are two main causes: one, creation of a vastly simplified session note template called Quick Note allowing providers to record session characteristics in about 30 seconds per patient. Two, we started giving bimonthly summaries of COMMEND data collected to the providers' manager, who began using it to evaluate and review group performance, in particular regarding the use of evidence-based therapies.

Conclusion
To encourage mental health providers to adopt measurement-based care software, one effective strategy was to streamlining the COMMEND software further, reducing the time taken for data entry to no more than a minute per patient. Equally important was gaining managerial acceptance and regular review of collected data.

Building medical informatics data system for quality improvement in Children's hospital setting

Haijun Wang[1] Ph.D. MPH, Terri L Brown MSN, RN, CPN[1], Charles G. Macias MD, MPH[2]
1. Quality and Clinical Systems Integration, Texas Children's Hospital, 1102 Bates Street, Houston Texas 77030. 2. Center for Clinical Effectiveness and Emergency Medicine, Texas Children's Hospital, 1102 Bates Street, Houston Texas 77030.

Quality improvement (QI) is now a driving force in health care and is an essential aspect of service delivery at all level. Medical data not only enables us to accurately identify problems, it also assists to prioritize quality improvement initiatives and enable objective assessment of whether changes and improvement have indeed occurred. In order to better server the QI needs and improve the process of quality improvement, we built a data system which made our QI initiatives more effective.

In addition to clinical data, QI need many different kinds of data, so we first built an enterprise data warehouse (EDW) which integrated EPIC Clarity, PeopleSoft and patient satisfaction and many different types of data together. SQL server 2008 R2 database was used to build EDW and ETL package was run daily, so the data will be one day late. The subject data mart (SAM) is built based upon metrics defined care process (CP) team for each QI project. The QI projects were determined based on the key process analysis (KPA) results and our CP team is multidisciplinary team consisting of clinicians, nurses, quality specialists, data architects, clinical data specialists and BI developers.

The QlikView was used as dashboard development and data visualization tool which consumes data in the EDW. In addition to dynamically display the metrics, we also developed dynamic statistical process control charts (SPC) to monitor the quality improvement project's process. The automated SPC chart allows us to observe the effective ness of our interventions. This automated feature eliminated all of the manual process we used before.

Up to know we have formed 8 CP teams, built more than 10 SAMs and corresponding dashboards. By using this system, we have successfully reduced the chest x-ray rates for asthma patients by more than 35%, and tremendously increase mono antibiotics rate to over 92 percent. We also fixed many data issues existing in out medical record system so our data quality have greatly improved.

Improving the Review of Individual Patients in a Clinical Data Repository

Nich Wattanasin, MS[1], Michael Mendis[1], Kenneth D. Mandl, MD[3], Isaac S. Kohane, MD, PhD[3], Shawn N. Murphy, MD, PhD[1, 2]
[1]Partners HealthCare, Boston, MA; [2]Massachusetts General Hospital, Boston, MA; [3]Boston Children's Hospital, Boston, MA

Abstract

The recruitment of a sufficient number of patients is a crucial part of clinical trials research. We have developed components and leveraged community projects in i2b2, an open source platform for secondary-use of clinical data for research, to accelerate the process of identifying and reviewing suitable patients for a study.

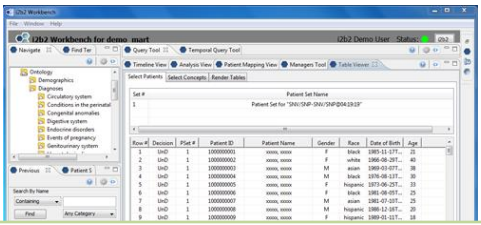
Background

Informatics for Integrating Biology and the Bedside (i2b2) is one of the sponsored initiatives of the NIH Roadmap National Center for Biomedical Computing. The primary goal of i2b2 is to provide clinical investigators with a cohesive set of software tools necessary to collect, host, and manage clinical data from the EMR, and enable the secondary-use of that data for research. The i2b2 platform is designed in a modular fashion consisting of interoperable "cells", or software modules that communicate through web services, which fosters the invention of additional plugins contributed by the i2b2 community that extends the functionality to a new "i2b2-CT" platform, which supports end-to-end identification of patients for clinical trials research. Today, within the i2b2 web client, an investigator can render views of patient centric data for review, as well as utilize newly developed tools, such as our clinical trial suite of apps, to make the review process more efficient for identifying patients qualifying for clinical trials.

Methods

We have developed a number of new components to enhance the i2b2 platform to support the patient recruitment process for clinical trials research. These elements include 1) a web service based ETL cell to retrieve the latest patient data from an institution's enterprise web services, 2) an identity management cell to manage encrypted patient lists and authorizations, and 3) a new workbench plugin to support a tabular display for selection of patients matching phenotypic criteria. In addition, we leverage community-driven projects such as the SMART-i2b2 platform (Substitutable Medical Apps Reusable Technologies) to further augment the determination of trial suitability workflow and allow for investigators to view PHI in a customizable patient-centric view. Utilizing the SMART application programming interface (API), we designed and developed a suite of clinical trials related SMART apps that run inside the i2b2 web client and allow one to manually specify eligibility criteria for a clinical trial or automatically import the criteria from ClinicalTrials.gov. The apps comb over the patient's data on a patient-by-patient basis, for example, looking for a certain medication or problem, or a text string in a note, and displays a matching score based on the defined criteria, allowing the investigator to flag the patient as a potential match.

Results



You can launch the **Patient Centric View** in a pop-up web browser for each patient directly from the i2b2 Workbench, or drag a row to save a patient of interest

We have implemented and deployed a limited release of the work described herein at Partners HealthCare for select i2b2 disease-based driving biology projects and as part of the Scalable Collaborative Infrastructure for a Learning Healthcare System (SCILHS) project, a Patient Centered Outcomes Research Institute (PCORI) grant at Harvard. After identifying a set of patients matching user-defined characteristics such as diagnoses, medications, procedures, etc., the set can be viewed in a tabular format and refined further. Next, a patient's record can be reviewed one-by-one in the SMART Patient Centric View, and the investigator given the opportunity to bookmark any patients of interest in the i2b2 Workplace.

Implementing an end-to-end patient identification workflow for clinical trials in a robust and extensible framework such as i2b2 allowed us to not only leverage existing community-driven projects, but also look forward to emerging initiatives based on this groundwork to support recruitment for multi-site clinical trials. This work was sponsored by Harvard CTSA, NIH U54LM00874, ONC 90TR0001/01, and PCORI.

Profiles Research Networking Software: An Open Source Community

Griffin M Weber, MD, PhD[1]
[1]Harvard Medical School, Boston, MA

Abstract: *Profiles Research Networking Software (RNS) is a social networking website for scientists used at more than 30 institutions across the country (http://profiles.catalyst.harvard.edu). As an open source platform, it has benefitted greatly from software contributions from other universities, partnerships with commercial companies, and feedback from users and developers. This poster reviews how these pieces have come together to create a successful open source platform, and it presents a timeline for future enhancements to the product.*

Introduction: Profiles RNS automatically generates online expertise profiles for investigators using a variety of data sources, including local administrative databases and public repositories such as publications from PubMed. Profiles are linked together using automated algorithms that discover investigators who are prior coauthors, who perform similar research, who are in the same organization, who are physically close, etc. Interactive data visualizations and social network analysis metrics help users understand and navigate through these networks.

Academic Partnerships: Although Profiles RNS was originally at Harvard in 2008, its freely available code and BSD open source license has enabled other universities to contribute to the product: Profiles RNS is a Semantic Web application that uses the VIVO ontology, which was developed by Cornell and University of Florida. VIVO provides a standardized way of describing the scholarly activities of researchers (http://vivo.org). University of California San Francisco (UCSF) incorporated the OpenSocial framework into Profiles RNS, which lets developers (e.g., Wake Forest and others) easily create modular social networking "gadgets" that plugin to the website (http://orng.info). Boston University added a feature to Profiles RNS that automatically synchs publications with ORCID, a non-profit organization that assigns unique identifiers to (http://orcid.org).

Commercial Partnerships: Recombinant Data Corp (now part of Deloitte) was the first Authorized Service Provides for Profiles RNS. In addition to providing commercial support for institutions using Profiles RNS (installation, customization, training, etc.), they played a significant role in managing the open source codebase by moving Profiles RNS to GitHub, reviewing and testing contributed code, writing documentation, and adding new features to the software. Symplectic (http://symplectic.co.uk) is picking up where Recombinant left off, as a new Authorize Service Provider for Profiles RNS. KNODE created ORNG gadgets that lists investigators' collaborators outside their own institutions (http://knodeind.com). Elsevier and Thomson Reuters, through Scopus (http://info.scival.com) and Web of Science (http://researchanalytics.thomsonreuters.com/incites), have provided commercial publication data for institutions' Profiles RNS websites.

Collaboration: Several mechanisms exist for institutions to learn about Profiles RNS or participate in its development. A Google Group (http://groups.google.com/group/profilesrns) provides a mailing list, which has more than 200 members, who frequently share tips, bug fixes, feature requests, etc. A monthly Users Group webinar hosted by Harvard discusses long-term plans for Profiles RNS and often has invited speakers. A separate Developer meeting hosted by UCSF focuses on technical issues. Conferences (such as AMIA) are an important venue to disseminate information Profiles RNS and collaborate with developers of other research networking tools.

Next Steps: Harvard's five year plan for Profiles RNS includes: automatic import of grants, patents, and medical licensures; recommendation tools that provides personalized search results; and bibliometric and social network analysis reports that enable individuals and institutions to review their scholarly portfolios. Though, many other new features will be added in parallel by the numerous academic and commercial developers.

Conclusion: Profiles RNS was built to foster collaboration. It therefore seems fitting that the software itself is result of many contributors working together. Close relationships with commercial partners has been essential, and this should be considered by other institutions selecting among open source license types. Frequent communication among geographically separated development teams, for example, though regularly scheduled conference calls, is important for coordinating efforts and maintaining enthusiasm and momentum. An open model for Profiles RNS ultimately helps the end users, who benefit from the ideas and efforts of not one but many development teams.

A Keyword Suggestion Strategy Based on Citation Networks

Wei Wei, MS, Shuang Wang, PhD, Xiaoqian Jiang, PhD, Lucila Ohno-Machado, MD, PhD
University of California, San Diego, La Jolla, CA

Motivation

In order to write review articles, it is necessary to select effective keywords to conduct the queries, and this is a very time-consuming task. In traditional literature searches, keywords are manually prepared based on experts' knowledge. However, these manually selected keywords might miss some other essential ones. We propose a strategy to suggest related keywords using machine-learning techniques.

Strategy

We infer new related keywords from pre-selected keywords. Our machine learning algorithm is based on a corpus of relevant literature and its corresponding citation network. We are preparing a corpus of biomedical informatics literature using the article collecting system we developed. We have collected over one thousand articles in the biomedical informatics domain and are developing tools to build their citation networks. We will use ParsCit[1] to extract reference information from articles and calculate Levenshtein distances to match related articles and construct the citation network. We will then collect keywords to retrieve the top *k* cited articles from PubMed. Each target article will be mapped to the pre-built citation network. Then, based on the topology among the citation relations, we will generate a local graphical model (GM), where each article node contains a list of MeSH term weights. We will then build a global GM by combining all local GMs. A non-leaf node aggregates the weights of MeSH terms from child nodes; it also propagates the aggregated weights to the parent nodes, where message passing methods can be used to efficiently learn the weights of MeSH terms at the root node K (see Figure 1)[2].

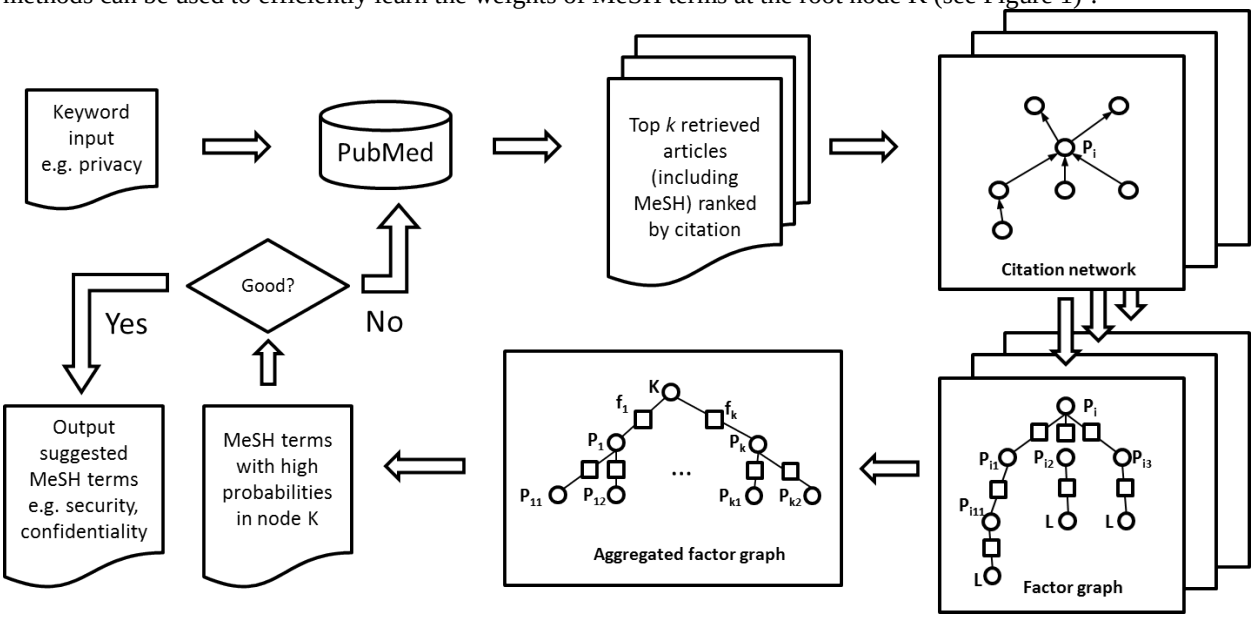

Figure 1. Procedures of the keyword suggestion system. A circle P represents an article; a square represents a factor; a circle L denotes a prior. Each node P maintains a list of weights for the entire MeSH term set. If a term appears in the article, its prior might be assigned a large weight; otherwise, it might be assigned a small but non-zero weight. A factor node contains a pre-defined voting rule and other information such as the article's metadata. A factor node collects partial weights of a term from its child article nodes and then passes the weights to its parent node. For example, P_1 to P_k are *k* articles; f_1 to f_k calculate weights w_1, …, w_k for the term "privacy" from their child nodes. The final weight of "privacy" at node K is proportional to $\prod_{i\in[1,k]} w_i$. The suggested MeSH terms are calculated by collecting MeSH terms associated with high probabilities in node K.

Developing an online social network platform to collect family health history

Brandon M. Welch, MS, PhD[1], Robert Lario, MSE, MBA[2], Joshua D. Schiffman, MD[2]
[1]Medical University of South Carolina, Charleston, SC; [2]University of Utah, Salt Lake City, UT

Abstract

Family health history (FHx) is one of the most important and consistent risk factors for disease. Unfortunately, FHx is often poorly collected in the clinic. To improve the ability of individuals to collect and record their own FHx, we're developing an online social platform that helps family members connect and share health information with each other. We believe that a social network will help individuals collect a more comprehensive and accurate FHx from their family.

Introduction

Family health history (FHx) is one of the most important tools available for genetic diagnosis and disease risk assessment,[1] and is the most consistent risk factor for almost all human diseases. Half of all families display a positive FHx for one or more common chronic diseases.[2] Unfortunately, FHx is often inadequately collected in a clinical setting as clinicians are typically hindered by limited time, inadequate reimbursement, and lack of expertise related to genetics and FHx.[1] As a result, FHx is discussed with only half of new patients and less than a quarter of return patients.[3] As such, a comprehensive FHx data collection and documentation may be best accomplished outside the timeframe of a physician office visit.[1] As a result, several researchers and organizations, such as the Surgeon General, have built patient-oriented tools to help individuals collect and record their own FHx. However, these tools tend to be difficult to use, disease specific, collect limited structured data, have limited interoperability, and lack useful clinical decision support. Furthermore, these FHx tools require the patient to recall all their relatives' health information, which results in inaccuracies and data gaps, particularly in 2nd and 3rd degree relatives.[4] In general, patient-oriented FHx collection tools have had limited adoption and impact outside of research settings.

Our approach

To overcome the challenges of current patient-oriented FHx collection tools, clinicians and informaticists at the University of Utah and the Medical University of South Carolina are currently developing an online social network platform called ItRunsInMyFamily.com. This website will allow individuals to record their own health information and link up with relatives to exchange health information to create a more comprehensive and accurate FHx. ItRunsInMyFamily.com will leverage both popular social networking techniques and health information technology approaches to help individuals and their relatives collect and share health information with each other. At its core, ItRunsInMyFamily.com is being developed as a Meaningful Use-aligned, standards-based personal health record (PHR). The platform will use social network techniques to generate a family pedigree of available health information. ItRunsInMyFamily.com will be a free resource that also provides basic care recommendations (e.g. talk to your doctor about your risk for disease X) to individuals. Clinicians would also be able to access their patients' FHx information and receive personalized risk assessments and care guidelines for their patients. In the future, we are anticipating the incorporation of genomic information into the platform. In this poster, we will describe our architecture approach, standards used, the user interface, and approaches to data privacy & security being incorporated in the development of ItRunsInMyFamily.com.

Conclusion

We believe that an online platform using social networking technology which helps individuals share and discuss their health information with relatives will create a more comprehensive and accurate FHx than current approaches.

BCMA use in the psychiatric population: Challenges in the inpatient setting

Kandace M. Whiting, MSN, RN1, Linda Harrington, PhD, DNP, RN2, Pat Matos, DNP, Constance Johnson, PhD, RN1
1Duke University, Durham, NC; 2Texas Christian University, TX; 3UCLA Resnick Neuropsychiatric Hospital, Los Angeles

Abstract
Consistent use of BCMA safeguards improves medication safety. Psychiatric illness symptomology presents additional challenges to BCMA use. BCMA use in the psychiatric setting was evaluated to identify factors that negatively impact BCMA compliance. Although adherence to BCMA protocols remains integral to medication safety, patient specific considerations need to be considered when developing and implementing BCMA protocols.

Introduction

Barcode Medication Administration (BCMA) effectiveness is contingent upon consistent use of embedded safeguards and compliance with best-practice protocols[1]. Nonetheless, noncompliance is well documented in the literature[1-2]. The psychiatric population presents additional challenges to adhering to BCMA best-practice recommendations that are not present in other patient populations. The purpose of this project is to evaluate BCMA use in the psychiatric setting to identify BCMA workarounds and address issues associated with BCMA policies, organizational resources, workflows, and end-user training that negatively impact BCMA compliance.

Methods

We evaluated BCMA use in a 24-bed in-patient psychiatric unit by comparing unit policies to best-practice using the Harrington BCMA Checklist[2] and observing medication administration episodes (MAE). All steps of each observed MAE were documented and we created visual diagrams depicting MAE workflows. These visual diagrams were compared to the BCMA Checklist[2] and deviations were deemed workarounds. Workarounds were categorized and analyzed based on Koppel et al (2008) workaround classifications and corresponding causes. Discrepancies between current practice and best-practice dictated policy revisions, workflow redesigns, and end-user education programs.

Results

Twenty-four workaround types were identified in the observed MAEs. Of the 24 identified workaround types, six were related to patient identification challenges associated with psychiatric symptoms. For example, patients who were severely disorganized, delusional, or paranoid were frequently observed not wearing wristbands and/or refusing to be scanned. Thus, patient wristband barcodes were either scanned while not on the patient or not scanned at all. Other identified challenges included use of workstations on wheels when caring for aggressive patients and burdensome workflows related to the mobile nature of psychiatric patients.

Conclusions

Behavioral compliance with BCMA best-practice is impacted by factors related to tasks, technology, patients, organizational policies, and the environment[1]. Psychiatric symptoms including paranoia, disorganized thought patterns, aggression, and delusions present additional challenges that impact best-practice BCMA use. Although adherence to BCMA protocols remains integral to medication safety, patient specific considerations need to be considered when developing BCMA protocols. Additional research is needed to determine how to account for these challenges to assure medication safety in the psychiatric population.

Embedding a medical search engine within an electronic health record

Jayne A. Williams, MA[1], Robin L. Kruse, PhD[2], Patricia E. Alafaireet, PhD[3], Jeffery L. Belden, MD[2], Karl M. Kochendorfer, MD, FAAFP[1,4]

Abstract

This study aims to investigate the impact on and user satisfaction with embedding an information retrieval tool into electronic health record (EHR) system used by family physicians and residents at an academic medical center. The tool, 1-Search, provides a single search box for retrieving information from a variety of content sources and types. A pre and post implementation survey were used to gather users' awareness and feedback about their experience with 1-Search. Initial results suggest that physicians support incorporation of the search engine in the EHR.

Introduction

Physicians' information needs are often complex and require access to a variety of information sources, such as guidelines, primary research, patient education materials, and their clinic's internal algorithms.[1] Physicians working at the point of care need quick access to high-quality, specialized information from varied sources to treat patients as effectively as possible. 1-Search is a federated search engine built using Microsoft SharePoint and FAST Search Server. It retrieves results from evidence-based clinical resources as well as an organization's intranet. In 2013, to help meet this need, 1-Search was embedded in the electronic health record system at a large Mid-Western academic health center and made available to members of the department of Family and Community Medicine. We surveyed physicians to determine likelihood and frequency of use, physician acceptance, and usability. Specifically, this study funded by the National Institutes of Health (1R43LM0115909-01) sought to answer the following questions:

1. What type of information sources do physicians use at the point of care?
2. What is the impact and user satisfaction of a medical search engine embedded in an electronic health record?

Methodology

The initial product was developed from a multi-source knowledge base composed of literature and previous student findings as well as substantive input by practicing physicians and health science library professionals. Post development and prior to full deployment, a short training was provided to all potential users. Surveys were administered before (N=97) and after (N=98) implementation to measure usefulness and impact of 1-Search. The pre-survey determined the extent of physicians' information needs and their knowledge about 1-Search. The post-survey addressed user satisfaction and perceived impact of the tool on clinical decision making. Search time, number of clicks, and selected links were recorded by the system.

Results

Response rates to the pre- and post-surveys were 70% and 59%, respectively. Forty-one people responded to both surveys. The proportion of 1-Search users did not differ between pre- and post-surveys (42% and 53%, p=.23). Among 1-Search users on the post-survey, respondents reported that they used 1-Search primarily to address a question about a specific patient (25 of 29), look up treatment information (17 of 29), or to confirm thinking (14 of 29). Of 56 respondents who completed the question, 26 reported being more likely to use 1-Search now that it is embedded in the EHR.

Conclusion

This study provided the necessary evidence to support the continued use of 1-Search as well as its further development. Tools, such as this type of embedded information retrieval tool, hold promise to improve care though reduced physician cognitive workload, through more compressed reference information delivery and through timely access to information within a typical clinical workflow.

Title: Important information to communicate between clinicians and families in the intensive care unit

Michael E. Wilson MD, Sumanjit Kaur MD, Alice Gallo De Moraes MD, Brian W. Pickering MD, Ognjen Gajic MD, Vitaly Herasevich MD PhD
Multidisciplinary Epidemiology and Translational Research in Intensive Care (METRIC), Mayo Clinic, Rochester, MN

Introduction: Family members of patients in the intensive care unit (ICU) play an integral role in medical decision making and supporting patients. Communication with families is often a difficult and complex task for ICU clinicians. Few studies have attempted to systematically identify information important for clinicians to know about family members in the ICU. Our objectives were to:

1) Identify important information for ICU clinicians to know about family members
2) Identify important information for ICU clinicians to communicate with family members

Methods: A literature search and semi-structured interviews identified 21 items perceived to be important for clinicians to know about family members and 32 items perceived to be important for families to know about patients from clinicians. Family members and clinicians of two ICUs from a single institution were asked to rate the identified information as necessary to ICU decision making using a seven point Likert scale. (7=necessary information, 4=neutral, 1=unnecessary information).

Results: Fifty-four family members and 50 ICU clinicians completed the survey (response rate 64%). Subjects rated each identified piece of information as necessary (mean ratings 5.1-6.6 for family members, 4.7-6.8 for clinicians), although significant variability existed regarding necessary and unnecessary information. Themes important for clinicians to know about family members include: family background, questions, understanding, goals, concerns, wellbeing, and requests for additional help. Themes important for families to know about the patient's medical care include: diagnosis, treatments, prognosis, clinical status, schedule, comfort, goals of care, medical team, and family participation. Family members rated 25 of the 53 pieces of information as more necessary than did clinicians (p values ranging from <.0001 to .05).

Table. Family member trust of information from the following sources

	Family members (n=54) mean ± SD
Doctor in the ICU	6.5±1.00
Nurse in the ICU	6.3±0.79
Doctor outside of the ICU (such as primary care provider)	5.4±1.29
Family or friends	4.7±1.50
Brochures, pamphlets, etc.	3.7±1.48
Internet	3.7±1.60
Religious leader or spiritual advisor	3.4±1.25
Newspapers, magazines, etc.	2.9±1.44

Discussion and Conclusions: We identified information important for clinicians to know about family members and information important for family members to know about the patient from clinicians in the ICU. There is variability between information that clinicians and family members considered as important. This variability may contribute to miscommunication, decreased family and clinician satisfaction, and poor quality decision making. Our findings and survey results can be utilized to design tools to improve information exchange between family members and clinicians in the ICU. Successful communication between family members and clinicians in the ICU is a key to improve mutual understanding and shared decision making.

Evaluation of Real-Time Use of the EHR in Documenting Pain Scores

Tamara J. Winden, MBA, Jennifer M. Krueger, MS, Karl Fernstrom, MPH, Kai G. Hanson, MS, Michelle Ophaug, BSN. Allina Health, Minneapolis, MN

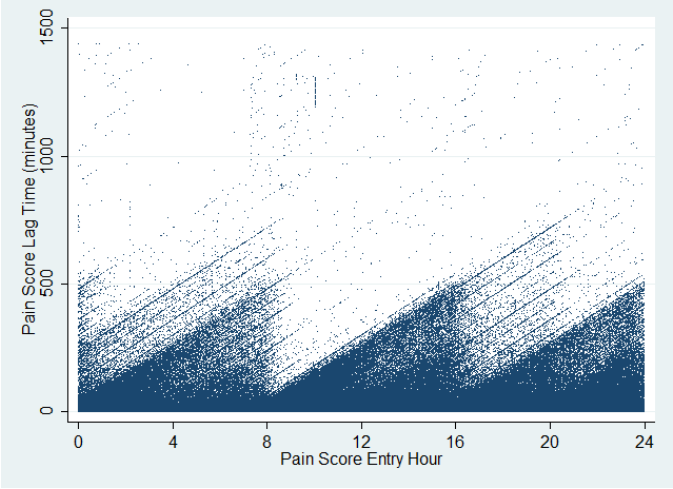
Abstract: ***Real-time use of Electronic Health Record (EHR) systems by clinicians is a vital component of the current and future healthcare provision in the U.S. Delay in documentation into the EHR could influence patient satisfaction, safety, and healthcare decisions. The goal of this mixed methods study is to examine the lag time between observation and data entry of pain scores into the EHR and identify barriers to real-time documentation. This project will present an analysis of current practice in documentation of pain scores, identify barriers to real-time EHR data entry, and evaluate impact to patient care.***

Introduction: One challenge with EHRs is making sure documentation is as current as possible. This requires that EHR tools are appropriately incorporated into the clinician's workflow. To increase accessibility and reduce documentation lag times, many institutions have invested significantly in improving EHR efficiencies. They have also invested in additional computer hardware for patient rooms, hallways, as well as moveable carts to increase EHR availability to staff. However, documentation appears to still lag behind observation times and this latency has the potential of impacting patient care and safety. This, combined with current federal initiatives around the control of pain in the inpatient setting, was the impetus for this project. The objectives of this study are to examine the latency in documentation of pain scores in the EHR, understand the current documentation practices and barriers to real-time documentation of pain scores, and examine the impact to patient care. This study was approved by the institutional review board.

Materials and Methods: This project is a mixed methods study of real-time documentation practices of nursing and other clinical staff in 10 inpatient hospital settings. The primary focus is on data entry of pain scores into the EHR. Retrospective secondary data from the EHR will be examined along with a cross-sectional survey of clinical staff that enters pain scores into the EHR and observations on hospital units in an effort to describe barriers to real-time documentation.

Results: Preliminary analysis of the secondary data shows that most of the variation in the pain score lag time between hospitals may be due to hospital size. Larger hospitals have an increased median pain score lag time and increased interquartile range. There seems to be little variation in lag time between shifts as a whole. Though when we looked at common transition times there was both an increase in the median lag time and its variability. This may be a symptom of clinical staff waiting to complete documentation until the end of their shift (Figure 1). Finally, there does seem to be a negative association between pain score lag time and the level of pain intensity. As pain intensity increased both the median lag time and its variability decreased significantly.

Figure 1. Pain score documentation over a 24 hour period



Creating Clinically Homogeneous Groups of Prostate Cancer Patients

Janusz Wojtusiak, Che Ngufor, Lorens Helmchen, Jack Hadley
George Mason University, Fairfax, VA

Introduction

Comparative effectiveness analyses that use observational data require methods, such as propensity score matching and instrumental variables, that "simulate" randomization to avoid bias associated with the effects of unobserved factors that influence both the treatment selected and the clinical outcome. Despite such adjustments, the results of these methods apply essentially to an "average" patient. Personalized medicine requires finding the treatments most appropriate for a specific patient, not on the average. A promising approach to address this goal is creation of homogeneous groups of clinically similar patients and performing comparative effectiveness analysis within the clusters. Several methodological and practical issues need to be addressed before such groups are created.

The presented project focuses on using machine learning methods to create homogeneous groups of prostate cancer patients using a combination of classification learning and clustering to create groups that are clinically similar. Construction of the groups uses information typically available to urologists making treatment decisions: prostate cancer characteristics (PSA, Gleason score, stage) and predicted survival based on conditions existing prior to prostate cancer diagnosis.

Method

The presented method works in two stages. First, it creates models of the competing mortality risk based on pre-cancer clinical conditions. We compared parametric and machine learning-based classification models applied to predict short-term mortality (1 year) and long-term (7 years) mortality. In order to select right models several methods were tested including logistic regression, support vector machines, decision trees, and random forests. The models are trained using non-prostate cancer patients to specifically address only the competing mortality risk.

Second, competing mortality risk is combined with prostate cancer risk factors and unsupervised learning algorithms are applied to create homogeneous groups. The experiments compared two popular unsupervised learning methods: k-means and hierarchical clustering. For comparison we created a set of 6 clusters based on an arbitrary high/low split of predicted survival and the 3 level D'amico prostate cancer risk score.

Evaluating clustering methods requires checking clustering consistency when multiple clusterings are applied to discover optimal number of clusters that consistently capture "patterns" in the patient population. In order to do so, each clustering was bootstrapped 100 times, and entire process cross-validated 5 times. The Jaccard similarity measure and cluster prediction strength [1] were used to find the optimal method and number of clusters. Homogeneity of groups also needs to be evaluated using measures independent from those used to create clusters. We assumed that similar patients who receive the same treatments should have similar outcomes. (This assumption ignores variance in treatment quality, but is sufficient for the presented work). Thus, at the last step, clusters are validated by measuring area under ROC curve (AUC) for logistic regression model that predicts true mortality based on cluster membership and treatment. The assumption is that the higher the AUC, the more similar are patients within a group.

Results

Data used in this study were from the SEER-Medicare database, complemented with claims for 5% random sample of Medicare beneficiaries. Main inclusion criteria for the study were: for non-cancer patients: continuous enrollment in Medicare Part A or Part B for at least a year prior to January 1 2004 and were at least 66 years old for the non-cancer patients; and for prostate cancer patients: at least 66 years old at age of diagnosis. A total of 119,028 non-cancer and 104,213 cancer patients were identified for potential inclusion in the study.

Based on 100 bootstrapped samples of cancer patients using predicted mortality and prostate cancer-specific characteristics the k-means and hierarchical clustering both indicated the data are best clustered into 5, 6 or 9 clusters (Jaccard index = 0.9, 0.8, and 0.85 respectively). The independent validation of clusterings indicated that the AUC for mortality model was the highest for 6 clusters obtained with the k-means algorithm. The results are: AUC(5 clusters)=0.83; AUC(6 clusters)=0.84; and AUC(9 clusters)=0.84. These numbers were significantly higher ($p=0.035$) than the AUC for a simple tabulation of predicted survival and D'amico scores into 6 clusters (0.80) and 9 clusters (0.82).

SimProtocols – A Software Prototype for In Silico Comparison and Evaluation of Computer-based IV Insulin Infusion Protocols

Anthony F. Wong, MTech[1], Senthil K. Nachimuthu, MD, PhD[1], Peter J. Haug[1,2]
[1]University of Utah, UT, [2]Intermountain Healthcare, UT

Abstract

We are developing a prototype for in silico comparison and evaluation of computer-based IV insulin infusion protocols. It has three major components: patient module, interface module and comparator module. We used clinical data from ICU patients who were supported by eProtocol-insulin to simulate insulin-blood-glucose interaction in the patient module. The interface module manages the interaction between the computer-based insulin protocol and the simulator. The comparator module measures the performance of competing protocols by evaluating its outcome.

Introduction

Computer-based clinical protocols can standardize clinical decisions while adapting to contextual changes and individualizing patient care. Different computer-based protocols can generate different results and lead to different patient outcomes. An efficient method for comparing and assessing different computer-based clinical protocols, before committing them in clinical trials, would be valuable. We used IV insulin infusion protocols as an exemplar.

Methods

The prototype is based on a framework we developed for in silico comparison and evaluation of computer-based clinical protocols. The main function of the patient module is to simulate specific physiological process using data derived from real patients. We used clinical data from ICU patients who were supported by eProtocol-insulin[1], a heuristic rule-based protocol used for managing blood glucose. Internally, eProtocol-insulin assumes a linear rate of change in glucose in response to changes in IV insulin. Thus, the resulting clinical data is unique because it reflects the individual patient response (measured through the blood glucose) as a result of a controlled insulin treatment regime. We used these responses to simulate the next appropriate level of blood glucose once the patient module received the insulin dose recommendation from the competing computer-based IV insulin protocol.

The interface module manages the interaction between the working modules and various competing computer-based IV insulin protocols. It sends patient-specific data required by the computer-based IV insulin protocols in order to generate the necessary insulin dose recommendation. It then channels this result to the comparator module for further evaluation.

The comparator module compares the recommended insulin doses by competing computer-based protocols at different blood glucose ranges (low, on target, high)[2]. A favorability score is used to measure how well the competing computer-based protocol perform. We measure the performance using a set of rules we defined based on the recommended insulin dose. At low blood glucose (<80 mg/dL) and on target range (80-110mg/dL), we prefer lower insulin dose. At high blood glucose (>110 mg/dL), we prefer higher insulin dose.

Results & Discussion

Our clinical data included 408 patients with 18,984 eProtocol-insulin recommendations. We used this dataset to simulate new levels of blood glucose when regulated by insulin in the competing protocols. The projected change in blood glucose was calculated based on the aggregated change in blood glucose level for every given insulin dose in that specific patient. We used linear regression to predict the outcome of the new blood glucose value for every plausible recommended insulin dose. At this stage, we are developing a competing protocol to complete our simulation. We believe our proposed novel simulation framework using real patient data is a viable method of comparing different computer-based protocols.

Engaging Patients with Advanced Directives Using an Experiential Information Visualization Approach

Janet Woollen, RN, MS[1], Suzanne Bakken, RN, PhD[1]
[1]Columbia University, New York, NY

Abstract

Despite the substantial benefits of advanced directives to both patients and care providers, they are often not completed due to lack of patient awareness. We propose designing an Experiential Information Visualization (1) to promote advanced directive awareness through vivid illustration of options, and (2) to inspire contemplation and conversation regarding patients' end-of-life journeys.

Background and Significance

An advanced directive (AD) is beneficial to patients and care providers in guiding end-of-life care; however, ADs are often not completed. A primary reason for this is lack of patient awareness[1]. Healthcare providers operate under great pressure in a system that does not provide incentives or training to discuss end-of-life care with patients and their families. It is unrealistic to expect that system to change any time soon, so it is left to patients and their families to navigate many of the decisions regarding end-of-life care. Patients want to be active participants in the end-of-life process; however, patients and families lack access to information on what to expect, what to look for, and what their options and rights are. They know the principles but they need ready access to pertinent information, presented in a way that facilitates understanding of the specifics.

Uninformed individuals confront numerous challenges when facing end-of-life trials: significant decisions being made under stressful conditions; unintended financial burden on patients, families and society; moral distress and conflict for healthcare providers; and perhaps most importantly, medical care that may be carried out contrary to an individual's wishes and values. Clinicians typically turn to family members for decision making when patients cannot advocate for themselves, but studies reveal that neither families nor clinicians accurately predict what patients want[2]. A lack of awareness and understanding of ADs must be addressed to remedy such problems and to set the stage for desired outcomes.

Approach

The purpose of this project is to introduce an experiential information visualization that would furnish immersive information to patients and families on end-of-life directives.

We propose designing an innovative tool to (1) promote AD awareness by engaging patients to learn about their options and (2) inspire contemplation and conversation regarding patients' end-of-life journey. An Experiential Information Visualization (EIV) may be able to communicate insights that are often communicated in words, but are much more powerfully communicated by example. An EIV could facilitate vivid understanding of options and inspire the beginning of often-difficult conversations between care providers, patients and loved ones. It may also save clinicians' time, as care providers may be able to spend less time explaining details of end-of-life care options.

Results

Study in progress.

Conclusion

It is important to ensure that patients have time for reflection and are informed of their options to die with dignity. Our goal is to investigate if an EIV can increase awareness and understanding of an AD and promote contemplation of the end-of-life journey.

Analysis of Patient Portal Use in Underserved Populations and Settings

Maria D. Wright, RN, BSN[1], Tammy Toscos, PhD[1], Ayten Turkcan, PhD[2], Brad N. Doebbeling, MD, MSc[3]
[1]Indiana University Purdue University, Fort Wayne, IN [2]Northeastern University, Boston, MA [3] Indiana University Purdue University, Indianapolis, IN

As health information technology evolves to meet the needs of healthcare providers and health systems seeking financial incentives through the HITECH Act, the needs of the underserved patient population should be considered. Underserved patients, including those who are uninsured or underinsured, comprise a patient population that has many challenges with access to care. A patient portal can improve access to health care by enhancing patient-provider communication, empowering patients, and supporting care between visits. Addressing obstacles that interfere with the uptake and use of patient portals is not only important for improving the patient experience, but can impact multiple quality dimensions including access, efficiency, satisfaction, and health outcomes.

Community Health Centers (CHCs) that provide care to the underserved are working to implement electronic health records and attest to meaningful use through multiple approaches, including the implementation of patient portals. The goal of our Patient-Centered Outcomes Research Institute (PCORI) funded research effort, *Improving Healthcare Systems for Access to Care and Efficiency by Underserved Patients*, is to redesign CHCs to deliver timely care to underserved patients with common health problems. As part of this project we conducted a review of literature that examines patient portal use in underserved patient populations. We are also examining patient perspectives on barriers, access to portals, and desired functions in a sample of seven CHCs from across Indiana.

Our review of literature explored peer-reviewed journal articles published from 2009 to 2014 with a focus on access to technology, perceptions and attitudes toward patient portals, and barriers to enrollment in underserved patient populations. This population has been found to have access to different forms of technology, search for health information online, and have an interest in using healthcare information supplied digitally [1-3]. Positive perceptions about the use of patient portals include themes of enhanced understanding, empowerment, a strengthened patient-provider relationship, and convenience [3-4]. Negative themes include privacy and security concerns, limited health literacy, usability, and fear of a change in the relationship with the healthcare provider [3-4]. Because disparities have been found in the enrollment and use of a patient portal, it is important to examine the root causes as they pertain to this patient population so that potential barriers can be addressed before implementation [4-7].

Our work with CHC patients, staff, and providers has uncovered several strategies to address the negative patient perceptions found in the literature review. Gradually adding functionality to a portal may allow privacy and security concerns to be addressed. Getting patients accustomed to using the portal for lower risk information first, e.g. scheduling and appointment reminders, allows for opportunity to provide education on the safeguards in place. There must be a concentrated effort to educate patients on how they can benefit from using the portal, e.g. for routine management of a chronic disease, and its use must be encouraged by the providers and staff to mitigate any concerns about changed relationships. In order to accomplish this, we suggest including providers and staff in the discussion of what functions the portal should possess. This may act to improve provider and staff acceptance of the technology and in turn stimulate use by the patients.

Clustering Analysis of the Gene Chip Data for Two Types of Leukemia

Cai Wu, MS
The University of Texas MD Anderson cancer Center, Houston, TX

Abstract

This project distinguished leukemia subtypes acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL) with clustering methods. The pre-processing, normalization and log-transform were involved in data preparation. Hierarchical and K-means algorithms were used for clustering analysis through Matlab built-in and modified functions. The two types of leukemia samples were clustered into different groups in hierarchical algorithm and K-means algorithms; the pre-preparation made datasets suitable for analysis.

Introduction

Leukemia is a type of cancer that affects developing blood cells in a patient's bone marrow. There are as many as 150 subtypes postulated to exist. So we need to find an effective way to distinguish between two important leukemia subtypes: acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL). Array technologies have made it straightforward to monitor simultaneously the expression pattern of thousands of genes. The challenge now is to interpret such massive data sets. Genes (rows) can be clustered to identify groups of co-regulated genes and expression patterns; samples (columns) can be clustered to identify new classes of biological samples and detect experimental artifacts. This project uses pre-processing, normalization and log-transform for data preparation and clustering analysis to distinguish leukemia subtypes from the dataset.

Expression Data Preparation

The dataset was downloaded from http://www-genome.wi.mit.edu/cgi-bin/cancer/datasets.cgi, which included 59 control genes, 7070 test genes. There were 38 patient samples, 27 were ALL and 11 were AML. In such large data set, not every gene acted on the same level with the samples. Thus, data preparation could be the effective way to treat the data before clustering analysis.

First all negative values were set to 1; then the mean values of control samples were calculated to normalize the dataset; if the sample value less than the mean of same sample values (mean of the column), the small expression value (< mean of the column) was converted to the mean; if all same gene expression values (one row) were less than the mean, the row was eliminated; then the dataset was Log-transformed for clustering analysis.

After the pre-processing, the gene numbers (row of the data set) became 1250. Since the first 27 samples were ALL type and the rest 11 were AML types, the sample correlation coefficients with the expression values were checked. Meanwhile, the 50 selected gene datasets from neighborhood analysis were also being calculated. Based on the correlation image, the 50 selected gene expression values were significantly correlated with sample types. The first 27 ALL type samples were all positively correlated with ALL samples and negatively correlated with the rest 11 samples (AML type). The same trend was also shown in AML samples, although the correlations between the sample types were not strong as the 50 selected samples.

Clustering Analysis

Hierarchical and K-mean algorithms were used for clustering analysis. In hierarchical clustering, the similarity or dissimilarity between every pair of objects in pre-processed dataset were found first using pdist function; then the objects were grouped into a binary hierarchical cluster tree using linkage function; finally the hierarchical tree was divided into clusters using cluster function and using dendrogram to plot the cluster tree. In K-mean clustering, K centers in the data set were randomly selected; sum of square of distance between each data point and nearest center was minimized by using the Euclidean distance to calculate the distance, and the distance between clusters was maximized, the mean of each cluster was calculated; each record to one of the K means was reassigned. The threshold as 0.9 to get the clustering group for hierarchical algorithm, and 3 as cluster numbers for k-means algorithm.

Both Matlab built-in function and modified K-mean function clustered two types of leukemia samples into two different groups using Matlab, the hierarchical algorithm gives more cluster groups than k-means; the pre-processing extracted and enhanced meaningful data characteristics and normalization accounted for systematic differences across datasets; log-transformed dataset was suitable for clustering analysis.

Extract and Analyze Useful Information from a Noised DNA Chip Image

Cai Wu[a,b], MS, Yiqing Chen[a], MS

[a]Department of Computer Science, University of Houston, Houston, TX; [b]The University of Texas MD Anderson Cancer Center, Houston, TX

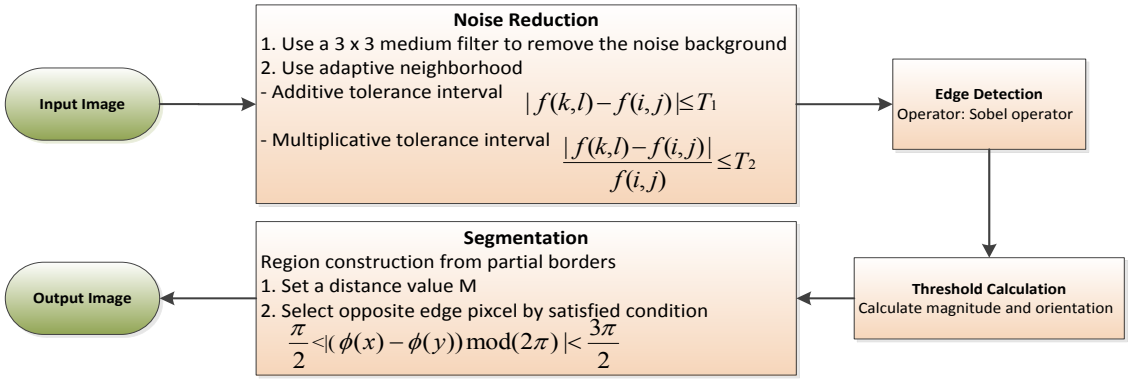
Abstract

This project analyzed a DNA chip image which contained DNA reaction spots and strong noise background, identified and extracted useful information, made a clear output image for further analysis. Median filter, Sobel operator and Hysteresis were used for edge detection, and region forming by checking opposite pixels was used to extract useful information. The processing reduced noise background and prevented edge blurring. The distance for region forming removed most of the noise background and kept the useful object information.

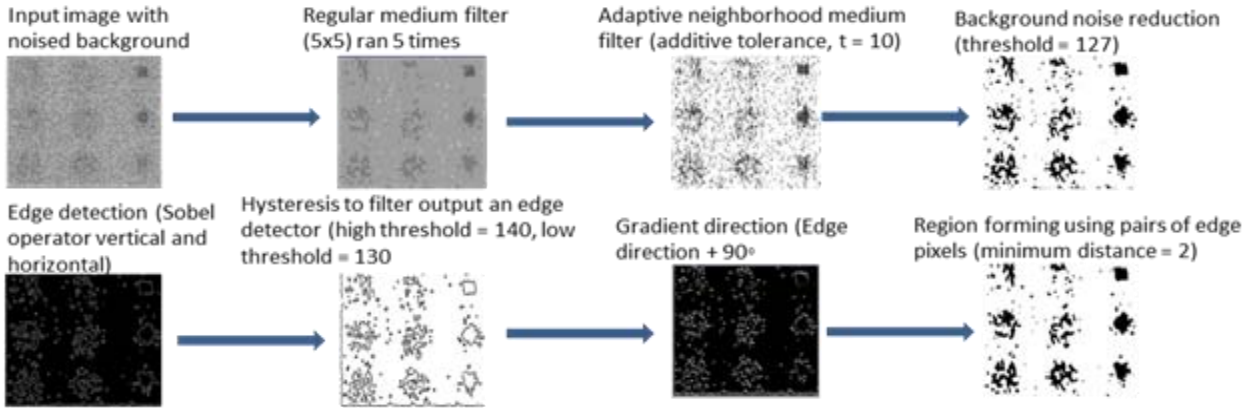
Introduction

Microarray is an important tool for gene expression analysis. However the noises introduced during the experiment affect the accuracy of the gene expression. Thus eliminating the noise effect is an important step for analysis. Image analysis includes grinding, spot recognition of the scanned image and removal noising background. In this project, median filter, Sobel operator and Hysteresis are used for edge detection, and region forming by checking opposite pixels is used to extract useful information in the microarray image processing procedure.

Input Image Processing



Results



Conclusion

Median filter, Sobel operator and Hysteresis reduced noise background and prevented edge blurring. The distance setting for region forming kept the useful object information.

Extending tranSMART for Meta-Analysis of Genomic Data Across Trials

Haiguo Wu, Ph.D[1], Elisabeth L. Scheufele, MD, MS[1,2], Dina Aronzon, MS[1], Matvey B. Palchuk, MD, MS[1,2]
[1]ConvergeHEALTH by Deloitte, Newton MA; [2]Harvard Medical School, Boston MA

Abstract

tranSMART is an open source knowledge management and high content data analytics platform. Data analyses were limited to a single clinical trial at a time. We constructed a data model and updated the application to load genomic data and run cohort analysis across multiple trials within tranSMART.

Introduction

tranSMART supports cohort discovery and hypothesis generation by combining clinical study data with genomic data. Initially, tranSMART was developed to run analysis within a single clinical trial. However, due to significant interest in analyzing the data from across multiple trials, we extended tranSMART to run meta-analysis across trials using clinical data. We are continuing to extend the meta-analysis functionality by including genomic data (e.g., gene expression data) and linking them to clinical data to enable more powerful analysis.

Methods

The data in tranSMART are stored within each trial and are mapped to separate ontology trees. For genomic data, there is the additional challenge of the data being normalized based on samples within a single study. The required extension is three fold: 1) support the genomic data node in custom across-trials ontology; 2) recalculate z-score; and 3) extend application layer for advanced data analysis.

The z-scores for each probe of each sample need to be recalculated and refreshed when a new study with genomic data is loaded. We extended the existing data model by adding a separate column to store the new z-score data for across-trial functionality. The ETL process was modified to handle these requirements, and application code base will be adapted to support the new data structure.

To test the new functionality, we used four parallel breast cancer studies, GSE32072, GSE22093, GSE23988 and GSE5462 (see Figure 1) with the raw gene expression data downloaded from the GEO repository (www.ncbi.nlm.nih.gov/geo/). These studies overlapped on the experiments performed - pre-treatment breast tissue tested with Affymetrix Human Genome U133A Array. We normalized the expression data with the RMA algorithm[1] for log values and calculated z-scores[2] for each study and across trials.

Implementation Example

The four studies had 21, 58, 61 and 103 patients in the genomic data node, respectively, which totalled to 243 patients. There are 22,283 probes in this array, which means that 5,414,769 records were updated. The z-score recalculation used about 3 minutes on a single-threaded server. This overhead only affects the initial loading but not the actual analysis. The benefit to run genomic data across trials surely outweighs the loading time.

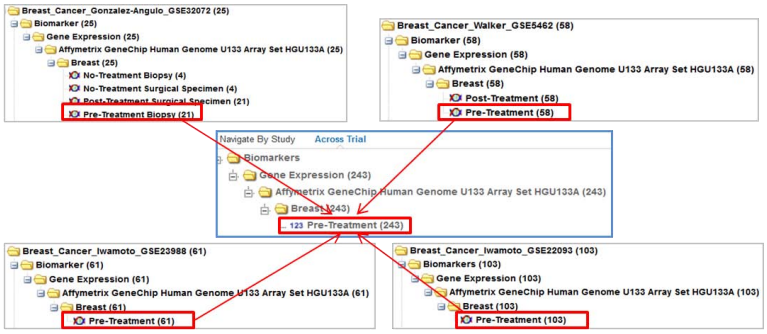


Figure 1: Mapping Genomic Data from Individual Trials to Meta-Analysis in tranSMART

Conclusion

We are actively working to extend tranSMART to perform meta-analysis of genomic data across trials, with good initial results.

Challenges in Quantifying Narcotic Use from Drug Dispensing Records

Jianmin Wu, PhD, MS[1], Jon Duke, MD, MS[1,2], John T. Finnell, MD, MS[1,2]
Regenstrief Institute, Indianapolis, IN [1], Indiana University, Indianapolis, IN[2]

Introduction The epidemic of narcotic prescription drug abuse and its associated high cost and mortality have attracted national attention. Much research has been done to explore the distribution and determinants of the narcotic abuse. Narcotics prescriptions are usually ordered on a PRN basis (i.e., "as needed") with guidelines regarding the appropriate frequency of administration. Most researchers look at narcotic daily dose and days supply to determine a patient's risk for drug abuse. Currently, no standardized method exists to calculate these metrics from observational data. Inconsistency in narcotic measurement methods might lead to discrepancies in daily dose calculation and affect the stratification of patient risk for drug abuse. In this study, we will describe some of the challenges in quantifying narcotic prescriptions into morphine equivalents, the standard unit used for assessing patient risk and predicting mortality.

Methods Narcotic prescription data were collected from the Emergency Department of Wishard Health Services, from 2008 to 2010. Data elements used for calculating daily dose and supply days are: order_name, sig (free text describing administration instructions), quantity, script_dose (the amount of drug taken each time), frequency (time interval between doses), daily_dose, rx_dose (strength of the prescription per unit dispensed), and dose_unit (defining the dose in milligram or milliliters). The completeness of each data element was summarized as a proportion of the non-missing counts divided by the total prescription orders. "Maximum" rule was applied to dose calculation. For rx_dose PRN, e.g. '12.5-25 mL PO', the maximum volume '25ml' was selected as the dose taken by patient each time; for frequency PRN, e.g. 'PO Q4-6 hours', the time period between two doses was standardized as 4 hours; for any specified maximum dose, e.g. '1 tab PO Q4-6H prn pain (Do not take any more than 4 tablets per day)'; the maximum amount '4 tablets per day' was selected instead of the dose (6 tablets) calculated from structured data elements. Total morphine equivalents (Meq) for a single prescription was calculated using equation = quantity × rx_dose × dose_unit × conversion factor for Meq.. Supply days for each prescription were equal to the quantity divided by daily_dose or by the product of script_dose multiplied by frequency/24hours. Average daily morphine equivalent dose (MED) were determined by total Meq for a single prescription divided by supply days.

Results A total of 46140 patients generated 74266 narcotics prescription orders. The raw completeness of each data elements are: 100% (order_name), ~100% (sig), 100% (quantity), 1.5% (rx_dose), 85.9% (frequency), 22.3% (daily_dose), 22.3% script_dose, and 22.4% (dose_unit), respectively. Overall, about 20% of the prescriptions had sufficient data to calculate the average daily MED using the structured data elements. Around 80% of prescriptions required information from the free text 'sig' in order to calculate the daily MED. Only 0.1% of the prescriptions were could not be converted to daily MED due to missing or discrepant data. Some examples of these problematic prescriptions are listed in the table below.

Table. Examples of prescription orders with inadequate data to calculate morphine equivalent dose

Order_Name	Sig	Rx_dose	Quantity	Frequency	Daily_dose	Script_dose	Dose_unit
HYDROcodone & Actmnphn Elixir (7.5mg&500mg/15mL)|31383|M	5 mL PO Q6H PRN pain		***1 bottle***	Q6H	20	5	ML
HYDROcodone 5/Acetaminophen 500|12983|M	5 mg hydrocodone, ***1 tab PO q6h prn pain (Do not take any more than 2 per day)***		#15	Q6H			
HYDROcodone 5/Acetaminophen 325|36966|M	5 mg hydrocodone,***1 tab PO q6h prn pain*** (***Do not take any more than 1 per day per day***)		#10	Q6H			
OXYcodone|21543|M	***not more than 5 tab/day***	5mg	#30		5	5	TAB/D
Hydrocodone/Ibuprofen|32803|M	Take one tablet PO every 6 hours ***no more than 5 tablets per day***		#20	Q6H			
HYDROcodone 5/Acetaminophen 500|12983|M	***max 8 tabs/day***		#20		8	8	TAB/D
Tramadol|22482|M	***Take for headaches if necessary***		#10				
Tramadol|22482|M	25 mg PO QAM for 3 days duration then 25 mg PO BID for 3 days duration then 25 mg PO TID for 3 days duration then 25 mg PO QID for 3 days duration then 50 mg PO Q6H PRN pain (not more than 400 mg per day	50 MG	#20	***QAM|BID|TID|QID|Q6H***	25|50|75|100|200	25|25|25|25|50	MG|MG|MG|MG|MG
HYDROcodone 5/Acetaminophen 500|12983|M	5 mg hydrocodone, ***1 tab PO once daily before sleep q6h***		#10	QDAY,Q6H	9	5,1	MG,TAB

Conclusion A standardized method for measuring the daily dose of narcotics PRN prescriptions is important for secondary use of narcotic prescription data. Such standards will help improve the reliability of research identification from narcotics research.

Implementation of a Computer-Based Documentation System Improves Workflow Efficiency: A Case Report

Tzu-Yu D. Wu, MS[1], David J. Bradley[2], MD, Kai Zheng, PhD[1, 3]
[1]School of Information; [2]Division of Pediatric Cardiology; [3]School of Public Health, University of Michigan, Ann Arbor, MI

Abstract

Computer-based documentation (CBD) systems should promote workflow efficiency in addition to facilitating secondary use of data. In this case study, we examined the impact of implementing a CBD system designed to manage the performance, interpretation, and reporting of cardiac monitors at a referral academic medical center, and found a 45% reduction in the interpretation turn-around time by physicians. The observed improvements may be attributable to a more usable user interface and a higher level of accessibility of the system, which is being verified using qualitative methods.

Introduction

Computer-based documentation (CBD) systems have existed for over a decade. While their main design objective is to improve the quality and computability of clinical data captured in order to support both primary (i.e., patient care) and secondary use (e.g., quality assurance and research) purposes, they should ideally be designed to facilitate workflow to improve efficiency and to reduce user adoption barriers. In this abstract, we report a case where the introduction of new CBD system led to significantly improved workflow efficiency.

Method

Data were collected by a clinical team performing 24-hour ambulatory cardiac (Holter) monitoring on pediatric patients in a large teaching hospital. The team, consisting of three attending physicians, five technicians, and several nurses, has been using a legacy CBD system to record the progress of Holter cases for more than ten years. A Holter patient case has four milestone dates: the date when the monitor is placed on the patient, when the device is returned, when data are processed, and when data are reviewed and verified. In this study, we used the intervals between these milestone dates as surrogate measures of workflow efficiency. A shorter duration indicates better efficiency and more timely interventions. A new, web-based system, which provides a significantly streamlined user interface and a higher level of accessibility, was deployed in the hospital in October 2012. The analysis reported in this abstract compared three time periods: (1) The year beginning 24 months prior to deployment of the new application; (2) The 12 months prior to deployment; and (3) the 12 months following its deployment. The differences of time intervals were examined by ANOVA and TukeyHSD test with a 95% confidence interval.

Results

Table 1 shows the interval from preliminary Holter report creation to report verification for three time periods: Average Holter verification was reduced from 17.8 to 9.14 days ($p<0.001$) with implementation of the application. In contrast there was no significant difference between the two 12-month periods prior to application deployment ($p=0.45$). Figure 1 visualizes the results.

Table 1. Number of studies included

Stage	Period	# Studies	Avg. Dur. of Verification
D−24	Oct 10 ~ Sep 11	953	17.86
D−12	Oct 11 ~ Sep 12	1,176	16.64
D+12	Jan ~ Dec 13	1,315	9.14

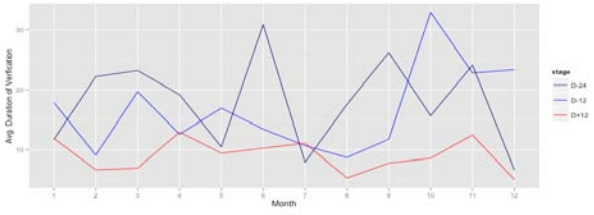

Figure 1: Avg. duration of verification per month

Conclusion

A properly designed CBD system improves workflow efficiency. This improvement has both clinical and financial implications. In this case, a shorter turnaround means that clinical reports can be returned to the ordering physicians more quickly to inform further decision-making processes. Faster return may also shorten the cycle of insurance reimbursement. Additional data are being analyzed and a follow-up qualitative study is ongoing to identify the specific aspects of the new CBD design that contribute to the observed improvements.

Development of a Unified Computable Problem-Medication Knowledge base

Yonghui Wu, Ph.D.[1], Adam Wright, Ph.D.[2], Hua Xu, Ph.D.[1], Allison B. McCoy, Ph.D.[3], Dean F. Sittig, Ph.D.[1]

[1]School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX, USA

[2]Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

[3]Department of Biostatistics and Bioinformatics, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, USA

Introduction: Medications and clinical problems are critical components of Electronic Health Records (EHR). A comprehensive knowledge base containing frequently used medications and their possible indications derived from clinical practice is very useful for clinical care and research. We developed a unified computable problem-medication knowledge base by integrating five knowledge bases derived from two EHR data sets and one patient claim data set.

Methods: We developed five problem-medication knowledge bases from two large scale EHR implementations and one large patient claim database, including the Brigham and Women's Hospital (BWH) EHR[1], the University of Texas Health Science center at Houston (UTH) EHR, a crowd sourcing (UTH_CS) knowledge base from the UTH EHR[2], a refined knowledge base from the UTH_CS with high reputation scores (UTH_REP) and a knowledge base developed from four years of patient claim data of Blue Cross Blue Shield of Texas (BCBSTX). We then developed an ensemble method to integrate the five knowledge bases into a unified computable problem-medication knowledge base. The medications from different resources were mapped to RxNorm using NLP and normalized to the ingredient level. Problems were normalized to root ICD codes. The confidence scores from different resources were integrated into a matrix to facilitate problem-medication knowledge extraction using various user-defined criteria.

Results: The unified knowledge base contains 128,928 problem-medication pairs among 2,118 normalized medications and 2,186 normalized problems. For the problem-medication pairs, the various confidence scores, including the chi-square score, the p-value, the Interest score, the crowdsourcing ratio score and the reputation score were incorporated into a matrix. Table 1 shows the number of problems and medications before and after use of the ensemble method for all the knowledge bases. To the best of our knowledge, this is the first time wherein a collective problem-medication knowledge base has been generated from heterogeneous data sets.

Table 1 Number of problems/medications/pairs before/after ensemble

	#Medications	**# Medications after ensemble**	**#Problems**	**#Problems after ensemble**	**# Pair**
BWH	1144	762	196	188	7593
UTH	2368	1394	563	501	16715
UTH_CS	2537	874	1575	1105	5719
UTH_REP	572	300	368	314	731
BCBSTX	7285	2577	1738	1202	106106

Conclusion: We developed a unified computable knowledge base using the ensemble method. The unified knowledge base can facilitate problem-medication knowledge extraction using different user defined criteria, potentially benefiting clinical care and research.

Investigating the Genetic Architecture of Pulmonary Arterial Hypertension Shared with Other Diseases.

Luke A. Yancy Jr[1,2], Atul J. Butte, MD, PhD[2]
[1]Biomedical Informatics Training Program, Stanford University School of Medicine, Stanford, CA; [2]Sytemems Medicine, Stanford University School of Medicine, Stanford, CA

Abstract

Pulmonary arterial hypertension (PAH) is a rare and fatal disease with a median survival of approximately 4 years for those afflicted. Many genome-wide association studies (GWASs) have attempted to determine the variants predictive of PAH, but often due to small sample sizes, studies have not led to highly predictive markers. However, GWASs have been successful in determining variants associated with many other diseases. We have an ongoing effort to curate these variants into a database called VARiants Informing MEDicine (VARIMED). VARIMED contains results from over 17,000 peer-reviewed genetic epidemiology studies (e.g. GWAS), covering over 460,000 variants associated with over 6,500 phenotypes. In this study, we leverage VARIMED to determine if PAH exhibits a shared genetic mechanism with other diseases. Finding other diseases that have a significant enrichment of PAH associated variants may provide insight into (novel) variants that play a significant role in PAH (and are otherwise not detectable in a PAH GWAS due to small sample size) or even novel therapies for PAH that can be "borrowed" from diseases with similar genetic architecture. Here, we perform a GWAS on exomes from PAH subjects, prioritize those variants, and use the top ranked variants to identify diseases in VARIMED with a similar genetic architecture. We found similarities between PAH and an unusual acquired kidney disease. This work can be extended to investigate the shared genetic architecture of other diseases (rare or otherwise understudied) by taking advantage of the large spectrum of diseases now with characterized genetic architecture.

What Tasks Are Clinical Teams Tracking in Daily Practice?
Usage of a Web-based Care Management Tool in Eight Veterans Affair Medical Centers

Jianji Yang, PhD, Judy McConnachie, MPH, Jonathan Sun, MS, Lisa Winterbottom, MD, MPH
Portland VA Medical Center, Portland, Oregon, USA

Abstract

The Care Management Tool is web-based application developed to support care coordination and task management in both Primary Care and Specialty Care teams within Veterans Health Administration. An analysis of the usage pattern indicates that it is used most frequently for prompting: a) telephone contacts with patients, b) scheduling future appointments, and c) lab test and consult follow-up. The analysis provides insight in the use of tasks for clinical reminders and can inform future development and deployment efforts.

Introduction

The Care Management Tool (CMT) was implemented in 8 Veterans Affair (VA) Medical Centers in mid-2012, initially in Primary Care (PC) and later introduced to Specialty Care (SC) services. CMT is a shared clinical task management platform and provides functionalities not available in most electronic health record systems such as task creation and tracking, role-based task cross-coverage and flexible reminders of tasks due (e.g. email reminders). Tasks are created to support care sourced in the medical record. For example, a PC provider orders a follow-up imaging study to be done in 6 months then schedules a task due in 6 months to confirm that the study was competed timely. When creating a task, the user can select from predefined lists of 'Task Type' (e.g. record review), as well as 'Task Reason' (e.g. education). Additionally, users can enter more details in the 'To Do Notes' field (Figure 1). In this work, the task data was analyzed to study the usage pattern by different clinical services, and to understand the types of clinical and administrative activities that are supported by the CMT . This analysis offers insight into users' needs and helps to inform future functionality development.

Methods

Task data from June, 2012 to Feb. 2014 was extracted from the database and analyzed in the following areas. First, descriptive statistics were calculated on number of tasks created by service, number of users by service, and the number of tasks per user by service. Second, the frequency of 'Task Type' and 'Task Reason' used were analyzed. Third, text in 'To Do Notes' was tokenized into single words. English stop words were removed and remaining terms were stemmed. The frequency of root terms was compared with 'Task Type' and 'Task Reason' results.

Results

Total number of tasks is 29,245, of which, PC, with the highest number of users (246), contributed the most at 14,482. Consult Management Service had 3 users, but created the most tasks/user (538). The most used Task Type and Task Reason were 'Telephone Contact' and 'Coordination of Care' respectively. In the 'To Do Note', the most used terms were: 'call', 'check', 'lab', 'bp', 'appt', 'consult', and 'schedule'.

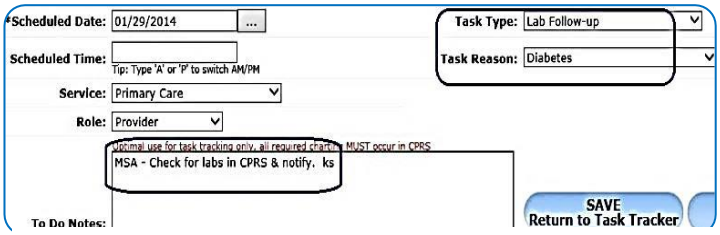

Figure 1. Partial screenshot of CMT showing task edit screen. Circled areas are where users enter the task attributes.

Discussion

As the service that provides the medical home to most VA patients, PC has the highest volume for CMT use. Heavy per staff usage appears to be in services that perform case management duties, e.g. Consult Management, Pain Management and Cancer Care Coordination teams, indicating that intense tracking of patient activities is a norm for these services. Additional workflow analysis may suggest future developments to better support multi-step or longitudinal care tracking in these services. The text analysis confirms the frequent use of "Telephone contact" and "Lab follow up", but also suggests scheduling appointments, checking on blood pressure and consult tracking are highly performed tasks that rely on a reminder system for completion.

Conclusion

Analysis of the two-year usage data for a web-based care management tool in eight VA facilities showed that the CMT supports clinical care by offering a common platform that is highly utilized to manage tasks for coordination of care. While PC has the highest volume of use, SC services also rely on the functionalities to support their work. The analysis of the task details provides insight into clinical staffs' use of the tool and informs future developments.

Design of Vendor-neutral Platform for Fast Prototype Model Verification and Deployment

Shiming Yang[1] PhD, Peter Hu[1] PhD, Yulei Wang[1] PhDc, Amechi Anazado[1] MD, Catriona Miller[2] PhD, Raymond Fang[2] MD, Stacy Shackelford[2] MD, Colin Mackenzie[1] MD

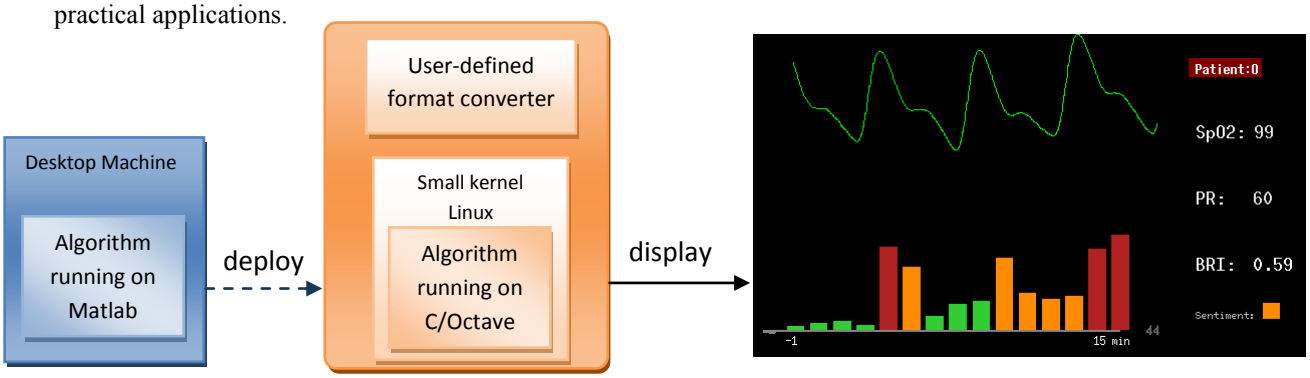
Introduction: High fidelity continuous vital signs waveform signal collection has great potential to assist emergency medical treatment, allowing real time visualization of the evolving physiological status of the patient and early detection of aberrant physiological events. In combination with vital signs feature selection and real-time processing, such information rich datastreams could potentially provide emergency decision-support on the need for life saving interventions, appropriate patient triage and resource acquisition or preparation for patients. Clinical deployment of algorithms requires both rapid prototyping and testing of algorithms' accuracy and robustness. Major obstacles to rapid prototyping are proprietary vital signs monitors with proprietary noise reduction algorithms, compression algorithms, and data storage formats and the commercial programming software environment, such as Matlab or LabView. The aim of this study is to describe the development of a vendor-neutral prototype system in the form of an inexpensive mobile device for the validation and testing of algorithm accuracy and robustness, testing and optimizing human factors concerns, and usability analysis.

Methods: We developed an algorithm to predict the probability of near-future blood transfusion or the Bleeding Risk Index (BRI) based on features of continuous photopletysmograph (PPG) 240Hz waveforms collected from pulse oximeters during trauma patient resuscitation. We designed a vendor-neutral platform to deploy our algorithm for near-real time use and testing. To minimize device start-up time and real time data processing and analysis by our BRI algorithm, a configurable, light-weight Linux operating system was utilized. The BRI algorithm was coded in native linux in a modular fashion, allowing future upgrades to decode proprietary datastreams or future algorithm optimization and development.

Interface design: To provide user friendly display and to maximize the information presented on a space-limited device, we divided the display into three areas. The top left displays the past 3 seconds raw PPG waveform. On the bottom, the past 15 minute BRI values are displayed minute by minute, color coded to corresponding to pre-defined 'critical' (RED: BRI≥0.5), 'neutral' (YELLOW: 0.2≤BRI<0.5), 'safe' (GREEN: BRI<0.2) threshold levels of the need for blood transfusion. The right most column, displays real time readings of oxygen saturation (SpO2), pulse rate (PR), BRI, and a sentiment score which aggregates past 15-min BRI as an overall indicator.

Results & Discussion: Proprietary medical devices and platforms do not allow for the implementation and testing of new algorithms. We developed a vendor-neutral platform deployed on small single-board computers for fast prototype algorithm validation, development, and user feedback. In preliminary tests, representative data files from 8 patients with a total of 2 million data points were processed immediately after collection with an average run time under 0.5 seconds for each BRI calculation, matching the efficiency of an a top of the line computer. The flexibility of streaming external device-independent data into the platform allows our algorithms to be quickly tested for many practical applications.



Using Narrative Storyboards to Inform Design Improvement of Hands-free Communication Devices

Yushi Yang, MS[1], Joy Rivera, PhD[1], Susan Bethel, MSN, RN[2]
[1]Clemson University, Clemson, SC; [2]Greenville Health Systems, Greenville, SC

Introduction: In recent years, there has been an increase in the implementation and use of Hands-free Communication Devices (HCD) in the clinical settings. While adding such devices to an already complex system can in some ways benefit healthcare professionals' (HCPs) communication, many questions arise related to their appropriate use and their fit within HCPs' workflow. Research using grounded theory found that nursing performance related to communication access is improved because HCD provide nurses with the flexibility to contact other HCPs anywhere and at any time[1]. Other research using quantitative data analysis showed that HCD increased the rate of responses and therefore increased efficiency of nurses' workflow[2]. However, there is little research focusing on the evaluation of HCD and their use within context to inform design improvement opportunities. Additionally, there is little evaluation of the design of HCD based on the results of field research conducted from a sociotechnical perspective[3]. The purpose of this study is to examine the end-user's interactions with HCD, to learn how they impact nurses' performance within the working environment, and to elicit design recommendations that will support a better work system.

Method: A total of 12 nurses were observed in two acute patient care units. Each nurse was observed for 2.5 hours totaling 30 hours of observations. The observation data were aggregated, coded and categorized into themes using the thematic analysis software NVivo 10. Three overarching themes were identified: interruptions, operational failures, and usability. Under each theme, narrative storyboards were created based on real-world data. Narrative storyboard is a method to describe the human-product interaction. It is informed by real-world field observations and the deliverable is a sequence of images, showing the location of the interaction and tasks individuals complete while interacting with the product[4]. By using this method, the most prominent problems related to HCD can be easily translated into a language that product designers understand.

Results: The final results, representing unintended consequences of HCD, were presented in a narrative storyboards format. For the interruption theme, the storyboards describe a nurse working on patient charting in a hallway while a call comes in, however, the nurse has limited mental resources for multitasking on both documentation and talking via the HCD. For the operational failure theme, the storyboards describe a nurse in the patient room with poor reception signal, which required the nurse to switch the call from the HCD to a telephone that is outside the patient room. For the usability theme, the storyboards describe a nurse who was in the patient room administering medication to her patient; she rejects an incoming call by saying "no" but her voice was not successfully recognized by the device. Each of the three storyboards includes a set of images with associated annotations.

Discussion and conclusions: From the storyboards, it is concluded that HCD can increase nurses' workload and escalate the complexity of the medication administration workflow during certain contexts. Therefore, designers need to consider the management of mental resource availability, which can be achieved through a program that is able to proactively reject an incoming call based on an automatic assessment of the nurses' availability. Also, the voice quality and voice recognition needs to be improved. High-level system design recommendations from the perspective of sociotechnical perspective were also proposed based on the storyboards, for example, the integration of Radio-frequency Identification (RFID) or other locating technologies with HCD would let the device recognize nurses' location. When it is identified that the nurse is close to the patient when administering medications or doing other direct patient care tasks like repositioning the patient, it would not allow incoming calls that are not emergency.

Visualization of Publication Timelines using 4K Monitors

Dean Yergens[1,2,*], Evan Minty[1], Christopher J Doig[1]

1.University of Calgary, Canada, 2.Healthcare Simulations Inc,, Canada

Abstract

Introduction

High resolution monitors (4k) are beginning to enter the marketplace. These 4K monitors have the ability to represent 4 to 6 times the standard resolution of a typical monitor. With this increase in resolution the ability for displaying increasingly complex visualizations is possible. One such application area is the visualization of literature review references due to the massive amounts of information that is often included. We present a web-based application developed for displaying academic publications based upon a national public health cross sectional survey using these high resolution displays.

Methods

A literature review was previously conducted to examine how the Canadian Community Health Survey (CCHS) was presented in the literature during the years 2002 to 2012. The results (data) of this literature review were then exported into a custom developed web-based application for displaying the literature information. The application consists of several visualization techniques including a Timeline approach for displaying temporal data, calendar view for displaying frequency of publications and standard charting techniques (bar, line, pie) for displaying quantitative information. The java-script visualization frameworks D3.js and MIT SMILE widgets were used in the development. A 39" 3840x2160 high resolution monitor was then used to display the web-based application.

Results

677 references from the CCHS literature review were displayed in the application. A Timeline visualization which represents the detailed individual information about the references was displayed by title with the timeline interface having the ability to scroll across the multiple publications. Supplemental information on the reference is available through clicking on the reference. This supplemental information included the authors, journal, abstract and a link to the PDF article. The references were color coded based upon which year of the CCHS survey was used in the analysis for the paper. Aggregated information including publication year, top journals and frequency of publications is also displayed at the bottom of the interface.

Conclusion

High resolution monitors present the next evolution in the visualization of health informatics information. Our web-based system presents one application where these higher resolution monitors may be of benefit. Future research will include evaluating information understanding using the 4K interface compared to standard size based monitors and mobile devices.

A New Corpus for Structured Microbiology Results

Wen-wai Yim[1], Xavier Engle[2], Heather L Evans[3], Meliha Yetisgen, PhD[1,4]
[1]Biomedical and Health Informatics, [2]School of Medicine, [3]Department of Surgery, [4]Department of Linguistics, University of Washington, Seattle, WA

Abstract

Microbiology results data is an important part of clinical diagnosis, disease treatment, and outbreak detection. However, the free-text form of microbiology reports limits their incorporation into real-time surveillance applications. Our task is the extraction of microbiology information from free-text into a structured form for secondary use. To create an extraction system, it is important to define a template that captures microbiology results, such as bacterial microorganisms, microorganism concentration, and drug susceptibilities. In this abstract, we describe a corpus annotated using our microbiology results template. Our corpus is comprised of microbiology culture and gram stain reports, where we extract results from a variety of microbiology reporting free-text.

Introduction

Microbiology results provide clinicians with the relevant information to identify sources of bacterial infection, determine between differential diagnoses, and adjust antibiotic treatment. However, these results are represented in dense, domain-specific free-text statement. In order to leverage such information in downstream surveillance applications, such as our ongoing ventilator-associated pneumonia project, we thus needed to develop an extraction system for microbiology results. To accomplish this, we defined a microbiology results template with help from a clinical expert to capture relevant infection information and used this template to annotate microbiology reports. Our annotated corpus included 1442 microbiology reports.

Annotation

In our template, microbiology results in our corpus were represented as a collection of the microbiology results entities: (1) *organism*—a microorganism found in a culture (e.g., bacteria, flora, fungus, yeast), (2) *organism quantity*—a measurement of the amount of the organisms found in a culture (e.g., >10,000 col/ml, one colony, no, isolated), (3) *rating*—a qualitative measurement of the amount of organisms found in a culture (e.g., 1+,2+,3+,4+), (4) *drug*—a drug that was tested on an organism (e.g., penicillin), (5) *drug resistance*—a susceptibility of an organism to the drug (e.g., susceptible, intermediate, resistant, no CLSI interpretive criteria), (6) *MIC*—minimum inhibitory concentration of an antimicrobial that inhibited the growth of a microorganism after overnight incubation (e.g., 2.0 µcg/ml), and several other entities. A template can have several of the same entities, while some fields may be empty. Since microbiology reports may describe multiple cultures, multiple templates are needed. To determine which entities belong together, entities in the same template are joined by relations. Figure 1 shows two examples of microbiology reports annotated with entities and relations. Two annotators, one medical student and one graduate student, annotated microbiology results for 100 records. The inter-rater agreement showed an entity-level f1-measure of 0.982 (macro) and 0.964 (micro), a relation-level f1-measure of 0.937, and a template-level f1-score of 0.833. Using the brat rapid annotation tool, one annotator annotated the rest of the 1442 report corpus with 3720 entities and 1196 templates. We plan to release the corpus through our research lab's website (http://depts.washington.edu/bionlp/index.html).

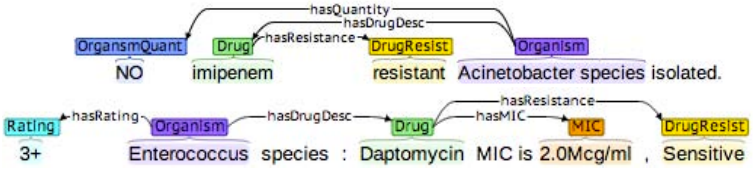

Figure 1. Example microbiology reports with entity and relation annotations.

Future Work

We used this corpus to build an information extraction system based on natural language processing and machine learning to extract culture information from microbiology reports. Our current entity, relation, and template extraction f1-score performances are 0.889, 0.795, and 0.606 respectively. The details of the extraction tool will be presented in another paper. Our ultimate goal is to incorporate the extracted microbiology results as features in an overall statistical real-time surveillance. One application is in our ongoing ventilator-associated pneumonia project.

Application of Data Mining Techniques to Predict Physical Activity

Sunmoo Yoon, RN, PhD[1,2], Suzanne Bakken, RN, PhD[1,2]
[1]School of Nursing, [2]Dept. of Biomedical Informatics, Columbia University, NYC, NY

Abstract
We applied data mining techniques to a community based behavioral dataset to develop prediction models for gaining insights for a social media based intervention for an urban Hispanic population. Main predictors for active transport were look up internet for seek health information on Internet and perceived stress. The main predictors for sitting time were age, ability to make time and having a place for exercise. Data mining methods were useful to build physical activity prediction models prior to designing self-management interventions.

Introduction
Despite proven health effects, promoting physical activity has been challenging in population health. 'Promoting walking to school or work (active transport)' is the most recent community based guideline by CDC. And HealthyPeople 2020 emphasizes 'reducing screen time' as a community-based strategic plan. The Washington Heights/Inwood Informatics Infrastructure for Comparative Effectiveness Research (WICER) project aims to build an infrastructure to understand health behaviors to improve the health among an urban underserved population. Seventeen percent of those who completed the WCIER survey use social media. Given this, social media has a potential to be an interventional platform for promoting physical activity. To examine this potential, this study aimed to develop prediction models for physical activity by applying data mining techniques to the WICER dataset.

Methods
We extracted data on the sample participated behavioral survey (n=6,579) from the WICER RDW using the RedCap. The unique sample (n=5,868) was identified using manual review and automated abnormality detection mining techniques such as temporal activity sequence detection. 127 behavior variables were iteratively selected from 945 variables by a domain expert (SY). 114 variables were further selected after applying M99.0 algorithm to remove useless attributes. 51 unique variables were selected using *CFS attribute evaluator*[1], to select variables that were strongly related to the physical activity. 10 variables were ranked according to its degree of correlation to physical activity after manual removal of variables of multicollinearity. Physical activity was operationalized as an outcome variable of 1) engaging in active transport – walk to school or work or do errands (yes or no) , and 2) screen time for TV or video watching (≤3 hours a day, > 3 hours day).We applied several classification algorithms (J48, RandomForest, MultilayerPerceptron, AdaboostM1), to iteratively generate models with random 10-fold validation. We selected final models based on predictive ability and clinical meaningfulness of variables.

Results
Perceived stress (confidence score of handling personal problem, 0-4 scale, higher; more confident) and use the Internet to seek health information were the main predictors of active transport (accuracy 65%, AUC=.63). Those with confidence scores >2 were more likely to engage active transport. Among those with confidence scores <3, using the internet for seek health information was associated with increased likelihood of engaging in active transport (Figure 1). The prediction model for sitting behavior had higher accuracy (accuracy 68%, AUC=.69%). Age, ability to make time and have a place for physical activity were the main predictors for screen time. Participants less than 59 year old were more likely to have shorter TV or video time (Figure 1).

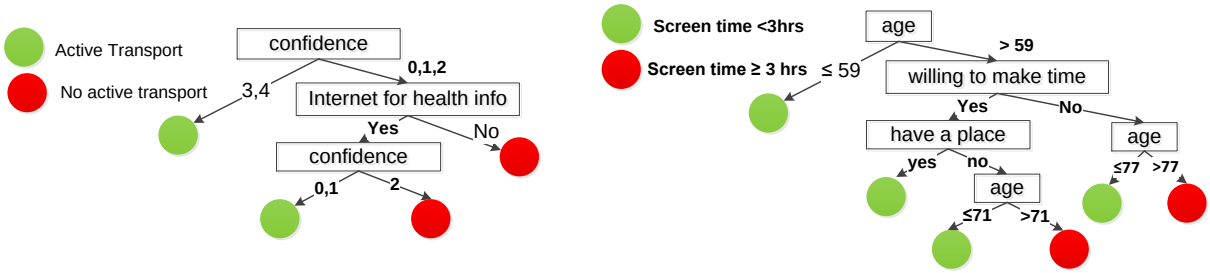

Figure 1. Prediction model for physical activity; active transport (left) and screen time (right)

Conclusion
Data mining methods were useful for domain experts to build prediction models for physical activity.

M-health for Individuals with Dexterity Impairments: The Needs & Challenges

Daihua X. Yu, MS, Bambang Parmanto, PhD, Brad E. Dicianno, MD, Valerie J. Watzlaf, PhD, Katherine D. Seelman, PhD
University of Pittsburgh, Pittsburgh, PA

Introduction

Mobile health (mHealth) using a Smartphone is a cost-effective solution to improve health through supporting self-care tasks. However, before people with dexterity impairments who experience difficulties in manipulating small buttons, icons or control scan harness the potential of mHealth, the accessibility of mHealth apps must be examined. We have developed a mHealth system for supporting self-care and adherence to self-care regimens, called iMHere (interactive Mobile Health and Rehabilitation). The overall goal of this study is to explore and to identify the accessibility needs and preferences of individuals with dexterity impairments when they use the iMHere system.

Methods

Two iMHere apps were used in this study: 1)MyMeds app for managing medications; 2)Skincare app for managing wounds and other skin issues. Nine subjects were asked to use these apps for approximately one week in a field trial. A lab test implementing the following tasks was conducted after the field trial: 1)Scheduling a new medication alert, which includes searching and finding the correct medication and setting up a medication schedule; 2)Modifying a medication reminder; 3)Scheduling a skin checkup alert; 4)Responding to a skincare reminder that includes taking a picture and reporting issues. The time for a subject to complete each task, the number of possible errors a subject made, and the number of errors a subject was able to self-correct were recorded and analyzed. The Telehealth Usability Questionnaire (TUQ) data was collected during the interviews so that subjects could rate their experiences and give feedback on usability factors (e.g. usefulness, ease of use, effectiveness, reliability, and satisfaction). Framed questions were also asked and responses were recorded by the researcher during the in-depth interviews.

Results & Discussion

Nine subjects with various levels of dexterity abilities were included in the study. Ages ranged from 18-55 years, including four women and five men. Eight had spina bifida (SB) and one had a spinal cord injury (SCI). Based on Pegboard instrument scores, subjects were classified into three groups: 1)Subjects with mild dexterity impairments; 2)Subjects with moderate dexterity impairments; 3)Subjects with severe dexterity impairments. A significant difference in error ratio was found among the three groups: $F(2, 33)=3.604$, $p=0.038$, using ANOVA. Bonferroni's t-test revealed that group 3 subjects had significantly higher error ratios than subjects in group 1 ($p=0.045$). A statistically negative correlation was identified between subjects' dexterity levels and their error ratios by using a Pearson product-moment correlation, $r=-0.434$, $n=36$, $p= 0.004$. This means subjects with a higher degree of dexterity impairments may experience more problems in task completion. Approximately 51% of errors were self-corrected without any help, but other errors called for resolution from a researcher. The average TUQ score was 5.94 (out of 7 points). Although subjects were overall satisfied with the iMHere system and stated they would like to use it in the future (average=6.39), the sections for "ease of use & learnability," "interface quality" and "reliability" received lower scores (5.56, 5.67 & 5.56 respectively).

Conclusion

The current design of the iMHere system might not be suitable for users with dexterity impairments. Due to the diversity of subjects dexterity impairments, their needs and preferences differ one from another. The most common suggestions from subjects to improve the accessibility of iMHere system are as follows: 1)Simplify and reduce the complexity of these apps; 2)Provide longer training time; 3)Provide feedback within the apps themselves to users as to whether they are doing the task correctly. In addition, more than half of the subjects commented on the button size. They would prefer to have larger buttons. Two of them indicated that they might be more comfortable with dark text on a white background. Some of them would like to try different picture backgrounds to make the apps more personalized. Features identified by subjects in this study will help developers and designers enhance the usability and accessibility in future studies. Finally, personalized design may be the key to approaching thse challenges in improving accessibility.

PinTopics: A Tool for Visualizing Topic Models Using Multiple Redundantly Coded Word Clouds

Zhiguo Yu, MS[1], Todd R. Johnson, PhD[1]
[1]The University of Texas School of Biomedical Informatics at Houston, Houston, TX

Abstract

Topic models are powerful tools for automatically characterizing and categorizing documents and their contents, but there is very little work on user interfaces that support human use of topic models for understanding and navigating sets of documents. In this poster, we present a tool that allows a person to easily and interactively use topic models to navigate, explore and understand large sets of PubMed citations by presenting topics as word clouds that use redundant visual features to make the gist of each topic "pop out" of the display.

Introduction

Topic Models[1] are a class of statistical machine learning algorithms that when given a set of natural language documents, extract the semantic themes (topics) from the set of documents, and also describe the topics for each document, and the semantic similarity of topics and documents. Although researchers continue to develop better and faster topic model algorithms, there is very little work on user interfaces that support human use of topic models for understanding topics and navigating sets of documents. Topic Browser[2], developed by Chaney and Blei, has shown great potential to summarize the corpus and reveal the relationships between topics and documents. However, each topic in Topic Browser is displayed by a list of ranked words (Figure 1a), which makes it a challenge for users to see what the different topics are about (Figure 1c). Our tool, PinTopics, displays each topic by using a word cloud that uses redundant visual codes (font size, intensity, and color) to encode word frequency. These redundant codes create a visual saliency map that can guide the observer's attention, making the general gist of each topic "pop out" of the visualization.

Figure 1 (a) and (b) compares the Topic Browser and PinTopics representation of a single topic. Figure 1 (c) and (d) compares the Topic Browser and PinTopics representation of multiple topics. The Topic Browser does not use visual salience to convey word frequency, making it difficult to get an immediate sense of what each topic is about. In contrast, PinTopics' use of redundant visual codes makes it easier and faster to scan topics and comprehend their meanings. We are presently conducting usability tests to compare PinTopics and the Topic Browser on a number of tasks using PubMed query results. We are also exploring algorithms for creating topic models in real time to support highly interactive query refinement.

(a), list-of-word (b), word-cloud (c), list-of-word topics overview (d), word-cloud topics overview

Figure 1. (a) and (b) are the same topic: 'Clinical Natural Language Processing'. (c) and (d) show multiple topics. We used LDA-C to generate 60 topics from 7095 citations (titles and abstracts) returned by the PubMed query 'biomedical informatics'.

Informational Support Exchanges in Online Health Communities

Shupei Yuan, MA[1]; Jina Huh, PhD[1]
[1]Michigan State University, East Lansing, MI

Abstract
Informational support provides critical help to those visiting online health communities. In our small pilot study with an online diabetes community, community members received informational support the most, and the main contents of informational support consisted of clinical information and patient expertise. In our main study, we examine how community members respond to conversation initiators who ask for these two kinds of information sources and, depending on the response, how the conversation threads evolve accordingly.

Introduction
Studies have found that online social support can bring positive influence for various diseases[1,2]. Heaney and Israel[3] argued that social support consists of instrumental, informational, appraisal and emotional support. Among these social support types, informational support can play a critical role in fulfilling community members' information needs while visiting online health communities[4]. When a community member is asking for informational support, whether the members will receive the source of information they ask for is still a question. Our research questions are: What types of informational support are being asked and received in online health communities? How do community members provide the information that the conversation initiators ask for?

Pilot study
To answer the research questions, we first conducted a pilot study to gain insights on developing codes for examining informational support exchanges in online health communities. We chose the WebMD online diabetes community as our starting dataset due to its active, diverse support activities among community members[2]. We randomly selected 250 posts and qualitatively examined, using open coding[5], centering on our research questions.

Our preliminary results showed 56.1% of the informational support provided in the replies contained clinical information and 47.7% of the threads were patient expertise (not mutually exclusive). 81.3% of the conversation initiators were looking for clinical information and 96.1% of them received clinical information. Although members received needed clinical information, needed patient expertise was not necessarily received. Our main study then is to further examine the possible reasons for this phenomenon.

Main Study Design and Conclusion
We use a larger sample to further understand how clinical information and patient expertise exchanged. Conversation initiators' replies can reflect their engagement and attitude toward the threads and the information received. To analyze the conversation initiator's follow-up with the replies, we focus on conversation threads with only one unique replier. We randomly selected 20% data that fit (277 cases) as our study sample.

With the data collected, we will code and record the following items: The type of informational support asked; the type of informational support offered by the first replier; the engagement of the initiator. The concept "engagement" in this study includes whether initiators expressed appreciation, query, or other feedback, etc.

We will further conduct simple linear regression tests to help us understand the relationship between initiators' engagement with the type of information they received. Moreover, moderation analysis can help us find the factors that moderate this relationship, such as the length of the conversation.

Our work helps to further develop online social environments in which patients receive enriched social support specifically around receiving peer patients' support unlike other clinical environments. The findings from this study can provide insights to how we can help online forum users exchange appropriate information. Our study also helps the community organizers provide better solutions in facilitating informational support exchange.

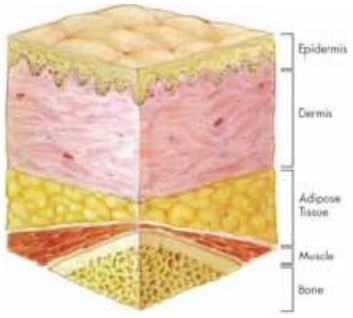
Human-Centered Design in Wound Care Guidelines

Rafeek A. Yusuf, MBBS[1], Amy Franklin, PhD[1]
[1]The University of Texas Health Science Center at Houston, School of Biomedical Informatics, Houston, TX

Abstract
Current clinical guidelines, including those for wound care, are often generated following medical content rather than principles of user centered design. Although guidelines may be shared with patients and caregivers, appropriate modifications for non-clinical users may be absent. Using the TURF framework for usability in human-centered design, we explore methods for creating useful and useable guidelines in the home setting.

Introduction
Although clinical practice guidelines are defined as "systematically developed statements for practitioner and patient decisions about appropriate health care for specific clinical circumstances"[1], it appears current guidelines have laid more emphasis on the practitioner than the patient. For example, most health education materials, including guidelines, are written at the 12th grade level without consideration of the average American's 8th grade reading ability[2]. We propose that usability methods often employed to assess, develop, and redesign medical technology such as medical devices and electronic health records systems can be extended to the domain of guideline materials. In our case study, we focus on wound care guidelines. Approximately 6.5 million people in the U.S. live with chronic wounds[3] and a third of these individuals require home based care[4] provided by family and other caregivers[5]. In this project, we explore homecare guidelines for pressure ulcers and highlight the need for (re)design following usability principles. Through expert review, we demonstrate areas of modification necessary given the health literacy level, reading ability and visual acuity[6] of the caregiving population using these guidelines.



Methods
A heuristic evaluation following Zhang's[7] principles was conducted by the authors on a published wound care guideline[8] directed towards nursing assistants and caregivers. Adherence to design principles such as reducing memory demands and match between the system and the real world was assessed.

Results
291 violations of 11 types were noted across the guideline. The average severity rating of these problems was 3.1 (i.e. major violation). For example, images depicting different classifications of wounds are stylized three-dimensional cross-sections not reflecting the actual view (point) of a caregiver (see diagram).

Conclusion
Usability in human-centered design can be applied to redesign useable guidelines for healthcare providers, patients and caregivers particularly in the home setting. Ongoing efforts include the redesign of this guideline to more strongly adhere to usability principles and to better serve the home care provider.

Placeholder Registration Addresses in a Regional Health Information Organization

John Zech[1], MA, Jason S. Shapiro[1], MD, MA, Gregg Husk[2], MD, Thomas Moore[3], MPA, Gilad J. Kuperman[4], MD, PhD

[1]Icahn School of Medicine at Mount Sinai, New York, NY, [2]Beth Israel Medical Center, New York, NY, [3]Healthix, Inc., New York, NY, [4]New York-Presbyterian Hospital, New York, NY

Abstract: *To match patient records across sites for health information exchange, regional health information organizations (RHIOs) rely on a master patient index (MPI). An MPI is responsible for matching demographic information for each unique individual, including home address, across multiple healthcare provider organizations. This field is commonly mandatory, and some registration staff may use nonsensical placeholder values that do not represent legitimate addresses to complete this field (e.g., "X") when legitimate address data is unavailable. This may cause the MPI to incorrectly separate records belonging to the same patient. We examine some of the most common placeholder addresses used in a functioning New York City RHIO and describe how the use of these addresses may affect record matching.*

Introduction and Background: A Master Patient Index (MPI) assigns patient records at different healthcare facilities to an internal MPI identifier using probabilistic matching algorithms.[1,2] Each MPI identifier is intended to represent a unique patient. The address data a patient supplies at registration is frequently used as part of this matching algorithm: if a patient's records at different sites have different address information associated with them, the MPI may not link them, causing it to appear as if a unique individual is actually more than one patient. This may happen when registration staff at different sites use different *placeholder* addresses when registering a single patient.

Methods: We analyzed patient registration data from Healthix, a New York City based regional health information organization (RHIO) that has enabled health information exchange. We linked registration records in the database using an exact match on first name, last name, and date of birth. We identified all address street lines with which 100 or more patients had registered. The number 100 was chosen as we believed it was very unlikely that a single legitimate residence would have such a large number of corresponding registrations. We determined which address street lines were *placeholder* values via manual review. We calculated the total number of patients who had been registered with a *placeholder* address.

Results: There were 587 address street lines with which 100 or more patients had registered. 84 of the top 587 address street lines (14.3%) were *placeholder* addresses. Examples include "1", "NEED", "…", "UNKNOWN", and "XX". There were 161,479 patients (2.1% of all patients) who had registered with one of these *placeholder* addresses.

Discussion and Conclusion: We determined that *placeholder* addresses were used for over 160,000 patients in Healthix data. These addresses may cause records not to be successfully linked by an MPI's probabilistic matching algorithm. With awareness of this issue, RHIOs can implement strategies to mitigate its impact on the performance of their matching algorithm. Realizing that *placeholder* addresses do not represent legitimate address information, a RHIO could treat *placeholder* addresses as missing values if their algorithm can accommodate missing data. Alternatively, a RHIO could reduce the weight their algorithm gives to address agreement when one address is a known *placeholder* address. Ideally, if human review is available, RHIOs could prioritize records with *placeholder* addresses for human review.

A Quest for HIE Success - Agency Theory and Technology Mutual Adaptation Framework

ABSTRACT: This work proposes a framework that explains the factors that hinder successful implementations of HIE solutions and offers potential solutions to overcome them. The framework approach is based on two theoretical lenses: technology implementation mutual adaptation model and agency theory. We argue that during HIE implementation, there are misalignments between available HIE technologies and the actual HIE stakeholder environment, which leads to a loss of productivity and the inability to reap the benefits promised by HIE. These misalignments are often compounded by the divergence of interests and ineffective cooperation of different stakeholders during HIE implementation and adoption. We propose a framework to explain what causes these misalignments in HIE implementation and adoption and how they can be mitigated for successful HIE implementations.

METHODOLOGY: In this study we adopt the technology implementation mutual adaptation model between user and environment proposed by Leonard-Barton [1]. According to Leonard-Barton, the initial implementation of technical innovations is best viewed as a process of mutual adaptation- the reinvention of the technology and the simultaneous adaptation of the organization. The main tenants of the theory is: 1) adaptation processes are necessary because a technology almost never perfectly fits the user environment, 2) misalignments can be corrected by either altering the technology to fit the environment or vice versa, or both and 3) misalignments result in productivity losses, which spurs the adaptations. Three types of misalignment are identified: 1) technical-which is the misalignment of technical specifications; 2) delivery systems- which are the organization's infrastructure, and 3) value- which is the job performance criteria. Misalignments leads to adaptive responses, represented as cycles in Figure 1, which can cause the redesign of technology (to fit the environment) or organizational change (to fit the design). Cycles can be (figuratively) large or small, where large represents changes that are more fundamental (e.g. the replacement of an old technology with a new one) and small cycles represent changes are less substantial (e.g. fine-tuning). This model was developed to explain the dynamics of technology implementation in very large companies. We, nonetheless, find that the model is very appropriate for the research of Health Information Exchange (HIE), and we make necessary modifications of the model to reflect the more macro, inter-organizational relationship based HIE research. We propose a modified framework. The two basic structures of our proposed framework, technology and environment, are slightly altered. More specifically, technological solutions (for HIE) replace technology because the latter is what the end users of HIE actually utilize and consequently, are concerned about. These solutions can be HIT vendors' HIE products, such as Epic Connections ®, or government solutions, such as Florida's Patient Look-Up (PLU), or some healthcare providers' privately owned, in-house developed HIE project. We replace user environment with all the different HIE stakeholders: healthcare providers (either the aggregate level—hospitals or individual level—medical professionals), payers (either the aggregate level—insurance companies or governments or individual level—patients), patients, software vendors, and the government. Multiple studies, and evidence from current HIE implementations, reflect that misalignments for HIE are common. On one hand, many HIE initiatives were terminated because of the lack of success. On the other hand, we suspect that the convergence of technology and environment are inevitable, but not necessarily in the short run. In any on-going HIE project, while misalignments exist, adaptive responses from both technology and environment are present. Technologically, large cycle adaptations are typified by the change of the technology (and its capabilities) offered by vendors, and/or the termination and re-initiation of HIE projects. We also observe complex dynamics among different stakeholders where different parties try to make adjustments in how they work and interact with each other in order to make HIE a success.

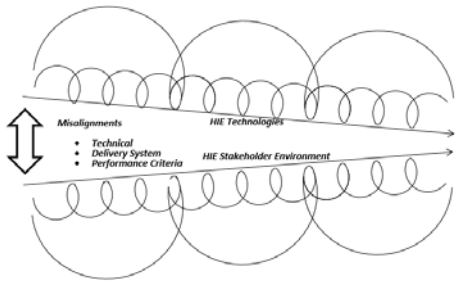

Figure 1- HIE Technology Mutual Adaptation Model adopted from Leonard-Barton (1988)

We argue that the stakeholder environment adaptation is the largest obstacle that hiders the development of HIE, which can be readily explained by the agency theory [2]. Agency theory posits that is any agency relationship there are two parties: a principal and an agent. The principle relegates work responsibilities to an agent but because of the asymmetry of information, the principle does not have total knowledge about what the agent is doing. Because of the divergence of interests between the principle and the agent, the principle must moderate the work of the agent, thus incurring agency costs. Because HIE's success is largely based on the participation of different stakeholders, and different stakeholders have different interests, the agency cost is often so high as to render HIE projects ineffective. For example, although HIE in theory can improve the quality of patient care, the improved patient care often comes as a loss for the HIE participating hospitals, for reasons such as reduced lab revenue due to the reduction of duplicated tests or reduced hospitalization due to a healthier population. Thus we argue that the alignment of the interests of different HIE stakeholders is of the tantamount importance, which may be achieved by formalizing technical standards for HIE and providing the HIE participants with both financial and policy support.

CONCLUSIONS: Using agency theory, technology implementation mutual adaptation model and IT Success model, we identifies factors that hinder the development of HIE and offer suggestions for solutions for future effective HIE implementations, which can be instrumental for both policy makers and practitioners alike.

A Motivation Framework for Knowledge Translation in China

Yinsheng Zhang[1], Haomin Li, PhD[1*], Huilong Duan, PhD[1]
[1] Zhejiang University, Hangzhou, China

Abstract

Globally, there exists a great gulf between medical knowledge and clinical practice. Translating knowledge into actionable clinical decision support application has become the biggest challenge faced by evidence-based medicine. A comprehensive motivation framework was designed to support the entire knowledge translation life cycle, including knowledge acquisition, management, and application. The framework has been implemented in a 3000-bed Chinese hospital, and typical clinical decision support applications were developed based on the framework.

A Motivation Framework for Knowledge Translation

Knowledge translation has now become the biggest challenge faced by evidence based medicine[1]. This research aims to build a comprehensive motivation framework to support the entire knowledge translation life cycle, which includes not only acquisition and dissemination, but also "ethically sound application of knowledge" in healthcare system[2]. The framework uses a comprehensive knowledge base based on a unified ontology to manage various knowledge, such as drug use rules, diagnostic rules, clinical protocols, etc. Knowledge can be acquired by computer aided knowledge discovery techniques, or manually edited through a knowledge authoring web portal (demo at http://www.cktp.org:8006). Based on the knowledge base, fundamental knowledge-driven services such as inference engine and NLP-based data acquisition are provided as an infrastructure for developing clinical decision support applications. This framework was implemented in a 3000-bed Chinese hospital (DaYi Hospital, ShanXi Province, China), and typical CDS applications have been developed with the framework. This pioneer effort is expected to eventually promote knowledge translation in more healthcare institutes in China.

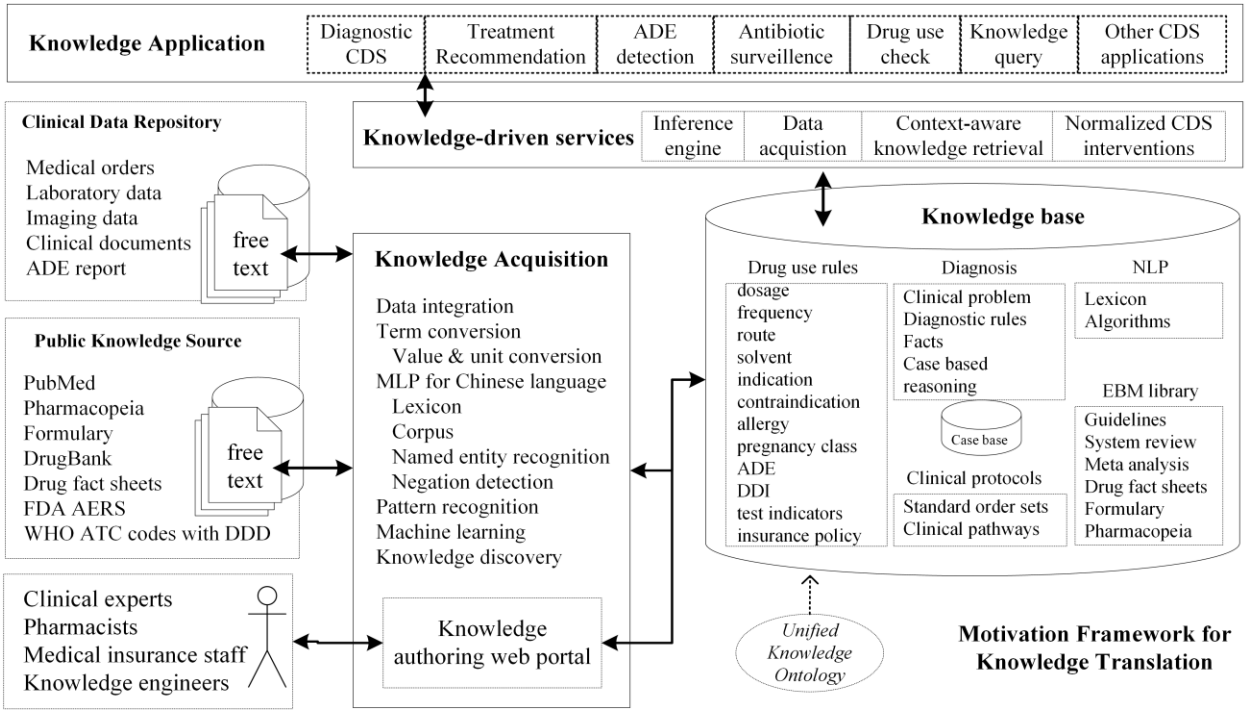

Figure 1. A motivation framework for knowledge translation.

An Extensible Integration Framework for CDS Applications

Xiang Zheng, BS[1], Haomin Li, PhD[1*], Yinsheng Zhang, BS[1], Huilong Duan, PhD[1]
[1]Zhejiang University, Hangzhou, China

Abstract

The lack of mechanism to easily integrate CDS (Clinical Decision Support) applications into clinical workflow has become the major obstacle for the adoption and utilization of CDS applications. We design and develop an extensible integration framework to effectively manage and targeted deliver CDS applications to appropriate scenarios.

Introduction

Reducing medical errors and improving health care quality via CDS applications is one of the most important goals of medical informatics. While in practice, CDS application are frequently blamed for not being well integrated into the workflow, a major cause of which is lack of an extensible mechanism for integrating various CDS tools into CIS (Clinical Information System). Because of the deficiency of workflow integration and data interoperability, clinicians have to do burdensome and repetitive data entry work. Furthermore, the interventions produced by CDS tools are not directly actionable for user. Meanwhile, though various computer-aided tools such as calculators, evaluators and planners are helpful in clinical practice, effective mechanism to make them spread is absent.

To address the above problem, this study aims to provide an extensible framework for the dissemination, update and management of CDS applications. The mechanism is able to targeted delivery CDS tool to where it is needed, and achieve interoperability between CDS and hosted information systems.

Method

A registry web platform was designed and developed to manage CDS applications and associated these CDS tools to specific clinical problems and treatments. Based on this information, an integration agent module embedded in CIS ~~(clinical information system)~~ could smartly push the CDS tools to the right scenarios based on the specific patient information. The interoperability between CDS applications and clinical information system was achieved through a two-level interoperability protocol.

The first level interoperability was used to integrate CDS applications which are legacy and independent third-part tools. These kinds of CDS are unable and usually need not to directly exchange data with host CIS. Through the registration and association process CIS will know how and when to invoke this application.

The second level achieves data interoperation between CIS and CDS applications. This is supported by a plug-in mechanism. Data interoperability makes it real that not only clinicians have no need to input data repeatedly but also the results produced can be translated directly into actionable items in CIS. We designed a plug-in interface protocol to achieve this. In this protocol, basic information such as patient ID and user ID is sent to CDS tool so that it can get more information from CIS via a public Web Service, which provides comprehensive data query functions for CDS applications. A normalized data format of various interventions which includes adding clinical problem, placing orders and sending messages or alert is designed. The CIS is ready to accept CDS output in compliance with this format.

Result

A prototype has been developed and implemented in a 3000-beded hospital in China. Several protocol-complaint CDS tools have been developed and some other third-party ones have been collected to verify this framework, including DAS-28 Evaluator, customized micro-pump helper and BMI widget. These tools can be invoked to provide information based on advanced research to help physicians to make decisions, or make it easier at least. Moreover, the results of tools can be put into CIS in forms of clinical problems or medical orders, which are actionable. For instance, DAS-28 is a quantitative measure used to monitor the treatment of RA (Rheumatoid Arthritis). In our applications, this tool can be invoked from clinical problems like rheumatoid arthritis.Thus physicians can use this method to evaluate the activity of RA and make a better decision.

iGenetics: An Individualized Genetic Test Recommendation System Based on EHRs

Qian Zhu, PhD [a], Hongfang Liu, PhD [a], Christopher G. Chute, MD, DrPH [a], Matthew Ferber, PhD[b]

[a] Department of Health Sciences Research, Mayo Clinic, Rochester, MN

[b] Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN

Introduction

In individualized medicine, genetic screening and other tests give doctors more evidence for tailoring treatments to patients, which can potentially improve health care and save money. With the recent advances in genetic technology, genetic testing is available at more than 500 laboratories in the United States for more than 2,000 rare and common conditions and can help health professionals determine or predict patients' genetic conditions. However, physicians have not actively incorporated these tests into their regular clinical practices due to insufficient medical educational resources and clinical evidence as well as genetic testing guidelines. Therefore, we introduce an individualized genetic testing recommendation, called iGenetics, which leverages a high volume of patient information and well-evaluated testing guidance to provide a comprehensive genetic testing knowledge base (GTKB) and suggest appropriate genetic tests that might be positive for individual patients by exploring emerging semantic web technologies (SWT) and advanced informatics approaches.

System Description

iGenetics is to recommend appropriate genetic tests to individual patients. Consequently, two major fundamental components have been developed and described as below, data support module and test recommendation module.

A) Data support module: Genetic Testing Knowledge Base (GTKB) [1], a centralized genetic testing repository contains genetic testing information extracted from Genetic Testing Registry (GTR) including general test information, publically authoritative genetic testing guidelines (GTG), and patient medical information from Electronic Health Records (EHRs). More specifically, common clinical characteristics for each genetic test has been identified and deposited into the GTKB to support genetic test recommendation by iGenetics.

B) Test recommendation module: "Clinical characteristics identification" component aims to identify relevant clinical characteristics for individual patients via clinical characteristics mapping between the GTKB and SemMedDB[2], which provides drug-gene-disease associations. "Genetic test recommendation" component is to generate prediction models by leveraging machine learning, network analysis and SWT for test recommendation. Figure 1 shows the architecture of this recommendation module.

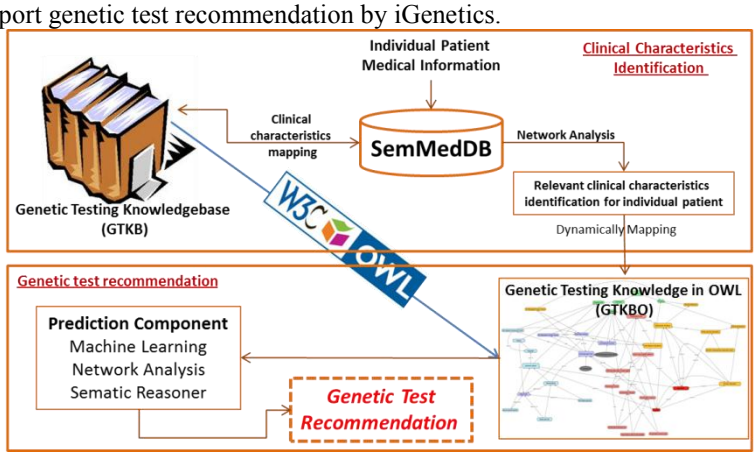

Figure 1. Test recommendation module for iGenetics

Discussion

We developed an intelligent genetic test recommendation system that not only provides a comprehensive genetic test knowledgebase serving as a genetic testing education resource, but also recommends appropriate genetic tests might be positive for patients on the basis of clinical evidence mined from the EHRs. iGenetics can encourage and assist physicians in incorporating genetic tests in their regular clinical practices to deliver high quality of health care.

Transforming NHANES Database to the OMOP Common Data Model

Vivienne J. Zhu, Rupa Makadia, Amy Matcho, Martijin Schuemie, Patrick B. Ryan
Janssen Research & Development, LLC, Titusville, NJ

Abstract: *We explored the feasibility of transforming survey-based data to the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM). The National Health and Nutrition Examination Survey (NHANES) data were transformed to five major OMOP CDM tables: PERSON, OBSERVATION_PERIOD, DRUG_EXPOSURE, CONDITION_OCCURRENCE, and OBSERVATION table. NHANES patient level data from 761 tables (7 cycles from 1999 to 2012) for 71,916 distinct participants were mapped to the OMOP CDM. NHANES source data were maximally mapped to the OMOP standard vocabularies using different strategies.*

Background: The OMOP Common Data Model (CDM) facilitates efficient, comparable and systematic large-scale drug safety analysis across disparate databases. However, most CDM transformations have been using claim-based databases, converting a survey-based data to the OMOP database has not been explored yet.

Methods: National Health and Nutrition Examination Survey (NHANES) includes demographic, socioeconomic, dietary and health-related questions. The examination component consists of medical, dental, physiological measurements, and laboratory tests. The CDC has been publishing these data every two years (cycle) since 1999. In this NHANES CDM transformation, patient level data were mapped to five major OMOP CDM tables: PERSON, OBSERVATION_PERIOD, DRUG_EXPOSURE, CONDITION_OCCURRENCE, and OBSERVATION table (Figure 1). Since no specific dates for survey events were provided in NHANES, we imputed that the observation period started at the first day of survey cycle (1st of January) and ended at the last day of survey cycle (31st of December). NHANES weightings (WTINT2YR, WTMEC2YR) for each participant were mapped to the CDM OBSERVATION table. Different mapping strategies have been applied to source codes to the OMOP vocabulary mapping: fuzzy string matching for NHANES drugs (previously parsed to single ingredients) to RxNorm ingredients, weighted string matching for NHANES questionnaires, and human expert matching (manually reviewing questionnaires for certain disease) for NHANES conditions.

Results: NHANES patient level data from 761 tables (7 cycles from 1999 to 2012) for 71,916 distinct participants were mapped to five major OMOP CDM tables. A total of 21 NHANES tables with pooled sample or subset of sample were not mapped to the CDM. A total of 1,967(95.7%) NHANES single ingredients were matching to the RxNorm ingredient concepts, 40 NAHANES conditions were mapped to SNOMED concepts, and 761 (9.7%) NHANES questionnaires were mapped to the LOINC concepts.

Conclusion: It is feasible to transform the NHANES data to the OMOP common data model. Although survey data usually vary on the data structure and have no standard code to record patient data, our study maximally maintains information of the NHANES raw data and effectively transforms most import information to the OMOP CDM. To evaluate the accuracy and robustness of the NHANES CDM, we will conduct a replicate study using the NHANES CDM compared with NHANES raw data in the near future.

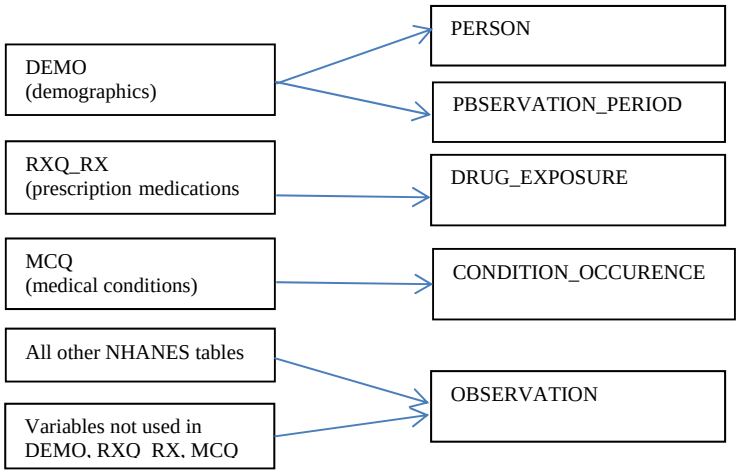

Figure 1. NHANES and OMOP Tables Mapping

Patient-Centered Decision Support for Pediatric Asthma Signs and Symptoms: Development of a Web-Based User Interface for Parents

Maryam Zolnoori,, Katherine Schilling, Josette F. Jones
m.zolnoor@iupui.edu

Introduction

Asthma is a complex, chronic disease with a heterogeneous distribution across in all regions of the World [1]. Epidemiological data for asthma, particularly in developing countries, show a considerable disconnect between asthma diagnosis, versus the actual prevalence of the disease [2].

In recent years, a variety of computer-based applications have been developed to assess and manage this chronic disease [6]. One of the negatives inherent in many existing, computerized applications is their minimal reliance on and inclusion of the gold standard, evidence-based research on asthma, particularly within pediatric populations [7]. Additionally, existing tools often fail to adequately represent medical knowledge to parents in text and formats that are easily read or understood.

Purpose

This poster describes the design and development of a patient-centered, web-based application for improving patient families' understanding of pediatric asthma signs and symptoms.

Methodology

Evidence-based literature, in combination with clinical decision support systems (web-based CDSS) approaches were leveraged in the development of the asthma application user interface.

Contextual inquiry techniques also informed the design, based on input from five nurses (for clinical representation) and parents (for familial understanding of asthma signs and symptoms). The interface was tested through heuristic evaluation, a method that identifies usability problems in the user interface design.

Results

Participants (nurses and parents) evaluated the application on three metrics including effectiveness, efficiency, and satisfaction. Additionally, the Questionnaire for User Satisfaction (QUIS) measured parents' satisfaction with the web-based tool for helping them understand their children's asthma signs and symptoms.

Initial results demonstrate that the application positively influenced patient engagement and patient empowerment, providing parents with a better understanding of the causes of pediatric asthma, and signs and symptoms with which they should discuss with their physicians for an official diagnosis. In addition, research may help the authors to understand the types of customization that could be considered in electronic personal health records when chief complaints include lung symptoms (coughing, wheezing, chest tightness, and shortness of breath) indicative of asthma. Detailed findings will be reported.

Conclusion

Improving health disparities in developing countries, particularly in asthma diagnosis and treatment depends, in part, on the development of quality, patient-centric, evidence-based applications.

Patient engagement is an important determinate of the success of health applications, particularly those that are designed to provide evidence-based information for understanding the signs and symptoms of pediatric asthma and other diseases. Patient engagement depends on several factors including user-interface design, content display and readability, and others. Ultimately, improving our understanding of the impact of system features and design elements on patient satisfaction and application usage will improve our abilities to develop products that empower parents to make informed choices on behalf of their children's health.

Online Patient Center: Expanding Patient Portals by Integrating Patient-Generated Data Directly into a Primary Care Provider's EHR Workflow

Jon-David Ethington, MHS, PA-C[1], Jianlin Shi[1], Scott Nelson, PharmD[2,1]
[1]Biomedical Informatics Department, University of Utah, Salt Lake City, UT;
[2]Department of Veterans Affairs, Salt Lake City, UT

Abstract

Patient portals are in need of new tools to increase patient engagement and improve communication between patients and providers. An Online Patient Center (OPC) is a repurposed, multi-tethered Personal Health Record (PHR) with connectivity to act as a single portal integrated with EHRs from multiple healthcare data providing organizations. The OPC contains an integrated app that guides patients in reporting clinically relevant data in a format preferred by providers, and integrates that data into the specified provider's EHR workflow. The OPC also allows for connected health apps, currently used by PHRs, which educate and promote health self-management. Beyond increasing patient engagement, an OPC provides closed-loop feedback and a reward system, which further encourages patient participation. An OPC utilizes the ONC's "Three A's" initiative to provide patients with better access to their healthcare data, an avenue to take action with that data, and tools to shift provider-patient attitudes towards collaborative efforts.

Background

Patient portals are patient-oriented E-health tools that aim to engage patients by providing access to their medical data and a method to electronically communicate with their health care providers. However, Patient portals have suffered from low adoption and are in need of new methods to engage patients [1] (Common barriers are explained with Appendix A in the supplement). Patient engagement has recently been identified as an area needing increased attention by the Office of the National Coordinator (ONC). In its primary role to improve health through health information technology (HIT), and to support the adoption of HIT, the ONC has developed a "Three A's" strategy to increase patient engagement. This strategy aims to increase **A**ccess of health information to patients, enable patients to take **A**ction with that information, and to shift **A**ttitudes so that patients and providers think and act as partners in managing health and health care [2]. More specifically, current patient portals do not effectively promote patient engagement due to a lack of integration in provider workflows and the need for using institution-specific portals. First, electronic messaging through patient portals is not well integrated into provider workflows (Figure 1b) [3], especially when patients want to take action by sharing data from externally obtained health care encounters (i.e. specialist visits, radiology reports, etc.) with their provider. In a review of patient portals, Ammenworth et al. [4] found that the use of patient portals resulted in decreased office visits, an increase of messages sent to providers, and no change in health outcomes. In outpatient settings where providers are reimbursed for services provided in-office, this translates to adverse effects on workflow with no additional reimbursement and can further hinder attitudes of the patient-provider relationship. Additionally, the risk of miscommunication with patient portal messages increases because in order to view patient messages, providers commonly need to open a tab or mailbox that is outside from their normal EHR software. In many cases, providers can even grant proxy access to other staff members so that they don't even check for or see messages. This discourages patient use of portals.

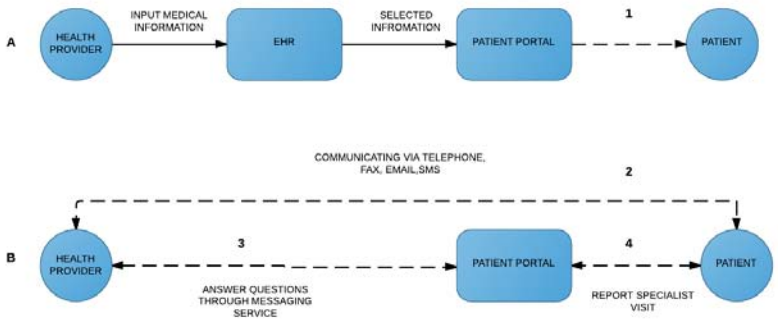

Figure 1. Current information flow when using a patient portal. Dotted lines indicate areas where barriers exist and are further explained in the supplement Appendix A

The second area that is a challenge for patient portals is that one portal typically links a patient to only one healthcare organization (Figure 1a). This creates an access problem for patients who receive care from more than one organization because they would have to create a new user account for each system they use in order to access their data. This scenario is very common, even in areas where only a few health care organizations serve a large portion of the population [5]. For patient portals to increase patient engagement and address the ONC's "Three A's" strategy, they need to integrate patient messaging into provider workflows, and provide a way for patients to access their healthcare data from multiple organizations in one location.

Approaches

Current alternative strategies to integrate patient messaging of specialist visits and other healthcare encounters into provider workflows include further implementation of the Direct platform [6], achieving system interoperability, and expanding current patient portals to integrate with provider EHRs. The Direct platform is a method to securely transmit personal health information to intended recipients, and transmit other document types. The Direct project however only sends and receives data. Any integration of messages into EHR workflows would be dependent on each EHR with which the system interfaces. Achieving system interoperability would be another solution, and would reduce the need for patients to report summaries of healthcare encounters to their providers because they would already be viewable in the provider's EHR. However, despite current efforts, there is much progress to be made in this approach. Another approach includes expanding current patient portals to allow patients to communicate specialist data directly into the provider's EHR workflow, but this approach may be difficult to convince EHR vendors to commit resources to build independently. Additionally, any data entered by patients through this method would then become part of the organization's data silo, and would not be owned by the patient. Furthermore, even if patients could communicate directly to providers' workflows, access would still require multiple logins, and data silos would still exist for patients who receive care from multiple healthcare organization.

An existing platform capable of providing more forms of communication between patients and providers than a patient portal is a personal health record (PHR). Despite the relatively low utilization of PHRs, it has been suggested that by integrating the PHR with the EHR, adoption would increase and patient-provider attitudes could be shifted in a manner that could improve health[7]. PHRs can be tethered to multiple EHRs to allow for direct connectivity between the PHR and EHR, without the need for patients to manually load their data. This could allow patient messages to be integrated into an EHR workflow, and would provide a way for patients to access their healthcare data from multiple organizations in one location. Furthermore, patients have more ownership of data in a PHR compared to a typical patient portal. New communication methods utilizing existing tools, such as those available from PHRs are needed to augment patient portals in new ways that foster patient engagement and provide better information exchange between patients and providers. This new application of existing technologies will be referred to as an Online Patient Center (OPC) hereafter.

An ideal arena to implement an OPC is in the primary care setting. Primary care providers (PCP) and PHRs have similar fundamental roles of "advising and supporting patients in education and health self-management." [8]. Patients would have the opportunity to have multiple interactions with such a system in this setting due to the frequent encounters that occur in a longitudinal fashion. It is also common for a patient to have multiple healthcare encounters in-between primary care visits, such as for specialist visits, emergency department encounters, or even hospital admissions. An OPC could provide much-needed, timely summaries of these encounters to PCPs at the point of care in order to provide high-quality healthcare. Furthermore, PCPs have generally positive views about integrating this type of data into the EHR as long as it does not adversely impact their workflows[3]. The primary objective of the solution presented here is to describe how an OPC can transform the nature of patient engagement by allowing a patient to electronically report information received during a specialist visit directly into his/her PCP's EHR workflow. This will be done in a way that meets Meaningful Use criteria, reduces the burden on the provider workflow, and empowers patients to play a more central, productive, and active role in their own healthcare.

Solution description

An OPC improves patient engagement by providing patients with access to their healthcare data, giving them the ability to take action with their health information, and shifting attitudes of patients and providers towards a more collaborative effort. An OPC is a repurposed, multi-tethered Personal Health Record (PHR) with connectivity to act as a single patient portal integrated with EHRs from multiple healthcare data providing organizations. Apart from

being a multi-organizational health portal, an OPC leverages PHR tethering connectivity to share clinically relevant patient-generated data directly into a specified provider's EHR workflow. For example, creating an email message from scratch may be difficult for patients. The OPC provides patients with a template that prompts them to enter the information that will be most valuable to their healthcare provider and then puts that information directly into the providers EHR workflow- not their message box. The OPC also adds an incentive points reward program, similar to credit card reward programs, to the list of patient health apps, currently used by PHRs, which can educate and promote health self-management. Because an OPC uses existing technologies, there are general requirements of PHRs and EHRs to implement an OPC in a primary care setting (Table 1). The specific functions of an OPC are listed in Table 2. A use case is found in Appendix B of the supplement and a link to a video demo is here: http://youtu.be/9E5H6PXoLIc

Table 1. *PHR, EHR, and healthcare organizational requirements for implementation of an OPC*

The use of an existing, secure PHR with either current or planned capabilities to tether with multiple EHRs	A healthcare organization currently using a qualifying EHR interested in expanding their current Patient Portal and meeting additional Meaningful Use requirements
An EHR vendor with connectivity capabilities to the selected PHR	All organizations should be willing to make adaptations to allow core functionality including EHR-OPC integration, user interface adaptations, etc.

Table 2. *OPC components and functions*

Integration of a patient-generated summary of a specialist visit into a primary care provider's EHR workflow
Component/Function: With guidance from providers and patient representatives, create a short form that will guide the patient in creating a clinically relevant visit summary of his/her specialist visit. • **Description:** Compared to having a blank email, this form will make it easier for a patient to describe their visit. Only the most critical pieces of information (type of provider seen, what they told the patient, were any tests done, etc.) will be transmitted to the provider, ensuring that any time spent reviewing the data will help move the clinic forward.
Component/Function: Provide the OPC module/app that creates a new section in the PHR called "Visit Summaries." This module allows the patient to fill out the specialist visit summary form, and saves it as "patient-generated" data. • **Description:** Provides a location in the OPC for secure patient to provider messaging of specialist visit data.
Component/Function: Once the patient completes the visit summary form, allow patient to specify which provider(s) will have access to the data. • **Description:** This puts patients in control of which providers see this data. Additionally, providers will not receive extraneous messages.
Component/Function: Link "patient-generated" data to EHRs as a "Patient-Generated Encounter." • Create screen space or an icon in the EHR workflow where a link to the patient-generated data can be displayed (i.e. Integrated into the existing chronological list of encounters already common to EHRs). • **Description:** Providers do not have to navigate away from their EHR software and to their messaging service to see the specialist visit summary.
Component/Function: When this information is accessed by a provider, send a notification to the patient explaining that the data they entered has been viewed. • **Description:** This closed loop feedback can positively shift attitudes of patients and providers towards collaboration because patients will know that their action of completing the specialist visit summary form were viewed as valuable information by their provider. As providers use this data it can additionally demonstrate that their patients are capable of accurately recalling medical encounters [9].
Component/Function: Reward points to the patient each time a summary visit is entered and each time that information is viewed by a provider. Provide a health-app marketplace in the OPC similar to credit card reward points where points can be redeemed for health products, discounts, etc. • **Description:** Uses a familiar, successful method to encourage and reward patient involvement.
Leverage PHR tethering to provide a single access point for patients to view data from multiple organizations
Component/Function: Provide a combined display containing all linked data shared by available EHRs in one, longitudinal format. • **Description:** One login for patients and one location to view data.

Healthcare organizations using OPCs have additional potential to meet additional Meaningful Use criteria. The specific functions of an OPC (Table 2) can help an organization attest to meeting Meaningful Use in the health outcomes policy priorities of engaging patients and families, and improving care coordination [10]. Depending on the function, one or both of these areas may be met in any of the Meaningful Use stages, one through three.

Implementation and Dissemination

Implementation of an OPC can be approached following a common Systems Development Lifecycle Model [11], consisting of five main phases: plan, analyze, design, implement, and maintain. Throughout all phases, tasks will be developed with the end goal of engaging the main two groups of end users- patients and providers. Key stakeholders will need to be identified in the first phase including PHR and EHR vendors, a participating healthcare organization, and provider and patient representatives. During the planning phase, a query to identify and secure core businesses that will participate in the points reward program will be initiated. While core components and functions (Table 2) are developed, stakeholders will also develop marketing strategies that will educate both patients and providers about the benefits of the system (Table 2) as well as how to enroll. During the design phase, the OPC functions will be integrated with the Meaningful Use system attestation module. Instructional video tutorials will be developed and imbedded into the OPC for viewing by patients. Additional instructional videos will be made available to providers and healthcare staff on their workstation desktops. Prior to system roll-out, core OPC functions will be deployed and tested and a baseline evaluation will be conducted to be used as part of the overall evaluation approach.

Dissemination of an OPC for use on a large scale would be facilitated by its foundation in existing PHR and EHR vendors. Once the core components and functions have been successfully implemented between the chosen PHR and any one particular EHR vendor, only a willing healthcare organization using that particular EHR vendor would be needed to implement another OPC. For every single EHR vendor that participates, it then becomes possible for any or all of their clients to participate. This scalable dissemination method could provide additional motivation for EHR vendors to participate beyond the benefits already discussed in this design.

Evaluation

A pre-post design will be used to evaluate the implemented functions, along with qualitative, descriptive, and human-factors research. Evaluations will be conducted through system audits and surveys administered to patients and providers at baseline (pre-implementation), 1, 3, and 6 months (post-implementation) to assess the OPC. Topics of interest include Meaningful Use attestations, usability of OPC interface using the Systems Usability Scale[12], satisfaction with specialist visit summary form, patient satisfaction with the point reward system, perceived engagement of patients, barriers to enrollment, provider satisfaction with availability and quality of information, impact on provider workflows, overall system adoption, and other perceived or realized benefits (patient outcomes). In order to minimize selection bias, surveys will be available electronically, via mail, and via in-person temporary staff members stationed in waiting areas and clinical areas. User engagement will be evaluated by the point reward system. Through measuring the system use as well as rate of system use, we can identify how both patients and providers are using the OPC.

Discussion

While an OPC uses existing PHR and EHR technologies, it is not just an appendage application to those systems. An OPC takes the best components of those systems, adds fully integrated electronic messaging, and provides these services to the patient in one online center. Because the OPC is reliant on PHR and EHR technologies, there is some inherent risk with this model, as key assumptions must be made. First, this project assumes that EHR vendors will be willing to collaborate with stakeholders and modify their user interfaces. Mitigation strategies for this potentially serious risk include achieving additional areas of Meaningful Use that the vendor may not otherwise meet on their own. By focusing on satisfaction of patients and providers, this may put added pressure on EHR vendors to participate. Secondly, the project assumes that patients will participate by logging into the OPC and completing the specialist visit forms. By providing a system focused on the ONC's "Three A's," we submit that patients will feel empowered with this opportunity to take charge of their own health information. Furthermore, patients will continue to use the system as they see their providers using that same information and they receive closed loop feedback. For those patients who need a different kind of motivation to use the system, the point reward system, which is similar to credit card rewards, may encourage participation. As the reward system develops, points earned by patients could be

used towards sponsor services or products (i.e. pharmacy discounts, wellness coaching, exercise equipment, gym memberships, etc.), or for reducing insurance premiums in a manner similar to many employee wellness initiatives.

By creating integrated EHR communication between providers and patients, as with this transformative approach, new opportunities of patient-provider communication and collaboration will appear. Rather than requiring patients to login to the OPC to report a specialist visit, the OPC could potentially use natural language processing to discover and process the specialist visit information from the patient via their smartphone or social media feed (see supplement Appendix C). Another example is when patients view radiology reports through the OPC and don't understand a particular section, the patient could highlight that line or paragraph, and when the provider views that same report, they will see what the patient highlighted. The provider would then know to address that during the next visit. Yet another possibility would be to allow providers to create links that appear on certain lab criteria (Vitamin B levels for example) explaining his/her opinion about what the optimal level for that test is. This provides the patient with more personalized guidance above and beyond the laboratory reference ranges commonly provided.

Conclusion

To emphasize the ONC's "Three A's" initiative, patients need better access to their healthcare data, an avenue to take action with that data, and our healthcare system needs tools to help shift provider-patient attitudes towards collaborative efforts. Primary care settings can especially benefit from increased patient engagement and are an ideal area to implement the OPC. A successful implementation of this solution will demonstrate that patients can understand the key aspects of their healthcare encounters and that they are motivated to share that understanding with their primary care providers in a manner that decreases the provider's burden. Further study will be needed to see if this new level of engagement can help lead to better health outcomes.

On the SamePage: Supporting Communication and Informed Decision Making Through a Surgical Portal Extension

Rebecca J Hazen, Amanda Lazar
University of Washington, Department of Biomedical and Health Informatics, Seattle, WA

Abstract
Motivated by an experience of a close family friend, we present a patient portal solution designed to aid patients in making decisions about gynecological surgeries and procedures. Gynecologic conditions often have a stigma attached to them, and are not openly talked about. This can make finding and discussing information about them challenging. Surgical repairs for these conditions have long-lasting implications on many facets of a woman's life. After identifying challenges with current communication and information-sharing mechanisms in the patient-clinician interaction, we isolated a design question and created a series of personas and scenarios to better illustrate the users, uses, and implications of the proposed solution. Our portal solution, SamePage, includes avenues for detailed information about conditions and surgical options, utilizing diagrams and information tailored to the patient's specific anatomy and diagnosis, shared question lists, and venues for continuous communication with healthcare professionals. Next steps include iterative user testing and evaluation.

Introduction
Health Information Technology (Health IT) is changing how patients and clinicians communicate, exchange information, and interact with health data and each other. Innovations in biomedicine, computer science/information technology, and human computer interaction research, as well as federal initiatives continue to motivate the use of technology in healthcare. Use of Health IT has largely been seen inside the walls of the hospital in the form of electronic prescribing and laboratory systems, and the use of the electronic medical record in clinical practice and billing activities. With the implementation of Meaningful Use, Health IT is expanding beyond hospital walls to provide access to health information and services to patients at home and outside of the clinical environment. Patient portals allow patients to view and interact with their health data, and carry out routine administrative tasks such as requesting appointments, refilling prescriptions and sending secure messages. Despite their potential to provide the patient with access to information and services, they are often underutilized[1]. Getting patients enrolled is a significant challenge, but once achieved, repeated use is becoming more common[1, 2]. Barriers to enrollment and long-term use include lack of information or motivation, distrust and negative perceptions of the portal technology and its usefulness, concerns about timely responses, and prior negative experiences, especially in regards to the secure messaging functionality, and to a much lesser extent 'connectivity obstacles' [2, 3]. The nature of these reasons suggest that the challenge is social rather than technical, and that the ways in which they are introduced and used in clinical interactions is important to uptake and long-term use. While patient portals have great potential for patient-provider communication and transfer of information, current underutilization exposes an opportunity for redesign, both of the portal technology, and the clinical workflow in which it is used. By taking a new approach to these portals, we create an environment supportive of engaged and informed communication and decision-making for patients and their healthcare providers.

Background and Challenge
For this design challenge, we have chosen to focus on improving communication between patients and their healthcare providers to support patients as equal, informed partners in the decision-making process. We accomplish this by stepping beyond the features typically embedded in these portals and providing patients with resources to support elevated participation. Our proposed solution is designed for women who are candidates for gynecological and urological surgeries and need assistance in understanding and making decisions about their surgical options. We began our design process with a persona and scenario based on a real-world encounter. We then identified problems and challenges associated with the encounter, and developed an updated scenario and persona to illustrate the proposed solution and its role in the patient encounter.

Brief Scenario: Our interest in this challenge arose from a real-world encounter experienced by a close family friend of one of the design team members. The scenario, presented in depth in the supplemental materials, involved an encounter with a gynecologic surgeon for a diagnosis and consultation for a pelvic organ (bladder) prolapse repair. The patient, Karen, was presented with several surgical options during the appointment, and was then sent on her

way with an informational pamphlet and a web address. Karen left the encounter feeling dissatisfied and confused; she felt as though the options presented did not reflect her understanding of the diagnosis. Karen and her doctor were not seeing eye-to-eye, especially on the issues of how urgent the procedure was and whether or not a hysterectomy would be necessary. Wanting to start a family soon, this was unacceptable. The resources provided by the surgeon left her with many unanswered questions. She tried searching online on her own, but was unsure of the details of her diagnosis and could only find a cryptic, one line description in her online portal. She considered contacting the surgeon again, but felt that without having a better understanding going into the appointment, the unsatisfactory encounter would likely repeat itself. Feeling dismayed, she put surgery on hold until she felt that she and her doctor could better communicate and come to a mutually acceptable decision.

Pelvic organ (bladder, rectum, or uterus) prolapse is a common condition that occurs in women as a result of weakening of the muscles and ligaments supporting the pelvic organs. Typical symptoms include incontinence, bulging or pressure sensation, painful intercourse, and spotting or bleeding[4, 5]. Over 200,000 women undergo surgery to repair the condition each year, with as many as 30% of patients experiencing recurrence after the initial surgical repair[5]. Age and childbirth increase the risk of developing a prolapse[5]. Due to trends in aging, it is estimated that by 2050, the prevalence of pelvic organ prolapse in US women will reach 4.9 million[6]. The actual prevalence of pelvic organ prolapse remains unclear, as definitions and classifications vary, and it is unknown how many women do not seek medical attention[5]. It is likely that many additional women would benefit from treatment, but due to reasons such as stigma, embarrassment, or lack of knowledge and resources, they do not seek treatment and instead opt to live with potentially painful or embarrassing symptoms. As illustrated in the scenario above, decisions surrounding these types of surgeries are not always simple and straight-forward. Many procedures are irreversible and can have lasting effects on overall health, including childbearing abilities. It is essential that the patient understands her options, and is able to work with her surgeon to reach a mutually acceptable plan moving forward. In order to reach this point, the patient must understand her diagnosis and treatment options, and must be able to trust and communicate effectively with her clinician. This is often difficult to achieve in a single consultation as patients may not know the extent of their diagnosis and treatment options prior to their appointment. Moving communications outside of the clinical appointment adds an additional challenge to the information sharing and decision making process. Patient portals have the potential to facilitate ongoing communication between patients like Karen and clinicians outside of the clinic by presenting patients like Karen with resources and information needed to make informed decisions.

DESCRIPTION OF THE PROPOSED SOLUTION

Reflecting on the experience presented in this scenario, it is clear that the patient did not feel as though she knew enough about her options to be able to make an informed decision. She faced challenges in understanding the information presented, accessing applicable information, and in interpreting her diagnosis and treatment options. Challenges in communication were also identified as barriers to moving forward with the decision making and treatment process. In an attempt to resolve some of these challenges and reduce barriers between the patient and her clinician, we developed the SamePage Patient Portal Solution, as illustrated in the form of an updated scenario.

Updated scenario: Elaine is a 56 year old secretary living with her husband of 36 years and two daughters in Los Angeles. After experiencing increasingly frequent urinary incontinence and pain during sexual intercourse over the past few years, Elaine decided to see her doctor for a referral to a specialist. Before Elaine's appointment with the surgeon, registration staff introduced her to SamePage and made sure her account was set up so she could access a pre-appointment question list. During the appointment, Elaine and her doctor discuss treatment options and preferences. Instead of handing Elaine informational handouts and web links, the surgeon logs into the provider-side of SamePage through the EHR and hands Elaine a tablet to log into the patient-side. Elaine's diagnosis and health information populate in the portal via an HL7 interface between the EHR and the portal system. Her doctor quickly and easily adds information and personalized diagrams tailored to her individual anatomy using basic checkboxes and lists as they talk. They discuss the fact that Elaine is finished having children, and has placed a high value on pain-free sexual intercourse. These values and preferences are reflected in the personalized information included in Elaine's account. Together they review the information, using diagrams, images, and information features within the portal to better explain and understand each other. As there is much to consider, Elaine decides that she would like to review the information further before making a decision. At the end of the appointment, the surgeon dictates an exam summary which is automatically transcribed, approved, and transmitted to SamePage for Elaine to view.

At home, Elaine logs into her secure patient portal and reviews what she and her surgeon discussed in the office. Here, she reads more about her condition and what it means for her overall health. She reviews her recent vitals, medications and lab results made available by her doctors. In SamePage, she clicks through the surgical options discussed and reads an in-depth explanation of how each is performed, details of the recovery process, and potential complications. Personalized interactive diagrams and simulations are displayed alongside these explanations to help her better understand each approach. As she reads through the relevant medical information, she highlights the things she would like to remember to discuss with her surgeon. She discovers that she can also attach notes to the highlighted sentences and add them to a question list for her next appointment. The question list helps Elaine and her surgeon prepare for the appointment, and directs conversation towards what Elaine is most interested in and concerned about. She can also send secure messages ahead of time to request additional information. The Help menu explains features and functions and answers basic questions about the portal technology. Elaine also visits the Settings menu where she can grant limited or full access to a family member or health delegate.

After reviewing the information available on SamePage, Elaine requests a follow-up consultation through the portal. She has the option of an in-person appointment, or a video conference appointment carried out through the portal. Real-time video conferenced appointments take full advantage of the portal features and telemedicine technologies, allowing the patient and the provider to simultaneously view materials, and address any questions the patient may have from the privacy of their own home. Feeling confident about how well SamePage has worked so far, Elaine chooses to avoid LA traffic and try something new and schedules a video conference appointment. Elaine's surgeon allows option of audio recording the appointment and storing it for future reference, a feature Karen is impressed by. During the appointment, Elaine is able to communicate her concerns to the surgeon and feels confident that they are on the same page. Together they come up with a decision on how to proceed. At the end of the appointment, the surgeon dictates a summary which then becomes available on the SamePage and in her medical record. She then submits a request to the scheduler to be contacted to set up a surgery date and her surgeon activate the appropriate prep and follow-up documents, as well as a module for collecting patient-reported outcomes and symptom updates.

DISCUSSION OF ALTERNATIVE SOLUTIONS CONSIDERED

In the process of designing SamePage, we considered several approaches. One alternative was the use of mobile health technologies in supporting and expanding patient portal functionalities related to communication. Mobile health applications have been widely used as a means of accessing, distributing, and collecting health related information in the US and worldwide. Successful examples of mobile health technologies can be seen across the literature for activities including promoting self-management in chronic conditions including diabetes, asthma, and hypertension, and medication adherence in HIV/AIDS[10]. A second, approach considered was shifting patient portal technologies to the level of the Regional Health Information Organizations (RHIO) or Health Information Exchange (HIE). RHIOs and HIEs have been established across the country in order to allow for the exchange of health information, and to provide clinician access to patient information obtained at other connected healthcare entities. We considered the potential of using these exchanges as an access point for providing enhanced communication and information services to patients as a part of our exploration, potentially providing fewer points of central implementation and more widespread use.

DISCUSSION OF STRENGTHS AND WEAKNESSES AS COMPARED TO ALTERNATIVE SOLUTIONS

In identifying a design solution to pursue to address these challenges, we considered the strengths and weaknesses of each potential idea before selecting the option that we believe best supports the patients we are designing for, as well as the clinicians and healthcare organizations where we imagine this solution being implemented.

Comparative strengths: Our proposed solution is ideal for patients needing additional time and information before making a major medical decision. Patients have access to relevant health information when they want it and can learn on their own time, and in the privacy of their homes. Our solution allows patients to interact with personalized health information and carry out consultations remotely using video communications or in person. This provides flexibility for patients who are unable to make repeat office visits due to distance or scheduling constraints, serving to reduce a major barrier to access. It also allows patients to interact with personalized information and diagrams to assist them in understanding of their own diagnosis. Question lists created beforehand allow the patient and clinician to prepare for and guide discussion throughout the appointment. By using the portal solution in office as well as at home, we also increase enrollment and utilization of these technologies. In-clinic interactions help the patient to see the value and benefits of the portal, and understand the ways in which each person will interact with the system.

By using the existing infrastructure and extending traditional portal features, we reduce barriers to entry for patients, clinicians, and organizations. Patients and clinicians will be faced with fewer changes, and organizations will not be forced to make significant investments of time, money, and other resources to implement technologies duplicating those already in place. A major strength of SamePage is that once the initial set-up is complete, creating individualized patient material is very simple and efficient. SamePage features and functionalities not only support the patient at home but provide an interactive tool for us in the clinic as well. The novelty in our approach involves restructuring expectations of the technology, and changing how it is used in the clinical environment and at home to better serve communication and information needs of patients.

Mobile health: While mobile technology has provided unprecedented access to health information and new methods of patient-provider interaction, it also raises privacy concerns. The sensitive nature of the condition, volume of information, and personalized diagrams would likely be inappropriate for accessing in public locations or environments where a mobile device is more convenient than a PC. Additionally, the information would ideally be presented on a large screen so patients could simultaneously interact with information and images displayed.

RHIO/HIE: The advantage of working with an HIE/RHIO is that data collected by various organizations is available at a centralized access point, meaning fewer log-ins and systems to learn. However, developing even simple access functionality is difficult, and requires compromise and narrowing of scope, as experienced and reported by Ancker et al[7]. The many technical, logistical, political and financial challenges involved in this approach make it an impractical option for our focus of improving communication mechanisms and providing information to engage and inform patients. The use of standards and the demands of transforming and translating information at the interface level would need to be addressed, as well as concerns about privacy and data ownership. Moving portal activities away from the individual healthcare organization adds additional steps to the clinician workflow and introduces new potential failure points. Many healthcare organizations are still struggling to connect with HIEs, or do not yet have exchanges to connect to, limiting the ability of organizations and patients to access these features. Another challenge is that these systems are built in different ways; some exchanges are centralized, storing all data in a single location where it can be accessed, while others are federated, remaining in their home institution's database and provided to the requesting user through a call to that database. This poses many challenges developing portal applications to access this information, and questions to feasibility of such functionality in the future.

Comparative weaknesses: Our portal has several acknowledged limitations. The current solution only addresses a single group of conditions for a specific patient population. Even with increasing numbers of patients being affected by pelvic organ prolapse, it is unclear whether this will lead to widespread change in how portal technologies are developed and incorporated into the clinical workflow and decision making process. However, we believe that portal solution could easily be adapted for other conditions and scenarios where treatments options require careful consideration and has heavy implications such as joint replacement and bariatric surgeries. Another limitation of our solution is that it does not inherently support long-term use. While repeat surgery for corrections/failures is not a rare event, repeat use of the main consultation feature is not assumed. Instead, we approach this as an initiating event that will serve to build trust in the technology, and will lead to long-term use of other included and potential future features. Because we are proposing incorporating SamePage into the existing portal infrastructure, it would be reasonable to believe that existing functionality would still exist, and that it would be relatively straight forward to develop and include other modules for self-management activities in the future.

Plan for Dissemination and Implementation

Prior to dissemination and implementation, additional evaluation and user testing will be necessary to ensure usability issues are resolved and that the needs of the patient and provider are met. This is especially important as SamePage has thus far been designed around the needs and experience of a single subject, which poses a large risk towards generalizability. We advise further iterative design and evaluation involving all stakeholder groups.

We created this solution with the idea of creating as few barriers to dissemination and implementation as possible. Acknowledging that resources have already been put into developing and implementing EHR technologies and the low likelihood of uptake for a system that would replace one already in production, we created SamePage to be integrated within existing infrastructures. This allows current portal features to remain in place, and permits single sign-in access to these features alongside those we have proposed. Although the portal is re-designed and the workflow restructured, transition to the new use case should be straightforward. The best approach to dissemination involves partnering with existing EHR vendors to incorporate the new functionality and features into their build, and

providing them to healthcare organizations as a part of a planned upgrade. This would allow time for testing and training on new features in advance, and for adapting and adjusting to the needs, values, and workflows for clinicians. By making SamePage available through popular vendor systems, wide spread dissemination will be more rapidly achieved. Our plan will take into account factors from Roger's Diffusion of Innovation[8]. Organizations, clinicians, and patients need to believe that the proposed solution is an improvement on existing technologies, see how it will benefit them, and understand any associated consequences. The portal must align with user and stakeholder beliefs, values and perceived needs, and must not be overly complex or inflexible to adaptations. For the organization as a whole, trialability and observability can be addressed by rolling out the portal features to a smaller group at first and allowing other clinicians to test and train on the new features as they wish, receiving regular updates from clinicians who are currently using the system as a part of their clinical workflow[8]. This works well for our solution, as it would initially be implemented with a small group of specialized surgeons to start who will interact with other potential future users and stakeholders including primary care and referring providers.

EVALUTION PLAN

Prior to implementation, several evaluations will be carried out, with future iterations to follow throughout the implementation and usage periods including an expert evaluation of the patient and provider interfaces based on the criteria set forth in Neilsen's heuristics[9]. Once implemented, we are interested in how the portal experience affects the clinic visit. We will evaluate the technology and any corresponding interactions to determine whether these interactions are optimized by the intervention, and whether patients feel engaged as informed decision makers after interacting the clinician and the portal system. This can be investigated through surveys and interviews with patients and clinicians, comparing their comfort and understanding of their diagnosis and options following the initial consultation and again following the second meeting. Qualitative approaches to ascertaining such information can serve to inform design evolution, and determine whether communication and engagement goals are met. We will also analyze is the impact of providing interactive, comprehensive patient-specific information through the portal and will look at quantitative data such as the number of questions asked during appointments to determine whether this is influenced by the implementation of SamePage. The ultimate goal is to have patients feel informed and confident in their ability to communicate and make decisions alongside their healthcare providers. Evaluation and iterative improvement will continue throughout the life of SamePage to continuously ensure that this goal is met.

Sintesi: Making Health Information Meaningful

Silis Y. Jiang[1], Jennifer E. Prey, MA, MS[1], Jamie S. Hirsch, MD, MSB[1], Andy Chiang[1]
[1]Columbia University, New York, NY

Abstract

Our project, Sintesi, which is Italian for synthesis, aims to bring patient data together in a meaningful, personalized way. Beyond being a patient portal with only basic data, sintesi will bring customized visualizations to users based on their health conditions and literacy levels. We believe that to fully engage patients, a 'one size fits all' solution is not adequate. It is only with specific tailoring that we can make information become more than just words and numbers on a page.

Introduction

Almost every person in the world will, at one point, be considered a patient. For many of us, we were literally born into it. We are present at every doctor's appointment, procedure, and episode, making us the "sole subject matter expert"[1] on ourselves. Therefore, it is important to leverage the knowledge we, as patients, have and to be included in managing our health and making healthcare decisions. Historically, healthcare has been a particularly paternalistic environment, where patients simply followed the directions their clinicians gave them. More recently, with the 'blockbuster drug' of patient engagement, we are seeing the tide begin to turn, and patients becoming involved.[2] This involvement creates an "increased burden on patients to understand health-related information to make fully informed choices about their medical care."[3]

While the need to put consumers 'in charge' of their own healthcare is beginning to be acknowledged, how to do so remains uncertain. The current challenge in information delivery is that data are rarely contained in a single system, making it difficult for patients to consolidate their health information, and severely constraining effective continuity of care. Additionally, information provided to patients is often not formatted in a 'patient-friendly' manner, but rather is simply repurposed from electronic health records without patient-centered annotation or formatting. Meaningful use requirements have encouraged the proliferation of patient portals, but the legislation is very vague on the details, including requisite data and format. Many of today's patient portals lack information which is actually useful to patients. For over 15 years, studies have shown that patients value custom-tailored information specific to their personal situation and data.[4] Even with today's technological advances, this type of tailored information is still very difficult to find.

The value of providing useful health information to improve health communication and engagement is clear. Engaged patients tend to have higher levels of patient satisfaction [4–7] as well as increased understanding of their care and motivation to adhere to the treatment plan.[4,5,7] Studies have shown that provision of information can have positive outcomes. For example, three-quarters of the OpenNotes project study participants reported taking better care of themselves as a result of having more information.[8]

Our goals were to explore what information patients would like to see, and how they should see it, and then to design a system which could facilitate patients' understanding of their health and improve communication with their care providers.

Design Methodology

To inform the design of our system, this project was rooted in a user-centered design model. We conducted ten semi-structured interviews with English-speaking adults. The participants were sourced from the research team's personal relationships with friends and family members. Conversations were audio-recorded and notes from the interviews were aggregated, synthesized, and discussed with team members. Participants ranged in age from 24 to 93, with a median age of 31 (average of 44). Four males and six females were included. We also conducted a brief review of the literature to identify the needs of patient populations which we did not address in our interview demographics (e.g. low literacy and low income populations).

Based upon participant interviews and the literature review, we identified user needs and used them as the basis for an iterative design method. A design solution was conceived, mocked up, reviewed, and then iterated based on team feedback.

Proposed Solution

Based on the results of our interviews as well as a review of the literature, we believe that to facilitate patient engagement and patient-clinician communication, it is very important to provide patients with access to their own data. Patients consistently commented that gaining access to information was difficult, and often required multiple phone calls to follow-up. They also commented that finding and understanding appropriate information was difficult. Therefore, we believe it is important that information be presented in a way which is appropriate to each particular patient. This is consistent with findings in the literature; Alpay, et. al. commented that it has "become a prime importance to develop Information and Communication Technology (ICT) based tools that can provide tailored information."[9]

Tang et al. identified key basic attributes for sharing information with patients including that it is "concise, clear, and illustrated with graphics if appropriate."[4] They found patients wanted a permanent record which they could keep and refer to after a visit so they could access the information later, especially when talking about their care with family and friends. Additionally, with the varying levels of literacy in patient populations, we believe that data visualization customization that is patient-specific, and appropriate, is key to increased comprehension.[10,11]

Sintesi is a customized patient portal in which the presentation of information to the patient is dependent upon his/her characteristics, namely, the patient's level of health literacy and health conditions. These criteria will help determine which data should be most easily available to the patient, and in what format the data should be visualized. The full set of mockups of *Sintesi* is available in Appendix A of the supplementary materials.

A key feature to creating useful visualizations of data involves having a robust data source. We believe having a central repository where patients are able to aggregate their data from multiple sources is important to allow for greater continuity of care and for end-to-end data analysis. We envision a model similar to the online personal finance software, Mint.[12] Mint is an aggregator of financial information. The user provides his/her login information to each of his/her financial institutions, and then Mint is able to pull account information from each of these sources. All of the user's data are then in one place and are more easily analyzed for trends and budgeting. While others have failed at being a health data aggregator (e.g. Google Health[13]), we believe the healthcare technology environment has changed to make this idea more feasible. For example, one industry start-up, MDCapsule is following this model.[14] Additionally, with the expansion of projects like the Veteran Administration's Blue Button, interoperability is slowly becoming a reality.

In *Sintesi*, upon first login, literacy will be evaluated through a two-part, 11-question survey. The first part will assess health literacy using the three-question Brief Health Literacy Screen.[15,16] The second part will assess numeracy using the Subjective Numeracy Scale (SNS).[17] The SNS tests numeracy level without having to ask actual math questions. It can be conducted in less time and with fewer burdens on the participants than traditional numeracy tests. The results of these questions will be used to place each patient into one of three health literacy levels: Basic, Intermediate, or Proficient, as adapted from the National Assessment of Health Literacy levels.[18] Each of these levels will have different representations of information. Design of the graphics themselves was informed by the work of the Washington Heights/Inwood Informatics Infrastructure for Community-Centered Comparative Effectiveness Research (WICER) patient visualization project[19] and the HARVEST project[20] which developed visualizations for clinicians. Design of the medication display was informed by Kripalani et al.[21] While patients will be automatically assigned to a particular level of health literacy, and thereby shown visualizations from a certain group, s/he may switch to the other forms of visualizations as desired.

The patient's health conditions will be obtained from the patient's problem list; if there is more than one item in the problem list, multiple visualizations will be shown. The varying metrics which are important per condition type will be retrieved from a reference list which is currently in development (Appendix B) and will default to general values of weight and blood pressure if a disease or condition-specific variable is not available.

Additionally, while we believe this portal will primarily be accessed by patients while they are away from the doctor's office, we believe it could be a useful tool to facilitate communication during the doctor's visit itself. A new workflow could be one in which the patient is able to login to the portal while sitting in the doctor's office. The doctor and patient could discuss which metric(s) are important for the patient to keep track of, and look at the trend of those measurements together. They could then decide on a treatment plan, and even add a goal on to the portal. This way, there is a visual representation to facilitate communication and the patient will have a record of what they are working towards.

Additional features to be included on the portal are facilitating secure messaging with providers and assistance in understanding clinician notes. Secure messaging is a feature which is part of Meaningful Use Stage 2 and as such, most institutional portals will be able to do this. Our portal will display all members who were involved in the patient's care, and allow the patient to send them a direct message or obtain their phone number. As more and more information is being shared with patients, including notes, it can be difficult for patients to understand the 'doctor-speak' in which the notes are written. A fairly simplistic way to help make the notes more patient-friendly is to partially 'translate' these notes. This could involve mapping acronyms to spelled-out words and including a feature like InfoButton to help explain terms which might not be familiar to the patient.[22]

In order to increase utilization and gather more patient-generated data, there will be a mobile component to the website (not shown in mockups). Using a mobile application or text messaging (as decided by the user), the system will occasionally check-in with the patient. Use of text messaging to engage with patients is a growing trend and is especially effective for low-income populations.[23] Trigger events for these check-ins could include when a patient begins a new medication, the mobile system could prompt the patient to provide how they are feeling and ask if they are having any new side-effects. A mobile application could also facilitate collection of patient-generated data from personal devices (e.g. fitness trackers or glucose monitors). Patient-generated data are becoming more common and it is suggested that these data can useful to physicians.[24,25]

Alternative Solutions

Our team considered a variety of solutions to address how to increase patient engagement and patient-clinician communication. Some ideas were completely outside of a portal and others were varying design characteristics of the portal which we settled on.

One alternative we considered was to simply provide a better system for direct phone contact between patients and providers. Some of our older interview participants described their desire to be in greater phone contact with their providers. As the older generations are less likely to be computer-savvy, we believe that our enhanced portal solution is unlikely to provide much benefit to them. This alternative would provide a direct line to a physician for patients who are above a certain age or describe themselves as non-computer users. By providing this increased communication access, patients could have their questions answered more immediately and it is possible that they would more appropriately come into the office. In order for a system like this to be feasible, a reimbursement structure for this interaction would need to be put in place. This type of solution could also potentially put a heavy burden on clinicians and overwhelm their already busy schedules. We chose not to go with a phone-only solution as we believe that by providing patients with more direct access to information, they will be able to more fully understand their health situation and be more engaged in their care, rather than primarily relying on responses from clinicians. Additionally, as the population ages, more and more elderly patients will be proficient with electronic devices.

In our research we found many new healthcare startups that are designing mobile-only solutions. While we believe that having a mobile component is important to increase interaction and data collection, we decided that with data as complex and vast as healthcare data, it really necessitates online, web browser use and the ability to see more than can be displayed on a 3.5" screen.

An important design choice, about which we had lengthy discussions, was whether to create a solution which was tethered or untethered to a particular personal health record (PHR). This debate has existed as long as patient portals have. While some studies suggest that a tethered solution seems to be the only successful option,[26] we believe with the changing healthcare environment and increased interoperability, the idea of a central repository which is patient-controlled, and institution-agnostic, can be a reality. If we had chosen to go the tethered route, another approach to integrate our design on a portal-by-portal basis, could have been to develop a plug-in which would sit on top of each institution's PHR and would be able to interact with the data at that institution directly. While this could have allowed for easier access to individual sites' data, we believe there is significant value in cross-institution information visualization and thus went with the stand-alone design option.

One additional solution we considered, but did not implement, was to focus on facilitating decision-making for patients. The ability for patients to convey priorities to their physicians when discussing treatment options is crucial, and there are currently few ways to help clinicians obtain these priorities from patients. By using tools such as dynamic decision trees, which could take patient preferences (e.g. quality of life, pill burden, etc.) into consideration, recommended treatment options could be updated so patients receive the best treatment for them. We hope this could be a feature in a future implementation of our portal.

We believe the solution we have chosen is one which addresses the important problem of providing patients with their information in ways which are comprehensive, understandable, and can facilitate communication with their providers. We also believe that this framework allows for future features to be integrated. Additional improvements we believe should be considered are working to further optimize the verbiage and visualizations based on patients' cultures and additional demographics, and integrating other common portal services (e.g. appointment scheduling). Overall, we believe this solution to provide valuable information and be flexible enough to allow for future growth.

Implementation and Dissemination

To further develop this solution into something which is fully functional and available, more work would need to be conducted to iterate the design. We would recommend conducting usability tests with various types of users including those from all three literacy levels and with different health conditions. Feedback from the usability tests should be integrated into new designs until the product is ready for deployment. Frameworks from work already accomplished by others such as the EnTICE software design platform could be leveraged during development.[27] Once recommendations from the usability tests are integrated, it's time for a staged roll-out in which certain patients are targeted to sign-up and use the system prior to a full go-live. Any feedback from early adopters can then be incorporated into the design. Once these updates have been made, we recommend doing a full release.

Gaining users for the system could be initially difficult. Many people have portals they are currently using and would therefore need to see the benefit of a new portal in order to switch. We believe that by marketing our solution as a 'Mint.com' for healthcare, it could entice users to take the time to join a new portal, input their credentials to link to other existing portals, and find the enhanced capabilities we provide. The addition of 'gamification' features and social media in the future could also encourage users to return to the site repeatedly to provide additional data points to supplement those provided by their healthcare providers. Challenges to implementation will include interfacing with the institutional portals and guaranteeing security of data. Additionally, a data-sharing model needs to be developed, particularly concerning appropriate access for parents of children and adolescents.

Evaluation

Multiple rounds of evaluation should be completed on this project. As discussed in the implementation plan, usability testing should be completed prior to rolling out the system. After the system is operational, we would recommend evaluating the portal through comprehension testing to ensure the information is being presented in an understandable and satisfying way. Thereafter, we would like to measure changes in engagement based on portal usage. This could be done either through finding matched controls to people who are already participating in portal use, or by finding a sample to randomize to having access to the portal or not. After a certain amount of time, perhaps a year, we could then analyze changes in patient activation using the Patient Activation Measure[28] and analyze other data such as the amount of health services used, the number of communications conducted with their care providers, and changes in health status.

Conclusion

In today's culture, with "Have it your way" slogans at places like Burger King, the idea of 'one size fits all' no longer applies. Especially in an arena as important as healthcare, information should be shared in a way which is customized for the person viewing it. Provision of information allows for more sophisticated communication and expression of personal preferences and desires. It is only with real understanding by both the patient and the provider in which we will be able to really achieve improved health.

Beyond Patient Portals: Engaging Patients with their Healthcare Providers: "HealthUp": An Active Patient Portal Beyond Sickness

Maher Khelifi, Pharm.D, Ahmad Aljadaan Ms, Micheal Anando Seng, BA
University of Washington, Seattle, WA

I. Abstract

A challenge in the effort to engage patient's with medical providers is the low utilization of patient portals. One aspect that contributes to this is that portal tools are currently more relevant for periods when the patient is in ill health. In this paper we outline a design for a portal that encourages patient engagement with the portal in periods of good health through active patient participation - reporting health data and challenge identification. To achieve patient participation our design includes features of gamification and interaction of the tool with those of patients' families and friends.

II. Introduction

Patient portals are online digital healthcare tools that provide patients with secure access to their health information and allow protected methods for communication and information sharing.(1) These portals are intended to extend the effect of health care outside of medical visits and health incidences by providing the appropriate tools to the patient for health management.(2) *Meaningful use terms* have helped to raise the number of health settings provided by such tools. Unfortunately, in spite of their potential benefits, some studies have shown that patient portals have generally low enrollment rates(3)(4).

III. Specific challenge defined

According to the Health National Statistics Report(5), patients visit physicians' offices an average of four times per year in USA. Outside these visits the patient manages their health by themselves. Regrettably, adherence to physicians' recommendations involving lifestyle changes, such as exercise, frequently pose significant difficulties for patients. Outside medical visits and when health has improved there is a tendency for patients to grow less compliant with recommended lifestyle changes. Our challenge is to transform the patient portal by extending its role, of providing health information and communication tools, to a platform that the patient can use to identify challenges and manage his health beyond sickness conditions. We aim to make the portal more interactive with the user and his environment to expand the adoption of these portals and to ensure a successful patient engagement. To achieve this, we need the portal to:

- Help the patient manage relevant information about his health conditions.
- Personalize health challenges based on patient's profile and health information.
- Create an engagement process to optimize the utilization of the patient platform.

Our goal is to create portals for patients to use in both ill and good health conditions by integrating the portals into patients life. The fact that the patient portal currently only provides reports from the patient's period of ill health, limits the use of the portal to sickness conditions. Patient portals should have use also when the patient is feeling better, to increase the chances of having an engaged patient who is equipped to manage his own health in the case of sickness. We hope to change patients behavior to encourage him check his health information more often, make healthier lifestyle choices, and manage his health condition. Our idea is encapsulated in the following quote: "The patient's role is changing from a patronized patient to an informed patient and further to a responsible, autonomous and competent partner in his or her own care".(6)

IV. Description of the proposed solution and design process:

1. The proposed solution:

We propose, as a solution; a patient portal accessible from a website and phone application.
This portal will help the patient to a) manage his health information, b) personalize his challenges, and c) engage with gamification platform.

a) Manage health information

The platform will provide the patient's medical records and proffer a space for collecting real-time health information. It will additionally display this information based on patient priorities and health challenges.

i. **Collect Health information**:

The health information will not be only entered by the provider, but also by the patient. The user can add information to his profile but it will not be saved in the medical record in order to not detract from its quality. Information captured outside of the medical visit will be saved in a different section.

Information sources are:

- Health providers: health providers can enter information to the medical record. Then the medical record will be synchronized with the portal.
- Automatic reporting from technology sensors: technology used by the patient can help him update his health information. The platform will facilitate automatic reporting by devices used by the patient. Smartphones, for example, can be a very valuable aid; they can report sleep hours, heart rate, and activity. The automatic reporting will help to reduce the burden on the patient and keep the platform running.
- The patient: patient can update his own information manually. This is especially useful for information not obtainable by technology.

ii. Display of health information

The platform will highlight the categories that the patient should attend to. The health provider will be able to help in identifying what health variables the patient should monitor. For these highlighted categories, the patient will be able to see the last recorded value. For example, a diabetes patient could have his glucose level highlighted and then he will be able to see the last reported value.

Having (close to) real-time information will provide patients with a clear thorough image of their health. It will aid in the objective and continual evaluation of the patient's health.

b) Personalize health challenges

After collecting health information, the application will help the patient identify and personalize his health challenges. Health challenges and tasks will be primarily identified by health providers during medical visits. Since the application is collecting lifestyle information about the patient, it can help the provider identify the barriers stopping the patient from living a healthy life. The application will propose a course of actions, or "health-plan", that the patient can follow to achieve his challenges. For example, if the patient's challenge is to manage diabetes, the health-plan will include diabetes diet, activities tasks (walk twice a week), and health monitoring (measure your blood sugar daily).

Challenges can also be updated based on new health information updated by the patient. For example if the patient's reported blood pressure is high, the application will invite the patient to add some tasks to lower his blood pressure.

c) Apply Gamification to close the patient engagement loop

After collecting health information and identifying challenges, we need to encourage the patient to use our platform. We found that gamification can be a good asset for that. According to gamification experts, when used properly, it can be deployed to achieve a wide range of desired outcomes such as fostering engagement or improving motivation.(7) Gamification is defined as "the application of game elements and theories to non-game contexts with the intention of modifying behaviors, increasing fidelity or motivating and engaging users"(8) Gamification design frameworks, found in the internet and literature, state that the application should create activity cycles to keep the stream of motivation going.(9) We used the engagement loop mentioned in gamification literature. We applied the engagement loop framework to our platform.

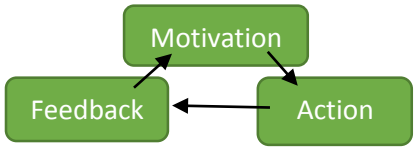

Figure1. Gamification Engagement loop(9)

i. Motivation

Self-determination theory (SDT) is one of the most well-known theories in motivational psychology. It explains human beings' innate psychological need for personal development and wellbeing and the impact on individual's motivation.(10)(9) This theory defines three innate needs: Competence (experience a sense of ability), Relatedness (social interaction, relationships, connectivity), and Autonomy (give the player the freedom to make their own choices). These needs are not affected by gender or culture, they are universal.(11) This theory delineates also the origins of motivation. According to SDT these include:

Extrinsic motivation: external stimuli such as rewards, threats, financial compensation.

Intrinsic motivation: experience being successful, social connections, satisfying work.

Extrinsic rewards such as monetary incentives are not enough to maintain behavioral changes or engagement. According to Zichermann,"The best systems of motivational design speak to intrinsic motivation of the user while providing extrinsic rewards that they value(9)(12).

Features added to the portal:

- Progress bar: The patient can evaluate the progress of his work.
- Patient network: the patient can have his family members and his selected friends connected to his portal. Users can share activities and post achievements (if they want to) .Social facilitation or the fact that people perform better in group can help motivating users.(13)(14)
- People support: High-five System. If the user share a post, his network can support him by giving him a high-five

ii. Action

After building up motivation, the user is ready to perform actions. The application will coach the user in organizing his tasks. It will help the user add tasks to his calendar, based on his life schedule. This technology will also remind the user to achieve his tasks. Instead of simple reminders, we will use geolocation and time factors to personalize alerts and reminders.

Features added to the portal:

- **Add task:** the patient can add tasks to his timeline, additionally he can invite people to participate in his tasks. Friends can join in real life (e.g. go for runs simultaneously) or they can just motivate each other virtually through the application.
- **Smart-reminders:** Smart phones can recognize when the user comes back home (medication reminders) and when he's within 5 minutes to Walgreens ("You are close to Walgreens: do you want to check your blood pressure?")

iii. Feedback

Achievement stars: the patient will receive a star every time he accomplish a task. These stars can be changed to reduction coupons for Fitness centers, healthy restaurants.

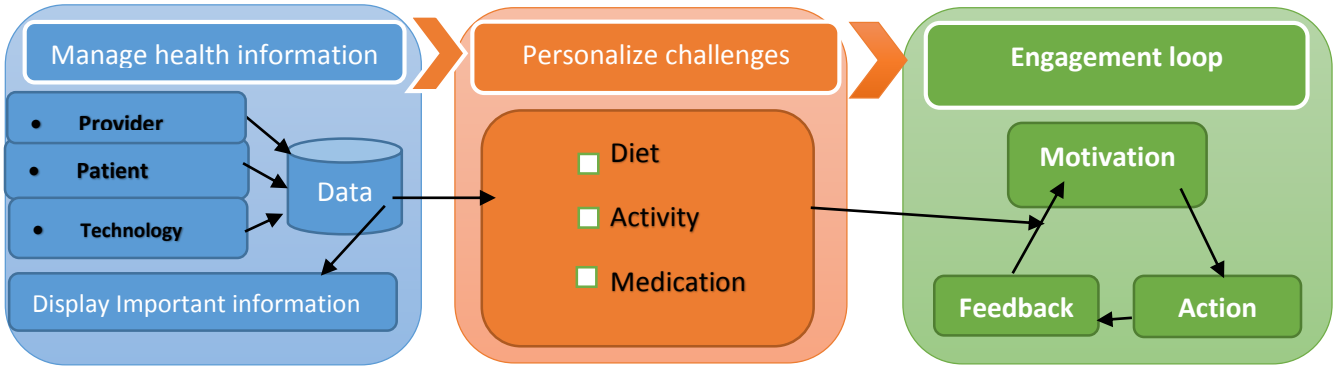

Figure2: Working process of the proposed solution

2. The process of the design:

During our design process, we had to go through different steps that can be summarized in the following list:

- Brainstorming different solutions for the three parts of the application (managing information, identifying challenges, and the gamification dynamics).
- First mockup of the platform.
- Scenarios and personas for different potential users (chronic patient, healthy user, patient network). This work helped us to optimize the features and functionalities used in the design and optimize the workflow of the portal.
- Realize a new mockup. (Described in the appendix)

V. ALTERNATIVES CONSIDERED

The research on patient engagement in health portals is dense and multidimensional due to the different problems that they currently have. We started our thinking to focus on one problem which is the existing gap between the information provided in the health portal and the patient. The information provided in the health portals are dense and speaks in medical terms that is hard for the normal patient to interpret. For that, we came up with the "Down-to-earth education". An app that can transform medical images, medical information- found in patient portals- to be more understandable by the patient. The patient can use this app to record physician notes, his own notes to improve his knowledge and skills in managing his own health.

Then, we started thinking about the problem that patient portal have as a one to one portals (patient to providers). We wanted to introduce the patient network (family, friends) as part of the patient portals. The network can assist patient in accomplishing their task or motivate them if needed. Therefore "The Angel Guardians" idea came to life. A network for patient-patient and patient-family where patient can look for help or provide help in a network.

VI. TRENGTHS AND WEAKNESSES

The proposed design focuses on 4 features that will help to increase patient engagement in the portal.

Table1: Strengths and weaknesses

Features	Strengths	Weaknesses
Dynamic Information Exchange	- Continuity of information where patient can send their real time information to the provider. - Facilitate the patient-provider meeting in which appointment times are increasingly truncated.	- Interoperability: Bridging our platform to existing Electronic Health Records (EHR) used in different hospitals - Information reported by the patient might be inaccurate. - Accessibility limited to patients with internet access and smartphones.
Personalize Challenges	- Adaptive Learning from patient-reported data to tailor tasks based on behavior. - Patients will be more motivated to complete the challenge knowing that it is designed for them personally. - Strengthens the relationship between the physician and the patient. - Develops skills and knowledge of the patient in maintaining health.	- There is potential that patients may provide inaccurate information about their behavior which will lead to ill-suited challenges. - May cause patients to overestimate their ability to manage health.
Patient Social Network	- Social facilitation: people perform better in groups(13) - Using the power of influence to galvanize behavior change(15)	- Privacy challenges. - Some tasks can be too personal to be shared with the social network.
Gamification	- Sense of control provided by the game spirit. - Follow the progress. -Motivation. - Engagement loop.	-The line between game and gamification is so delicate. There is a risk that the portal wouldn't be taken seriously. - It is important to find a balnce between cooperation and competetion in the gamification spirit. - Patient can overestimate their health condition (having a lot of reward stars doesn't necessarily mean don't return to the doctor)

VII. PROPOSED IMPLEMENTATION AND DISSEMINATION PLAN

We propose to realize our implementation and dissemination plan over 3 steps:

1. Pre-implementation:

Before starting the implementation, we need to study the existing systems used by hospitals to be sure that our application can integrate with the existing processes. It is important to understand the work flow of health providers. We intend that our solution will save time and improve communication between patients and providers. We need to identify our stakeholders and guarantee that we have them onboard to adopt this new solution. Then, we need to bridge our portal to the current EHR system that most hospitals are using (such as EPIC and Cerner).

2. Implementation and dissemination

The most two important stakeholders of our platform are: patient and health providers.

a) Health providers

It is vital to confirm that health providers are ready to adopt our solution. To optimize the adoption process we can develop learning tutorials to aid the provider in using the platform. Providers will have an adapted screen to check on their patient and to communicate with them by sending personalized or group texts. Additionally the portal should be easy to use and will hopefully reduce the burden on providers of managing patients outside of medical institutions.

b)Patients

Adoption is easier for people prepared to change. We should identify user groups that are least resistant to change and most willing to try a new tool to manage their health. The network aspect will help us to disseminate the application after recruiting the first group. We believe people with healthy life style are our target and from them we will build our network and diffuse it to others.

3. Follow-up

Provide feedback mechanism for users and providers to improve the application functionalities.

VIII. PROPOSED EVALUATION PLAN.

In order to determine that our developed tool is having the intended impact, we must have a comprehensive evaluation plan that assesses our solution. To measure the portal effectiveness we will need to focus on provider and patient satisfaction, usability testing, and portal compliances with other EHR system.

1. Provider and Patient Satisfaction.

Though we would keep our two populations (providers and patients) separate throughout the data collection period; they would essentially each be exposed to similar protocols during the evaluation process. First, a group of subjects would be asked to complete a pre-intervention survey. The survey would contain a mix of Likert-scale, True/false, and short answer questions to assess aspects of the portal relating to the following outcomes: usability, accessibility, design and usefulness. For patients, the survey would be oriented towards the gamification concept of the portal and the effect of social network has on their use of the portal.

2. Usability Testing

Approximately 15-20 subjects would participate in a focus group. The focus group would attempt to assess the needs of each profiled group of users of the portal. We would provide computer consoles on which providers and patients could use an interactive mock-up of the portal. Then we would elicit comments as they use it which examine the outcomes above.

After the pre-survey and focus groups, we would ask providers to use the portal in the actual health record for two weeks. Information would be available to us from usage logs and interactive feedback features. In addition, at the end of the two week period we would ask the providers to complete a post-survey, thus giving us pre/post study data.

3. Compliance with other EHR Systems

We will be working with teams from two of the major EHR providers (Cerner and Epic) to make sure our portal is entirely compliant with their EHR system. We chose Cerner and Epic because combined they have about 75% of the market share of the Electronic Health Record in large US hospitals. We will be conducting a conformability testing with those teams to make sure that the portal meets their EHR standards.

4. **Quantitative indicators**

We will identity a list of quality indicators like number of users, log-in times per day, interaction between network members, rewards shop. These indicators can be used to further develop and improve the portal tool.

IX. Future Direction:

The portal will be built in a rapid prototyping environment where we will be adding features and rules as we keep developing. Gamifying patient portal and adopting an online social network raises privacy concerns. We hope this portal will create rules that can protect the patient privacy while fostering a cooperative environment. To ensure sustainability of the portal we hope to develop an evolving process in our portal. One possible way that we considered is to develop ranking system, however it is important to be sensitive to the patient state of heath.

Abstract

With the increasing use of health information technologies and patient-centric focused care and involvement in healthcare practices, collaborative and cooperative systems, in the shape of patient portals, will be vital for maintaining ones health. In its current state, patient portals require an additional push to increase its use. Here we provide a potential solution to the patient portal conundrum by utilizing novel features and employing aspects of Computer Supported Cooperative Work, Persuasive Technology, and User-Centered Design in the creation of our mobile device patient portal application, UHealth. We then examine the strengths and weaknesses of our solution and present a potential plan for implementing, disseminating, and evaluating this application through the use of a scenario-based evaluation method and user satisfaction survey.

Introduction

Patient portals are a collaborative and cooperative system that aims to provide streamlined communication, collaboration, and cooperation between patients and their providers[1]. When available, patient portals have given the consumer an opportunity to engage and interact with their providers and their own data in novel ways. Such interactions have the opportunity to contribute to the well-being of the patient and the respective relationship with the medical team as it offers a myriad of abilities such as emailing questions to providers, requesting refills online, reviewing medical records, reviewing lab and imaging results, paying bills, and scheduling appointments[2]. Despite all of these benefits, many patients and clinicians are having problems with consistently using their patient portal. A 2013 study by the Cleveland Clinic, whom had 240,000 patients enrolled into their respective patient portal, found that only five percent of those patients actually used the patient portal[3].

In examining this problem of patient compliance, several reasons could account for such poor use. 1) Many portals have a modular structure with specific functionalities turned on and off, so many patients are left with experiences that lack content to interact with and subsequent cognitive involvement is voided. 2) Patients with multiple providers potentially have several portals to follow their own health. This leads to confusion in functionalities and capabilities to interact with respective providers in different systems. 3) The portal may lack the ability to download the record for a patient's own use or to share with family, friends, or other members of the care team. 4) Patient portals might lack many of the common functions a patient would seek outside of the provider's offices (*e.g.*, scheduling, prescription refills, or feedback). 5) Usability could be an afterthought in the patient portal design. 6) The portal is not available in the ways which patients are engaging data in their regular lives with mobile platforms and through many different data sources.

With so many opportunities for failure in engaging the patient portal, it is no wonder why patient adoption and use is such a challenge. To help foster the benefits of these systems, this research team is focused upon making the portal accessible to patients when they want it, where they want it, how they want this information delivered, with the right information, and in a user-friendly format. To drive this development, this team's aim will be to develop a solution for a patient portal that will be accessible from any mobile, tablet, laptop, or desktop device via respective browsers or cross-platform applications that will incorporate principles from some of the following areas: Computer Supported Cooperative Work (CSCW), Persuasive Technology, and an eye towards User-Centered Design (UCD).

Computer Supported Cooperative Work

Computer Supported Cooperative Work is the coordination and collaboration of information, in this case health information, with others at any moment in time facilitated by a number of technologies, asynchronously or synchronously, and its social, psychological, and organizational effects[4]. For the design of our solution, we have kept in mind some of the tenets of CSCW by viewing the patient, patient's family, and providers as a group coordinating and collaborating health information through the means of a patient portal or health information technology. Therefore, all users must have an awareness and shared knowledge of what one another has to offer

within the coordination of the patient care process to promote better management of health and positive changes in health behaviors.

Persuasive Technology

Persuasive Technologies are systems designed to help reinforce, change, or shape behaviors without coercion or deception[5]. A reinforced behavior occurs when a pre-existing behavior is further reinforced by the technology causing further resistance to change. Persuasive technology that changes behaviors influences the user's initial response to a situation, task, or issue[5]. Behaviors that are shaped by the persuasive technology result from creating a behavior that was not previously existent[5]. These technologies utilize a computer-human or computer-mediated persuasion[5]. To create a successfully persuasive technology, it is important to understand the issues or needs, the context of the use of the technology, and how the technology's features can promote these changes. We have kept these elements in mind as we have created our solution using computer-human persuasion. We are hoping to shape a user's patient portal behavior and change current health behaviors to healthier behaviors.

User-Centered Design

User-Centered Design is an iterative design process that takes into account the users' requirements or needs when designing a system. The user's role (*e.g.*, patient, patient's family, providers), the number of users (*e.g.*, individual or group), the user's needs (*e.g.*, medication adherence, information guidance, motivation), the user's tasks (*e.g.*, maintain health goals, create appointments, update information), and the visualization of these requirements (*e.g.*, immediate access to items most used, like information near like information) are analyzed before and during the design process in order to provide a usable and viable product for the end users[6]. We have kept these factors in mind while creating our solution to create a solution that provides the most positive impact.

Mobile Technologies

Data and information are exchanged in mass quantities every millisecond, and more and more people have access to knowledge than in any other time in history thanks to current advances in technology. The Pew Internet and American Life Project, a department of the Pew Research Center, conducted a 2009 study examining the demographics of internet users and found that teens and millennials are the widest adopters to the internet landscape as they have grown up with the internet and view it as a part of life, a necessity[7]. For those born before the millennial generation, they have slowly adopted these technologies into their work life and personal life. A large part of this adoption comes with ease of use. Ease of use is one of the most important factors that contributes to technology use. The ease of faster connections increases the percentage of people and frequency of technology use. Sharing data and information has increased both awareness and knowledge in the global population at an ever expanding rate, creating a new global culture linked by technology.

With the ubiquity of mobile phone use, new consumer expectations increased. Mobile phones are the new accessory to life and the need for knowledge and information on the go grew from a luxury to a necessity. In 2013, nearly two-thirds of adults with cell phones use it to go online[8]. Mobile Applications (apps) were the newest accessory to cell phones as millions were created to entertain the user. The Facebook app lured online users to take their networking with them and games like Angry Birds and Candy Crush kept the users glued to their phones. Yet, not all software companies set out to create the next best entertainment app. Once the influence of mobile apps was clearly seen as a way to reach this new technological audience, financial, educational and business companies took notice.

Now, desktop and wired internet connections are phasing out of popularity and mobile and wireless access has taken over. In 2009, 75% of teenagers and 83% of American adults owned a cell phone[7]. The Pew study concluded that a person's technology use is correlated to how a person chooses to connect with others and access information[7]. This brings to light the circumstances that are necessary for optimum adoption of cell phones and information exchange. Ease of information exchange can influence people to use their already ubiquitous cell phones to connect to the world. Our proposed solution uses an already created opening for healthcare and informatics to create useful and novel ways to exchange vital information to help patients better manage their disease or improve their health.

Our Proposed Solution

Patient portals have traditionally been coupled with the electronic health record (EHR) system that the provider might be currently using. There have also been standalone personal health records that can be accessed through the Internet and created by the user. Increasingly, a mobile app for managing health is now the new trend. For this project, we have chosen to utilize a patient portal app that is accessible in all types of technological mediums with a focus of its mobile app format for our mockup demonstration. Besides the usual patient and provider information management features available in patient portals, (*e.g.*, paying bills, creating appointments, and managing personal

health information), we have also included features that we hope will empower users by giving them the ability to access the information that they want to immediately see when using the patient portal, providing them with an ability to promote communications and discussion of their health with providers and family members, and supplying an additional personalized and persuasive way of enhancing the user experience while using the patient portal (Figure 1).

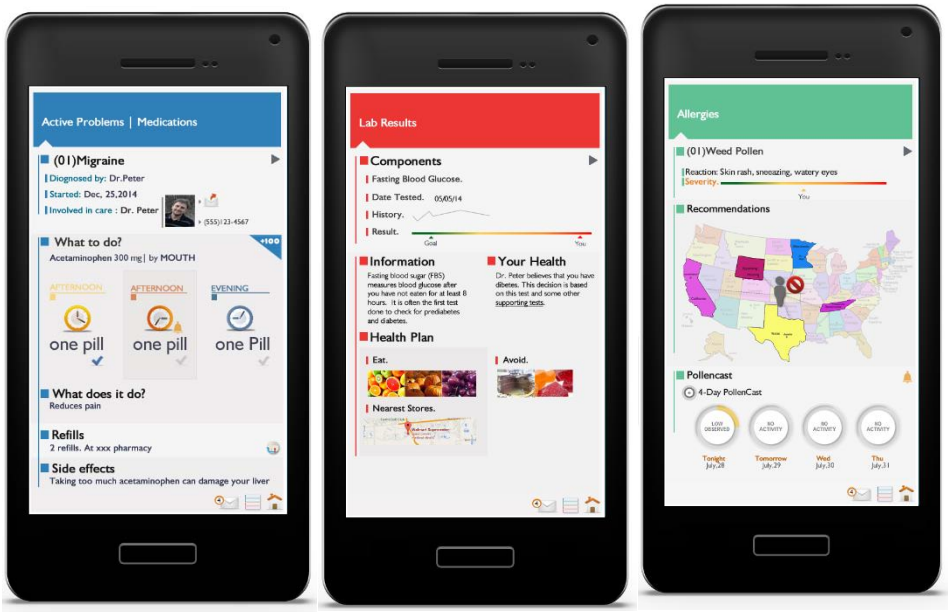

Figure 1. Some examples of UHealth's potential features empowering users and promoting healthier living.

The first image highlights a patient's ailment and the corresponding medication, pill dosage, and information for managing this ailment. In the second image, helpful hints and suggestions are given to the patient to help them manage a potentially healthier lifestyle. The third image provides users with their current location and awareness of potential health issues that may occur in that area due to their sensitivity to pollen, in this case [a].

Strengths and Weaknesses of Our Solution

Strengths

Our solution has several strengths over current features available in current patient portals that may increase the perceived benefits and actual use of patient portals. We are promoting greater occurrences for patients, their families, and providers in communicating and documenting health issues with one another in an asynchronous and synchronous way. This enhances the quality of the patient care experience for all involved in the patient care process.

UHealth also provides users with a more customized experience, not only by their own additions of health information, but also by giving them suggestions, motivations, and notifications on health choices, and use of a geographic information system (GIS) to help guide potential changes in health management. The suggestions and notifications would be generated from verified health-related resources and the motivations (*e.g.*, points earned for medication adherence towards a prize of the user's choosing) all help to promote trust in the system as it may better fit the user's needs and perception of the app's benefits.

In addition, UHealth is device agnostic, meaning it can be accessed in mobile format (*e.g.*, mobile phone or tablet) or over the Internet on a desktop computer. Being device agnostic helps the user to have the option to have their health information with them at all times (*i.e.*, mobile phone) or at their convenience on a larger screen (*i.e.*, desktop computer). Having the option for the extent of the app's convenience to the user can enable users to get a reminder for a medication refill and the closest location for the pharmacy based on the user's current location.

[a] More in depth explanations of UHealth's features can be found in our accompanied interactive PDF.

Weaknesses

A potential weakness of our solution is the amount of data exchanged through the app that might make users wary of how secure their information is within the app. Our attempts to mitigate these concerns include providing the users an option in the "Settings" tab to selectively restrict when or where their location status can be pulled by UHealth and by having all information sent and stored using a 256-bit AES encryption and Secure Socket Layer (SSL) transmission. Our solution may also not provide as much of a benefit to those that are less inclined to use technology or do not have an easy access to it. In addition, we must verify that we have correctly met all of the users' needs

Implementation and Dissemination Plan

Patient portals can be very beneficial to patients, patient's families, and providers, therefore, it is important to provide all users easier accessibility and knowledge of the product. Implementation and dissemination of our UHealth app has the following goals: 1) to promote downloads of UHealth and 2) to facilitate use of UHealth. In order to accomplish these tasks, suggestive marketing strategies will be used to increase UHealth's attractiveness to patients.

UHealth Application Downloads and Initial Use

The first step is to get UHealth into the hands of patients. When a provider sends email reminders for a checkup or appointment, a QR code or the UHealth logo can be included in the reminder that will direct the patient to go to the Google Play Store or Apple AppStore to download the patient portal app onto their smart phone. This information will also help to guide patients to UHealth's corresponding online app. In addition, providers can also include the QR code or UHealth logo on their business cards to be distributed to current patients and their families or potential patients. In addition, fliers with the main features offered by the UHealth app could be available in the provider's office for the patient's perusal during their appointment. These business cards can be attached to forms that the patients may need to fill out to update their personal information on file at the office.

Another possibility to promote downloads and initiate use is to incentivize downloads of UHealth. For instance, if a patient downloads the UHealth, they can be entered into a raffle to win a $50 gift card at their local grocery store or a free gym membership for a month. These incentives can further promote use of the features found in the UHealth patient portal such as the suggestions for healthier food substitutions and local grocery stores that may carry these items. With a gift card to that store, patients may find it easier to locate and purchase these foods and maintain healthier eating habits.

Verifying UHealth Use and Obtaining Patient Feedback

The UHealth app is only effective in helping the patient if he or she is using it and can tell where improvements are being made. Every two months, patients will receive an email or smart phone notification encouraging them to keep using UHealth. These alerts are meant to be non-invasive, but are also utilized to help increase adherence to using the patient portal on a regular basis. These notifications will also provide a healthy suggestion corresponding to a relevant health concern of the patient's. Acknowledging the notifications will provide the users with another chance to enter a raffle to win a gift card to a restaurant providing healthy food options.

Additionally, when patients return to their providers for another appointment, the providers or staff could ask them if they have downloaded UHealth. If the patient has not downloaded the app, they will be given the business card with the QR code and instructions on how to download the app. If the patient has downloaded UHealth, the patient will be given a comment card with the patient's contact information on one side and a space for comments on the other side. While the patient is updating his or her information, they can give their feedback on the comment card and put it in a drawing for another health-related prize. By obtaining patient feedback, we are both driving the dissemination and potential use of the app and motivating the iterative design process of UHealth to better answer patient's needs in their patient portals.

Moreover, patients could be asked to bring in the app, if they have already downloaded UHealth on their smart phone or as a print out if they prefer another mode of technology, in order to help assist the patient and provider communication during the visit. This can also potentially promote patient portal adherence.

Evaluation Plan

In order to gauge the effectiveness of UHealth, much analysis is needed. First, we must determine how many patients consistently use the app. By using the number of responses from the feedback cards or downloads of the app from Google Play Store or Apple AppStore, we could verify how many people downloaded and continued to use the app.

Secondly, to gauge how this app directly impacts the patients, before speaking to each patient, the provider could see if the patient has downloaded UHealth on the patient's EHR patient file. At the next visit, the doctor could also review the patient's current health compared with the prior visit and determine how many of the patients that used UHealth were healthier over time compared to the patients that did not use the app.

We will also ask all of UHealth's users to provide feedback on the app and fill out a System Usability Scale (SUS) survey in order to determine the subjective impression of satisfaction on the app[9]. The SUS is a ten question established survey traditionally used to provides a quick assessment of the app or device's usability[9]. Coupled with the feedback from all of the users, we can determine how well UHealth meets users' needs and how usable it is. Any omissions or extra features that are not required by the users' needs or tasks will be modified and pushed through to the next iteration of the app.

Additionally, we could implement an evaluation plan based on the Scenario Walkthrough and Inspection Method (SWIM) which is a method to characterize the technical, psychological, organizational, social, and economic outcomes of a collaborative system[10]. This method requires four parts. First, a requirements analysis must be conducted on all of the users and tasks that they might have to accomplish when using a patient portal[10]. This can be accomplished through ethnographic observation of the users. Second, scenarios that users currently must undertake in order to complete functions in the patient portal will be acquired as well as scenarios users wish to have will be collected through semi-structured interviews and coding of the scenarios and needs or claims by the users[10]. Third, these scenarios will be validated with both individual users and groups of users through focus groups[10]. Lastly, the results of the scenarios in relation to the claims stated by the users will be analyzed while keeping in mind the user's role, the task goal, system's features, and scenarios[10]. All four steps would be completed during the pre-UHealth implementation and during the post-UHealth implementation, six months later. A comparison of the patient care factors and user's responses will be analyzed.

Conclusion

Patient portals have the potential to help patients, their families, and providers impart more effective care and better management of health. Here, we have suggested a potential solution that is accessible across multiple platforms incorporating elements of CSCW, Persuasive Technology, and UCD as well as a potential implementation, dissemination, and evaluation plan to verify its viability. UHealth is a potential solution that may positively influence and increase use of patient portals.

A Patient Portal for Clinical Trials: Towards Increasing Patient Enrollment

Maurine Tong[1] and Mary McNamara[1]
[1]Department of Bioengineering, University of California, Los Angeles

Abstract

Clinical trials face delays due to the inability to enroll the necessary number of patients. A survey performed on cancer clinical trials demonstrated that American adults are willing to participate in clinical trials, however there is often an inability to recruit the required number of participants to a clinical trial study. To address this deficit, we propose an application that mines patient records, to extract diagnoses via ICD 9 codes obtained by natural language processing (NLP), and links patients with clinical trials relevant to their diagnoses. The patient portal searches relevant clinical trials tailored to a user's personal demographics, allows users to save trials from previous searches, provides a medium to initiate contact with a recruiter prior to enrollment with a click of a button, and presents additional information targeted towards patient needs such as options for continued care, cost of participation and required appointments and procedures. We theorize that this application will improve patients understanding of clinical trial information and potentially increase enrollment rates.

Introduction

Failure to recruit the required number of participants to a clinical trial is a significant hurdle impeding clinical trial research[1]. Achieving the required numbers of patients is necessary to ensure statistical power and that results will be applicable to populations outside the clinical trial participants. The failure is not due to a participant's unwillingness to enroll. 32% of American adults surveyed indicated they would be very willing to participate in a cancer clinical trial if asked to do so and an additional 38% of adults are inclined to participate in a clinical trial if asked, but hold some questions or reservations about participating[2]. The primary problem with accrual of patients is due to the lack of awareness of an appropriate clinical trial[3]. Specifically within the domain on cancer, less than 1 percent of cancer patients enroll in clinical trials. In addition, while over a third of the U.S. population identifies as a minority, less than 1% of those enrolled in cancer clinical trials are minorities. In comparison to other types of cancer, lung cancer patients are less likely to enroll in clinical trials than other cancer patients[3]. Although the average age of a person diagnosed with lung cancer is 71[4], patients over the age of 64 are underrepresented in clinical trials. A lack of participants affects research quality. A diverse group of participants is needed to design effective therapies[3,4].

The emergence of the internet has brought new opportunities for patients to be more active in their care. A particular group of patients, cancer patients, have been shown to utilize medical information online. A survey of a group of patients' self-reported Internet use before and after the diagnosis of cancer found that use of the Internet either directly (i.e., patient themselves doing the research) or indirectly (i.e., someone else searching for the patient) increased[5]. Similarly, another survey of cancer survivors, cancer patients, and patients with no history of cancer found that survivors and cancer patients tended to have a more positive view of electronic health records (EHRs) and the potential for access to its contents, as well as Health Information Technology (HIT) in general[6].

Across patient types, patient portals are being implemented[7-10], and are likely to become commonplace. Patient portals allow patients to electronically access health information managed by a healthcare institution. This is in part driven by the paradigm shift from patients as recipients of care to active members of their healthcare team. Portals are documented as having the potential to help patients make care decision[11]. They also contain the potential for patients to make health decisions that benefit others in addition to themselves, such as staying abreast of public health campaigns or enrolling in clinical trials.

Background

Other attempts to increase clinical trial enrollment use more traditional forms of patient outreach, including: using physicians as the contact point and the distribution of public services messages (e.g., T.V. and radio commercials) [12]. Previously, an EHR, the clinical counter-part of a patient portal, had been enhanced to alert physicians when they were treating a patient that fit clinical trial recruitment criteria[1]. The enhanced EHR resulted in a significant increase in the number of clinical trial referrals a physician wrote, and the number of patients who enrolled in a trial.

Similarly, in an intervention where patients were exposed to educational content about clinical trials[12], patients had a more positive attitude regarding enrolling in clinical trials after they watched an educational video.

While other efforts have helped to increase the number of patients enrolled in a trial, they do not provide a platform for disseminating clinical trial information directly to patients across trial types and patients. Using doctors to recruit patients does not enable patients to search for trials on their own. The website ClinicalTrials.gov does allow for patients to search for trials, but does not provide a means to contact the recruiter via the site, or make inclusion criteria explicit. Nor does ClinicialTrials.gov let patients save information about trials, enabling them to review the information later, and compare trials to one another. Using other media to educate patients about clinical trials as seen in Nelson 2013[12] can only provide either general information on the subject of clinical trials, or information about one specific trial. Our application provides specific information about trials, including inclusion criteria, and allows for the user to communicate with recruiters. Our application enables patients to refer back to clinical trial information at a later time and to compare trials. Providing this level of detail and the ability to save and compare trials empowers patients, encouraging patient involvement based on the information they have received.

Proposed Implementation

I. System Architecture

Our proposed system provides a link between the patient's clinical data and relevant trials from ClinicalTrials.gov. The portal is intended to summarize patient information already disclosed to the patient, highlight aspects of this information, and rate its relevancy to current clinical trials. The system architecture is shown in Figure 1. The portal fetches the required patient information. Personal medical record information is automatically searched, and ICD-9 diagnoses codes are annotated from patient reports. The extracted features (age, sex, diagnoses) are stored in a database on the server. These features are submitted to ClinicalTrials.gov and the search results are returned to the portal database. A user can access the patient portal page with the appropriate authentication. Upon logging in, a dynamically generated HTML page will display relevant clinical trials based on the search criteria of extracted features.

II. Components of Patient Portal

The main components of our patient portal are as follows (Figure 2): (1) a panel summarizing diagnoses extracted by the NLP system; (2) a panel displaying a ranked list of relevant clinical trials tailored to the patient based on age, sex, and diagnoses (these filters can also be removed); and (3) a panel summarizing the clinical trials that a patient has flagged as "of interest," each with a requirement checklist provided by the recruiter.

(1) Extracted Diagnosis

NLP modules are used to identify extracted diagnoses. A candidate list of health concerns is automatically extracted from the summary or conclusion section of radiology, pathology, or physician reports using the Mayo Clinical Text Analysis and Knowledge Extraction System (cTAKES) natural language processing (NLP) software in combination with Systemized Nomenclature of Medical Clinical Terms (SnoMED-CT) terminology[13]. Negated health concerns are deleted from the final set using cTAKES integrated negation detector. Examples of extracted diagnoses include tumor, chronic obstructive pulmonary disease (COPD), and smoking status in 5-predetermined categories. The final list of extracted diagnoses is displayed in the My Diagnoses section, and each diagnosis can be clicked on to see its definition. These diagnoses are also used as search terms to retrieve relevant clinical trial results.

(2) Relevant Clinical Trials

The query is performed using the search engine from ClinicalTrials.gov. There are preset filters on the left-hand-side of the webpage to identify clinical trials based on age, location, and conditions. Initial search results will also utilize the diagnoses extracted from the patient's medical record that are listed in the My Diagnoses section. The user can click on trials within the Search Menu's results (Figure 2, Module 2A) to see a trial's details displayed in the Clinical Trial Information Panel (Figure 2, Module 2B). At the top, Clinical Trial Information Panel summarizes general information including the condition, intervention, and primary outcome. In the middle of the panel, a table displays the inclusion and exclusion criteria organized by category and compares each criterion to the user's

characteristics. User characteristics are extracted from defined fields within the EHR. Other characteristics can be manually entered by the physician or the user. At the bottom, the panel summarizes to the user whether the user is eligible for the study based on initial search results.

Within the Clinical Trial Information Panel there is a Contact the Recruiter interactive button (Figure 2). The Contact Recruiter button lets the user send an email to the primary investigator to request more information about the trial. This request message also contains the patient's original search criteria (age, sex, diagnoses), to help the recruiter to determine how eligible the patient is for the trial in question. The recruiter requests more information regarding eligibility from the patient using the Determine Eligibility form (Figure 4) and can then reply with the additional Clinical Trial Requirements form (duration of study, cost of study, compensation, number of visits, etc.) (Figure 5). The Determine Eligibility and Clinical Trial Requirements forms are dynamic, based on the trial criteria. When the patient returns the Determine Eligibility form via the portal, the recruiter has extra information, from which to assess the patient's eligibility. This user and recruiter communication workflow is seen in Figure 3. The Add to My Clinical Trials button takes the current selected trial and adds it to the patient's My List of Clinical Trials (Figure 2 Module 3B). Although the Clinical Trial Requirements form has not been standardized, past research suggests patients are interested in learning about the cost of trials, additional tests, and follow-up care for trials[2]. Our evaluation will assess whether these information interests hold true for patients. The Clinical Trial Information Panel also contains a Request a Brochure interactive button. This button sends a request for a general overview of the study, similar to the hardcopy brochures available on clinical trials currently. Using the Request a Brochure button takes the current selected trial and adds it to the patient's My List of Clinical Trials, which is updated with the brochure content provided by the recruiter.

(3) My List of Clinical Trials and Menu Bar

This panel displays all trials selected by the user. After a trial is added using the panel above, the trial is indexed in the Clinical Trial Menu Bar (Figure 2, Module 3A). The Clinical Trial Viewer (Figure 2, Module 3B) is populated with additional information provided by the recruiter in the Clinical Trial Requirements form, such as cost of participation and any compensation; and requirements of the trial, including intervention, follow-up requirements, and options for continued care. The purpose of this panel is to track the details of each clinical trial study prior to the initial meeting with the recruiter.

Within the Clinical Trial Menu Bar, a user can check the status of each trial and perform actions if necessary. Each tile contains a customized name given by the user, and the title of the trial. The status is displayed in green (i.e., Complete Form), demonstrating that action is necessary; or red (i.e., Awaiting Recruiter Response), demonstrating that no action is necessary. A user can scroll through the tiles and click on one to populate the Clinical Trial Information Panel (Figure 2, Module 2B) and the Clinical Trial Viewer. Before enrollment, the Clinical Trial Viewer displays the checklist of steps required. After enrollment, a distinction is made between steps completed, such as initial visit completed, and steps remaining, such as follow-up appointment (not shown). The user can also export the list, print it out, and show it to their physician for more input.

Proposed Evaluation

We designed a patient portal to improve understanding, perform queries more easily, and facilitate communication. To determine if users report improved understanding, we will conduct usability testing of the portal. During this usability test, patients will compare the search results of the portal to the status quo, ClinicalTrials.gov. This usability testing will be a two arm cross over test. Patients will be randomly divided into two groups: Group A and Group B. Group A will first use our designed portal and then the website ClinicalTrials.gov. Group B will use the website ClinicalTrials.gov and then the portal. Both groups will complete a questionnaire (Table 1) after each step, based on the survey by Wu 2013[14], to determine which format they found better improved their understanding of what clinical trials were applicable to them, and which format they found easier to use.

In addition to a usability study, patients will also be followed for one year via email to determine rates of participants' enrollment in clinical trials. To do this, patients will be sent an email twice, once six months after completing the usability study, and the second time, twelve months after, to ask if they have enrolled or attempted to enroll in a clinical trial. They will be asked if they have enrolled or attempted to enroll, as some patients may try to enroll but find themselves disqualified.

Perceived Usefulness	
1	Using this portal/website can make me accomplish clinical trial information tasks quickly.
2	This portal/website is useful to manage my clinical trial information.
3	Using this portal/website can increase my productivity in managing my clinical trial information.
4	Using this portal/website can enhance my effectiveness in clinical trial information management.
Perceived Ease of Use	
5	This portal/website is easy to learn how to use.
6	This portal/website is easy to operate.
7	It should be easy to become skillful at using this portal/website.
8	This portal/website is not difficult to use.
Patient-Researcher Communication	
12	Using this portal/website can assist my communication with clinical trial researchers.
13	Using a portal/website can assist the communication between patients and clinical trial researchers in general.
Health Information Understandability	
14	Using this portal/website can improve my understanding of what clinical trials are relevant to me.
15	Using this portal/website can improve my understanding of a trial's inclusion and exclusion criteria.

Table 1. Usability Test Survey

Discussion

This portal allows for patients to search for clinical trials that match their demographics (age and sex) as well as diagnoses found in their medical records. While this portal can be used to directly provide patients with clinical trial information, future work can include integration with a tool like the enhanced EHR in Embi et al. 2005[1]. The enhanced EHR interface could add the function of letting a physician send a message to a patient regarding a trial that matches their criteria. Patients could then access these messages via this portal, with each message linked to the trial information provided in the Relevant Clinical Trials list.

Limitations of this work include the reliance on NLP to extract all diagnoses from the patient's medical records, the assumption that patients want these types of information on clinical trials, that recruiters will spend time filling out additional forms to provide patients with more information, that there is the potential to increase primary care physicians workflow should patients need help filling out the Eligibility Criteria form, and the difficulty in mapping ICD9 codes to eligibility criteria. While cTAKES has been used to extract findings from patient records[9], it may not prove as accurate in this domain. In the event that NLP does not capture all of a patient's diagnoses, manual entry and review by a physician will be necessary. This process can be streamlined, with the physician reviewing the annotations made by the system, to determine their correctness. The portal provides additional information to the patient to assist with making a better informed decision. However, a usability study is needed to better assess the types of information patients want. Results from the study will be used to refine the information visualized in the portal, to better reflect patient information needs and preferences. The portal clearly matches eligibility criteria with a patient's characteristics. However, there is no definitive mapping between ICD9 codes and eligibility criteria. A translation is needed between EHR vocabularies and their corresponding eligibility criteria.

A considerable contribution of this portal is it provides additional screening to find more patients with a higher chance of eligibility. However, additional tasks added to the recruiter workflow are a considerable effort to make. While there is a startup cost, these additional tasks can save time in the end. Creating these forms one time can help to save time later in the recruitment process, allowing for some of the patient-trial matching to occur asynchronously. Similarly, while some patients may need the help of their physician to fill out the Determine Eligibility form, this request could also be accomplished online, with an additional feature added to the portal to forward the form to the patient's physician.

Future directions for this work include: the usability study mentioned above, integrating this portal with an EHR system, and providing a dictionary within the portal to define difficult terms for patients. Integrating this portal with an EHR would have the benefits previously mentioned of allowing practitioners to flag relevant trials for patients,

and allowing patients to request help filling out the Additional Criteria form. A dictionary of clinical trial terminology with patient friendly definitions could be used to provide scroll over definitions within the portal.

Conclusion

The presented patient portal provides a solution to assist patients with finding an appropriate clinical trial. The portal automatically populates a search function with a patient's criteria and formats the results in tabular format alongside the patient's characteristics. Compared with the visualization for ClinicalTrials.gov, the presented patient portal's visualization filters information to present only what is relevant to user's diagnoses. It also provides information on care, financial, and scheduling, to assist patients deciding what trials fit their needs. In addition, a user can initiate and track communication with numerous recruiters to find the best clinical trial for them. Provision of this information can increase awareness and understanding of the clinical trial enrollment process, increase communication between recruiters and patients, and potentially increase rates of enrollment.

Drawn Together: Enhancing Patient Engagement and Improving Diagnostic Tools through Electronic Draw-and-Tell Conversation

Deborah Woodcock MBA, Steven Williamson, Dana Womack MS,
Kimberley Anne Gray, Kate Fultz Hollis MS, Michelle Hribar PhD
Department of Medical Informatics & Clinical Epidemiology
Oregon Health & Science University, Portland, OR

Summary

Pediatric health professionals are able to assess children quickly and accurately when the children are engaged and empowered during an encounter. Research has shown that it is beneficial to have children draw their health-related symptoms and/or experiences before they speak about how they're feeling. However, capturing these children's "draw-and-tell" conversations in the electronic health record (EHR) has been challenging. We propose the creation of a mobile application ("app") named DrawnTogether™ that achieves this objective. An interactive prototype of DrawnTogether can be accessed at http://drawntogether.cooperativework.com/demo/ (please use patient Jane Smith).

The Challenge

Delivery of patient-centered care depends on the ability of providers to understand and respond to each individual's unique preferences, needs, and values[1]; eliciting and acting on this information requires providers to engage patients directly during an encounter's three primary activities: relationship-building, information exchange, and decision making.[2] These activities occur with all patients – including children.

While adults can speak directly with their healthcare providers, young children (ages 5-10 years) cannot. This does not mean that they are incapable of expressing themselves. Instead, they need a more child-centric approach to improve patient-provider communication. There are few of these approaches, so many professionals continue to defer to the child's parents, asking them to speak for their child.[3,4,5] Yet, no matter how well parents believe they know their child, they cannot fully represent the child's perspective and often relay a different story than the one told by their child. (Driessnack M 2014, personal conversation, May 15) Further, many of the current communication aids for children were originally developed for adults and later adapted for use with children by adding pictures or simpler language. For example, when children are asked to rate their pain, they are provided with a pain intensity scale of 1-10, accompanied by pictures and simple language. This is inappropriate for children as they do not yet have the cognitive skills to understand or use a scaled tool.[6]

The power of illustration. Children between 5 and 10 years of age communicate more accurately and completely when they are able to create drawings first, before they are asked to express their thoughts, feelings, and physical sensations. This child-centric approach capitalizes on children's (rather than adults') cognitive strengths.[7]

The Draw-and-Tell Conversation (DTC) approach has been shown to be an effective technique for capturing children's descriptions of their health experiences, offering insights not otherwise gained from existing tools. During the DTC, the healthcare professional invites the child to first draw how s/he is feeling, and then describe the picture. The drawing can be created on paper or electronically (e.g., using a tablet); regardless of the method used, the drawing's purpose is to facilitate the child's narrative. [6,7] However, storage and retrieval of children's drawings and accompanying narratives has proved challenging. (Driessnack M 2014, personal conversation, July 11)

Design objective. We chose to focus on the challenge of improving child-provider communication in patient-centered care. Our efforts center on the creation of a mechanism that allows for the active engagement of children at the point of care, facilitates relationship building, improves information exchange between the child and their providers, and makes it possible to incorporate child-generated data into decision making. Specifically, we endeavor to assure that children's drawings and narratives have a place both at the point of care and in the EHR.

Design Process

To understand the problem and deliver a solution, we decided to build a prototype on existing DTC research that served as an initial needs assessment, and to utilize rapid application development (RAD) software development concepts such as prototyping and frequent user involvement throughout the design and construction process. (RAD is a design philosophy that continuously incorporates user feedback to arrive at a solution more quickly than traditional "waterfall" methods.[8])

Problem definition and validation. In June 2014, Dr. Martha Driessnack, a researcher and developer of the Draw-and-Tell Conversation technique, presented an overview of her research as well as the clinical informatics challenges she continues to encounter. Through subsequent discussions with Dr. Driessnack and a review of her published research, the team identified electronic support for DTCs as the focus for the design challenge. The team ascertained the key stakeholders are children, parents, pediatric care providers and staff, and clinical informaticians.

Requirements planning. Once the problem had been defined and stakeholders identified, we further distilled design principles and workflows (Supplementary Materials Exhibits 1 and 2) and conducted a secondary qualitative appraisal of stakeholders' needs by observing Dr. Driessnack conducting DTCs in person and on video. To more deeply understand the clinical problem, team members held informal DTCs with children in their families, and conducted an extensive review of pediatrics and informatics literature (Supplementary Materials Bibliography).

User design and evaluation of application. Finally, we synthesized the design principles, observations, and literature reviews, brainstormed solution alternatives, and determined which option to develop. Representing the solution using interactive web-based prototypes (Supplemental Materials Exhibit 3), the team conducted 13 evaluative interviews to discover needs and solicit ideas from a wide variety of stakeholders (Supplemental Materials Exhibit 4), and iterated the design daily during development.

Evaluation of Possible Solutions

The team considered five different approaches for supporting DTC: 1) drawing on paper and storing in a paper chart; 2) drawing on paper and scanning into the EHR; 3) drawing using an existing mobile app; 4) using the EHR's image and annotation functionality for drawing and storing; and 5) creating a new custom mobile app. Table 1 highlights key points of comparison among these alternatives considered by the team, based on the design principles and clinical requirements we identified.

Paper creation and storage has the benefit of being low cost and low tech, but presents storage and retrieval complexity. Scanning drawings could also work, but requires more workflow steps than an app. We considered use of off-the-shelf drawing tools, but the lack of support for annotation and metadata limits their utility. EHR functionality could be extended, but requires prioritization by a vendor. Custom App Creation & Digital storage of DTC was selected because it meets all key requirements.

Proposed Solution

The proposed solution, DrawnTogether, is a mobile application that supports the capture, creation, and curation of children's drawings and, more importantly, their accompanying narratives. The name DrawnTogether reflects the linking of drawing and narrative, as well as the linking of child to provider. It is expected that children, who are now exposed to apps and devices at young ages, will find using DrawnTogether engaging, intuitive, easy to use, and fun. Based on DTC research, [6,7] we anticipate that providers using the app will be able to gather more complete and accurate information from children in the same amount of time that it would take to record a history. However, as Dr. Driessnack has shown, use of a DTC not only provides more information, but also provides information that is specific and insightful, thus having the potential to shorten time to diagnosis. Further, because visual and verbal information are brought together in DrawnTogether and accessible in the EHR, we also believe that the app will reduce the time providers spend locating and associating DTC information from multiple encounters.

DrawnTogether can also be used by parents, who can ask their child to make a drawing at home (pre-visit), while they are in the provider's waiting room, or during the office visit before the provider arrives (Supplementary Materials Exhibit 2). For maximum flexibility and widest distribution, the app is envisioned as separate from the EHR and available for multiple mobile platforms.

Table 1. Methods considered for creating and capturing drawing and narrative.

	Paper Creation & Storage	Paper Creation; Scanned Storage	App Creation; Digital Storage	EHR-Based Creation & Storage	Custom App Creation; Digital Storage *(selected approach)*
Supports paper drawing creation	Y	Y	N	Y	Y
Supports digital creation of drawings	N	N	Y	Y	Y
Digital image + text capture, storage, and retrieval	N	N	N	Y	Y
Child-friendly (intuitive, easy to use)	Y	Y	Y	N	Y
Touch-based "pinch and zoom" capability	N	N	Y	N	Y
Accessible by all users in home, ambulatory, acute settings	Y	Y	Y	N	Y
Ability to view image and text concurrently in EHR	N	N	N	Y	Y
Ability to view images and text sequentially over time	N	N	N	N	Y

The app will include the following features:

- **Zoomable touch screen for creating original images**. The drawing interface provides touch screen controls consistent with other drawing apps available for children.
- **Image capture of paper drawings.** For situations where touch screen drawing isn't desirable or available, children can draw using paper and art supplies and then take a picture of the drawing with the app. The image is loaded into the drawing screen, so additional markup can be done when the child discusses the drawing with their provider or parents.
- **Text entry for the drawing narrative**. The drawing interface provides an area for entering notes about the child's narrative. This part of the DTC is essential; the drawing cannot be saved or shared without an entered narrative.
- **Audio capture of child's narrative**. The app provides an audio recording feature that may be used when a child is describing his or her drawing. This is helpful for capturing the child's own words and speech characteristics. Because the text narrative is still important for sharing and retrieval within the EHR, the audio capture is not intended to replace text, but rather augment it.
- **Labeling with keywords and diagnoses**. Since the drawings and narratives will be referenced over time, the ability to label them with metadata is important. Doing so enables searching and easy identification of drawings in the future.
- **Display of all drawings done by a patient**. The app has a gallery feature that displays thumbnails of all drawings for easy retrieval of images. The gallery is also a way for children to view past artwork.
- **Upload the drawing and narrative or narrative only to the EHR**. The app sends the drawing and narrative to the EHR through a feature customized for each EHR: these might be as an image attached to a SOAP note; as a separate screen for DrawnTogether files (similar to the Media tab in some EHRs); or as a cloud-based web service. The app will also be built using the SMART-on-FHIR platform in anticipation of the FHIR standards for plug and play EHR applications in the future.[8]
- **Provide security and privacy controls for the app**. For the provider version of the app, authentication is required for accessing the app and for searching and accessing patients to ensure that patients drawing with the app won't be able to search or load another patient's drawings. The data from the app will be fully encrypted

using Advanced Encryption Standard (AES) and the app will be compliant with institutional protocols for secure tablets and mobile devices.
- **Provide online resources and support for the app.** The app will have a website (currently http://drawntogether.cooperativework.com) that provides tutorials on how to use the app, information about DTCs, and suggestions for incorporating the app into clinical practice.

The team believes DrawnTogether will provide a robust electronic method for initiating, annotating, retrieving, and sharing DTCs. In the initial 13 interviews, our stakeholders found the functionality of the app to be sound, but also identified challenges for its adoption, including:

- **The required tablet or smart device may not be available in clinics.** There is a workaround for this: the child can still use paper to draw and discuss their pictures while the provider can use a smartphone to capture the image and enter the narrative text.
- **Providers may not view the process of drawing as a worthwhile use of increasingly limited time available for encounters.** This can be addressed by allowing children to start their drawings before the provider is in the room, so they are ready to discuss them once the provider is present. The mobile app will allow flexibility: the drawing need not be done at the same time it is discussed. In addition, children and parents can create drawings and narratives at home that can be shared later with the provider. It is the team's hope that distributing the app to parents as well as providers will encourage the use of DrawnTogether in a clinic setting.
- **Providers may not feel confident about their ability to use DTC in their clinic practice.** A few of our stakeholders expressed concern about their ability to use the technique; specifically, they did not feel qualified to interpret the child's drawings. Since DTC does not require the provider to interpret the drawings, but rather involves listening to the child's interpretation and incorporating it into their assessment, we felt the best way to address this concern is to provide educational support during the implementation phase and through the website materials.

Implementation, Evaluation and Dissemination Plan

It is expected that many pediatric care clinics will benefit from use of the DrawnTogether app. Widespread implementation and clinical adoption requires a multi-phase implementation and dissemination plan encompassing pilot implementation with evaluation and publication of findings, development of an implementation toolkit, and educational campaigns. Once clinical effectiveness of the technique has been demonstrated, collaboration with the American Academy of Pediatrics to include electronically supported DTC in guidelines for pediatric medical homes is a suggested strategy to encourage widespread adoption.

Pilot implementation. Initial implementation of DrawnTogether will occur in a single pediatric clinic focused on management of children with chronic headaches. Stakeholders (children, parents, pediatric care providers and staff, clinical informaticians) will be engaged in all aspects of the pilot implementation. Change management will be supported by stakeholder education regarding the value and utility of DTC, and a communication plan will ensure that all stakeholders are engaged throughout the implementation. We have developed initial workflow recommendations (Supplementary Materials Exhibit 2), but local workflow redesign will be accomplished through observation of the local "as-is" visit workflow and subsequent redesign for the "to-be" workflow at each site, with stakeholder-led review and refinement. A technical readiness assessment will include software testing of the DrawnTogether app, integration testing to ensure that drawings and annotations accurately flow to the EHR, and security testing to ensure patient privacy and confidentiality. Software and workflow training will be provided to all end users, and plans for go-live will be communicated to clinic staff and patients/parents. On the day of go-live, extra staff will be on hand to provide user support and remediation training.

Pilot evaluation. Evaluation of the DrawnTogether pilot implementation can occur as follows: At the end of each DrawnTogether-supported visit during the pilot, patients/parents will be will be asked to answer a short set of questions focused on their perceptions of the ease of use of DrawnTogether, its value in facilitating child-provider communication, and its effect on child empowerment. Provider and clinical staff evaluation will occur via a post-pilot debrief/interview session to elicit experiences, perceptions, and suggestions regarding the use of DrawnTogether. Providers and clinic staff will receive a quantitative survey to elicit their perceptions of ease of use, value in facilitating child-provider communication, and value of incorporating child-contributed data in the EHR. Evaluation findings will be published in the professional literature to promote broader awareness of the innovation.

Application and workflow refinement: Consistent with a continuing RAD process, user feedback and findings from the pilot evaluation will be used to further refine the DrawnTogether app, associated workflows, end user training, and implementation processes.

Implementation toolkit. The DrawnTogether implementation toolkit will include the best practices, learnings, and artifacts from the pilot implementation and subsequent application and workflow refinement. The toolkit will also include educational materials for providers, clinic staff, and patients/parents, as well as sample documents that can be used as templates for stakeholder identification, communication planning, workflow redesign, end user training, go-live planning, and post-implementation evaluation. Additional checklists for cultural, training, and technical readiness assessments will be available in the toolkit.

Outcome evaluation and dissemination. Evaluation will occur at multiple points along the path from pilot implementation of DrawnTogether to widespread adoption of digitally supported DTCs in clinical practice. In addition to evaluation of the application, we anticipate the need for broader evaluation of the clinical effectiveness of DTC and its impact on pediatric care outcomes. Outcome evaluation planning will commence after completion of the pilot, but may include development of valid and reliable survey instruments to collect perceptions of utility, value, and impact of DTC on child-provider communication by patients, parents, and providers. Valid and reliable instrument(s) for assessing the clinical impact of DrawnTogether (e.g., long-term pain management and quality of life of pediatric patients with chronic migraines) may also need to be developed. Findings from all studies will be disseminated via peer-reviewed literature and professional conference presentations. Future directions for research include using DrawnTogether for pediatric conditions other than pain management, and for additional populations such as adults with limited verbal vocabularies.

Additional educational campaigns. We recommend a broad education campaign targeting health professionals, parents, and children in support of a wider effort to encourage providers to adopt DTC for pediatric pain management as well as other conditions. The focus of the campaign should be on engaging children in their health care and highlighting the value of using drawn images and narratives to meet this need. The campaign would invite parents to download DrawnTogether on their personal devices for use at home, and/or to create images at home or in the waiting room to support provider conversations in the clinic.

Summary

DrawnTogether is a novel solution designed to improve child-to-provider communication, increase child engagement, and allow for inclusion of child-generated information in the EHR. The project team has enjoyed this student design challenge, and we look forward to moving this project past the design stage and into clinical practice.

The Use Of A Gamified Platform To Empower And Increase Patient Engagement In Diabetes Mellitus Adolescents

Guido Giunti, MD[1], Agustín Ciancaglini, MD PED[1], Carlos Otero, MD[1], Analía Baum, MD[1], Fernán Gonzalez Bernaldo de Quiros, MD[1]

[1]*Hospital Italiano de Buenos Aires, Ciudad Autónoma de Buenos Aires, Argentina*

Introduction

Effective chronic disease management can result in improved health outcomes and increased quality of life[1]. Such is the case that the World Health Organization has an indicator known as DALYs[2] (Disability Adjusted Life Years) to quantify the Burden of Disease from mortality and morbidity.

The International Diabetes Federation estimates that in the North American and Caribbean region there are close to 109 thousand children under the age of 15 with Type 1 Diabetes. In the United States it is estimated that the economic impact of this disease is such that a person with diabetes spends 2.3 times more than the average person's in medical expenditures[3]. In the South and Central America Region an estimated 45,6 thousand children under the age of 15 live in the region with Type 1 Diabetes[4].

Patients with type 1 diabetes are often diagnosed and start treatment at an early age. The incidence of type 2 diabetes among youth is increasing[5–8]. This is of particular concern because diabetes is a chronic disease that requires a high degree of adherence to the medical treatment plan through self-management[9–11], which may be difficult for youth of this age[12–15].So far, despite advances in technology that ease insulin delivery with pens or pumps, adherence to diabetes regimens is often problematic for patients of all ages, but most difficult for adolescents[16]. There are studies that show a lack of correlation between insulin regimen and glycemic control[17]. It is likely that self-care behaviors and educational models have substantial impact on outcomes and that increased attention to these factors may lead to improved blood glucose control. Finding ways to help adolescents engage in self-management is a critical issue[9–11].

Patient empowerment is the enhanced ability of patients to actively understand and influence their health status[18] and would be achieved through proper 'Patient Education'[19]. However, providing information alone, without the necessary incentives, does not insure a positive effect[20,21] as many young diabetic patients are well informed about their situation but don't act accordingly[22]. A systematic review of ecological interventions for health behavior suggests that the use of mobile technology-based ecological momentary interventions can be effectively implemented for a variety of health behaviors and psychological and physical symptoms[23]. Also, there is research that supports the integration of social elements to incentivize behaviors[24].

A challenging scenario

Younger generations are designated by some as ''digital natives''[25,26], for them, technologies such as personal computers, video games and mobile devices have always existed and are used as something that was always part of their lives[27]. Recently self-tracking has become rather popular[28]. Such self-monitoring and self-sensing can combine wearable sensors and wearable computing. There are already more than 1.08 billion smartphones of a total of 5 billion mobile phones around the world, with 80% of the population having a mobile phone[29]. There is great opportunity for mHealth in using these mobile devices and, in fact, a significant number of mHealth applications have been already developed.

Self-determination theory (SDT) is a macro-theory of human motivation that has been applied to identifying which factors sustain individuals' motivation within video games[30]. SDT postulates that the more often basic psychological needs for autonomy, competence, and relatedness are satisfied within a game context, making

both the experience more enjoyable and the motivation more sustainable[31]. There is also evidence that a meaningful and engaging narrative seems to help sustain engagement[32].

The use of game elements in non-game environments to enhance user experience and increase engagement is called Gamification[33]. This practice has been incorporated with commercial success into several platforms like Linkedin, Badgeville, and Facebook and this has led researchers to theorize that it could also be used as a tool to increase student engagement and to drive desirable learning behaviors on them[34]. Game elements provide engagement consistent with various other theories of motivation as well[35], such as positive psychology (e.g., flow)[36,37], and also provide instant feedback on actions. Feedback is more effective when it provides sufficient and specific information for goal achievement and is presented relatively close in time to the event being evaluated[38,39]. Feedback systems can be used to reference individual progress, make social comparisons, or they can refer to task criteria[40].

Our proposed solution

Taking the above into consideration we have proposed the development and use of a platform to promote self-management by enabling patients to monitor their condition and track their treatment adherence while creating positive feedback loops through game elements that reward desirable behaviors and provide health information.

Monitoring Aspects

Home telemonitoring (HT) represents a promising approach for enabling patients with chronic conditions to be followed up by clinicians more frequently, over longer periods of time, away from hospital settings[41–44]. Within the healthcare sector, apps are supporting the management of illnesses, thereby promoting health awareness and well-being[29,45,46]. Specifically, a multitude of apps have been developed to assist patients in the management of diabetes mellitus type 1 or 2[29,47].

The documentation function of the platform includes recording and monitoring of individual eating habits (eg, the bread unit intake); log the frequency of the user's physical activity and the individual medical therapy (type and frequency). Recording blood glucose values is another feature included although during the initial stages blood glucose values would only be inputted manually, a feature to transfer data wirelessly and automatically from Bluetooth measuring devices is scheduled for implementation. As El-Gayar et al point out[48], this will probably be an important driver for the perceived ease of use.

Integrating our platform with our Hospital's existing Personal Health Record (PHR) will allow the platform to extract previously stored data.

A detailed list of monitoring features can be found in *Appendix A. Table* 1. Features that require and benefit from PHR integration are described in *Appendix A. Table* 2.

Gamified Aspects

In order to incentivize adherence, a point system will be implemented based on operant conditioning and schedules of reinforcement[49–51]. A combination of different schedules of reinforcement will be employed. Continuous reinforcement takes place when the desired behavior is rewarded or "reinforced" every single time it occurs, this is used in order to create a strong association between behavior and response. In partial reinforcement, the response is reinforced only part of the time which causes the subject to continue trying. Learned behaviors are acquired more slowly with partial reinforcement, but the response is more resistant to extinction. There are different schedules of partial reinforcement based on the number of responses that have occurred (ratio) or the length of time since the last reinforcer was available (interval). These in turn can be either fixed or variable[49–51]

This point system provides feedback to patients in the form of different "scores", breaking the long arc of managing a chronic lifelong condition into smaller, more manageable units. Feedback loops are essential parts of all games, and they are seen most frequently in the interplay between scores and levels[52,53]. Levels and other progress mechanics such as "achievements" further add to this positive feedback loop. An assortment of visual elements will represent the different increments to the individual's point score.

Points System

Performing actions that are needed for managing their conditions will be considered a "required goal" and the patient will receive "points". "Points" will be rewarded based on Diabetes Mellitus' clinical and treatment objectives[54] with the possibility of customizing a patient's reward to specific activities to allow fine-tuning. During the patient's initial use points will follow a continuous reinforcement schedule (see *Appendix A. Table* 3).

An accumulation of a sufficient number of points increases a *patient*'s "Level", acting in this manner as a fixed ratio partial reinforcement. A "level" is a number that represents the patient's overall performance and treatment adherence. By gaining levels, patients will gain status and "achievements" within the gamified platform. The level progression is geometrical, to give the patient a better sense of progress and growth during the game. See *Appendix A. Table* 4.

Achievements System

"Achievements" are rewards to "optional goals" in the form of arbitrary challenges. These achievements may coincide with the inherent goals the treatment itself, such as having perfect adherence to the treatment for a specific period of time, or may also be independent of the clinical and treatment objectives, such as helping a fellow patient stick to the treatment. Achievements act as fixed-ratio or fixed-interval partial reinforcements (see *Appendix A. Table* 5).

Social Aspects

Social support is an important part of chronic disease management which is why we decided to include social elements to provide encouragement and positive feedback between users.

User Profile

Patients will have a User Profile which will aggregate information from the Monitoring Aspects and the Gamified Aspects. This is meant so that the patient can display his or hers Points, Achievements and Levels giving the user a "bragging rights" about how well they are taking care of themselves.

Whenever the user gets Achievements or Levels, that information will be highlighted on their User Profile. The user will have full control as to which information, whether it's personal, clinical or treatment related, becomes public through adjusting the user account settings. Information can be shared with anyone on the platform (public), only Friends or no one (private).

Friending and Groups

Friending is the act of adding someone to a list of "friends" on a social networking service. The notion does not necessarily involve the concept of friendship[55]. The act of "friending" someone grants that person special privileges on the platform with respect to oneself. Users will be able to cheer and like their friend's updates to provide encouragement.

Friends can invite other users to be part of a Group. Groups will have access to special Achievements and Points bonifications when all members meet their weekly goals.

Messaging and Commenting

Commenting and instant messaging are features common in Social Networks but it was decided against implementing them into the platform because of the difficulty of moderating polite behavior.

Patient Education

Diabetes education has largely been accepted in diabetes care. Our proposed platform provides the patient with health and wellness tips. These tips, also include interesting facts about the condition to increase the patient's awareness of the condition.

The content of the different Tips of the Day is developed by an interdisciplinary team of Pediatricians, Diabetologists, Child Psychiatrists and Patient Education experts to optimize communication. These Tips are less than 260 characters in length to keep the patient from feeling burdened with information.

The time of the day at which the Tips are displayed can be set by the patient and it's a feature that can be turned off. The patient can also explore the list of previously displayed Tips for later reference. A sample Tips of the Day can be found in *Appendix A. Table* 6.

Alternative solutions considered

There's been several tries to bridge the gap generated between prescription and patient compliance. A common theme among the different therapeutic approaches is the creation of a dynamic and interdisciplinary support framework for the patient.

Telemonitoring

Gómez el al.[56] describe the DIABTel telemedicine system to complement the daily care and intensive management of diabetic patients. There was a trend towards HbA1c improvement during DIABTel use with no incidence in the number of hypoglycaemias.

Bujnowska et al.[57] published a study where a telemedicine support system for diabetes management was compared with standard monitoring. There was no significant difference in haemoglobin A(1c) between telemonitoring and the traditional group of diabetic patients during the survey.

Family Environment

Wysocki et al.[58]'s work with Behavioral Family Systems Therapy for Diabetes (BFST-D) aims to assist parents and adolescents as they work on communication skills, problem solving, and minimizing family conflict in relation to diabetes. This paper showed significant improvement in the quality of family interactions, family communication, and problem solving with BFST-D.

Social Support

Grey et al.[59] studied a form of cognitive behavioral therapy that they called coping skills training (CST) in 12–20-year-olds with T1D who were beginning intensive insulin therapy. The authors reported better glycemic control and quality of life with the addition of CST to intensive therapy.

Peters et al.[60] shows that the adolescents with diabetes identified various supportive behaviors of friends, particularly concerning emotional support: treating them normally, showing interest, having fun, providing a distraction, and taking their diabetes into account. Fear of stigmatization and sense of autonomy withheld some adolescents with diabetes from soliciting more support.

Strengths and weaknesses analysis

The use of game elements as a way of motivating patients is an interesting approach as it provides patients with instant feedback and positive reinforcements. This, we believe, will allow patients to conceptualize their condition in more manageable units and will seem like a less tiresome task. Balancing the point system is a matter that requires cautions otherwise patients might place too much emphasis in obtaining points and feel inclined to exploit the system.

Integrating a home telemonitoring system with our Hospital's PHR adds value as the monitoring tool will not be a standalone device but part of a larger system that will significantly improve the quality of care offered to patients.

While reviewing the literature, however, we realized that at this time our platform lacks a way to allow family participation. This is the subject of an ongoing discussion within our team as to what would be the proper role and the right approach.

Although the alternative solutions are not without merit our platform attempts a more integrative approach to the patient's condition. An illustrative comparison between our platform's strengths and weaknesses against the alternative solutions explored can be found in *Appendix A. Table* 7.

Implementation and dissemination plan

Our Hospital's Chronic Disease Program (CDP), Department of Pediatrics and Endocrinology Service will work with the Healthcare IT department during the planning, structuring, software development and the process of implementation and validation of a pilot. Given possible legal and ethical implications both the Hospital's Legal Department and the Bioethics Committee will stay informed of the project's coming and goings.

Implementation of the platform will follow a three stage process. In Stage 1 we will perform a functionality test with 20 healthy adults in order to validate the process and operation of the platform. Stage 2 will consist of a pilot test with 20 teenagers assessing flow and ease of use, once this pilot test is completed we will move to Stage 3. Stage 3 involves the massive dissemination and large scale implementation of the platform to susceptible and willing patients.

Diffusion and dissemination of the platform will be carried out through the Hospital's usual channels of communication such as newsletters mailing, Hospital magazines, website, internal TV, etc. The use of other social media is being considered to capture the interest of adolescents participating in the study.

Evaluation plan

As this is a patient-oriented platform, their input and feedback is crucial. Once our solution is implemented the idea is to advance on several assessment lines. We will assess user satisfaction through a SUS questionnaire, and conduct qualitative studies using semi structured interviews. To optimize the processes of patient interaction with the tool and generate an intuitive and easy to use application, we will perform regular assessments of interface usability.

Finally, a randomized controlled trial will be conducted to evaluate clinical outcomes, based on clinical parameters involved in the protocol, in order to assess the platform's impact.

Sharing My Health Data: A Survey of Data Sharing Preferences of Healthy Individuals

Elizabeth A. Bell, MPH[1,2], Lucila Ohno-Machado, MD, PhD[1], M. Adela Grando PhD[3]
[1]University of California San Diego Division of Biomedical Informatics, [2]University of Minnesota School of Public Health, [3]Arizona State University Department of Biomedical Informatics

Abstract

We interviewed 70 healthy volunteers to understand their choices about how the information in their health record should be shared for research. Twenty-eight survey questions captured individual preferences of healthy volunteers. The results showed that respondents felt comfortable participating in research if they were given choices about which portions of their medical data would be shared, and with whom those data would be shared. Respondents indicated a strong preference towards controlling access to specific data (83%), and a large proportion (68%) indicated concern about the possibility of their data being used by for-profit entities. The results suggest that transparency in the process of sharing is an important factor in the decision to share clinical data for research.

Introduction

In parallel with the rapid accumulation of electronic health-related data, ethical considerations and public concern related to clinical data sharing for biomedical and behavioral research have been raised[1]. The debate on how ethical it is to use data and biospecimens—collected primarily for clinical care—for research purposes spans scientific, legal/ethical/regulatory, and patient circles. Many patients may not know how their data are being used for research. Some may receive a re-consent form, but this requirement can be waived by IRBs (institutional review boards) in certain circumstances. Consent is typically broad and binary (i.e., patients either consent or not), and tiered approaches to informed consent are seldom utilized. Innovative systems that inform patients about the current use of their data and allow them to select tiered opt-out options could offer an alternative to current practices. However, institutions may be hesitant to adopt such systems, since this might decrease participation in data sharing for research and potentially bias research results. The financial and political costs of implementing such systems, as well as their efficacy in terms of patient and provider satisfaction, are currently unknown. A recent survey indicates that many patients believe the use of electronic health records will improve care[2]. Technical obstacles also exist, as ways of ensuring compliance to patients' choices may be difficult to implement and upkeep. The ethical gains in implementing choices for patients, however, may justify the development towards systems of granular control should continue[3].

Input from patients may potentially drive future policies for data sharing. In Great Britain, an open consultation was launched in October 2013 to give citizens an opportunity to share their views about the collection, use, and analysis of their personal medical data. The goal of this initiative was to determine peoples' expectations towards privacy and anonymity, as well as to address the ethical concerns of the use of private information. Results are expected mid- 2014[5]. In addition, a leaflet campaign through the NHS system distributed information to all residents about sharing data to improve quality and care for everyone, and how they could opt out of such a system[6]. Reactions have been mixed: 4 out of 5 surveyed patients in favor of sharing their data yet there is suspicion and distrust for the project, and indications that the methods by which patients are invited to control their own medical records may impact their feelings about data sharing[7,8].

Some literature suggests that patients may want to have control over which institutions have access to their data for research[3-4]. There may be multiple factors influencing subjects' attitudes towards sharing their medical data for research[9]:

1. Type of information: subjects are less willing to share information that is highly personal, such as sensitive information about drug abuse, sexual-related diseases, or mental health disorders[9].
2. The type of recipient: subjects' willingness to share decreases when the recipient of the information is a commercial or for-profit entity[10,11]. In a study by Willison et al., participants who had specific targeted health conditions or were generally healthy individuals thought that health information should not be used for marketing purposes, and that re-consent should be needed for use in the case of research by for-profit organizations[10]. Focus groups and interviews about different scenarios found that most participants were concerned about for-profit uses of their information[12].
3. Level of anonymity: subjects are concerned about privacy and are more willing to share information that is de-identified[13].
4. Health condition of the subject: if the subject has a progressive or chronic illness, the individual tends to be more willing to share[10,14].

5. Perceived value: recent emergence of many active Internet communities for patients experiencing similar conditions shows that subjects may value peer-based sharing models and the possibility of hastening treatment and cure of their medical conditions[15].

These studies indicate that using a broad consent for personal data may not be what people desire. If a tiered consent model is used, it can provide subjects with more options and opportunity for involvement in the information sharing process. The U.S. Office of the National Coordinator supports granular control models for Health Information Technology, and suggests that patients should have a "greater degree of choice to determine, at a granular level, which personal health information should be shared with whom, and for what purpose"[16].

Technological difficulties make it challenging to track and ensure compliance with patients' choices even if they are given options for sharing medical data. Currently, most health providers do not have a system for patients to see who is accessing their data for research purposes, and also do not allow patients to select certain categories of information for sharing. The literature suggests that patients may want to have options for keeping their information private[4,12]. A study by Caine et al., investigated tiered sharing for patients through a system of cards and questionnaires[4], while Meslin et al. gave a series of guidelines to consider when creating electronic health records[18], and these studies formed the basis of our investigation into different categories and sharing options for patients. However, we are aware that theoretical surveys can be limiting[4] as patients may respond differently when it is not their actual medical data at stake.

We surveyed 70 healthy volunteers to establish a baseline on patient preferences who responded to an advertisement posted at several different locations on the UCSD campus for a period of 4 months. The surveys and interviews were conducted between 7/15/2013 and 10/30/2013. The survey was designed at as preliminary study of a larger project that will implement tiered patient preferences for use with a clinical data warehouse for research (CDWR). iCONCUR (informed CONsent for Clinical record and sample Use in Research) is a project of iDASH (integrating Data for Analysis, anonymization and SHaring), an NIH-funded National Center for Biomedical Computing (NCBC)[21]. iCONCUR will record the patient's choices for sharing medical information and this information will be transmitted to the CDWR where permissions will disallow sharing of corresponding data about subjects who register their preferences in iCONCUR. iCONCUR will begin in late summer 2014, and will enroll 400 patients from 2 sites – a general Internal Medicine Clinic and a specialty clinic that exclusively treats HIV positive patients. By recruiting a diversified group of patients, we hope to discover trends among patient sharing choices that could be generalized to a wider population.

Materials and Methods

Participant choices were implemented in a graphical user interface (GUI). From the GUI, participants proceed through three taxonomies where choices about sharing data can be made: (1) *What am I sharing? (*2) *Who am I sharing it with?* and (3) *Which type of funding do I allow?* Participants had both the GUI and the survey open in web browser windows so they could refer to both as needed. The study took place at UCSD, and participants met with the researcher (EAB) in person for 45-60 minutes to discuss their choices. During the process of using the GUI and filling out the survey, participants were encouraged to ask questions or give verbal feedback in addition to the feedback that was collected in the survey. No connection of these choices was done with the individual's CDWR data, as the intent was only to test the appropriateness of available choices.

Educational Materials

An introduction section provided an overview of research, legal requirements for disclosure of medical information for research purposes, and information about how data sharing could contribute to research. All the material was written at an 8th grade reading level. As an example of how medical records could lead to important research discoveries, a link was provided to a recent article that explored data mining of electronic health records[17]. The idea to include this example came from preliminary interviews. Additional links led to websites about data anonymization, IRB policies, and NIH pages detailing HIPAA.

What am I sharing?

The first taxonomy of choices addressed the content of the person's health records. As depicted in Figure 1, options included "*demographics*", "*test and lab results*", and "*diagnostic information*". The diagnostic information was classified as "*sensitive information*" or "*non-sensitive information*". The sensitive information was classified in four categories: "*mental health*", "*sexual and reproductive health*", "*alcohol and substance abuse*", and "*genetic information*".

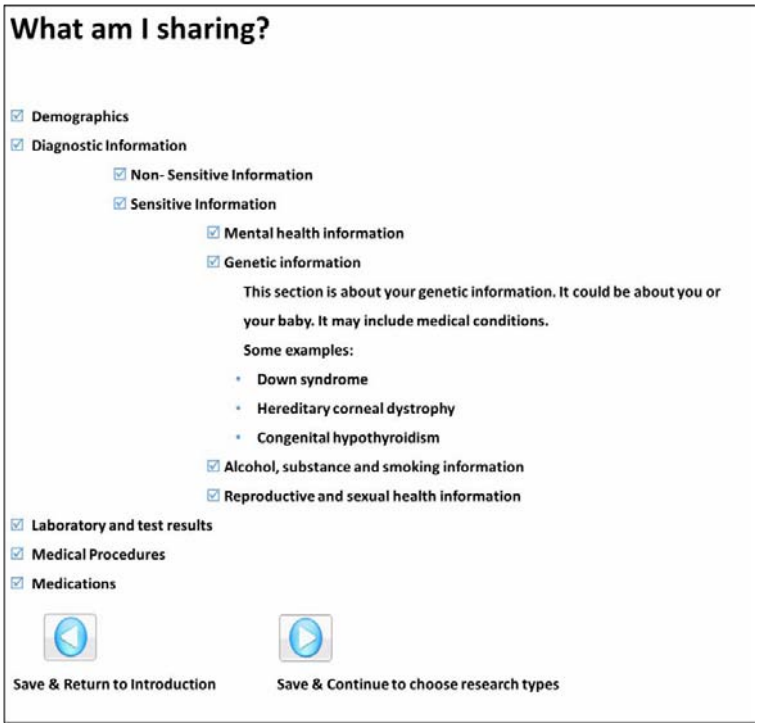

Figure 1. Screenshot of GUI with taxonomy of data sharing choices

Links were provided to the diagnoses for each category of sensitive information, which were selected by two clinicians. Each category expanded to give further descriptions, as depicted in Figure 1 with genetic information. A taxonomy of sensitive categories of information was chosen because previous investigations had shown that sharing sensitive medical data could be a concern to patients[4]. In previously published work when patients were given the option of choosing how to share their data, many chose to only share less sensitive data[4]. The definition of sensitive data is described by the National Committee on Vital and Health Statistics and includes five categories: domestic violence, genetic information, mental health information, reproductive and sexual health, and substance abuse[19]. For the development of the taxonomy, a group of UCSD clinicians used the definition of sensitive information from *Points to consider in ethically constructing patient-controlled electronic health records*[18] to categorize diagnosis codes from CDWR. This way, when a patient decides to share or not share a category of sensitive information, we can precisely determine the set of diagnosis codes available in the CDWR that the patient was selecting and comply with his/her choices. These categorizations were arbitrary, and we acknowledge that different clinicians could have selected the diagnosis codes differently. For the classification of sensitive information we decided to focus only on diagnostic codes. There may be sensitive information contained in other parts of a patient's medical record, but we have not addressed it in the current survey.

Who am I sharing it with?

In the second taxonomy, subjects had the opportunity to determine whether they wanted to share data with a research team that is: (1) entirely formed by UCSD or San Diego Veteran's Administration (VA) hospital researchers, or (2) led by UCSD or San Diego VA hospital researchers but involving members outside UCSD and San Diego VA hospital. These options were included because UCSD IRB protocols require that all the research plans that request access to clinical data from the CDWR should be led by UCSD or San Diego VA, and to indicate whether there are research members outside these institutions.

Which type of funding do I allow?

In the last taxonomy subjects had the option of deciding what types of institutions should have access to their medical data. The options included *no restriction on type of institution*. If this option was not chosen subjects could select some or all of (1) *commercial*, (2) *mixed*, (3) *non-commercial*, and (4) *unfunded research*.

Evaluation Study

Recruitment was conducted using flyers on the UCSD campus, the UCSD medical center, and the San Diego VA hospital. The inclusion criteria used were: (1) English speaker, and (2) Age 18 or older. Participants began by using the GUI to make their own personal choices about sharing preferences. All choices were saved for the evaluation. After participants completed their choices, a link led to a 28-question survey.

Eight questions collected demographic information, in order to detect possible trends in sharing choices based on gender, income, and educational level. Three questions evaluated the study to check reading comprehension, twelve questions captured the participant's opinions towards the sharing options and their motivations for sharing or not sharing medical data, and five questions related to the online GUI itself. In total, participants spent 45-60 minutes using the tool and taking the survey.

Participants choices for not sharing	
Sensitive Information	**N (%)**
Genetic information	9 (12.9)
Sexual and reproductive health information	12 (17.1)
Mental health information	10 (14.3)
Alcohol and drug use information	6 (8.6)
Types of Sponsorship	
For-profit	16 (22.9)
Mixed (for-profit and non-profit)	7 (10)
Non-profit	1 (1.4)
Unfunded	5 (7.1)
Researcher Types	
Teams composed of UCSD and VA researchers	0
Teams that included external researchers	8 (11.4)
Other Categories of Medical Information	
Demographics	3 (4.3)
Non-sensitive diagnostics	1 (1.4)
Laboratory and test results	0
Medical procedures	3 (4.3)
Medications	3 (4.3)

Table 1. Number and percentage of participants who selected 'do not share' for each data category.

Results

Choices about sharing were recorded in a database and are shown in Table 1. The numbers indicate the number and percentage of participants who would choose *not* to share data in each category. Not sharing with researchers from for-profit institutions was the most common choice. For all of the survey questions of interest, a chi-square test was applied to test for association of attributes and the outcome of interest. Representative comments for six of the survey questions that captured the participant's opinions towards sharing options and motivations for sharing are in shown in Table 2. Results that showed statistical significance at a level of of $p < 0.05$ are indicated.

The results show that participants were significantly more willing to have their health data shared for research if they were given choices about which aspects of their data they wished to share. Participants were also interested in knowing more about the researchers and indicated a significant desire to know who was accessing their data. Ninety-four percent of participants indicated that they wanted to be able to know what kind of organization the researcher belonged to, 89% wanted to know the aim of the research study, 84% were interested in being informed of the outcomes of the research, and 70% would like access to publications that resulted from using their data. Preferences for being notified of how and when their data are being used were quite varied. Forty-four percent of participants want to be informed each time a new researcher uses their data, 20% prefer once a month (even if there were no changes), 13% once a year (even if there were no changes), 17% never if they could go online to the site and find it themselves, and 6% had other suggestions. Participants correctly answered the three questions designed to check reading comprehension 91% of the time.

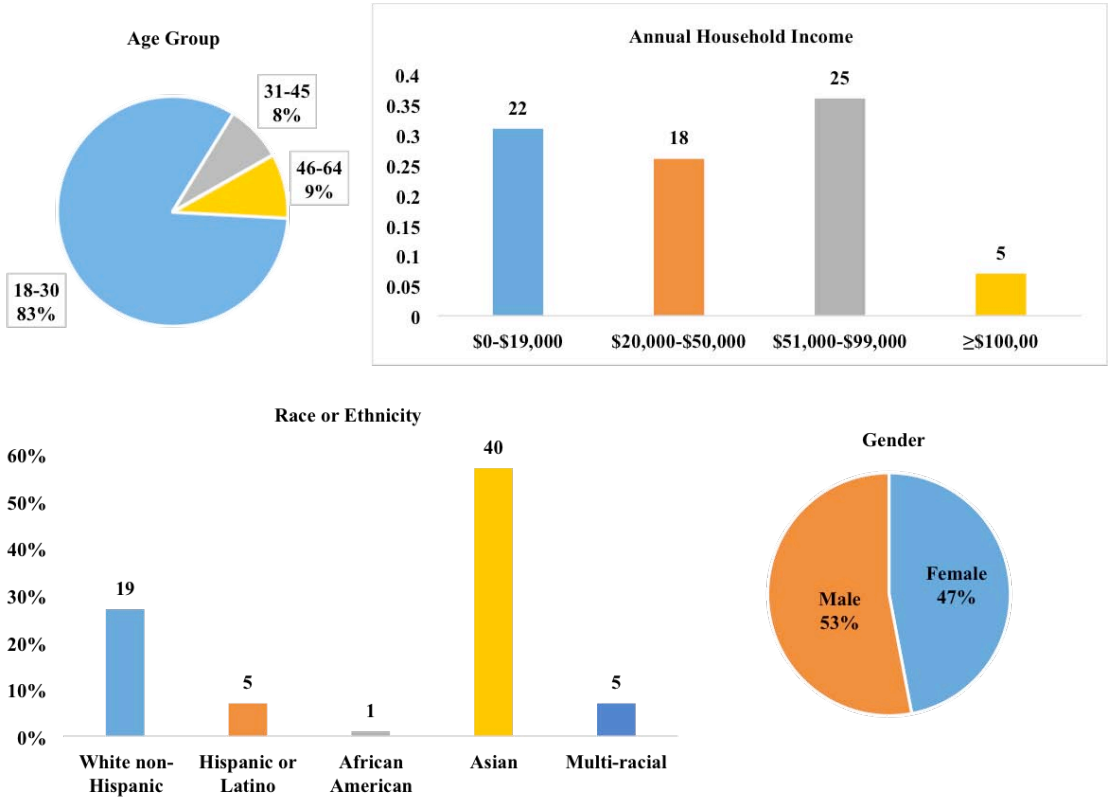

Figure 2. Demographics of participants

In addition to the demographics shown in Figure 2, information about education level, personal health status, weekly Internet use and health insurance status were collected. Participants were more highly educated than would be expected from a random sample of the US population[20]. Seventeen percent had a graduate or professional degree. When asked to describe health status, 14% said *fair*, 35% said *good*, 31% said *very good* and 20% said *excellent.* Four participants did not have health insurance. Regarding questions about the GUI and variety of choices presented, 94% of participants felt that the number of categories in *What am I sharing?* was adequate. However, 83% would like more granular control over sharing options, such as sharing mental health information with non-profit sponsored researchers but not for- profit sponsored researchers. Eighty-seven percent of participants were motivated to share in order to help other patients and contribute to science and research, and 44% would do it because they trusted UCSD and believed in the importance of the research being conducted.

Questions	Number of Participants	Some comments from participants
Are you more or less willing to share your data now that you had these choices?		
More	54[a]	"No change. I'm for research and would like to help either way. But, being explicit and providing this added information, makes me feel more at ease doing so."
Less	9	
Other	7	
Is it important to you to know whether your data are being shared with for-profit or non-profit institutions?		
Yes	48[b]*	"Slightly important because I would only want to share this information if I knew researchers were going to use it for well meaning purposes."
No	7	
I am indifferent	15	
If it were possible for you to know who is accessing your data, would you like to know this?		
Yes	62[a]*	"Yes, but more because of curiosity on what is going on with the research community, rather than actually feeling my privacy is being "invaded""
No	1	
I am indifferent	7	
Would you feel more comfortable sharing your information if you know who is accessing it?		
Yes	62[a]*	No comments
No	3	
I am indifferent	5	
If there were an option for you to control the sharing of biosamples, such as tissue, blood and urine, would you want to control this?		
Yes	34	No comments
No	10	
I am indifferent	26	
Is there anything else you would like to keep private in your medical record? (multiple choice)		
No	42	"DNA info" "potentially criminally-related illnesses or drug use" "STDs"
Chronic disease	5	
Acute disease	6	

Table 2. Selected survey question and responses. [a] $p < .001$ [b] $p < .05$.
* Indicates that this is a secondary hypothesis that was subjected to post-hoc analysis without correction for Type I Errors.

Discussion

Patients may not be aware of how their personal health information is being used for research. By presenting information and options, we sought to discover preferences for sharing health information. We hypothesized that participants would be more likely to share their health information if they were presented with choices, specifically for controlling categories of sensitive information. Having choices available did make participants more willing to share their data, and they expressed interest in keeping specific categories of information private. These results likely do not represent the opinions of all citizens, as recruitment was limited in scope. Since recruitment occurred on the UCSD campus, where most people are 18-30 years old and of Asian ancestry, the results may not generalize to the general population. Other important limitations include the fact that most of the participants had at least some college education and mostly were in *good* or better health status.

Furthermore, since this study was hypothetical, participants may choose differently than if they were actually making choices for their medical record. The results of the projected iCONCUR study on actual patients and with their preferences being implemented in data sharing for research should provide insights on those differences. During this study, the news regarding the NSA (National Security Agency)[22] and global security surveillance scandal was made public. Verbal comments from several participants of the study indicated that their decisions to share or not share their data were influenced by this event. Two distinct schools of thought were noted – some participants indicated that they were more willing to share because "the government has all our info anyways" and there was no longer a perceived benefit to keeping information private. Others stated they were less likely to share, as the government was potentially infringing upon their personal privacy and they would like control whenever possible.

Twenty-two percent of participants did not want to share health data with for-profit sponsored researchers. This finding was fairly consistent with the literature[10-12]. Although there were limitations in this study due to the small sample size, the sponsors of the research is important factor to participants. Concerns about sharing sensitive

categories of information were also consistent with the literature[4,9,18]. Some important new findings of this study are that participants appear to be more willing to share when given granular choices over what categories of information to share, as well as when they are given information about who is accessing their information. Many participants are interested in contributing to research but would like feedback about how their data are being used, and would like to be informed of the results from the research.

Acknowledgements

This study was supported by iDASH: Integrating Data for Analysis, anonymization, and SHaring (1U54HL108460). We would also like to acknowledge Mindy Ross, MD, MBA, and Robert El-Kareh, MD, MS, MPH, for classifying CDWR data into categories of sensitive information, Jihoon Kim, MS, for the statistical analysis of the study results, Claudiu Farcas, PhD, Michele Day, PhD and Hyeoneui Kim, PhD, MPH, RN, for feedback and Mona Wong for building the GUI used in this study.

Appendix 1

Survey questions

Learning about you

1. Which age group do you belong to?
    - 18-30
    - 31-45
    - 46-64
    - ≥65
2. What is your gender?
    - Male
    - Female
    - Unknown
3. What is your highest education level?
    - High school or less
    - Beyond high school or < 4 years of college
    - 4 year college graduate
    - Graduate or professional school
4. What race or ethnicity do you identify as?
    - White non-Hispanic
    - Hispanic or Latino
    - African American
    - Asian
    - Multi-racial
5. What is your annual household income?
    - <$5000
    - $5000-$14,999
    - $15,000-$19,999
    - $20,000-$49,999
    - $50,000-$59,999
    - $60,000-$99,999
    - ≥$100,000
6. How would you describe your personal health status?
    - Poor
    - Fair
    - Good
    - Very good
    - Excellent
7. How many hours per week do you use the Internet?
    - 1-10 hours/week
    - 11-15 hours/week
    - >15 hours/week
8. Do you currently have health insurance?
    - Yes
    - No

What is this study about?

9. How long will this study last?
    - One month
    - 6 months
    - 1 year
    - 2 years
10. Can you change your mind about sharing your information or participating in this study?
    - Yes
    - No
11. When your data is shared, will you be notified?

- Yes
- No

Your Suggestions for Improvement

12. Was the number of categories of information in "What am I sharing?" adequate?
    - No, it needed more categories [please explain in comment box]
    - Yes
    - No, there were too many categories [please explain in comment box]
13. Is there anything else that you would like to be able to keep private in your medical record? [multiple choice]
    - No
    - Chronic disease information
    - Acute disease information
    - Sensitive non-diagnostic information
14. If there were an option for you to control the sharing of biosamples, such as tissue, blood, and urine, would you want to be able to control this?
    - Yes, I would like to control the sharing of biosamples
    - No, I would not like to control the sharing of biosamples
    - I am indifferent
15. Do you feel more or less willing to share your medical information now that you had these choices?
    - More
    - Less
    - Other
16. What is your motivation for sharing your health information? [multiple choice]
    - Benefit future patients
    - Contribute to science and research
    - Trust in UCSD and a desire to contribute to the research they are doing
    - Establish a good relationship with UCSD
    - Other
17. Is it important to you to know whether your data is being shared with for-profit or non-profit institutions?
    - Yes
    - No
    - I am indifferent
18. The tool (GUI) does not allow different researchers to access different information from your medical record. For instance, the tool does not allow you to choose to share your mental health information with non-profit organizations but not to share it with for-profit organization. Would you like this option?
    - Yes, I would like to have the option to allow different researchers access to different information from my medical record.
    - No, I would not like to have the option to allow different researchers access to different information from my medical record.
19. Do you like to have control on what to share and with whom to share it?
    - Yes
    - No
    - Yes but not enough to go through the trouble of selecting options
    - Other
20. If it were possible to know who is accessing your data, would you like to know this?
    - Yes
    - No
    - I am indifferent
    - Other
21. Would you feel more comfortable sharing your information if you know who is accessing it?
    - Yes
    - No
    - I am indifferent
22. What would you like to know about the researchers who used your data? [multiple choice]
    - What kind of organization they belong to (e.g. a profit/non-profit organization, university or healthcare system)
    - What was the aim of their research?

- What papers were published using my data?
- What were the outcomes of their research?
- Other

23. How often would you prefer to be notified of updates about who is using your information?
    - Every time someone new uses it
    - Once a month even if there are no changes
    - Once a year even if there are no changes
    - Never, I can go to the site whenever I want to
    - Other
24. For each category of sensitive information (sexual and reproductive history, substance abuse, mental health, and genetic information), there was a paragraph explaining it and offering some examples. Do you feel like these paragraphs and examples were clear enough?
    - Yes, they were all clear enough
    - No, none were clear enough
    - No, some were unclear
25. Were the categories of sensitive information (sexual and reproductive history, substance abuse, mental health and genetic information) enough to cover your own preferences?
    - Yes, the categories were enough to cover my preferences
    - No, the categories were not enough to cover my preferences
    - Other
26. In this study, you are given the option of sharing or not sharing categories of information that are not considered sensitive. These include demographics, non-sensitive diagnosis information, laboratory and test results, medical procedures, and medications. Do you feel that these categories covered all types of information you want to control, or do you wish there were more categories for you to choose from?
    - Yes there were enough categories for me to control
    - No, I wanted more categories of information
    - Other
27. Did you have trouble understanding any of the information presented in the tool?
    - No, I was able to understand everything
    - Yes, I had trouble understanding parts of it
    - Yes, I couldn't understand it at all
    - Other
28. Did you have trouble understanding how to use the tool when selecting your choices on what to share and with whom?
    - No, I was able to understand how to make my choices
    - Yes, I had some trouble understanding how to make my choices
    - Yes, I couldn't make any choices because I didn't understand how to do it
    - Other

Automated Extraction of Family History Information from Clinical Notes

Abstract

Despite increased functionality for obtaining family history in a structured format within electronic health record systems, clinical notes often still contain this information. We developed and evaluated an Unstructured Information Management Application (UIMA)-based natural language processing (NLP) module for automated extraction of family history information with functionality for identifying statements, observations (e.g., disease or procedure), relative or side of family with attributes (i.e., vital status, age of diagnosis, certainty, and negation), and predication ("indicator phrases"), the latter of which was used to establish relationships between observations and family member. The family history NLP system demonstrated F-scores of 66.9, 92.4, 82.9, 57.3, 97.7, and 61.9 for detection of family history statements, family member identification, observation identification, negation identification, vital status, and overall extraction of the predications between family members and observations, respectively. While the system performed well for detection of family history statements and predication constituents, further work is needed to improve extraction of certainty and temporal modifications.

Introduction

Family history information is essential for understanding disease susceptibility and is critical for individualized disease prevention, diagnosis, and treatment (1,2). With greater and more widespread adoption of electronic health record (EHR) systems and mandates with Meaningful Use Stage 2 to utilize structured family history functionality (3), there is an increasing opportunity to perform secondary analysis of family history information. Important applications include researching genetic influences between family history and disease, performing association mining of the EHR, and supporting public health research (4). For instance, family history can be used to calculate odds ratios and relative risks using genotypic and environmental interactions (5) to estimate the level of risk for certain diseases, as well as signal the need for further consultation (e.g., genetic counseling) or diagnostic workup (e.g., preventative health screening).

We have previously analyzed the representation of family history information in the EHR (6) and characterized family history free text comments in an EHR family history module (7). Most recently, we have expanded upon this work and have used multiple sources to develop a more comprehensive family history representation model (8). While two previous studies have described preliminary approaches for automated family history extraction from clinical texts (9,10), these approaches did not include functionality to classify family history from other non-family history texts, nor were high-level linguistic features like predication or linguistic chunking used. Currently, most established clinical natural language processing (NLP) systems (e.g., MedLEE(11–13) and cTAKES(14)) are primarily focused on extracting named entities such as diseases, medications, or procedures or contextual information (15). Family history information is frequently expressed via relations between named entities such as family members or diseases and also may contain contextual information such as certainty and negation, as well as information about vital status and age modifiers. We sought to incorporate family history functionality into an open-source NLP system, BioMedICUS (16) and to evaluate the performance of this module for family history extraction.

Methods

Figure 1 depicts a broad overview of the NLP pipeline and the process for its evaluation. The system was developed as part of our larger BioMedICUS NLP system that uses the Unstructured Information Management Architecture (UIMA) framework. UIMA, originally developed by IBM, is now an open source Apache document annotation framework that provides functionality to write sets of analysis engines (pipelines) that annotate and process unstructured text. Authoring UIMA-based analysis engines involves design and development of algorithms that read document text and add annotations to it in progressive stages through a pipeline where each analysis engine has access to annotations added to the common analysis structure (CAS) by upstream analysis engines.

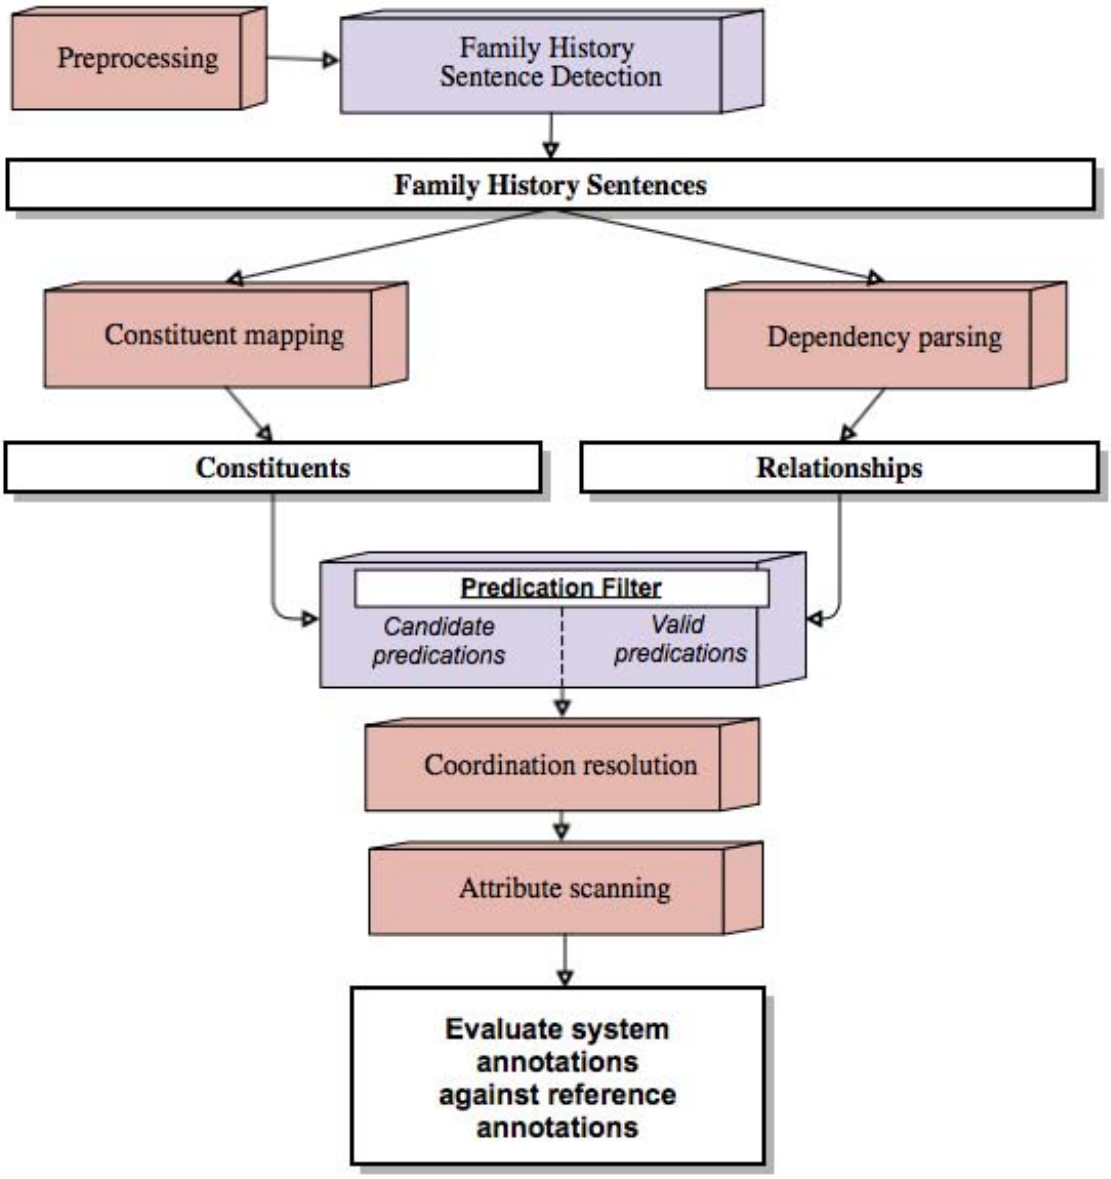

Figure 1. Overview of family history system and its evaluation

We used an approach to family history relationship extraction similar to the one developed by Rindflesch *et al.* for identification of semantic predications in biomedical literature (SemRep) (17). The NLP system shown in Figure 1 extracts family members and clinical observations as relationships where the relationship is usually identified by "indicator word(s)" (i.e., predication) appearing between the family member occurrence and clinical observation occurrence. After identifying the primary relationship, dependent phrases are then mined for attributes such as certainty, vital status and age. The pipeline was evaluated using an expert-based gold standard, as described below. Table 1 details each of the pipeline steps.

Corpora and Expert Annotation

The corpus used to develop and evaluate the family history NLP system was from a publicly available resource, MTSamples.com (18). For the MTSamples corpus, all History and Physical (H&P) notes, which were not behavioral health notes, were included (N=491). The family history pipeline was then developed using 329 MTSamples notes

(training set). As part of the evaluation, the model built for detecting family history statements was evaluated with 10 by 10 cross validation of the training set of notes. For this, the model was built with 90% of the notes and evaluated on the remaining 10%, with the remaining 10% being a different set of notes for each of the 10 iterations. Other portions of the pipeline using rules instead of models were evaluated on the entire training and test sets of notes. The system was then also evaluated on the remaining 162 MTSamples notes (evaluation set) as a more objective evaluation "hold out" set. The reference standard was developed by having annotators first identify family history statements in 20 notes to establish inter-annotator agreement prior to annotating the remaining set of MTSampels notes. After review of the general annotations completed in the first step, annotators added specific attributes. The specific attributes included family member, observation, side-of-family, vital status, certainty, and other temporal information. Table 2 shows an example set of annotations for the family history text for the reference standard.

Table 1: Family History Pipeline Components

Component	Description
Family History Sentence Detection	Determines if the current sentence contains a family history statement
Constituent mapping	Annotates the family history members from the HL7 clinical genomics family history model as family-member entities, and annotates all the disorders or procedures from SNOMED CT as observation entities
Relationship extraction	Identifies relationships between family member(s) and observation(s)
Coordination and list resolution	Transforms relationships that have lists of family members and/or observations into a list of relationships that specify a single family member and single observation. Also, adds attributes based on rules (e.g., adds "paternal-side" to relationships with "father" as the family entity)
Attribute scanning	Search patterns to identify the essential attributes of a relationship: vital status, certainty, age of diagnosis, side of family

Four informatics experts, including a physician, one PhD, one informatics graduate student, and one informatics researcher, provided manual annotations. Two of the experts also had previous experience in biomedical standard evaluation. Annotators arbitrated ambiguous sentences by discussing similar sentences to agree on presence of family history information. The resulting sets of annotations were provided in GATE (19) XML format and then converted to the UIMA XMI/CAS format for using in the UIMA pipeline developed for this study.

Table 2: Annotation Examples

Sentence 1: "He says his father might have died of heart disease."

Sentence 2: "Significant for epilepsy on the father's side of the family."

Sentence 3: "Mother with colon cancer but no other cancers."

	Family Member	**Observation**	**Vital status**	**Side of Family**	**Negation**	**Certainty**
Sentence 1	Father	heart disease	died			might
Sentence 2		epilepsy		paternal		
Sentence 3	Mother	colon cancer				
Sentence 3	Mother	other cancers			no	

Table 3 summarizes the annotations and the frequency of their occurrence in the corpus. If a family history statement included multiple clinical observations for a family member, then the UIMA annotators created all possible member-to-observation pairings. For example, the statement "*father died of stroke due to uncontrolled hypertension*" would result in the following pairs: *father-stroke* and *father-uncontrolled hypertension*.

The automated system was evaluated based on the accuracy with which it could extract these family member-observation pairings from text. Evaluation was challenged by a number of different complexities in the text, including the finding that many of the pairings were missing an explicit mention of a family member (e.g., "Significant for Alzheimer's.") The annotation for this statement does not include a family member; in this case, the automated system would then generate a pairing with a null value for the family member slot or position.

Table 3: Reference Corpus Annotations

Sentences	***Number***
Total Sentences	*23,155*
Family History Sentences	*284*
Predications	
Family member to observation predications	*364*
Attributes	
Side of Family	*15*
Family member	*417*
Observation	*745*
Vital status	*131*
Negation	*73*
Certainty	*55*

Family history sentence detection

Section and subsection headings contribute significant information when identifying statements of family history. For instance, short phrases such as "*Significant for asthma"* could be difficult to identify as family history statements when considering only the sentence. In these cases, the section heading, and sometimes the subsection heading provided the context necessary to improve accuracy in classifying family history statements. The current version of the BioMedICUS section detection module uses regular expressions to identify the section and subsection boundaries and headings. This is effective and efficient for corpora that have a limited set of consistent spacing and punctuation patterns that identify the sections and subsections such as the MTSamples corpus, although future versions could potentially benefit from augmented section heading tagging techniques. The heading label for sections and subsections are included with the sentence as predictors for family history sentence detection.

Using the section heading, subsection heading and sentence text as features together, sentences were classified as family history sentences. The system used a classification approach for family history statements detection using the SGD module in WEKA (20). WEKA is software for machine learning and predictive modeling, and the SGD module implements the stochastic gradient descent learning model for use in a support vector machine (SVM) (or

other linear models). N-gram-tokenized text is used as predictors to the SVM. This was compared to a simple lexical match that utilized all family words from the HL7 vocabulary RoleCode - PersonalRelationshipRoleType as part of the HL7 Clinical Genomics family history model (21). If a section or subsection heading contains the text "Family History," then all sentences within that section were then classified as family history statements. Only those sentences automatically determined to be family history statements were then evaluated further in the pipeline.

Constituent mapping and relationship mapping for core family history named entities and indicator words

The syntactic units that were candidates for the family history annotations were generally phrases found in either the HL7 Clinical Genomics family history model for family relation entities or in SNOMED CT as observation entities, which were extracted as described below. The family and observation entities were then linked together by an indicator word or phrase thus forming a predication relation. Indicator words are those words or phrases that signal or indicate a relationship between entities. They usually appear between the family entity and the observation entity; therefore, mapping indicator words was key to identifying family history statements. A lexicon of indicator words and phrases was constructed from the annotations provided in the corpus training set. Examples of these words are those that indicate possession or experience. The lexicon of possession words include *has*, *is*, *with*, and the tense variations. Experience indicators include *suffered a*, *died of*, *recovered from* and the tense variations of those words. Words and phrases in this indicator lexicon are also mapped during the mapping stage of the pipeline.

Together, the identification of the triples composed of the predication indicator, family member, and observation arguments, along with subsequent attribute extraction, formed the core functionality of the system, The SNOMED CT observation candidates were limited to only disorders and procedures using a disorder/procedure subset created by limiting the SNOMED CT concepts to those with semantic types defined by the UMLS Semantic Groups (22) as disorders and procedures. When searching for matches to family or observation in the corpus, only the longest matches (greedy matches) were kept. The mapping results for family member were also mapped to relative entities defined by HL7 family member codes.

Negation

For all sample statements that contained a negation term in the training corpus, negation occurred within a window to the left of an observation. Guided by this discovery, the negation detection implementation scans terms to the left of the constituent object in question. All negative results were then annotated. For example, phrases such as *no significant history* are annotated with the relationship between family and observation being noted as negated. Additionally, in the example, "*father, but not mother*", the negation component in the pipeline will add a negation attribute to only the *mother* entity of the phrase. The latter example also clarifies how scanning terms to the right of a constituent to determine their negation status can risk incorrect attachment of negations, such as the *father* constituent being identified as negated. Instead of attaching the negation to specific constituents of the sentence, the predication/relationship was annotated as having negation or no negation. Thus, the two sentences "*Neither parent has diabetes*" and "*Parents without diabetes*" would produce the same predications between parents and diabetes that have the same negation attribute.

Predication filter to convert family history constituents to valid relationships

As previously described, the family history annotation structure is composed of a relationship triple involving three entities: family member, observation and indicator word. The chunks on either side of the indicator word are assumed to be the concepts in the relationship. With initial exploration of the MTSamples training dataset, we observed using the family and observation syntactic units on either side of the indicator word or phrase was a reliable means of identifying entities defining a family history statement. Many of the family history statements in the training corpus include coordination in the family member and the observation. For example, the statement *Mother and father had diabetes and asthma* indicates four family history predications. The combinatorial considerations also include lists, such as *father, mother* and *uncle* or the disease list of *cancer, high blood pressure*, and *glaucoma*. These examples require coordination resolution to create all the necessary family history triples. The resolutions required in the previous examples are lexical. An additional issue that had to be addressed for family member chunks is that there were sometimes semantic lists created by statements such as *parents, three brothers*, and *all grandparents*. In order to manage these statements, a simple lexicon is used to lookup the appropriate combinations of family members for family member constituents that indicate multiple family members. The predication filter noted in Figure 1 removes all the candidate predications that are not valid because the dependency parse cannot confirm a relationship between the constituents and indicator.

At the end of this portion of the pipeline, a set of relationships, or triples, were generated and resolved -- each

having one family member, one observation, and one indicator per triple. The final modification to the relationship status is to evaluate the negation status of each entity. If any of the entities are negated, then the predication was negated. The training set did not contain instances of double negation; therefore, any negation in entities is sufficient to annotate the predication as negated. This defines only the relationship; therefore, subsequent steps in the pipeline extract attribute information from the indicator, and dependent phrases.

Attribute extraction and evaluation

Additional relationship attributes include vital status, certainty, age of diagnosis, and side of family. Some attributes are determined by the relationship itself, as in the example when the indicator chunk is an experiential frame such as *died of* (indicating the vital status attribute). Other attributes are found in dependent words or phrases. In order to accurately attach attribute words and phrases to the correct entity, the attribute extraction component used the Link Grammar dependency parser to identify dependent phrases. Each token in the dependent phrases is compared to a lexicon of terms that define attributes. Successful scans for certainty words, vital status words, and temporal references become attribute assignments. Figure 2 depicts an example sentence with the mapping from a sentence to chunks, followed by attribute assignment. Attribute results are reported as precision, recall, and F-score where the totals are cumulative across the corpus. The test corpus was evaluated as a whole as a hold out unseen set of notes.

Sentence: The patient states that both parents had heart disease and thinks that a maternal grandmother might have died of cancer.

Entities: familyEntity{both parents}
indicatorEntity{had},
observationEntity{heart disease}
familyEntity{maternal grandmother}
indicatorEntity{died of},
observationEntity{cancer}

Coordination: Rel1 = relationship{father, had, heart disease}
Rel2 = relationship{mother, had, heart disease}
Rel3 = relationship{grandmother, died of, cancer}

Attribution: sideOfFamily{Rel1, paternal}
sideOfFamily{Rel2, maternal}
vitalStatus{died of, Rel3}
certainty{might have, Rel3}

Figure 2. Relation and attribute identification

Results

Evaluation separated each of the stages of the pipeline. The first step of the pipeline, after general pre-processing such as tokenization and sentence segmentation, is the binary classification of sentences as a family history statement or not. This classification of family history sentences had good performance (Table 4), with the caveat that keyword detection was equally effective as the SVM approach, and that the performance depended upon the accuracy of sentence detection in general as well as accurate section heading detection. Sentences outside of the family history section were detected; however, section headings proved to be significant because statements within the family history section were frequently abbreviated with context derived only by the heading. For example, many family history statements included only the word "*noncontributory*," or observation lists such as "*diabetes, heart disease*." Section headings are the only means of classifying these abbreviated sentences, but family history statements in other sections do not appear in abbreviated forms. The results for accurately classifying sentences as family history statements include sentences within and without the family history section of the clinical note. A high number of false positive classifications of a sentence as a family history statement occur among sentences outside the family history section, particularly statements regarding family dynamics that include many family member terms.

Once sentences that contain family history statements are identified, the subsequent step is identifying the family history constituents, including the family member, observation and the indicator word used to identify predications. The different constituents of family history statements were evaluated using the set of sentences known to contain family history statements (Table 5). We found family member detection results of 90.8% precision and 94.0% recall (F-score 92.4%) for a sample of text containing family history statements and 177 family member names. Observation detection had 80.2% precision and 85.7% recall (F-score 82.9%) on the evaluation set containing 325 annotated clinical observations. Following the identification of constituents, the next step is extracting the relationship between constituents to form predications. Predication detection performance achieved an F-score of 65.1% with precision of 70.3% and recall of 60.6% in the training corpus, with lower results for the test corpus, as shown in Table 4. Negation performance showed 49.5% precision and 68.2% recall (F-score 57.3%) over a sample of family history statements that contained 37 negation annotations. The performance of vital status and age of death are also summarized in Table 5.

Table 4. Evaluation of family history NLP module

	Training Corpus Results (10 by 10 cross validation)			Evaluation Test Corpus Results		
	Precision	Recall	F-score	Precision	Recall	F-score
Sentence detection	84.5	60.0	70.2	83.2	55.8	66.9
Predication detection	70.3	60.6	65.1	66.3	58.1	61.9

Table 5. Evaluation of individual components on family history statements

	Precision	Recall	F-score
Family detection	90.8	94.0	92.4
Observation detection	81.1	85.7	83.3
Negation	49.5	68.2	57.3
Vital status	96.3	99.2	97.7
Age of death	94.0	87.5	90.6

Discussion

In this study, we constructed a family history UIMA-based NLP module, specifically an annotation engine that classifies sentences that contain family history statements and a pipeline to extract important information about family history from clinical texts. The novel portion of the study was the system's conversion of narrative text into a family history data type for each family history statement with the family-member plus observation in the clinical note as the core relationship and then leveraging the use of predication in our NLP module. We found that the initial classification of sentences depended significantly on section information and, as such, the success of classification was dependent on accurate section detection, sentence boundary detection, and constituent mapping (family members and clinical observations). Individual sentences about family history frequently were found to have insufficient information to classify them without considering the section headings. Statements such as "*noncontributory*", "*unknown*", and "*nonsignificant*" are poor predictors for family history classification by themselves. Sentence segmentation errors also presented challenges for accurate detection of family history statements because the erroneous segmentation can be key in separating family member and observation entities that otherwise would be part of the same family history relationship. Furthermore, incorrect clinical and family mappings contributed to errors in classifying family history sentences.

Overall, we found that the core functionality of extracting the triple of indicator word or phrase, family member entity, and observation entity had reasonable performance. We also identified mechanisms for future system improvement by differentiating patient history, social history and family history early in the pipeline. The family member and observation detection results lag the performance reported by Goryachev *et al.* (10) and Friedlin *et al.* (9) although these studies were more limited in their evaluation. For instance, the former achieved 93% sensitivity and 97% positive predictive value; however, comparability is limited because they used a broader classification of family member. The Friedlin study was a limited report (poster) describing a potential family history system with limited results. The work by Goryachev *et al.* is more directly comparable and achieved higher reported results with family member detection of 85.12% precision and 86.93% recall; observation detection of 96.30% precision and 92.86% recall; and correct family member assignment to diagnosis of 92.31% precision and 92.31% recall. The previous work limited 'diagnosis' to 8 UMLS semantic groups as opposed to the 19 UMLS semantic types encompassing the disorder and procedure semantic groups used in this study. The system also did not address other modifications such as vital status, age of death, and certainty.

The lower performance of family history sentence detection results with the test set compared to training set may indicate some over-fitting to the training data. An additional limitation of this study is that the effectiveness on different sets of notes is unknown, particularly if section heading detection is troublesome. The mapping process of observations was limited to SNOMED CT observations and procedures, and that appeared to be sufficient for the corpora used in the tests. The largest influence on classifying and mapping statements was the section detection. Section headings supply significant information in identifying family history statements, and an important step to our future work will be improving the section detection phase and concept mapping phases of this system. We also observed the following pattern of errors when classifying sentences: the longest and shortest sentences were misclassified most often. The reason for the misclassification of the longer sentences was due to the errors in sentence segmenting, and misclassification of the very short sentences was due most often due to exclusion of either the family member or the observation entity. We also observed a high rate of false negatives for predication detection attributable to errors in finding the arguments for the predication. Furthermore, in many cases the misclassification was due to presence of family related information in statements reporting social rather than family history (e.g., *Mother was a smoker*). Future work with social history extraction may be helpful in reducing these types of errors as well as extending family history functionality for extraction of additional attributes such as temporal elements to improve the extracted family history information at a more detailed level.

Conclusion

Detecting family history statements and mapping them to regularized annotation structures holds promise for information extraction from clinical notes for important downstream uses. The results of our pilot study show that extracting family history information from clinical notes is a complex and challenging task that lends itself to NLP approaches developed for relation extraction. Specific challenges consist of a number of hard NLP problems including resolution of coordination and co-reference that, in turn, rely on the accuracy of lower-level processes such as sentence and phrase segmentation and negation detection. In this pilot, we were able to achieve reasonable performance and to identify a number of areas for improvement. Our next steps will include further refinement of both lower-level and higher-level components.

Abstract

Objective: Examine how the Electronic Health Record (EHR) and its related systems support or inhibit provider collaboration.

Background: Health care systems in the US are simultaneously implementing EHRs and transitioning to more collaborative delivery systems; this study examines the interaction between these two changes.

Methods: This qualitative study of five US EHR implementations included 49 interviews and over 60 hours of provider observation. We examined the role of the EHR in building relationships, communicating, coordinating, and collaborative decision-making.

Results: The EHR plays four roles in collaboration: a repository, a messenger, an orchestrator, and a monitor. While EHR performance varied, common themes were decreased trust due to poor quality documentation, incomplete communication, potential for increased effectiveness through better coordination, and the emerging role of the EHR in identifying performance gaps.

Conclusion: Both organizational and technical innovations are needed if the EHR is to truly support collaborative behaviors.

Introduction

For over a decade, experts have agreed that more collaborative, team-based care will be required to meet the increasing burden of chronic disease.[1,2] Unlike the acute care issues that dominated medical practice in the twentieth century, treating chronic disease in the twenty-first century will require multiple visits to providers in different disciplines. Not only will increasingly specialized medical expertise be required, but chronic disease treatment also involves changing lifestyles and navigating a complex web of treatments. Different health care professionals with different skills in different locations will need to collaborate to provide a cohesive care team. This increased collaboration is likely to constitute a disruptive change in the delivery of healthcare services.

In its broadest sense, collaboration simply means "to work jointly with others or together especially in an intellectual endeavor." [3] This definition may be too broad for use in healthcare situations; we found twenty-seven different definitions for healthcare collaboration in the literature. These definitions vary from a willingness to work with another party in any manner [4], to teamwork (defined roles and a common goal) [5], to shared decision-making.[6] For this study we adopted a taxonomy of collaboration behaviors based on the works of William Clancey[7,8] and Eduardo Salas [9] who suggest that collaboration includes the behaviors of trust and respect, communications, coordination, and adaptive collaboration. In table 1, we list the four behaviors and identify how the behavior can support a more effective healthcare process.

Table 1: the collaborative behaviors and their benefits

Collaborative Behaviors	Benefits
Trust and respect: willingness to rely on work of others	Less need to repeat diagnostics and procedures, more willingness to hand off or delegate
Communication: information flow, contextual background, understanding	Increased awareness and understanding, less mistakes due to missed data or context
Coordination: managing the timing and order of activities	More effective processes and increased efficiency in workflows
Adaptive Collaboration: changing the actual work content, tailoring solutions	Increased understanding across disciplines, when needed provides ability to tailor plans to meet patient circumstances

Team-based models of care based on collaboration have been implemented with improved results in primary care [10, 11], intensive care units [6], and operating rooms.[12] In the primary care setting, one prominent move towards collaboration and team-based care is the implementation of the Patient Centered Medical Home (PCMH). The configuration of the PCMH varies from system to system [13, 14] , but it consistently includes increased teamwork and collaboration within the clinic. In many cases it also includes improved collaboration with providers outside the clinic with whom they have working relationships (within the "Medical Neighborhood"). This is a disruptive change with significant effects on how care will be provided in the United States.

Another disruptive but potentially positive change is the introduction of the electronic health record (EHR) and its internal and related functions – computerized provider order entry (CPOE), clinical decision support (CDS) and health information exchanges (HIE). The EHR was originally designed as an electronic implementation of the paper chart.[15] Supporting collaboration (other than improved legibility) was not one of the original functional goals of this tool. [16] As the EHR has been deployed, the implementation has resulted in many examples of outcomes that are different from those anticipated when the systems were first designed. These are referred to as "unintended consequences." [17] Unintended consequences are not necessarily negative. For example, the EHR is being used to support care coordination, a process not included in the original vision of a documentation process to support medical decision-making. [16] The use of the EHR to support collaboration is, in many ways, a collection of these unintended consequences.

The relationship between the EHR and collaboration behaviors is evolving. This has been understudied. This paper presents the first multi-system qualitative study to delve deeply into the nature of this relationship and the roles the EHR plays.

Methods

Purpose: This qualitative study examines how the EHR and related systems affect the collaboration behaviors among providers in five systems that are implementing Patient Centered Medical Home delivery models.

Methodology: We used a modified Rapid Assessment Process [18,19] for data collection, and a grounded theory approach[20] for analysis. At the end of each site visit we summarized our initial themes and reviewed them with the site sponsor to verify our interpretations. Each aspect of the method is described below.

Sample: We studied five leading-edge multi-site organizations with EHR installations in the United States that were in the process of implementing their PCMH. These organizations were participating in SAFER project (Safety Assurance Factors for EHR Resilience [21]), which focused on developing guidelines for the safe implementation and use of EHRs and related systems. Sites were purposively selected to provide a cross section of successful EHR implementations in medium to large healthcare delivery organizations. As such they enabled a broad view of the potential advantages and challenges for collaboration in state of the art systems using an EHR. The characteristics of the sites are summarized in table 2. The visits occurred between May and November of 2012.

Table 2: Sites visited

	Location (US)	Structure	Number of physicians/providers	EHR
Site 1	Southeast	Augmented family practice/for profit	50 to 100	Centricity
Site 2	Mid Atlantic	Integrated System/ not for profit	More than 1000	EPIC
Site 3	Midwest	Community Health Center	Less than 50	Centricity through service provider
Site 4	Midwest	Community Health Center	50 to 100	Centricity through service provider
Site 5	Northeast	Academic Integrated Health System	More than 1000	Proprietary/ "Best of Breed"

Within each site we identified key individuals who were involved in the implementation, use, and monitoring of the EHR. These individuals included providers, clinical leaders, and informaticists. We then worked with our sponsor

at the site to schedule interviews with these individuals and field observations of providers working with patients using the EHR and other technology tools. The length of our visits varied from three to five days. The deployment of a multi-disciplinary team (see below) and a rapid assessment process [18] enabled us to reach saturation within a limited time period.

The data used for this collaboration study consisted of 49 interviews and 60 hours of field observation. This was selected from the larger SAFER project by focusing on how providers collaborate and communication with each other; over 500 pages of transcripts and field notes were annotated. The primary author and another analyst independently selected the interviews and observations included in this study from the larger set of interviews and field notes (over 2000 pages) gathered for the SAFER project.

IRB approvals: The Institutional Review Boards at Oregon Health & Science University and each of the sites approved the study.

Team: A multi-disciplinary team with experience in interviewing and observation conducted each visit. At a minimum, each site visit included a combination of professional qualitative researchers, informaticists and clinicians; several visits also included an expert researcher in communications and a human factors expert. The team met daily to debrief and prepare for the next day's encounters.

Collection Methods: During each site visit, we conducted field observation and semi-structured interviews. The semi-structured interview guides for this segment of our study focused on how the interviewees (or those working for the interviewees) collaborated with other professionals both within and without the clinic, the role the EHR played in facilitating or inhibiting the transaction, and implementation effects. All interviews were tape recorded and subsequently transcribed with the consent of the interviewees.

For the field observation, teams of two to six trained observers went to each site. We used a template for field observations which covered broad categories of foci of interest; each observer was responsible for gathering information on topics outlined on the template. Observation periods were three to eight hours, during that time we typically shadowed a provider to see how she used (or did not use) the EHR. In addition to shadowing providers, we also observed the work flow and meetings within a unit, and in one case we followed a patient. We were particularly interested in both safety issues (for the SAFER study) and how and when they collaborated with other providers (this study). Each day we documented their observations and then discussed them with the other researchers at a daily debriefing.

At the conclusion of each site visit, we prepared a summary of findings for the entire SAFER visit and met with our site sponsors and other leaders from each organization to confirm the veracity of our data.

Data Analysis: For the data analysis, we familiarized ourselves with the data, generated initial codes, then searched for and consolidated themes based on the codes. We produced reports consisting of quotations from interviews and field notes; these were translated into results based on "sense-making" sessions with key team members.

Coding: Two of the authors independently coded data for each site visit using NVivo 10. (22)Data tagged included portions of interview transcripts, field observation notes, and written artifacts collected in the site visits. After each site visit was coded, the analysts met to review codebook categories (codes) and relevant data elements. Discrepancies were analyzed and reconciled, and a new version of the codebook was prepared. This codebook was then used by both analysts for the analysis of the next site visit's data. New codes were added and old data elements reclassified after the analysis of each visit.

Theme generation: Following the initial coding, two of the authors met several times to identify emerging preliminary findings and implications from the analysis. During this period of reading and rereading (Miller and Crabtree's immersion phase[23]) the primary author drafted "memos" that helped her bring together key ideas.

Sense-making: Other co-authors with subject matter expertise in informatics, communications, and clinical delivery systems reviewed the themes during "sense-making" sessions. In these sessions, the team reviewed and refined findings, working to organize the findings, and sought to make connections between what we were seeing in these data and the current literature. Miller and Crabtree[23] call these steps in the analysis process the organizing and connecting phases. During these sessions, it became apparent that the collaboration models of Clancey and Salas [8,9] would provide a useful practice lens for organizing the emerging findings.

The data analysis resulted in 49 initial codes related to collaboration, and these categories were subsequently combined into 17 themes. These themes, in turn, were related to four roles played by the EHR discussed below.

Results

The four roles: We found the EHR and related systems play four distinct roles in collaboration: Repository, Messenger, Orchestrator, and Monitor. These roles are summarized in Table 2 below. The repository role was the most established at all sites; in all of the systems there was also a robust role for the messenger role. The degree of sophistication in the orchestrator role varied significantly from system to system. All of the sites we visited were actively working to improve and implement the EHR's performance in the monitor role.

Table 2: Four identified collaboration roles for the EHR

Role	Purpose	Examples
Repository	Contain all of the quality, accessible data needed for use by healthcare providers	Encounter and phone notes, lab and imaging results, and information from providers outside the system. Input may be by providers, by scanned documents, and increasingly, by vendor specific EHR to EHR communications (e.g. CareEverywhere) and Heath Information Exchange (HIE) mediated communications.
Messenger	Enable information transfer and communication between providers also between providers and other members of the healthcare team	Transmitted copies of encounter notes, pinned notes and flags sent to other providers, secure email, pop-ups, broadcast messages, clinical paging.
Orchestrator	Ensure that the right person is doing the right thing at the right time for the patient	Input templates that drive workflows, the use of standardized order sets, bundles and smart ordersets that implement best practice algorithms. Tickler messages generated by the system.
Monitor	Identify care gaps for patients and populations; provide a benchmark for measuring the performance of providers and teams	Registries, data warehouses and analytic tools, reporting tools for use by the clinic teams, dashboards, incentive performance displays.

In our interviews and observations, we found that the EHR can have varied, sometimes conflicting effects on the four collaboration behaviors (trust and respect, communication, coordination, and adaptive collaboration).

The EHR and collaboration behaviors: Each of the four roles had a primary effect on a single collaboration behavior (figure 2, below). They often had broader effects. One aspect of the EHR can and did affect several different behaviors at once (e.g. a lack of trust due to poor data quality cascaded throughout all four behaviors), but we have tried to avoid repetition.

Repository ←→ Trust and Respect
Messenger←→Communication
Orchestrator←→Coordination
Monitor ←→Collaboration

Figure 2: Each roles of the EHR had a primary effect on one collaboration behavior

Repository

The EHR, in its repository role had mixed effects – primarily on trust and respect. As provider told us, the major advantage to the EHR was that "*it's all there*" Because it is all there, the EHR can provide proof that one discipline can trust another: "*And our physicians saw [the data from the EHR] and realized 'wow, that really works… I can reliably delegate to my nurses*." But other times poor data quality would reduce their trust in other providers: "*This note that's 15 pages and it looks like they spent two weeks with the patient when the reality is they spent five minutes … and everything in there is either a fabrication and or was correct two years ago but not today*." Providers also complained about lack of context –the patient's "story" could not be adequately told with a series of check boxes.

A lack of quality in the notes can result from many factors. Time pressures are often a contributing factor: "*there is a trade-off between patient safety… and efficiency.*" "*If you are a busy PCP (primary care provider) with …one*

minute to prepare… you don't do it as thoroughly." It is not clear, however, how much this decrease in perceived note quality is simply an artifact of increased note visibility: "*people who wrote good notes on paper would write good notes in the electronic world, and people who wrote lousy notes …would write lousy electronic [notes]*."

As a repository, however, the function is not just to store data, but to make it available, When a provider could not find a specialist's note*, she became frustrated and began to blame the other provider for poor communications. We later found the note, but finding the note involved paging through three screens of poorly indexed lists of chart notes, consultant's reports, and laboratory data* (from our field notes). The ability to find necessary information is a key element in data accessibility.

The repository role also has an effect on the other collaboration behaviors. Although it did not guarantee good communications, it provided a common dataset that could speed and simplify communications. This was true, however, only when both parties had access to the same EHR. Commonly, we found that a copy of a chart note would be sent within a referral or other inter-provider communication; this provided the basis for other communications, but this often this transfer was not enough by itself, more contextual data was needed. For example, we were told that the radiologists in one system told us that the primary reason for poor implementation was the poor quality of the contextual data provided. The common data set also facilitated collaboration in multidisciplinary team meetings: "*As she describes the case the psychiatrist is displaying parts of the patient's history and progress notes from the EHR on the screen."* [from our field notes]

The repository function can improve coordination through increasing awareness: "*you can see a list of items that you need to complete for the patient. The nurse can see it, the physician can see it*." This increased awareness is, however, a two edged sword – "*now we are unearthing scope of practice issues … that we didn't have to deal with before*." At one organization a pharmacist could no longer complete a medication order with default parameters if they couldn't reach a provider, at another site the transition to an EHR unearthed the existence of hitherto unknown "personal order sets." These variations from standards were much more visible with the EHR than with paper records.

Messenger

The EHR and related clinical systems have significantly expanded the number of communication channels available to providers. Now, in addition to in-person, analog written, and phone/voicemail communications, providers can transmit information and communicate with other providers using secure email, clinical messages using a paging system, messages within the EHR (which can be attached to patient records), and pop-ups and general "broadcast notices." This multiplicity of channels can result in the choice of channels that are easier to use but providers considered less effective. In our visits, we were consistently told that sending a copy of the encounter note was the most frequent means of communication. And it is easy to do. As the one provider saved his encounter note, a routing box popped up and he clicked the name of the primary care provider to automatically send a copy: "*I just write a brief note and click.*" This was not uniform, there were also variations in practice between providers within the same healthcare settings. Some were more inclined to pick up the phone; some used paging or email.

In its role of messenger the EHR and related systems affected all of the collaboration behaviors, but its primary effect was on communication. While it could speed information transfer, it could reduce communication by inhibiting feedback. Asynchronicity facilitates information transfer by allowing EHR-related communications to bridge time and space; to facilitate providers messaging others on different shifts or in different offices or clinics. It also can increase awareness: *we know he's checking the vitals, he'll come when he needs to*."

But there are downsides to the default asynchronicity of information transfer. The ability to bridge time also came with a draw back – the lack of simultaneity made it difficult to give feedback and clarify, which could take more, rather than less time. Across all of the sites we heard: "*we call it brain freeze where with the technology implementation,* ***they think that they can no longer talk to one another."*** We also heard about the "communication illusion", when providers thought they were communicating, but weren't. Often a provider would send another a copy of their note, and assume the second would continue the plan. But the second provider might not find the plan or might misunderstand it due to a lack of contextual data. Delivery failure – particularly for lab results *("I've seem systems where 30% of the lab results weren't delivered to the right person"*) continues to be a problem. This was a problem that all of the sites we visited were trying to correct: "*You need to have that person communicate with the primary doctor …. and then have [the primary] them assume that responsibility and acknowledge it.*"

Orchestrator

The use of templates, smart order sets, and bundles has the potential to increase trust and respect, facilitate information transfer, and significantly improve coordination. The primary effect of the orchestrator role was, understandably, on coordination behaviors. Leaders at all of the sites were trying to use the EHR to improve quality by encouraging or 'orchestrating' "*the right person doing the right thing at the right time.*" Often this mean having someone work at "*the top of their license*." The degree of sophistication shown varied from site to site; for some it was templates that encouraged a given workflow, for others it was sophisticated smart order sets or bundles that created prompts and initiated workflows based on patient circumstances.

These smart order sets/bundles existed at more advanced sites only for the most prevalent ten to twenty-five conditions. "*We have lots of initiatives … most of them boil down to sophisticated checklists*." At one site they used "*automation to manage the preventative care needs of 220,000 patients … delegation of tasks [to non-physicians] as well as protocol*." As one of our key informants there told us, this does not happen well right after EHR implementation: "*We figure it takes about three months for the dust to settle…and [then we say]: What can we improve about the process? About the EHR? …The most valuable thing that happened … was that throughout the organization there are people who, when we say process redesign, say 'Okay, when and where?'"*

With smart order sets and bundles, there can be automatic dissemination and notification of results and follow-up. "*We look at [who]… can perform the task. The alerts fires to them and only that person. … We make it actionable so … they can address the alert at that time. … The nurse can see it. The physician can see it. And then, further in the work flow …, if they did not address the alert, it will display again*." The ability to generate tickler (reminder) notes based on a pre-agreed plan of care is a powerful communication tool within the orchestrator role.

Unfortunately, even the best thought out and planned bundles won't work if the providers don't accept the process. "*If we ever got any of ours 50 percent [of the new processes] accepted, I don't know what we'd do. We would be so excited*." One of the challenges for implementing EHR mediated coordinated care is getting physicians to trust in others: "*our physicians have been trained that really the buck stops with you. … [to offset this] we pilot everything…and then we show them it works.* Time is also an issue. All of the providers we met with felt time and productivity pressures, making them resistant to additional tasks: "*One the statements that can lead to failure is 'let's make the doctor do it …. Regardless of topic, I'll give you about a 30% chance … [of getting it to work when assigned to the doctors]."*, and "*you can have a great tool for asthma, but if it takes ten minutes to do it's not gonna happen*."

For many of the providers delegation helped relieve the time pressure. Care plans have long been a means of facilitating collaboration and team work. A more subtle point is the orchestrator role requires consolidating fragmented care plans, about which one participant noted: "*A human being should only have one care plan. This is a legitimate IT role."*

The EHR can only do so much to support collaboration, however; at every site we were told that when the situation was complex, they needed to meet with or "*pick up the phone and call*" another provider. One clinical leader told us that, as far as collaboration was concerned, "*the computer is giant hinder[ance]*" When collaboration was important, so was the person to person contact – either a warm handoff, a face to face meeting, or a phone call.

Monitor:

These systems of care were all striving to improve quality. With an EHR in place, data can be collected and analyzed to reveal care gaps. Several of the systems we visited were using these data to evaluate the performance of teams and individual providers; these data were also used to determine incentives and guide compensation decisions. By providing dashboard performance summaries to teams, and individual results to providers, systems were able to give feedback that could, in turn, facilitate performance improvement. It was in this role that we found the widest variation in system capabilities. None of the sites were completely satisfied with their EHR and the associated data warehouses that they were building to facilitate analysis. Given that, however, the capabilities ranged from automating data collection for mandatory reporting (e.g. HEDIS and meaningful use data) to enabling teams to use custom data extracts as they tried to improve their performance on quality metrics.

As a monitor, the EHR makes it possible to do ongoing reviews of process and outcomes. Perhaps because this is the least developed role, we found the most variation in effects. Uniformly organizations found that setting appropriate goals was difficult: "*If the A1c target is 6.9 and we are at 7.0, I'm not sure that is a fail*." And getting

good data could be difficult "*Our chlamydia and gonorrhea screening rates were three percent, and we said 'no way'…. It was a problem with the coding*." But once the goals were accepted, they could be used as an impetus for change: "*We roll out the measures…. [showed] there is a disconnect there… and so that allow us to change the workflow*."

When the monitoring through EHR data showed improvement, this willingness to change was reinforced. The use of dashboards, graphical indicators of provider and team performance, provided a sense of progress. The EHR as monitor could also trigger action: "*every month we pull a report [of diabetics] that includes nine different measures…and we then use this report to trigger telephone outreach…, vaccinations …and screenings*." Sometimes, however, the goals between providers would differ, and this would lead to conflict – for example when the endocrinologists were treating to an LDL goal of 100, but the primary care providers were only targeting a decrease to 120 ng/dl.

Overall:

We found four roles for the EHR – repository, messenger, orchestrator, and monitor; and that these four supported or inhibited collaboration behaviors and processes differently. Although they conceptualized it more in terms of the specific systems ("data warehouse", "clinical messaging," etc.), the leadership groups at every clinic we visited were actively working to improve the performance of their electronic health record in each of its roles. Table 3 summarizes the principle effects discusses above. In each role, we found evidence that the EHR affects all of the collaboration behaviors – both supporting and inhibiting collaboration. The inhibiting actions, however, appear to be more known, while the supporting factors are potential changes.

Table 3: The key issues for each collaboration behavior by role

	Repository	Messenger	Orchestrator	Monitor
Trust and respect: Enhancing positive relationships between providers	Increased awareness, but cut and paste and other quality issues decrease trust.	Asynchrony helps, but lack of richness in channel can result in misinterpretation	Particularly strong in establishing clear expectations	Key appears to be common goals and measurement
Communication: Providing the information and mutual understanding needed to care for patients	Facilitates information transfer "It's all there" (potentially), but "it's hard to find"	But doesn't guarantee communication Multiple channels can speed message delivery, but issues with "closing the loop"	Some successes, but clinical information is often not accessed/ignored by provider	When implemented can communicate gaps where practice improvement needed
Coordination: Having the right person do the right thing at the right time	A record of what actions and plans were, but each document frozen in time.	Issues due to variations in communications practice between providers	Bundles and "smart" worksheets particularly effective, but not implemented for enough conditions	Can facilitate team-based actions; if one member slips, another can fill in for them.
Collaboration: Facilitating collaborative decisions	Lack of interaction, one document per provider	No real time discussions, everything is lagged	Creates new boundaries, but doesn't encourage adaptation	Using dashboard and incentives to focus on common goals promotes dialogue

Limitations

Like any qualitative study, our results may not be generalizable. These sites were purposively selected to provide a cross section of successful EHR implementations in the United States. Readers will need to make their own judgments about the transferability of the results.

Discussion

Recent Research: Our results suggest that the EHR has evolved from its original role as a paper chart replacement (a repository) to also serving as messenger, an orchestrator, and a monitor. Issues with the performance of the EHR threaten its ability to support collaboration. Of particular concern were data quality and accessibility problems, which threaten the foundational behaviors of trust and respect. We also are concerned about the communication illusion, and issues with the multiplicity of communication channels. Other researchers have found similar issues at other locations using different EHRs and different qualitative perspectives.

Other studies with similar findings: One of our principal findings was that issues with the quality and accessibility of data threaten the EHR's utility for collaborative use. Weir, Hammond, Embi et al[24] used a lens based on Clark's theory of communication, joint action and common ground to examine the effects of computerized documentation on coordination and collaboration. Data were collected from focus groups at four different VA sites. Like our study, they found that the EHR could create a shared awareness and common database from which to act. They also found that "cut and paste" and failure to close the communications loop could create unintended consequences. Their work also discusses the value of narrative (richer contextual data) in building and maintaining shared mental models. This data were expanded to five sites and re-analyzed by Embi, Weir, Ehthiminiadis et al[25] using a grounded theory approach. Our work provides further evidence for the emergent themes from this expanded analysis. These included the inadequacy of the EHR as a sole communication channel, difficulties in finding relevant information, a need for better support for coordinated care, and disruptions in both trust and workflow due to problems with the EHR.

Our concerns about the communication illusions created by the EHR were foreshadowed by Lanham, Leykum, and McDaniel.[26] They used a complex systems approach to examine the effects of communication patterns on practice relationships. These relationships included trust and respect as well the appropriate use of communication channels. In a sample of six family medicine and specialty practices within a single system using the same EHR, they found that increased heterogeneity in communication patterns within each practice appeared to be related to increased practice fragmentation. We discuss a similar finding – the multiplicity of channels can result in communication patterns that inhibit collaboration.

Further research directions: EHR-related barriers to collaboration could be classified as predictable unintended consequences. The EHR was originally intended to replace the paper chart as a repository of data that would support medical reasoning and communication. But as healthcare is changing, so are the demands placed on the EHR and its related systems. It is unreasonable to expect an EHR to meet undefined needs. To meet these new demands we need a clear vision of what is needed. Both technological and organizational changes are needed. Processes need to be redesigned as well as technologies changed. We also need to be able to measure the effects of the changes once they are implemented.

Improved technology can help. Our study sites were developing better data warehousing and improved data exchange which would improve monitoring. We saw technology that could identify when a process step was missed and notify the proper person to get the gap filled to improve coordination. There is much innovation – and it is not confined to the sites we visited. The authors' informal discussion at both the AMIA student design competition and with EHR developers have shown possibilities for improving the EHR's ability to support collaboration. Better interface and data input technologies can provide time for better communications[27]. Curation can be improved by using plagiarism tools to identify inappropriate cut and paste[28]. Bundles that allow for more effective pathways and delegation can also free up time for providers[29].

More interestingly, the paradigm can be revised to fit a coordinated and collaborative process, rather than an individual practitioner. Models from other fields offer some possibilities. Ratings ("Amazon") for quality and usefulness might increase the quality of notes. Better identification of team members and their capabilities ("Facebook") could increase visibility and trust. With the advent of care managers, several "add on systems" have been developed to create a common care plan. What is needed is a reconfiguration of the basic structure of the

EHR. The ideal EHR for chronic disease management would allow for the integration of multiple care plans from different providers. This integrated care plan could be implemented as a wiki with the primary care provider or designee as the curator, or it could incorporate "column" care planning. It would be one care plan for one person.

Implementation and training are also key to improving collaboration through technology. As we saw in our visits, it is important to train users so they remember to keep talking, and not rely exclusively on leaner electronic media. Designing implementation processes that build buy-in from providers significantly increased adherence to the new protocols. And tying incentives to the data in the EHR – especially the problem lists – increased the value of the EHR data. There are other possibilities. Interventions to be tested include evaluating providers on the clarity and comprehensiveness of their notes, rather than on the number of billing factors; training providers on when to use what communication channels, and creating a "curators" who annotate and index of the documents for future use, accessibility would improve. Process innovations to gain acceptance are also understudied.

Finally, we need a tool to measure collaboration. The extant tools (cite) focus on supporting teams – collocated groups with a common goal. But collaboration between providers crosses organizational, geographic, professional and time boundaries. A more generalized tool would help us measure and manage the effects of the interventions discussed above.

Conclusion

In this study, we have identified four roles the EHR can and should play in the collaborative process. The organizations we visited demonstrated the potential for the EHR to support increased collaboration. These same systems also demonstrated barriers to collaboration presented by the implementations of current systems. Only by explicitly considering the different collaboration roles played by the EHR can designers and implementers develop the informatics tools needed for the twenty-first century. With these tools, the EHR can fill its role in the collaborative process.

MedMinify: An Advice-giving System for Simplifying the Schedules of Daily Home Medication Regimens Used to Treat Chronic Conditions

Allen J. Flynn, PharmD[1], Predrag Klasnja, PhD[1], Charles P. Friedman, PhD[1,2]
[1]School of Information; [2]School of Public Health, University of Michigan, Ann Arbor, MI

Abstract

For those with high blood pressure, diabetes, or high cholesterol, adherence to a home medication regimen is important for health. Reductions in the number of daily medication-taking events or daily pill burden improve adherence. A novel advice-giving computer application was developed using the SMART platform to generate advice on how to potentially simplify home medication regimens. MedMinify generated advice for 41.3% of 1,500 home medication regimens for adults age 60 years and older with chronic medical conditions. If the advice given by MedMinify were implemented, 320 regimen changes would have reduced daily medication-taking events while an additional 295 changes would have decreased the daily pill burden. The application identified four serious drug-drug interactions and so advised against taking two pairs of medications simultaneously. MedMinify can give advice to change home medication regimens that could result in simpler home medication-taking schedules.

Introduction

To minify is to reduce the amount of something[1]. We studied how to use information technology to help minify the number of times consumers have to take medications each day and the quantity of pills they have to take. It is important to simplify home medication regimens in these ways to facilitate medication adherence. While simpler home medication-taking schedules may diminish medication mishaps[2], this research is justified on the basis that better adherence resulting from simplified medication regimens improves the health and well being of consumers.

For individuals diagnosed with high blood pressure, high cholesterol, or diabetes, adherence to home medication regimens is known to improve health[3]. Conversely, lack of adherence to home medication regimens for chronic conditions causes considerable harm[4]. The overall cost of non-adherence to medication regimens has been estimated to be $100 billion per year in the United States[5]. Several categories of strategies to increase medication adherence have proven modestly effective[5]. These include strategies to improve communication of what to take and why, strategies to support behavior change such as self-monitoring of adherence, strategies to decrease out-of-pocket costs of medications, and strategies to cue consumers to take their medications such as reminder systems and calendars[5]. The most effective approaches combine strategies from multiple categories[5]. However, in terms of effect size, the evidence indicates that greater adherence improvements result from decreasing the complexity of home medication regimens than from combining educational, behavioral, and cueing interventions[5]. One strategy to decrease the complexity of medication regimens is to standardize the times of daily medication-taking events and limit their number to a maximum of four[6]. Another strategy is for health care providers to conduct medication regimen reviews intended to simplify medication regimens[7]. To facilitate these latter two strategies, we have developed an advice giving system to assist in the process of simplifying home medication regimens.

This paper describes the architecture and early stage evaluation of MedMinify, a new application that offers advice on how a home medication schedule could be made simpler by reducing the number of daily medication-taking events and the daily pill burden while accounting for drug-drug interactions. Because problems with medication adherence are widespread, MedMinify was developed to interoperate with a broad range of electronic health record systems. Our intent is to avoid the need to recreate the functionality of MedMinify in every different electronic health record (EHR) system. For the purpose of simplifying regimens, MedMinify advises users as to the availability of sustained-release or fixed-dose combination drug products and indicates whether certain drug interactions pertain. The literature supports the potential effectiveness of regimen simplification to improve medication adherence[7,8].

Background and Significance

In a systematic review of the association between the number of daily medication-taking events and adherence, Claxton, Cramer, and Pierce found mean adherence to a medication regimen declined as daily medication-taking events increased. Mean adherence for one, two, three, and four daily medication-taking events was 79% (SD 14), 69% (SD 15), 65% (SD 16), and 51% (SD 20) respectively[8]. The mean adherence differences between one daily medication-taking event and either three or four daily medication-taking events were statistically significant as was the mean difference between two daily medication-taking events and four daily medication-taking events[8]. In light

of more recent concurring evidence, these findings indicate that decreasing daily medication-taking events results in improved adherence[9,10].

Controlled studies of a standardized home medication schedule where patients take all of their medications either at breakfast, lunch, dinner or bedtime, have shown that in most cases consumers do not need to take medications for many common chronic conditions more than four times a day[11-13]. These studies suggest there is an opportunity to minify the number of daily medication-taking events[12].

Adherence to home medication regimens is also influenced by the number of pills taken per day or daily pill burden. To minify the number of pills taken daily can also be seen as a necessary adherence intervention[10,14]. In a recent meta-analysis, higher pill burden was associated with lower medication adherence to medication regimens that treat human immunodeficiency virus infection[10]. In another study agreement with the statement, "I am already taking too many medications", was a predictor of very low adherence amongst women being treated for osteoporosis[15].

One difficulty in minifying daily medication-taking events and daily pill burden to simplify home medication schedules is that consumers may actually increase the number of scheduled daily medication-taking events on their own for a variety of reasons[16]. A partial explanation for this behavior could be concern over drug-drug interactions[16]. Consumers may assume that taking oral medications at different times of day mitigates adverse events from drug interactions. Actually, relatively few drug interactions result from simultaneous oral ingestion[17]. More often drug interactions result from systemic effects at the sites in the body where drug metabolism, pharmacologic action, or drug excretion take place[17]. To counteract their largely false beliefs, what consumers may need is explicit information regarding which drugs they should and should not ingest simultaneously.

Previous research has examined the use of information technology to assist in reducing medication regimen complexity and polypharmacy[18]. Others have reported on the automated generation of pill cards and printed home medication schedules[13]. We have used information technology differently to give advice on how to minify daily medication-taking events and daily pill burden while ensuring that the advice given is in concordance with what is known about the relatively few serious drug-drug interactions that result from the simultaneous ingestion of drugs.

This research is significant for several reasons. While the majority of patients take multiple medications for multiple conditions, many interventional trials have focused on adherence to single medication therapies or to treatments for one condition. We intentionally sought to analyze prescriptions for all scheduled tablets and capsules consumers must take to adhere to their home medication regimens. In addition, whereas pharmacist-led medication regimen review helps to simplify medication regimens, a lack of pharmacist time to conduct home medication regimen reviews limits this intervention[7]. An information resource that gives advice on how to minify daily medication-taking events and daily pill burden may decrease the amount of time required to review home medication regimens for simplification opportunities. Such advice may also apply during medication reconciliation tasks. Finally, to facilitate future integration with EHR systems we set a goal to build MedMinify so that it would interoperate with a variety of EHR systems from the outset.

Motivated by these research findings and the clinical significance of the problem of medication adherence, this paper reports whether an advice giving system capable of offering potentially useful advice to simplify medication regimens could be built using the Substitutable Medical Apps, Reusable Technology (SMART) platform, how frequently potentially useful advice to assist in simplifying medication regimens could be generated, and in what ways and by how much the advice generated, if heeded, could change actual home medication regimens.

Research Questions

The following three research questions were investigated.

1. Is the Substitutable Medical Apps, Reusable Technology (SMART) platform robust and extensible enough to support the architectural and functional requirements of a system capable of giving advice on how to potentially minify daily medication-taking events and daily pill burden?

2. What types of advice and how much of each type can be generated by analyzing home medication regimens with an information resource capable of identifying candidate regimens for minification of daily medication-taking events and daily pill burden while accounting for drug-drug interactions from simultaneous ingestion?

3. To what extent would the requirements of home medication regimens change if advice given by a computer application on how to minify daily medication-taking events and daily pill burden were implemented?

Methods

SMART Application Development

MedMinify was developed to meet the following requirements. The application had to be able to access and analyze prescription data organized as medication regimens for individuals. To provide drug product advice, MedMinify had to be able to identify the active ingredients in all current prescriptions for an individual and check for other substitutable drug products containing the same active ingredients. To ascertain whether drug-drug interactions pertain, MedMinify required a drug-drug interaction knowledge table and the routines to check whether the active ingredients in the current prescriptions for an individual could be found in the drug-drug interaction knowledge table. Finally, to facilitate regimen review by the investigators, MedMinify had to render key facts about each individual's regimen within a browser window along with any advice that the application generated.

Software design and application development of MedMinify involved the SMART platform (smartplatforms.org), the Django Web framework (Version 1.5, djangoproject.com), and the RxNorm application programming interfaces (rxnav.nlm.nih.gov/RxNormAPIs.html#). The organization of the MedMinify application is depicted in Figure 1. The SMART Reference EMR was used for development, testing, and evaluation of MedMinify. SMART afforded data models for individuals and their corresponding prescription records with an application programming interface (API) for the SMART Reference EMR. The Django Web framework afforded a Python-based Web development environment integrated with SQLite database technology. The Django Web framework also included a host of ready to use tools that enabled the development, testing, and rapid iterative refinement of the application. The RxNorm APIs afforded automated lookup of drug products marketed in the United States and their ingredients. MedMinify used Javascript executed in a browser along with Hyper Text Markup Language and Cascading Style Sheets to call the SMART API, render and format application output, respectively (Figure 1).

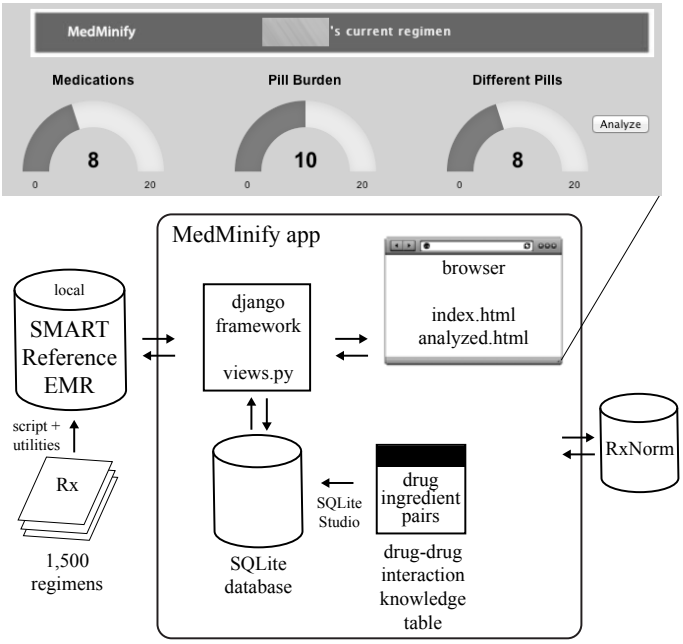

Figure 1. The MedMinify application architecture with a partial screen shot of its user interface. At the top of the image is a cutout of part of a user's view in a browser with counts of the Medications, Pill Burden, and Different Pills for one regimen. A local instance of the SMART Reference EMR platform was loaded with 1,500 sampled multi-drug enteral medication regimens (Rx). MedMinify used the Django Web framework and a SQLite database. Drug-drug interaction knowledge was loaded into the MedMinify SQLite database.

Several field value conversions were undertaken to convert data from the University of Michigan's EMR to the formats used by the SMART Reference EMR. These data conversions were made using rules in a spreadsheet. For example, the quantity of each dosage form to be administered was not a discrete field in the University of Michigan's EMR prescription data but the SMART EMR accepted a discrete value for the quantity of pills to be

administered. The quantity of pills to take at each medication-taking event was extracted from the instructions field in the original University EMR prescription data. A prescription instruction "Take 2 tablets daily" resulted in an extracted numeric quantity value of "2" for use by SMART. Similar data conversions were conducted for the frequency data from the University's EMR to transform the frequencies provided into the format used by SMART.

To support the drug interaction identification function of MedMinify, knowledge from drug interaction monographs was used (First DataBank, Inc. (FDB), San Francisco, CA). FDB provided the investigators with select fields from a complete set of their highest severity (FDB severity level 1) drug interaction monographs. The fields provided were the drug interaction monograph title, drug interaction mechanism, and clinical effects fields. Keyword analysis of the FDB knowledge source was conducted to select only those drug interactions related to simultaneous ingestion of medications. The 34 keywords included "gut", "intestine", "bioavailability", "absorption", "gastric", and "pH". A list of 59 unique, severity level 1 drug-drug interactions that are mechanistically associated with simultaneous ingestion was developed. After determining the drug pairs associated with each of the selected 59 drug-drug interactions and removing duplicates, a list of 559 interacting, active drug ingredient pairs for interactions due to simultaneous ingestion was created. For each active drug ingredient involved, the RxNorm ingredient (IN) code was identified. A free software application was used to load this drug interaction ingredient pair knowledge into the MedMinify application database (SQLiteStudio 2.1.5 by Pawel Salawa). An example row from this drug-drug interaction knowledge table includes the antacid omeprazole (RxNorm IN = 7646) and the antiviral drug atazanavir (RxNorm IN = 343047). It is known that omeprazole lowers the acidity of the gastric juices decreasing the solubility of atazanavir, disrupting atazanavir absorption, and thereby diminishing the potential efficacy of atazanavir.

After application development and testing using the publicly available SMART Reference EMR online sandbox, a local copy of the SMART Reference EMR was installed and made operable on an Apple Mac Mini computer running Mac OS version 10.8.5. A fictional name generator (http://homepage.net/name_generator/) was used to generate 1,500 fake names for loading the 1,500 randomly sampled regimens into the local SMART instance for use with MedMinify. After the 1,500 fictitious patients and corresponding regimens were loaded into SMART, data validation occurred by examining the SMART database. MedMinify application testing and use was conducted using an Apple MacBook Pro laptop running Mac OS version 10.8.5 connected via a local area network to the local SMART instance. The Safari browser was used (version 6.1.1).

Data source and sample

This study evaluated the function of a computer application we developed called MedMinify. To conduct the evaluation we used deidentified prescription data from the electronic medical record (EMR) system at the University of Michigan Hospitals and Health Systems (EpicCare Ambulatory Electronic Medical Record, Epic, Verona, WI). The Institutional Review Board of the University of Michigan reviewed and approved this study. Up to date medication regimens, provided as records of prescriptions for 41,903 unique individuals, were selected via query using the following criteria, a-c:

a. Each individual whose medication regimen was selected was alive and of a chronological age greater than or equal to 60 years on the date of the query, January 15, 2014.

b. Each individual whose medication regimen was selected had at least one medication list update documented in the University of Michigan's EMR during calendar year 2013 or the first two weeks of 2014 to ensure regimen currency.

c. Each individual's University of Michigan EMR profile had an International Classification of Diseases (ICD version 9) coded diagnosis for hypertension (401.x, 405.x, 416.x, 459.3x) and/or diabetes (249.x, 250.x, 253.5) and/or hypercholesterolemia (272.x).

These three criteria were specifically chosen to provide real medication regimens for adults using multiple medications to treat common diseases. This query of the University of Michigan's EMR resulted in data for 380,932 prescriptions. Besides patient identifiers such as age and gender, these data included prescription fields for ordering date, prescription start date, prescription end date, generic drug name, drug product strength, frequency, medication dosage form, route of administration, quantity to dispense, number of refills, medication therapeutic subclass, prescriber instructions, and RxNorm Semantic Clinical Drug code. Not all of these data were usable. A data exclusion diagram for the 380,932 prescriptions is given in Figure 2.

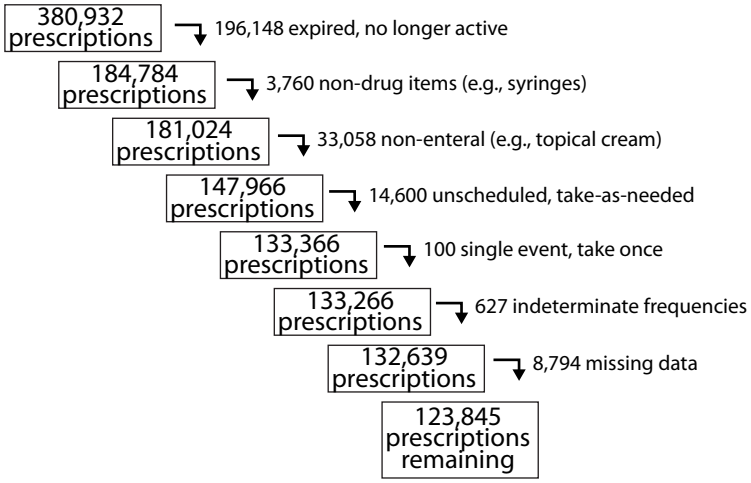

Figure 2. Prescription data was excluded for expired prescriptions, prescriptions for non-drug items, non-enteral prescriptions, take-as-needed prescriptions, single event prescriptions, and prescriptions with indeterminate frequencies. Prescriptions missing frequencies, product strengths, or RxNorm Semantic Drug codes were also removed.

After exclusions were applied and removal of prescriptions missing data, 123,845 active prescriptions remained for 35,042 unique individuals for scheduled and recurring home medications with known product strengths administered via an enteral route (e.g., orally or sublingually). Next, 8,105 complete medication regimens consisting of only one medication were also excluded leaving 115,740 prescriptions comprising the home medication regimens of 26,937 individuals with more than one scheduled and recurring medication of known product strength administered via an enteral route. These data included enteral medications prescribed for use on a weekly (e.g., "three times a week") or monthly (e.g., "once a month") schedule. For this study, these 26,937 medication regimens represent the population of qualified multi-drug enteral medication regimens used to treat chronic hypertension, hypercholesterolemia and diabetes. The 26,937 regimens include regimens for 14,403 females (53.5%) and 12,534 males (46.5%). The 26,937 individuals included had an average age of 71 years (SD 8.3, Range 60 to 103).

Because each regimen required approximately 10 seconds of time to analyze with MedMinify and 30 seconds more to assess if advice was given, instead of analyzing all 26,937 regimens a random sample of 1,500 regimens consisting of 6,241 prescriptions was taken from the population of 26,937 qualified regimens using SPSS (version 21). Random sampling was preferred over a selective sample of the most complex regimens because we believed random sampling to be the most conservative test of MedMinify's capabilities. The sample size of 1,500 regimens was chosen to give a desired margin of error of 0.025 for 95% confidence intervals for Chi-squared tests with one degree of freedom[19]. Sampling was done without replacement resulting in a hypergeometric distribution. However because the population of 26,937 is much larger than the sample size of 1,500 it was assumed that the binomial distribution provided a reasonably good approximation for calculating proportion confidence intervals. Therefore the Agresti-Coull adjusted Wald interval for large sample sizes was used to calculate the confidence intervals for sample proportions reported in this paper[20].

Generation of advice to minify daily medication-taking events or daily pill burden using a computer application

All 1,500 randomly sampled regimens were analyzed using MedMinify. For each regimen, MedMinify calculated the number of prescriptions in the regimen, the daily pill burden, the number of unique pills in the regimen, and the maximum number of daily medication-taking events required by the regimen. Next, for every immediate-release pill taken more than once a day, MedMinify checked RxNorm to see whether a sustained-release product was available as a potential substitute. If so, MedMinify recommended that the sustained-release product or products be considered as substitutes. Subsequently, for every pair of active ingredients prescribed as two single ingredient products, MedMinify checked RxNorm to see whether a fixed-dose combination drug product was available that combined two active ingredients in one pill. If so, MedMinify recommended that the fixed-dose combination product or products be considered as substitutes. Next, MedMinify screened every pair-wise combination of active drug ingredients in each regimen against the table of known FDB severity level 1 interacting drug-drug pairs where the drug-drug interaction is associated with simultaneous ingestion. When a potential drug-drug interaction was

identified, MedMinify gave advice not to take the two interacting drugs at the same time of day. Finally, MedMinify counted all instances when a single active ingredient in a regimen appeared in the drug-drug interaction knowledge table (i.e., one drug of an interacting pair) even where no drug interaction was found. Because this was a lab function study, there were no consumer end users and none of the advice generated was ever implemented.

Quantification of how much home medication regimen requirements would change if the computer-generated advice were implemented

All advisories given by MedMinify to change sampled medication regimens were documented and counted. Assuming MedMinify's advice was accepted and implemented, the potential change or changes to each regimen where advice was generated was assessed in two ways. First, if a sustained-release product or products was recommended, the pharmacist investigator (AJF) checked to see whether the maximum number of medication-taking events per day could be reduced, and, if so, by how many daily events. (The opportunity to minify the maximum number of medication-taking events per day depends on whether the recommendation to substitute a sustained-release product applies to the prescription with the most daily medication-taking events.) Next, if either a sustained-release or a fixed-dose combination product or both were recommended by MedMinify, the pharmacist investigator checked to see whether the daily pill burden could be reduced, and if so by how much. When overlaps implementing this advice arose, for example when the same active ingredient could be taken via a sustained-release drug product or as a component of a fixed-dose combination drug product, preference was given to minifying the number of daily medication-taking events over minifying the daily pill burden.

Results

1. Is the Substitutable Medical Apps, Reusable Technology (SMART) platform robust and extensible enough to support the architectural and functional requirements of a system capable of giving advice on how to potentially minify daily medication-taking events and daily pill burden?

The MedMinify application is an example of a SMART Connect application (Figure 1). SMART Connect provides the SMART JavaScript client for the purpose of communicating from a SMART container via the SMART API when connecting to the SMART Reference EMR with a browser. To meet MedMinify's requirement for access to prescription data organized as regimens, SMART permitted MedMinify access to prescription data stored in its database with one minor limitation. The SMART Reference EMR data model could not fully represent prescriptions with specific days and times in coded fields (e.g., "Take 1 tablet at 2:00 p.m. on Tuesdays and Thursdays."). A few prescriptions had to be represented in less detail with respect to dose timing upon conversion to SMART. To meet the requirement for RxNorm integration, procedural code written in a high-level programming language, Python, was used to manage calls and responses via the RxNorm prescribable APIs. The Django Web framework played a central role in the architecture of MedMinify. To meet the requirement for integration of drug-drug interaction knowledge, the Django Web framework provided an integrated SQLite database. Finally, to meet the requirement for rendering output to the screen within the SMART container, the Django Web framework provided a web server to serve various files including index.html and analyzed.html (Figure 1). The combination of SMART and the Django Web framework afforded a stable, extensible platform upon which MedMinify was successfully built.

2. What types of advice and how much of each type can be generated by analyzing home medication regimens with an information resource capable of identifying candidate regimens for minification of daily medication-taking events and daily pill burden while accounting for drug-drug interactions from simultaneous ingestion?

Three sets of results address the second research question, quantification of the overall amount of advice generated, categorization of the generated advice by type, and an analysis of MedMinify's drug-drug interaction checking function. Descriptive statistics and results quantifying the number of recommendations given as advice for minifying the 1,500 sampled regimens are given in Table 1 where the sampled regimens are categorized according to the maximum number of daily medication-taking events.

Table 1. Sampled qualified multi-drug enteral medication regimens (n = 1,500) data for individuals of age greater than or equal to 60 years with diagnoses for hypertension or diabetes or hypercholesterolemia (alone or in combination) according to the maximum number of daily medication-taking events per regimen.

Number of Daily Medication-Taking Events Category	Number of Sampled Regimens	Number of Sampled Regimens with Recommendations from MedMinify	Average Number of Prescriptions per Sampled Regimen	Average Daily Pill Burden per Sampled Regimen
Max. 8 events daily	1	0	7.0	26.0
Max. 6 events daily	3	2	5.3	15.6
Max. 5 events daily	4	2	6.3	15.8
Max. 4 events daily	44	22	5.4	11.3
Max. 3 events daily	178	126	5.7	10.4
Max. 2 events daily	643	388	4.6	6.7
Max. 1 event daily	626	79	3.2	3.4
Max. 0* events daily	1	0	2.0	0.0
TOTALS	1,500	619		

*One regimen included only prescriptions for medications to be taken weekly and no medications to be taken daily.

MedMinify identified 619 (41.3%) of the 1,500 randomly sampled regimens, 95% CI [38.7, 43.7] as candidates for minifying daily medication-taking events or daily pill burden.

In Table 2 below, the 619 regimens where at least one recommendation to change the regimen was given are further categorized by the type of recommendation. Population estimates for the proportion of regimens subject to each type of advice are given as 95% confidence intervals in Table 2.

Table 2. Counts and percentages of sampled regimens (n = 1,500) are provided by recommendation type with confidence intervals for population estimates of the percentages of regimens for which MedMinify would generate recommendations for the study population.

Recommendations Generated per Sampled Regimen	Number of Sampled Regimens	% of Sampled Regimens (95% CI)
Any Recommendation	619	41.3% (38.8, 43.8)
Sustained Release Product Recommendations Only	407	27.1% (24.9, 29.4)
Fixed-Dose Combination Product Recommendations Only	114	7.6% (6.3, 8.9)
Sustained Release and Fixed Dose Combination Products	94	6.3% (5.0, 7.5)
Sustained Release Product and Drug-Drug Interaction	3	0.2% (0.0, 0.4)
Drug-Drug Interaction Only	1	0.1% (0.0, 0.3)

For the 1,500 sampled regimens, MedMinify identified at least one drug on the FDB drug-drug interaction list in 1,209 (81%) of regimens, 95% CI [78.6, 82.6]. MedMinify recommended against taking two drugs at the same time in four cases due to drug-drug interactions related to simultaneous ingestion of drug products. Three of the four drug interactions involved the drugs cyclosporine and simvastatin. (There is a risk that competition for influx transporter proteins in the small intestine and liver could change the serum levels and efficacy of either drug[21]. It is not clear whether taking cyclosporine and simvastatin at different times of day mitigates the risk of harm from this interaction.) The fourth case of a drug-drug interaction detected by MedMinify involved the two drugs rosuvastatin and gemfibrozil. (There is a risk of muscle damage when using these drugs simultaneously. The exact mechanism of this drug interaction is unknown but there is a suggestion in the literature that simultaneous ingestion may play a role in the interaction[22]. It is not clear whether taking rosuvastatin and gemfibrozil at different times of day mitigates the risk of harm from this drug interaction.)

3. To what extent would the requirements of home medication regimens change if advice given by a computer application on how to minify daily medication-taking events and daily pill burden were implemented?

If MedMinify's advice were accepted and implemented for all of the regimens for which recommendations were generated, 320 out of the 1,500 regimens (21.3%, 95% CI [19.3, 23.4]) would have at least one fewer daily

medication-taking event. Three regimens would actually gain an additional daily medication-taking event to mitigate an identified drug-drug interaction by taking the interacting drugs at two different times of day. The daily pill burden for an additional 295 of the 1,500 regimens (19.7%, 95% CI [17.7, 21.8]) would be minified by an average of 1.4 pills per regimen. Table 3 includes more detail about these regimen changes.

Table 3. Changes for sampled qualified multi-drug enteral medication regimens (n = 1,500) according to the maximum number of daily medication-taking events per regimen if all of MedMinify's advice were implemented.

Number of Daily Medication-Taking Events Category	Number of Sampled Regimens	Number of Sampled Regimens with Fewer Daily Medication-Taking Events	Number of Sampled Regimens with Decreased Daily Pill Burden Only	New Average Daily Pill Burden per Sampled Regimen if Advice Implemented (Difference)
Max. 8 events daily	1	0	0	26.0 (0)
Max. 6 events daily	3	1	1	13.3 (-2.3)
Max. 5 events daily	4	1	1	14.8 (-1.0)
Max. 4 events daily	44	10	12	10.2 (-1.1)
Max. 3 events daily	178	80	45	9.3 (-1.1)
Max. 2 events daily	643	228	157	5.8 (-0.9)
Max. 1 event daily	626	N/A[†]	79	3.3 (-0.1)

[†]One is a minimum daily medication-taking event. MedMinify does not provide advice to discontinue medication therapies.

Discussion

Taking medications every day at home to treat chronic diseases is difficult for most people. Whether and how well one adheres to a home medication schedule is a result of a complex set of influences including economic factors, social support, individual dedication to the task, and beliefs about the utility of prescribed medication treatments[5,23]. For individuals with means who have supportive relationships and believe that taking medications is beneficial, adherence to complex medication regimens is still difficult[8]. More attention on simplifying regimens is needed to make every home medication regimen as easy to execute as possible[6].

Pharmacists have long been champions of simplifying medication regimens and reducing polypharmacy[24]. However, many consumers are unaware that their pharmacist can assist them to simplify their home medication regimens. Relatively few consumers are assured to have the simplest possible medication regimens. MedMinify could improve the efficiency of time-consuming home medication regimen reviews provided unsystematically to consumers today.

In this initial evaluation of the function of the MedMinify advice-giving system in the lab, advice to minify daily medication-taking event and daily pill burden was generated for 41.3%, 95% CI [38.7, 43.7] of actual home medication regimens for adults with one or more of three common chronic diseases. This result is bolstered by a previous analysis we did where we found that similar drug product substitution advice could be generated for 38.4% of 2,944 home medication regimens of retirees surveyed in 2007 and by results from Elliott that potential changes to reduce complexity were identified in 45.7% of reviewed medication regimens at hospital discharge[7,25].

Based on a careful analysis of the 1,500 sampled regimens we believe the 41.3% figure may overestimate the actual percentage of candidate regimens subject to applicable simplification advice. However, if for reasons of consumer preference, clinical indication, drug product cost, or perceived low marginal utility from changing prescriptions only 1 out of 5 home medication regimens for which advice was given by MedMinify would actually be simplified in practice, the fraction of regimens changed would be approximately 8% in this population. Routine screening with an information resource to try and minify daily medication-taking events or daily pill burden may be justified if 8 out of every 100 regimens could be made simpler. This is a particularly important finding when one considers that 15.3%, 95% CI [13.5, 17.2] of home medication regimens in this population require individuals to take medications more than two times a day (Table 1). We found that 151 of these 230 complex regimens (65.6%) were candidates for simplification, and that the greater fraction of the advice given to simplify these regimens would have resulted in diminishing the number of daily medication-taking events (Table 3). Because the regimens studied were real and current regimens for actual individuals, it is reasonable to generalize these findings to similar consumer populations.

Specific recommendations to substitute sustained-release products for immediate-release ones were the most common recommendations made by MedMinify (Table 2). An example would be to use the antihypertensive beta-blocker carvedilol as a sustained-release product once a day instead of twice a day as an immediate-release product. MedMinify generated fixed-dose combination recommendations for a total of 208 out of the 1,500 regimens (Table 2). An example of a fixed-dose combination recommendation would be to substitute a pill that contains both the antihypertensive drugs hydrochlorothiazide and lisinopril instead of taking these two drugs as separate pills.

Consumers may separate their medication-taking tasks throughout the day due to confusion over prescription instructions or concerns about drug-drug interactions[16]. It was expected that very few drug-drug interactions would be identified in real regimens like those studied because of prior drug interaction screening. In this study, while most regimens included one drug in the drug interaction knowledge table, rarely were two interacting drugs found in the same regimen. While commonly used medications such as the "cholesterol-lowering statins" are involved in severity level 1 drug-drug interactions, to cause an interaction these drugs had to have been paired with other drugs that are rarely used in this population. By checking for the rare drug-drug interactions that can be managed by taking medications at different times of day, MedMinify can be used to indicate how most medications prescribed to treat high blood pressure, diabetes, and high cholesterol can safely be taken together at the same time of day.

This study has several limitations. With respect to the methods used, the clinical appropriateness of the advice offered by MedMinify was not assessed. Also prescriptions for non-enteral drug products and take-as-needed prescriptions were excluded making the regimens studied less complex than they actually are. With respect to limits on MedMinify's functionality, the application cannot currently reconcile medication-taking events with individual preferences for meal times, work hours, or sleep schedules. MedMinify does not yet account for the differing cost of various medication products neither for prescription insurance coverage. MedMinify does not recognize the difference between temporary or trial prescriptions and other prescriptions. Also, by limiting the scope of drug-drug interaction assessment to only severity level 1 interactions as defined by FDB, we surely overlooked some less severe but important drug-drug interactions.

Future work will address some of the limitations. We also intend to study having MedMinify give other types of advice including advice about duplicative prescriptions, potentially inappropriate medications[26], and polypharmacy. We also look forward to further developing and evaluating a consumer-oriented user interface for MedMinify that will gather details about an individual's daily schedule and provide advice that is informed by it.

To achieve an ideal level of adherence to home medication regimens requires much more than decreasing the number of medication-taking events or the daily pill burden. However, adherence is improved when home medication-taking schedules become simpler. Minifying daily medication-taking events and daily pill burden is necessary, but not sufficient, to improve adherence to medication regimens used to treat chronic conditions.

Conclusion

A new advice-giving system developed for the SMART platform, and the advice it gave about drug products and drug-drug interactions, was studied. Advice to minify the number of medication-taking events per day and the number of pills taken daily was generated for 41.3% of home medication regimens for adults with chronic conditions. The percentage of regimens for which advice was given increased as the complexity of the home medication regimens increased. Even if only a fraction of the advice given resulted in regimen changes, a considerable number of home medication regimens would include fewer daily medication-taking events involving fewer pills. This study provides preliminary evidence that an information resource could be used routinely to help simplify home medication-taking schedules for adults with chronic medical conditions.

Could Patient Self-reported Health Data Complement EHR for Phenotyping?

Abstract

Electronic health records (EHRs) have been used as a valuable data source for phenotyping. However, this method suffers from inherent data quality issues like data missingness. As patient self-reported health data are increasingly available, it is useful to know how the two data sources compare with each other for phenotyping. This study addresses this research question. We used self-reported diabetes status for 2,249 patients treated at Columbia University Medical Center and the well-known eMERGE EHR phenotyping algorithm for Type 2 diabetes mellitus (DM2) to conduct the experiment. The eMERGE algorithm achieved high specificity (.97) but low sensitivity (.32) among this patient cohort. About 87% of the patients with self-reported diabetes had at least one ICD-9 code, one medication, or one lab result supporting a DM2 diagnosis, implying the remaining 13% may have missing or incorrect self-reports. We discuss the tradeoffs in both data sources and in combining them for phenotyping.

Introduction

The vast amounts of clinical data made available by pervasive electronic health records (EHRs) presents a great opportunity for reusing these data to improve the efficiency and lower the costs of clinical and translational research[1]. One popular use case is to identify patients for care management or research, prospectively, or as part of retrospective cohort for study. In this context, cohort identification using EHR data is known as EHR phenotyping.

The Electronic Medical Records and Genomics (eMERGE) consortium is a current multi-site research network sponsored by the National Institutes of Health of the United State. This network develops precise and portable phenotyping algorithms using heterogeneous EHR data[2]. To improve algorithm portability across different EHR systems, the design and evaluation of EHR phenotyping algorithms have relied on collaboration across institutions. For example, the eMERGE Type 2 Diabetes Mellitus (DM2) Case and Control algorithms were developed collaboratively by five institutions, resulting in the identification of over three thousand cases and controls to support a genome-wide association study (GWAS) on diabetes patients[3, 4]. The algorithm uses commonly captured EHR data elements for diagnosis, medications, and lab values to identify Type 2 diabetics. The emphasis on portability imposes a tradeoff due to the inherent data quality issues of those commonly captured EHR data elements. For example, ICD-9 billing codes are a coarse representation for nuanced narrative notes, medication orders do not necessarily reflect medication adherence, and as reported by Wei et al., EHR data fragmentation could negatively impact clinical phenotyping[5]. Moreover, while EHR data like lab values may be objectively correct, they may not actually reflect patient awareness of their own health status.

The eMERGE DM2 algorithm was originally validated using chart review. The expense of chart review typically limits sample size and only 50-100 each for cases and controls were reviewed in this example[3, 4]. Moreover, the chart review process does not sample from patients excluded from the case and control groups, meaning that a true sensitivity for identification of diabetes cases may not be established. Finally, chart review is still internal validation, implying the reference standard is still limited to information captured within the EHRs of related institutions[5]. Richesson et al. compared the identified individuals from different diabetes phenotyping algorithms[6]. While different algorithms might be created for different purposes, for example maximizing sensitivity for a registry versus specificity for a genetic study, the results do suggest that any given algorithm may fail to identify all diabetics in a database.

With the increasing emphasis on patient and community engagement for clinical research, self-reported diseases status has risen as an alternative data source for clinical phenotyping. These data are usually collected directly from patients, as opposed to EHR data that reflect the encounters of a patient with a single institution. Prior studies

checked the self-reported diabetes status against EHR data and achieved sensitivities around 0.75, and specificities around 0.9 [7-10].

While pieces of patient self-reported data have informed specific elements of clinical data used for phenotyping, such as self-reported smoking rate[11] and date of diagnosis[12], little is known about how self-reported disease status data might be useful for clinical phenotyping. Both EHR data and patient self-reported health data have advantages and disadvantages for patient identification. We faced an unusual opportunity to address this research question.

The Washington Heights/Inwood Informatics Infrastructure for Community-Centered Comparative Effectiveness Research (WICER) Project has been conducting community-based research and collecting patient self-reported health information[13]. A subset of surveyed individuals have clinical information stored at the Columbia University Medical Center, allowing direct comparison of diabetes status derived from clinical data to the self-reported diabetes status. Therefore, in this study we will validate the eMERGE DM2 Case algorithm using patient-reported diabetes status. This study is part of a larger research effort to use research data to verify clinical data accuracy.

Table 1: eMERGE DM2 algorithm criteria and definitions

Criterion	Definition	Query Terms
DM1 Diagnosis	Patient has ICD-9 codes indicating Diabetes Type I.	250.x1, 250.x3
DM2 Diagnosis	Patient has ICD-9 codes indicating Diabetes Type II.	250.x0, 250.x2 excl 250.10, 250.12
Control Diagnosis	Patient has ICD-9 codes indicating diabetes, conditions which may lead to diabetes, or family history of diabetes	250.xx, 790.21, 790.22, 790.2, 790.29, 648.8x, 648.0x, 791.5, 277.7, V18.0, V77.1
DM1 Medications	Patient has medication history for drugs treating Diabetes Type I.	insulin pramlintide
DM2 Medications	Patient has medication history for drugs treating Diabetes Type II.	acetoexamide tolazamide chlorpropamide glipizide glyburide glimepiride repaglinide nateglinide metformin rosiglitazone pioglitazone troglitazone acarbose miglitol sitagliptin exenatide
Control Medications	Patient has medication history for drugs treating diabetes.	Combination of DM1 and DM2 Medications
DM Lab	Patient has recorded lab value for HbA1c > 6.5, Fasting Glucose >= 126, Random Glucose > 200	HbA1c, Fasting Glucose, Random Glucose

Methods

1. Data Collected by WICER

Through cluster and snowball sampling methodologies, the WICER Community Survey collected data from residents in Washington Heights, an area of Northern Manhattan in New York City with a population of approximately 300,000 people. Surveys were administered to individuals over the age of 18 who spoke either English or Spanish. Survey data was collected and processed from March 2012 through September 2013. A total of 5,269 individuals took the WICER Community Survey in either the household or clinic setting.

The survey collected information about social determinants of health and health seeking behaviors as well as established some baseline health information. Survey participants were explicitly asked whether they had been told they had diabetes, high blood sugar, or sugar in the urine when not pregnant. The answer to this question was extracted as the self-reported diabetes status.

2. Data Collected by the Columbia University Clinical Data Warehouse

The Columbia University Medical Center's Clinical Data Warehouse (CDW) integrates patient information collected

from assorted EHR systems for about 4.5 million patients for more than 20 years. Commonly available structured EHR data elements include visits, medications, diagnostic codes, lab values, and clinical notes.

3. The eMERGE DM2 Case and Control Algorithms

As stated above, the eMERGE DM2 Case algorithm consists of three sets of criteria: diagnosis, medications, and lab values[4]. Diagnosis and medication criteria have components which indicate Diabetes Mellitus Type I (DM1) or Type II. Only patients with DM1 ICD-9 codes were completely excluded from the Case algorithm. For the purpose of this study, any patient reporting positive diabetes status who also had DM1 ICD-9 codes had their status reset to negative. DM1 medications only denote insulin dependence, which may also be found in DM2, and so additional logical criteria are required.

In contrast, the criteria for the eMERGE DM2 Control algorithm are very similar to the case algorithm, albeit inverted. Controls must have at least two visits recorded, a normal glucose measurement, and no evidence of either diabetes or conditions which might lead to diabetes. The other differences are that no effort is made to distinguish between the types of diabetes (i.e., I or II), and the range of ICD-9 codes for the diagnostic criteria is expanded to include observations that co-occur with Type 2 diabetes. Criteria and their definitions are presented in Table 1.

4. Cohort Identification

Patient data were extracted for every patient in the CDW for 2009-13. We chose this time window to replicate the time scale used by Richesson, et al. and to accommodate the fact that the medication data in our data warehouse are not complete prior to 2009. A subset of CDW patients who also have a WICER-recorded diabetes status was identified for validation of the eMERGE DM2 Case algorithm. The remainder of the CDW population was used to investigate potential differences between the self-reported population and the general data population.

5. Data Element Extraction for Each Cohort

Table 2: Patient level data variables and definitions

Variable	Definition
Sex	Sex of the patient.
Age	Age in years on 1/1/2014.
Visits	Number of visits between 2009 and 2013.
Span	Length of time in days between first and last recorded visit.
DM1 Diagnosis	Number of ICD-9 codes meeting the Diabetes Type I diagnostic criteria.
DM2 Diagnosis	Number of ICD-9 codes meeting the Diabetes Type II diagnostic criteria.
Control Diagnosis	Number of ICD-9 codes meeting the Control algorithm diagnostic and family history exclusion criteria.
DM1 Medication	Earliest prescription date for medication meeting the Diabetes Type I medication criteria.
DM2 Medication	Earliest prescription date for medication meeting the Diabetes Type II medication criteria.
Control Medication	Number of medication orders meeting the control algorithm exclusion criteria.
Glucose Tests	Number of glucose test values recorded for the patient.
Abnormal Labs	Number of lab results high enough to indicate diabetes.
Diagnosis Criteria	1 if the patient meets the diagnostic criteria for Diabetes Type II, 0 otherwise.
Medication Criteria	1 if the patient meets the medication criteria for Diabetes Type II, 0 otherwise.
Lab Value Criteria	1 if the patient meets the labs criteria for Diabetes Type II, 0 otherwise.
Case	1 if the patient is identified by the eMERGE Case algorithm, 0 otherwise.
Control	1 if the patient is identified by the eMERGE Control algorithm, 0 otherwise.
Survey Diabetes	1 for a positive patient-reported diabetes status, 0 otherwise. Exists only in Matched Data

Table 2 presents the variables and definitions required for cohort identification and comparison using the eMERGE Case and Control algorithms. For each patient in a dataset, the data elements in Table 2 were either extracted or calculated. The self-reported diabetes status for each individual was extracted from their survey response and included in the patient level data. For the purpose of this study, any patient reporting positive diabetes status who also had DM1 ICD-9 codes had their self-reported status reset to negative.

6. Analysis Plan

Several groups of patients were collected for comparison from both the subset of patients with self-reported diabetes status and general patient population. These groups are the patients identified by the eMERGE DM2 Case algorithm (eMERGE Case: Case = 1), the pool of potential cases meeting any of the diagnostic, medication, or lab value criteria (Case Pool: Diagnosis OR Medication OR Lab), and those patients meeting none of the criteria (Excluded: Not Diagnosis AND Not Medication AND Not Lab AND Not Control). For patients with self-reported status, patients responding "Yes" and "No" were also separated for analysis. The number of patients, fraction of patients who are female, average and standard deviation for age, number of visits, and time between the first and last recorded visit for each group were reported. For groups of patients with self-reported status, the number of patients identifying as diabetic was also reported. Summary values for each group were quantitatively described and compared.

Sensitivity, specificity, and positive predictive value against all patient self-reported statuses were calculated for the eMERGE DM2 Case algorithm, the component criteria individually (Diagnosis, Medication, Lab), the group of patients meeting all the criteria (Diagnosis AND Medication AND Lab), and patients meeting any of the criteria (Diagnosis OR Medication OR Lab). Sensitivity, specificity, and positive predictive value were also calculated for the eMERGE DM2 Case group using just the individuals identified by the paired Control algorithm.

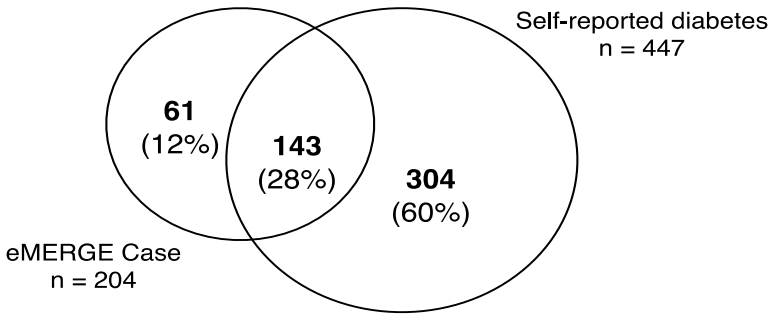
The eMERGE DM2 Case algorithm was expected to identify patients who do not report having diabetes, and not all patients reporting diabetes were expected to be identified by the algorithm. To investigate whether identification by the DM2 Case algorithm was a result of different subtypes of diabetes, with different patterns of comorbidities, all ICD-9 codes were pulled for each patient. ICD-9 codes were truncated at the root code level, or the whole number component of the code, and the frequencies of codes for each group were reported.

Results

We report our results in Tables 3-6, which includes summary statistics and demographics on specified patient groups, as well as validation statistics against all patient self-reported diabetes statuses and only those identified by the Control algorithm. See Figure 1 for a Venn diagram displaying the overlap between the patients identified by the eMERGE DM2 Case algorithm and those patients self-reporting positive diabetes status.

There were 2,249 WICER Survey participants with self-reported diabetes status who had at least one visit recorded at our institution within the last five years. Table 3 presents summary statistics and demography for patients reporting diabete s and no diabetes. The patients identified by the eMERGE DM2 Case algorithm (eMERGE Case), the pool of potential cases meeting any of the diagnostic, medication, or lab value criteria (Case Pool), and those patients meeting none of the criteria (Excluded) are presented for both the patients with reported diabetes status and the general population. In

Figure 1: Venn diagram of overlap between patients identified by the eMERGE DM2 Case algorithm and patients self-reporting positive diabetes status.



patients with self-reported status, eMERGE Cases and patients in the Case Pool are, on average, more than 15 years older than the Excluded group, and have twice as many recorded visits. The same difference is more than 24 years in the general patient population, with three times as many recorded visits. Patients with reported status are more likely to be female, as expected, but follow the same trend with regard to age and visits, albeit with 1.8-3.5x as many visits. While patients with reported status do tend to be older than the general population in general (46.1 vs. 36.4), those in the respective Case Pools are approximately the same age (61.8 vs. 61.0).

Table 4 shows the validation statistics against self-reported status. Sensitivity and specificity for the eMERGE phenotyping algorithm were .32 and .97, respectively, while positive predictive value was .70. The highest positive predictive value (.85) was achieved by requiring all criteria (Diagnosis AND Medication AND Lab). This combination also has the highest specificity (.98). While the highest sensitivity (.87) was achieved by the least restrictive combination (Diagnosis OR Medication OR Lab), the sensitivity of the combination requiring all criteria (.55) was still higher than that of the eMERGE algorithm.

Validation statistics were also computed for the eMERGE DM2 Case algorithm using only the eMERGE DM2 Control patients for comparison. These results are presented in Table 5. As a pair the DM2 Case and Control algorithms excluded 1,449 patients, reducing the pool of analyzable patients to 800. The majority of self-identified diabetes patients fell into the excluded group, which raised the apparent sensitivity of the eMERGE DM2 Case

Table 3: Cohort Demography and Characteristics. Groups are patients identified by the eMERGE DM2 Case algorithm (eMERGE Case), pool of potential cases meeting any of the diagnostic, medication, or lab value criteria (Case Pool), and those patients meeting none of the criteria (Excluded). Patients answering "Yes" or "No" to diabetes status are also presented.

Cohort	Group	N	Patient-reported Diabetes Count	Fraction Female	Average Age (SD Age)	Average Visits (SD Visits)	Average Time between First and Last Visit (SD Time)
Patient-reported Diabetes Status	**Yes**	447	447	0.76	62.0 (12.1)	40.3 (45.4)	1223.6 (665.3)
	No	1,802	0	0.79	48.0 (16.9)	24.4 (33.6)	1052.2 (654.6)
	eMERGE Case	204	143	0.72	62.4 (12.3)	34.8 (36.7)	1293.6 (568.5)
	Case Pool	670	387	0.76	61.8 (13.0)	43.3 (45.9)	1285.1 (520.1)
	Excluded + Control	1,579	60	0.79	46.1 (16.3)	20.9 (29.7)	1159.0 (564.9)
General Patient Population	**eMERGE Case**	25,310	n/a	0.50	65.8 (15.2)	18.7 (29.6)	902.1 (641.0)
	Case Pool	106,569	n/a	0.50	61.0 (21.3)	19.0 (32.2)	848.4 (649.7)
	Excluded + Control	680,324	n/a	0.58	36.4 (22.8)	5.8 (11.6)	677.3 (589.2)

algorithm to .93. However, the apparent specificity fell to .91.

The 15 most frequent ICD-9 codes for the intersections between the patients satisfying the eMERGE DM2 Case algorithm and the patients with positive self-identified diabetes status (+eMERGE +Self) are presented in Table 6. Codes for groups where the two methods disagreed (+eMERGE –Self, -eMERGE +Self) are presented in the same table as well as codes for the group of patients with no identification for diabetes (-eMERGE –Self). Note that DM1 and DM2 share the same root code (250) and no steps were taken to distinguish between types in this analysis. In general, the rank order of codes by frequency, as well as their general prevalence, is the same for the three diabetic groups regardless of how they were identified. The prevalence for diabetes ICD-9 codes is notably high in these groups. Prevalence for many of these codes is very different from patients without any indication of diabetes. Other comorbidities which are at least twice as prevalent in a diabetes group as in the non-diabetes group are hypertension, high cholesterol, diseases of the esophagus, and obesity. Patients with some identification for diabetes resemble the non-diabetic, general patient population in the prevalence of codes for follow-up examination, special investigations

Table 4: Positive predictive value, sensitivity, and specificity for the eMERGE DM2 Case algorithm using only the patients identified by the eMERGE DM2 Control algorithm.

Set	N	Patient-reported Diabetes Count	Positive Predictive Value	Sensitivity	Specificity
eMERGE Case	204	143	0.70	0.32	0.97
Diagnosis	517	369	0.71	0.83	0.92
Medication	320	260	0.81	0.58	0.97
Labs	549	330	0.60	0.74	0.88

or examinations.

Discussion

The results of the eMERGE DM2 Case algorithm, as well as its component criteria, was validated against all patients with self-reported diabetes status, prompting several points for consideration. We will discuss issues surrounding the generalizability of the patients with self-reported diabetes status to the general patient population, discrepancies between identification from the eMERGE DM2 Case algorithm and the self-reported statuses, and the potential contributions of patient self-reported data to EHR phenotyping.

Patient Comparison and Generalizability

One concern with this dataset is the patients with self-reported diabetes status, those who participated in the WICER Community Survey, are known to differ from the general population in several ways.

The group is older, containing more women, and is mostly Hispanic. However, the portion of these patients with positive indications for diabetes do resemble their counterparts in the general patient population in terms of age, and

the relatively increased number of recorded visits, as shown in Table 3. These findings suggest that the characteristics of patients with diabetes do not depend on the population from which they are drawn.

In Table 6, ICD-9 codes for diabetes are the most frequently represented in patients with some identification, either by the eMERGE DM2 Case algorithm or self-report, for diabetes, as expected. However, there are some discrepancies. The relatively lower prevalence of diabetes ICD-9 codes in the portion of self-reporting patients not identified by the eMERGE DM2 Case algorithm may indicate self-report inaccuracies or the effect of missing data in this group. The 5% prevalence of diabetes ICD-9 codes in the group with no identification for diabetes (-eMERGE –Self) may be a result of codes specific for DM1 which were filtered out by the DM2 case algorithm and not in that analysis.

Discrepancies in Identifying Diabetes

The eMERGE DM2 Case algorithm is known to perform well against case review and does achieve very high specificity in this evaluation. The algorithm performs less well in selecting all of the individuals who self-report having diabetes, and this may be for many reasons. First, the case algorithm is restrictive in order to limit the inclusion of DM1 patients. While steps were taken to exclude any patients who obviously had DM1, some of the patients who remain in the pool of potential cases may be rightfully excluded for this reason. Second, the non-selected patients may be incorrect about their diabetes status, though this is probably unlikely as this group of patients resembles the selected patients in patterns of visits and other demographics as well as the presence and frequency of comorbitidies. Moreover, if a large number of patients were in fact incorrect about their diabetes status, we would expect to see more discovered by the control selection algorithm. Lastly, and suggested by Wei, et al., the non-selected patients may be the product of data fragmentation, which is to say they do not have enough of their healthcare data consolidated in our system to allow identification by the eMERGE DM2 Case algorithm. For example, 83% of the self-reporting diabetic patients have at least a ICD-9 code for DM2 in our data warehouse, but at least 60% of those fail to be identified by the eMERGE DM2 Case algorithm for lack of sufficient clinical evidence for that diagnosis.

The more interesting group may be those patients selected by the eMERGE DM2 Case algorithm who do not self-identify as having diabetes. They have met the algorithm's stringent inclusion criteria, have visit patterns, other demographics, and comorbidities in common with the self-identifying diabetic patients, suggesting by very objective measures that they do have diabetes. That these patients seem to not be aware they have diabetes may have large implications to their treatment, adherence to that treatment, and their engagement with any treatment. Pacheco reported that only approximately half of the patients identified by the eMERGE DM2 algorithm at Northwestern had diabetes as part of the patient’s problem list, further suggesting that this effect is not confined to the patient[14].

Contribution of Patient Self-reported Data

There are pros and cons to both EHR data and patient self-reported data (Table 7) which point to how the two data sources might complement each other. EHR data is very heterogenous, with many data types, but that data may have issue such as missingness and inaccuracies that limit their secondary use for research. The more common elements have successfully been used for patient phenotyping algorithms, but that does not necessarily imply the algorithms have high sensitivity. In contrast, patient self-reported data reflects the patient's perception of their health status and may imply higher patient engagement in treatment, but may also be inaccurate and does not imply there is a useful quantity of clinical data at any one institution.

The best use of patient self-reported status may be augmenting EHR-based phenotyping algorithms. Phenotyping algorithms like the eMERGE DM2 algorithm typically require multiple criteria for successful identification of a disease and in our study the majority of patients who self-reported positive diabetes status did not have enough data in our system to be selected by the DM2 Case algorithm. Yet, 87% of them did have at least one ICD-9 code, medication order, or lab result to support a diagnosis of diabetes. If patient self-reported status could be standardized and used in addition to commonly captured EHR data elements for phenoyping algorithms, our study suggests the number of patients identified by such algorithms could be greatly increased.

This recommendation comes with two caveats, however. First, the contribution of patient self-reported status to phenotyping algorithms for research will depend on the needs of that research. If clinical data are important, as in a retrospective observational study, then patients who cannot be identified from their data alone may not be useful. Approaches such as the eMERGE DM2 Case algorithm would therefore be the best way to identify meaningful cases within a data source. On the other, if the goal is to simply identify as many patients with a disease or status as possible, for a potential prospective study or a GWAS, then self-reported data would be a valuable addition.

Table 7: Pros and cons of EHR and Patient self-report data sources.

	Data Source	
	EHR	Patient self-report
Pro	Heterogenous data types support high specificity. Common, standardized elements support portability.	Reflects patient perception. Might imply higher patient engagement.
Con	High rate of missingness. May only reflect encounter with a single institution	Does not imply useful quantity of clinical data. Patient perception may not be clinically accurate.

The second caveat is the issue of standardization. The portability of phenotyping algorithms relies on the use of common and standardized EHR data elements, such as ICD-9 codes. If the source of patient self-reported disease status is not standardized down to the exact wording of the question being answered, then the results may not be comparable and the resulting algorithm may not be portable. For example, the source of patient self-reported diabetes status in our study did not distinguish between DM1 and DM2. While steps were taken to address this limitation, the exact results of this study would probably be different if the survey question had specifically addressed DM2 alone. Therefore, any potential phenotyping algorithm built using our data might not perform the same on a data source with a patient self-reported data source specific to DM2.

Limitations

This study has several limitations. First, relatively few people were surveyed compared to the size of the large volume of patients in the EHRs. While the patients with self-reported status do appear to resemble identified cases from the general patient population, the population taking the WICER Community Survey is known to be older, and contain a higher proportion of women and Hispanic individuals. Weighting approaches exist which could be used to approximate the expected census distribution. These approaches were not used for two reasons. First, our prior research suggests the differences in measured variables are not large[15]. Second, the purpose of this paper was to explore the performance of the algorithm and we wished to leave its operation as transparent as possible. An additional limitation is that the WICER Community Survey does not distinguish between DM1 and DM2. While obvious DM1 cases were removed from the dataset, it is unknown what percentage of the remaining patients may have DM1.

Conclusions

There are pros and cons in both EHR data and patient self-reported health data. Phenotyping algorithms typically require multiple criteria for successful disease identification and may miss many patients with the disease in question. Likewise, self-reported health data does not imply sufficient EHR data to support a clinical diagnosis. If patient self-reported status could be used in addition to commonly captured EHR data elements for phenotyping algorithms, our study suggests the number of patients identified by such algorithms could be greatly increased.

Abstract

The development of acute hypotension in a critical care patient causes decreased tissue perfusion, which can lead to multiple organ failures. Existing systems that employ population level prognostic scores to stratify the risks of critical care patients based on hypotensive episodes are suboptimal in predicting impending critical conditions, or in directing an effective goal-oriented therapy. In this work, we propose a sequential pattern mining approach which target novel and informative sequential contrast patterns for the detection of hypotension episodes. Our results demonstrate the competitiveness of the approach, in terms of both prediction performance as well as knowledge interpretability. Hence, sequential patterns-based computational biomarkers can help comprehend unusual episodes in critical care patients ahead of time for early warning systems. Sequential patterns can thus aid in the development of a powerful critical care knowledge discovery framework for facilitating novel patient treatment plans.

Introduction

Critical care patients in an intensive care unit (ICU) may undergo dynamic and rapid physiological changes, subject to various biological conditions. There are multiple symptoms which require immediate attention in an ICU. Among these, acute hypotensive events (AHE) are of great importance[1]. An AHE is defined as a drastic minimization of patient blood pressure for an extended period of time. It can be caused by shock, and it may lead to multiple organ failures. As a result, changes in hemodynamic conditions need to be detected as early as possible, so that effective medical interventions can be staged. Subsequently, the effectiveness of a medical intervention in an ICU can be assessed by the associated risk of mortality and the medical costs involved[1, 2]. Both these factors tend to rise with the passage of critical time. Hence, a medical intervention could be termed most effective if it has been staged pro-actively to prevent a shock, based on an early warning system. A pro-active intervention is contingent to obtaining clinical evidence of an impending event in a patient. Good clinical evidence may have two important properties viz. 1) predictive capability and 2) interpretability i.e. intelligible to a clinician, so as to make a quick decision. Interpretable evidence is probably the first step that helps a clinician decide the next course of action. The path to a good treatment plan is thus largely dependent on a clinician's strong understanding of the patient's physiological state, from the time the treatment was initiated. Discovery of such representatively simple yet effective clinical evidence requires the development of a powerful knowledge discovery framework which possesses the above properties and can process readily available streaming critical care data. Stream bed monitors, which continuously monitor physiological variables viz. arterial blood pressure, heart rate, pulse and blood temperature, generally have embedded rules to predict critical events, but they are also known to generate a lot of false alarms[3]. Such devices seldom take into account the sequences of micro physiological events and numerous associations among physiological variables in the course of the patient's ICU stay. Thus, a system that is capable of deriving events that are based on temporal relationships to predict future hemodynamic behavior can be highly beneficial to clinicians in various ways such as - 1) reduction in ICU operational costs and increase in efficiency, 2) in the development of novel goal directed therapies and 3) reporting of a patient's state for scheduling additional services[2].

Generally, multivariate analyses of existing data are very useful for ascertaining prognosis at population cohort levels and to holistically improve the efficiency of resource allocation in hospitals, but may not be of much help, in the context of a specific ICU patient with a rapidly developing critical condition[2]. In contrast, individual goal directed therapies could be administered to an ICU patient, based on dynamic analyses of streaming physiological data to help counter critical conditions in a shorter span of time[4, 5]. Typically, an array of machine learning methods has been employed in the past to make individualized patient predictions. Although, the theoretical novelties of

* Address correspondence to Jinyan.Li@uts.edu.au

these methods are substantial, yet their black-box nature impedes the model interpretability[6]. As a result, significant results in machine learning may not be transformed into interpretable solutions, which could be analyzed by clinicians towards developing evidence-based therapies. In contrast, identifying interesting structures from continuous streams of physiological data may be useful in providing a dynamic view of the patient's hemodynamic state[7] and help develop a testable hypothesis towards initiating a medical intervention.

In this study, we propose to mine interesting minimal sequential contrast patterns from blood pressure time series, which can be used as novel computational biomarkers in a predictive model to stratify the risks of patients for the onset of a future AHE. These informative sequential patterns are extracted from a given patient population, who had historical occurrences of AHE and/or had been administered pressor medications to stabilize blood pressure levels.

The importance of this work lies in the fact that long-term physiological time series data in ICUs that register episodes of sharp rises and falls in various sequences are extremely hard to be explored by general machine learning models. In contrast, sequential pattern mining methods can extract unique episodes of arbitrary length which may be over or under-represented in medical time series data. These episodes may not just be employed to determine the onset of an AHE, but can also gauge a clinical understanding of the types of episodes that are characteristic of specific critical conditions like AHE. . The motivation towards this study is thus driven by a requirement to generate novel medical insights in critical care, which is possible by the application of promising sequential pattern mining approaches to discover clinically relevant episodes connected by temporal relationships.

Our contributions in this work mainly involve - 1) the advancement of existing work in acute hypotension prediction using a sequential pattern mining approach, 2) a demonstration of the feasibility of extracting easily understandable distinguishing sequential patterns from physiological time series that could be effective in predicting AHE ahead of time, and 3) validation of sequential patterns using a large scale critical care database like MIMIC II[9], with the intention of developing novel pattern mining methods for making predictions in ICUs.

The Blood Pressure (BP) Prediction Problem

The objective of the BP prediction problem is to predict the arterial blood pressure (ABP) of patients in an ICU. Knowledge of the ABP state within normal function or hypertensive (high BP) or hypotension (low BP) regimes, in a future time window may turn out to be critical information. Typically, the ABP is a variable that registers strong correlation with the heart beat frequency within normal physiological limits and is measured in mmHg[8]. A derived variable known as the mean arterial pressure (MAP) is often used in medicine as the popular measure of blood pressure which can be defined as

$$MAP = \frac{2(diasPress) + sysPress}{3} \qquad (1)$$

In equation (1), *sysPress* (the systolic blood pressure) denotes the arterial blood pressure when the heart beats while pumping blood, whereas *diasPress* refers to blood pressure when the heart is at rest between beats.

For learning BP behaviour, as shown in the MAP time series in Figure 1, the learning window is shown as beginning from the ICU admission to T_0. Our aim is to predict the occurrence of an AHE in the prediction window demarcated by the period T_0 *to* T_0*+1 hour*.

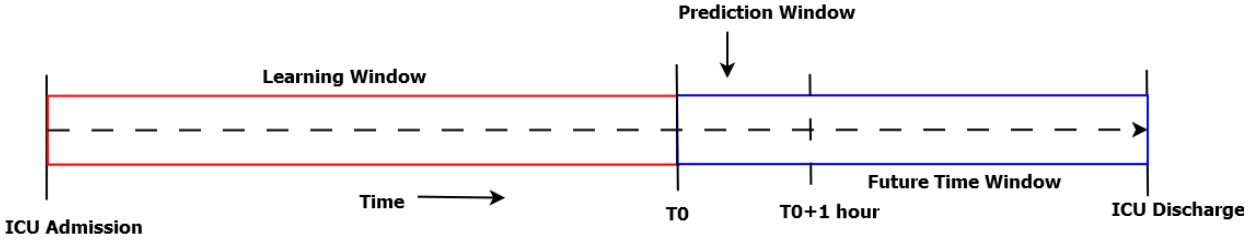

Figure 1: Mean Arterial Pressure time series with learning and prediction windows. T_0 indicates the time point following which, an AHE prediction is to be made. Typically the window after T_0, up to the patient's discharge, is part of a future time window. For purposes of prediction, one may choose to predict an event (an AHE) in a prescribed prediction window (i.e. from T_0 *to* T_0*+1 hour*).

Towards this objective, a dataset for a large number of patients has been made available as part of MIMIC II - a multi-parameter intensive care monitoring database[9]. MIMIC II consists of approximately 30,000 patients with ABP waveforms in various contiguous segments ranging in minutes to hours to even days that were recorded for patient

stays in the ICU. In the context of BP prediction, a subset of patient data with occurrences of acute hypotension was extracted from MIMIC-II and distributed as part of a set of challenges organized in 2009 by Physionet[8]. The details of the challenge datasets are provided in the following section.

Data Description

Acute Hypotensive Episode (AHE): Given a MAP time series, an acute hypotensive episode (AHE) may be defined as a period **of 30 minutes or more when 90%** or more of the MAP measurements are below the 60 mmHg regime. For training purposes, MIMIC II waveform signals were divided into two major groups viz. H and C, which indicated an occurrence of AHE in the forecast window and no occurrences of AHE in the forecast window. The groups H and C were further subdivided into H1, H2 and C1, C2. The definitions for each sub-group are as follows.

- ***H1***: Patients receiving pressor medication.
- ***H2***: Patients not receiving pressor medication.
- ***C1***: Patients with no acute hypotensive episodes during entire hospital stay.
- ***C2***: Patients having AHE before or after the forecast window.

Vital signs time series variables like heart rate (HR) and mean, systolic, and diastolic ABP were available for all the patient records. Some of the records often included respiration rate and SpO2. Although for the purposes of this study, we only consider the MAP time series (mean ABP) for each patient, as done in earlier studies. Accordingly, the prediction tasks consisted of the following two events -

- *Event I*: Patient risk classification between H1 and C1
- *Event II*: Patient risk classification between H and C

Dataset specifications are as given in Figure 2.

Number of Training samples for H and C	
H	***C***
H1 = 15	C1 = 15
H2 = 15	C2 = 15

Number of Test Samples for Event I and II	
H1 = 5, C1 = 5	*Event I*
H = 14, C = 26	*Event II*

Figure 2: Dataset Specifications for the AHE prediction problem

Especially in the case of *Event I*, the objective of the classification is to distinguish between two groups of patients, in which both received pressor medications. According to Moody and Lehman (2009), these two sets (H1 and C1) represented the extremes of AHE-associated risks.

Related Work

In recent years, a number of methods and scores have been suggested for understanding and predicting patient hemodynamic behaviour[7]. The Physionet 2009 AHE detection challenge served to advance such studies further by providing a test-bench for the use of neural-network based multi-models, static rules, support vector machines, histograms and statistical indices[10,11,12,13,14]. Although, these models extract informative features to construct off-line predictive models, they may be limited in their scope when analyzing real-time longitudinal medical data. Moreover, complete utilization of long range time series data may not be possible without powerful dimensionality reduction techniques. Typically, sequences of unusual spikes or falls in the physiological variables if detected may go a long way in the understanding of critical blood pressure behaviour that tends to occur before the onset of critical conditions. In a related context, Wang et al.[15, 16] indicated that pattern extraction from medical data is particularly challenging due to their sparse and longitudinal nature. Towards this aspect, the authors proposed a geometric image based mapping framework to mine temporal event signatures from large scale heterogeneous records of hospital patients. Moreover, popular methods like motif mining in bioinformatics have also been applied to cardiovascular time series for classifying medical events[17]. Accordingly, recent attention on data mining in healthcare indicate the shifts from traditional pattern mining problems to handling specific cases towards medical care improvements. Mining complex medical patterns could thus be more predictive of immediate outcomes, and may be able to report episodes soon after ICU admissions. From a clinical point of view, identifying such patterns are paramount, to detect

and understand the variability of a critical care patient's physiological response to an event like hypotension and thus help in the determination of the most optimal treatment combinations.

Methodology

In the following sections we provide an overview of sequential pattern mining and subsequently describe the processes involved in the discovery of sequential contrast patterns that were over-represented in the positive samples and under-represented in the negative samples. Sequential patterns are generally described in the form of short sub-sequences. Depending on the constraints of the formulated problem, representative sequences of certain lengths may be grown, which may demonstrate extensive repetitive behavior in the concerned datasets. In this context, sequential pattern mining techniques can provide a flexible and fast way to deal with streaming physiological data to derive interesting patterns which may provide important insights in the form of a chain of episodes, which could be of concern.

Symbolic Data Transformation

With the explosion of streaming real-valued physiological time series data generated from stream bed monitors in ICUs, it becomes essential to transform such data into symbolic representations for large scale data mining operations. Symbolic sequences can subsequently help avail a variety of existing pattern mining algorithms for efficient manipulation of such representations. Pattern mining algorithms typically employ techniques related to hashing, markov models, suffix trees, decision trees etc., which may be applied to symbolic sequences unlike real-valued continuous representations. In the last decade, the symbolic aggregate approximation (SAX) method has emerged as a popular technique which achieves efficient informative symbolization of large-scale time series data (for e.g. more than a billion time points) [18]. SAX first transforms the real-valued time series into a piecewise aggregate approximation (PAA) representation[19] and then converts the PAA series to a symbolic string. As claimed by the authors, the advantages of SAX involve that of dimensionality reduction and lower bounding. As a result, due to the nature of physiological time series generated over a number of days, and their importance in determining critical conditions, SAX provides a proper platform to create efficient indexing and pattern mining algorithms for medical purposes. Figure 3 illustrates a real-valued time series being converted to a sequence like *PQRQQPQ*, where *P, Q* and *R* are the three regions demarcated by the X and Y cut-points on the vertical axis.

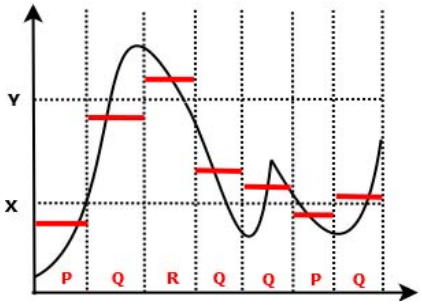

Figure 3: SAX Approximation of a time series. The given time series is symbolically represented as PQRQQPQ, using P, Q and R which denote three equiprobable regions.

Each MAP time series patient record before being discretized to a symbolic form goes through certain data transformation steps based on the SAX algorithm. This involves normalization of the time series to have a mean as 0 and variance as 1. Since normalized time series follow a Gaussian distribution, breakpoints are selected such that discrete symbols are equiprobable in the time series. For a normalized time series, this means that with five symbols, discrete regions are given by [-inf, -0.84, -0.25, +0.25, +0.84, +inf]. SAX thus adopts a symbolic representation which characterizes the inherent properties of the time series data. Hence SAX ensures that there exists an equiprobable distribution of symbols in the given time series.

Contrast Patterns

Mining contrasting patterns between groups of data under various labels was initially introduced as Emerging patterns by Dong & Li[20]. It is a sub-field of pattern mining, which typically aims to discover statistically significant patterns based on principles of frequency support, in various kinds of data viz. transactional, sequences, time series etc. Given that sequences are an important representation for data, minimal distinguishing subsequences (MDS) were later proposed as sequential contrast patterns[21]. Typically, an MDS is a sequential pattern that does not have a

subsequence, which itself is a sequential pattern satisfying algorithmic preconditions of minimum frequency support in the given data. In the following sections, we briefly describe the terminologies and processes associated with extracting MDS patterns.

Definitions and Terminologies

Subsequences: Let us define a set of items as $\boldsymbol{I} = \{i_1, i_2, i_3 \ldots, i_n\}$, also known as the *alphabet*. A sequence $\boldsymbol{S} = e_1\text{-}e_2\text{-}\ldots\text{-}e_n$ can be defined as an ordered collection of items belonging to $\boldsymbol{I}$. A sequence $\boldsymbol{A} = e_{k1}\text{-}e_{k2}\text{-}\ldots\text{-}e_{km}$ is said to be contained in $\boldsymbol{B} = e_1\text{-}e_2\text{-}\ldots\ \text{-}e_n$, such that $1<k_1<k_2<\ldots<k_m<n$. This means that the order of sequence $\boldsymbol{A}$ is maintained in $\boldsymbol{B}$, although the exact items may not be consecutive i.e. occurrences of A in B, may have gaps between the exact items, but the order will always be maintained. Thus if $\boldsymbol{A}$ is contained in $\boldsymbol{B}$, then $\boldsymbol{B}$ is a supersequence of $\boldsymbol{A}$. For example, given a set of symbols, $P=\{X, Y, Z\}$, XY is a subsequence of $XZYZ$, but not YX.

Suppose $\boldsymbol{D} = \{D_1, D_2 \ldots D_n\}$ be a set of sequences organized in a database. Now if there exists a sequential pattern $\boldsymbol{P}$, such that P is contained in '**q'** number of sequences in the database, then '**q'** is defined as the frequency support of $\boldsymbol{P}$, denoted as ***freqsup***.

Minimal Sequential Contrast Patterns: Given two sets of sequences $\boldsymbol{D}^+$ and $\boldsymbol{D}^-$, where $\boldsymbol{D}^+$ comprises of sequences with a positive class label and $\boldsymbol{D}^-$ is from a negative class label, we need to find the set $\boldsymbol{S}$ of all subsequences of a given length **L**, such that each subsequence $\boldsymbol{s_k} \in \boldsymbol{S}$ has the following properties:

i) $\boldsymbol{freqsup_{pos}}\ (\boldsymbol{s_k}) \geq \alpha$ (2)

ii) $\boldsymbol{freqsup_{neg}}\ (\boldsymbol{s_k}) < \beta$ (3)

iii) There is no subsequence of $\boldsymbol{s_k}$ *that satisfies (2) and (3) [**condition of minimality**]*

Here α is the minimum support required for $\mathbf{D}^+$ and β is the maximum support allowed for $\mathbf{D}^-$.

Thus given $\mathbf{D}^+$, $\mathbf{D}^-$, α and β, the MDS mining problem is concerned with finding all the minimal sequential patterns that are highly likely to occur in the positive set of samples but less likely to occur in the negative set.

Gap Constraint: While mining for a sequential pattern or a sequence, it may not be necessary for elements in a sequence, to occur consecutively. In such a scenario, defining a maximum gap constraint denoted as $\boldsymbol{g}$, allows the mining algorithm to search for a sequence, in which consecutive elements may have contiguous differences upto $\boldsymbol{g}$. For example, if $\boldsymbol{g}=2$, then XY is a subsequence of XZY but not $XZZZY$.

***Max-prefix*:** The max-prefix of a sequence **A** is the leading sequence of elements, without the final element of **A.** Thus the max-prefix of XZY is XZ.

Suppose, $\mathbf{D}^+ = \{XYZY, YZXY, YYZY\}$ and $\mathbf{D}^- = \{XZXZ, ZXXY\}$, are two sets of sequences. Let us consider ZY as a sequential pattern. Then for G=1, ZY has a frequency support of 3 in $\mathbf{D}^+$ and 0 in $\mathbf{D}^-$. In this context, if the positive (α) and negative (β) thresholds are set to 2 and 1, then ZY may be accepted as a sequential pattern.

Mining Minimal Contrast Sequences in Symbolic MAP Data

Towards the purpose of mining minimal contrast subsequences we employ the *ConSGapMiner*[21] algorithm, which is used to solve the MDS mining problem with gap constraints. The algorithm involves the application of a depth first search (DFS) technique to generate a set of distinguishing subsequences between two sets of sequences. Internally, the frequency support of each generated subsequence is computed for comparison with α and β, as per conditions (2) and (3) (the minimum positive and maximum negative support thresholds). After the set of all contrast subsequences are obtained, a post-processing step is employed to remove sequences that are non-minimal. These three stages of the algorithm are described next.

Generating Candidate Subsequences: Traditionally, every pattern mining algorithm begins with the candidate generation process. A candidate solution is one that can satisfy all the constraints posed by the concerned problem formulation. To generate candidate subsequences for MDS mining, DFS is performed to obtain a lexicographic sequence tree (LST) as shown in Figure 5. The DFS operation is a popular technique to grow rooted trees which have user-defined nodes. In the present context, each node in the LST (i.e. the DFS constructed tree) represents a sequence, along with its positive and negative frequency supports[21]. For example, in the LST in figure 5, node AAC(2,1) represents the sequence AAC with 2 as positive and 1 as negative supports. A child sequence may be grown by extending the parent sequence with a unique symbol from the alphabet, based on a certain lexicographic order. Thus, given the present LST, whose alphabet is defined as I = {A, B, C}, AAC may has three children nodes

as AACA, AACB and AACC. Subsequently each node's supports are computed from the positive ($\mathbf{D}^+$) and negative ($\mathbf{D}^-$) sample sets.

Pruning non-minimal distinguishing subsequences: After a sequence node is generated, if it satisfies the conditions (2) and (3), then the sequence is not extended any further. This is based on the fact that a supersequence of a distinguishing contrast sequence cannot be minimal[21]. Testing the minimality condition on generated sequences allows us to restrict the generation of redundant sequential patterns or superseqeunces. Handling minimality thus turns out to be extremely important since it can be a major factor in speeding up the mining process.

Pruning infrequent max-prefix extensions: If the current node's positive support is less than α, then we need not extend that node further. This is because, if a certain node fails to satisfy the condition in equation (1), its descendent nodes are also expected to be infrequent[21].

Checking Gap Constraints: Given a sequence XY, a gap constraint of g in a sequence P may be considered satisfied for XY if the sequential difference between the position of X and Y does not exceed **g**. For verifying if a generated candidate satisfies the gap constraint, a bitmap representation[22] is employed.

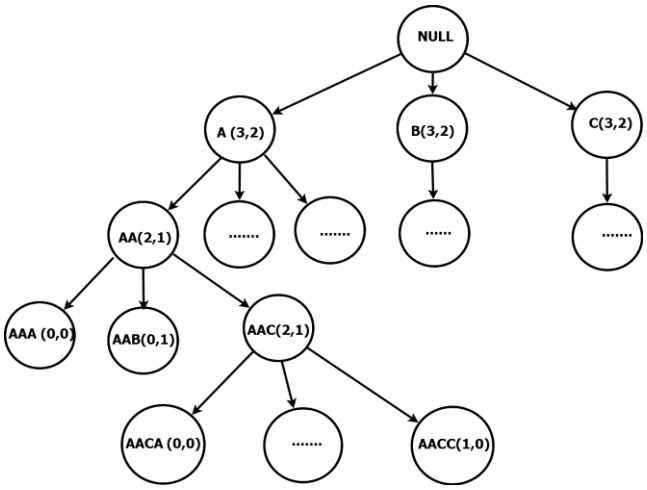

Figure 5: Part of a lexicographic sequence tree (LST), where the symbol alphabet consists of {A, B, C}.

Table 1. Checking gap constraint satisfaction of *XY* in *XZXZY*. The existence of a '1' in the last (7^{th}) row denoted by *AND* indicates that a maximum gap of 2 is satisfied by *XY*.

	X	**Z**	**X**	**Z**	**Y**
Index	*1*	*2*	*3*	*4*	*5*
$\mathbf{X_{index}}$	1	0	1	0	0
$\mathbf{1_X}$	0	1	1	1	0
$\mathbf{2_X}$	0	0	0	1	1
$\mathbf{1_X(OR)2_X}$	0	1	1	1	1
Y	0	0	0	0	1
AND	0	0	0	0	1

As shown in Table 1, we check for the gap satisfaction of *XY* in *XZXZY*, when maximum gap is set to 2. Initially, all the occurrences of X in the given sequence are set to 1(as shown in $\mathbf{X_{index}}$). In the present case, these are positions 1 and 3, in the given sequence. Later, (g+1) bits are set to 1 for each occurrences of X, separately as illustrated in rows 3(given as $\mathbf{1_X}$) and 4(given as $\mathbf{2_X}$). The bit vectors in rows 3 & 4 are then processed by the logical OR operator in row 5. Finally, a logical AND operation is carried out on the bit vectors in row 5 and for the occurrence of Y in row 6 to obtain a final sequence of bits, as in row 7. An occurrence of 1 anywhere in the final bit vector indicates that the gap constraint of 2 has been satisfied.

Post Processing: A post-processing step is finally applied to remove any sequence, which turns out to be a supersequence of at least another shorter subsequence in the resultant MDS set.

A flowchart illustrating the data flow architecture of the system is given in Figure 6.

Results and Discussion

The above described methodology was employed to mine sequential contrast patterns for the Physionet 2009 AHE prediction challenge datasets. Towards this purpose, we employed the SAX converted truncated MAP time series data from the given observation windows, for each patient in the given AHE training datasets. For event I, the training set comprised of H1 (for positive) and C1 (for negative), whereas for event II the whole dataset of size 60 was considered for training purposes.

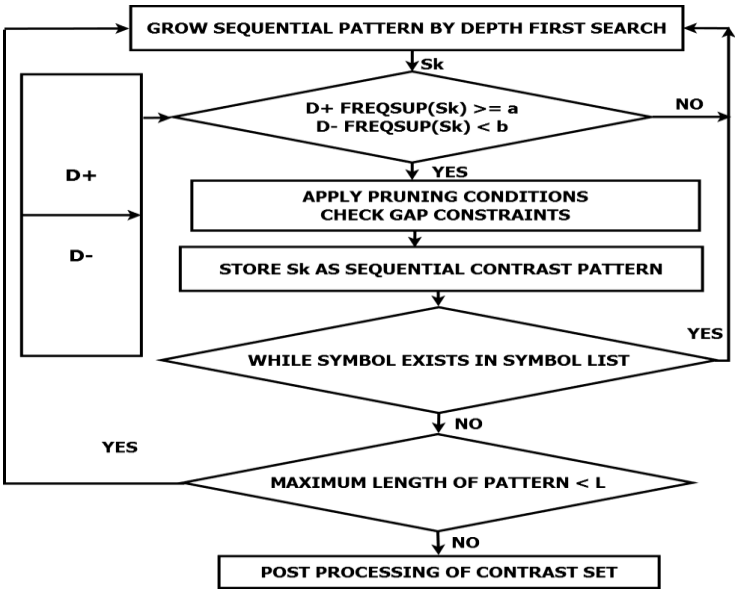

Figure 6: The Data Flow Architecture for mining sequential contrast sequences using a depth first search method (DFS).

In this context, an example training record like *a40439* consisted of T_0 indicated as 18.30 on 04/09/2008 (T_0 was provided with each record). The time series data prior to T_0 was thus used for training purposes (treated as the observation window). The extracted contrast sets for the two events were then applied to the test sets (as given in Figure 2). Each test segment comprised of an unlabeled MAP time series segment. If a test sample matched any one of the sequences in the contrast set, it was predicted as positive (H1 for event I and H for event II). A number of simulations were carried out with various parameters viz. subsequence length (L), alphabet size (S) and maximum gap (G). A 2 –fold cross validation (CV) was also performed using the larger training dataset consisting of 60 samples (30 – H and 30 - C), which reported a CV accuracy of 94.9%. In Table 2, the AHE test prediction accuracies have been given for event I and II, when the gap constraint was set to 3. As seen, the best performances were achieved using a maximum gap of 3, subsequence length of 10 and alphabet of cardinality 5.

Table 2. AHE Test Prediction Classification Accuracies while varying S and L for events I and II. Best performances are recorded for G=3, S=5, L=10/11 for event I and II.

G=3	**Event I**			**Event II**		
	S=3	*S=4*	*S=5*	*S=3*	*S=4*	*S=5*
L=5	5/10	5/10	7/10	19/40	19/40	32/40
L=6	5/10	5/10	7/10	19/40	19/40	32/40
L=7	5/10	5/10	7/10	19/40	19/40	32/40
L=8	5/10	7/10	7/10	23/40	23/40	32/40
L=9	5/10	7/10	9/10	23/40	25/40	33/40
L=10	5/10	7/10	10/10	25/40	32/40	36/40
L=11	5/10	7/10	10/10	25/40	32/40	36/40

Table 3: A Comparison of classification methods employed for the AHE prediction problem. Sequential patterns report comparable accuracies against existing methods.

Method	**Event I**	**Event II**
GRNN[11]	10/10	37/40
5-min average of diastolic ABP[10]	10/10	37/40
MAP averaging Rule [12]	10/10	36/40
5-min average of ABP[10]	10/10	36/40
Linear Regression[10]	10/10	36/40
Median of MAP[10]	10/10	34/40
NN with feature selection[12]	9/10	32/40
SVM[13]	10/10	30/40
RPS-NN[12]	2/10	25/40
Sequential Contrast Patterns	10/10	36/40

In Table 3, we provide a comparison of our results with the reported results from the Physionet 2009 challenge. As seen, models employing neural networks (GRNN, RPS-NN) and kernel methods like SVM are heavily dependent on several parameters, and can have performances over wide ranges[11, 12, 23]. Most of the other methods employed rules based on simple averaging measures and still performed fairly[10, 13]. Moreover, hidden markov models (HMM) for hypotension had reported a cross-validation accuracy close to 97%[24], which compares well with our cross-validation results too. Given this context, our results are comparable to the physionet 2009 challenge results. A general trend may be observed, where informative sequences could be extracted if the maximum gap constraint is iteratively increased. This is demonstrated by the Figure 7. The given results indicate that G=3 provides a good coverage to the length of the sequence.

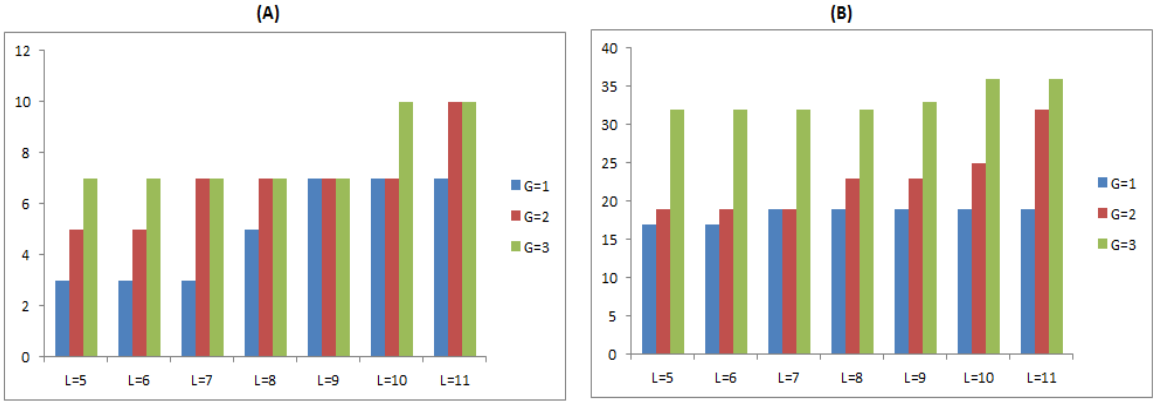

Figure 7: Effect of parameters L and G on the performance (A) For Event I, (B) For Event II.

It may be observed that performances tend to improve with larger values for gap sizes. At the same time keeping G too large, also means that two consecutive symbols in a sequential pattern may have occurred over a wide range, whose size was G. Extremely large gap sizes can thus impede a proper interpretation of contiguous events of importance. Finding an optimal value of G is therefore important to obtain meaningful predictions. Thus finding interesting sequences is highly dependent on the use of various parameters like the number of symbols, subsequence length and gap sizes. Based on the results, for detecting differential blood pressure patterns, obtaining optimal gap sizes may be more effective in reporting important episodes. For larger cohorts, finding out the optimal gap would thus be very important, given their dependency on the resolution of the time series (i.e. the sampling frequency). In addition, increasing S provides more number of discrete cut points for MAP, and enables the algorithm to capture patterns which characterize significant fluctuations in the BP. Thus, for cases with S=5, the algorithm is able to find a more expressive pattern, than for S=3. This also contributes to making improved predictions. Hence, selecting an alphabet size of 5 turned out to be an optimal choice, both in terms of the discretization of blood pressure range as well as keeping the algorithmic running costs within limits.

In contrast to our method, the 5 minute averaging measures are statistical features obtained from a 5 minutes window prior to the immediate occurrence of an AHE. Thus, a major difference lies in the fact that our method considers a wider window prior to the onset of AHE in comparison to just a 5 minute window using averaging measures[10]. This also indicates that a method which is effective in predictions within a 1 hour window may be more suitable in a real time scenario, in comparison to statistical measures obtained from a 5 minutes time window (prior to AHE). In this context, better results from 5 minutes prior to an AHE, may be due to temporal proximity to the onset of an AHE. For methods based on neural networks, both GRNN and RPS-NN report 10/10, 2/10 (for Event 1) and 37/40, 25/40 (for Event II). These methods tend to be strongly dependent on parameter tuning, as was also discussed by the authors[11]. The contrast mining method, on the other hand, helps to extract discretized sequential representations of the MAP time series, which provide the maximum support towards the occurrence of an AHE. These patterns are later useful, to not only predict an AHE for an unknown record, but may also be employed for further clinical interpretation by domain experts.

Our results indicate that sequential contrast patterns are capable of extracting informative symbolic episodes, which may be employed for both AHE risk prediction and understanding of hemodynamic behaviour towards effective analyses of sequential episodes that may be indicative of medical symptoms.

Clinical Significance of Sequential Contrast Patterns

In contrast to traditional machine learning models, the purpose of pattern mining is to extract hidden and interpretable knowledge from large amounts of data. In a typical medical care environment, the consumers of an important medical insight are both clinicians and computational systems. Machine learning methods like neural networks, SVM etc. which are heavily dependent on parameters may use extracted patterns as inputs/features to fine tune models, but do not crawl large-scale medical databases towards clinical knowledge discovery. Some of the sequential contrast patterns from the contrast sets extracted by the MDS algorithm are given in Table 4 for each of the two events.

Table 4: Examples of sequential contrast patterns for AHE prediction events

Event I	*DEDEDABCDC, DCEDCBCDCD, BCDCACDEDC, DCECACDEDE*
Event II	*CABAEECBCD, ABAEDBBBCA, ECBABABCD, ABBDECBCD*

Our approach was accordingly able to extract a sequential pattern like *ABAEDBBBCA,* which was prominent in acute hypotensive patients. Since the mean arterial pressure area was divided into 5 equiprobable regions (given by A , B, C, D, E), the above pattern indicates that the blood pressure signal follows a situation where majority of the AHE patients record an episode of events represented by the MAP value in the following order of blood pressure regimes - $A < B < A < E < D < B < B < B < B < C < A$. Extracting a pattern of this nature which may be regularly occurring in AHE patients, in contrast to patients with no occurrences of AHE , provides a sound basis towards carrying out a medical analysis of the given train of events. If later, we could derive the exact symptomatic signs displayed by a patient corresponding to this chain of events, we can establish a potential combination of observable physical indicators that precede AHE. Traditional machine learning models like SVM, neural networks are typically unable to extract such patterns that may lead to a significant discovery of a sequence of important stages or events which possibly lead to critical condition. Thus a higher frequency of the occurrence of complex contrast sequences while comparing hypotensive and normotensive patient groups may be beneficial to a clinician to develop a clinical hypothesis relating a succession of clinical events leading to an AHE. Thus, extracting sequential patterns from hypotensive patient groups can inform decision-making towards the diagnosis and investigation of AHEs. Moreover, the MDS method is flexible enough to accommodate clinician-defined constraints to detect specific types of patterns in medical care databases. Future work in this area, would concentrate on mining contrast patterns for larger populations with AHE. Although, earlier studies have reported good results using MAP, yet the development of real-time robust predictors using multivariate physiological data has still remained an open area. Additionally, a significant problem in predicting hypotensive events arises when the prediction window is placed further away from the observation window.

Conclusion

In this study, we present a novel application for mining contrast sequential patterns to predict acute hypotension in critical care patients. Mining sequential patterns has typically been a difficult problem for streaming long sequences. Moreover, this study aimed to introduce the extraction of contrast sequences for predicting critical conditions in ICUs. The importance of this work is associated with the introduction of a powerful sequential pattern mining based knowledge discovery process for analyzing time series data towards critical care predictions. In the future, we intend to enhance the existing framework for real time analyses while considering temporal associations and computational speed, in the context of specific issues in intensive care units.

A Novel Method to Assess Incompleteness of Mammography Reports

Francisco J. Gimenez, BS[1], Yirong Wu, PhD[2], Elizabeth S. Burnside, MD, MPH[2], Daniel L. Rubin, MD, MS[3]

Abstract

Mammography has been shown to improve outcomes of women with breast cancer, but it is subject to inter-reader variability. One well-documented source of such variability is in the content of mammography reports. The mammography report is of crucial importance, since it documents the radiologist's imaging observations, interpretation of those observations in terms of likelihood of malignancy, and suggested patient management. In this paper, we define an incompleteness score to measure how incomplete the information content is in the mammography report and provide an algorithm to calculate this metric. We then show that the incompleteness score can be used to predict errors in interpretation. This method has 82.6% accuracy at predicting errors in interpretation and can possibly reduce total diagnostic errors by up to 21.7%. Such a method can easily be modified to suit other domains that depend on quality reporting.

Introduction

Breast cancer affects 1 in 8 women in the United States. It is the second leading cause of cancer deaths amongst women. Mammography has shown to be beneficial for early detection of breast cancer[1]. Currently, the American Cancer Society recommends that women over 40 with no specific risk for breast cancer get yearly screening mammograms to detect malignant findings early[2]. However, a major issue with mammography for breast cancer detection and management is the inconsistency and variability in practice, particularly in terms of variations in sensitivity and specificity of diagnosing malignancy[1,3-7]. Such variability is not limited to diagnosis. It has been shown that variability extends to report findings[2,8-10]. Variability in diagnosis and reporting hamper the utility of mammography: false negatives result in delayed treatment at the expense of patient health while false positives cause excessive additional invasive testing (e.g., biopsy), rising healthcare costs, and long-term psychosocial harm for women [11,12].

Decision-support systems have been developed to improve upon mammography interpretation and diagnosis[13-16], however most of these systems follow the *Greek Oracle* model of decision-support: they simply give an answer to the diagnostic task rather then assisting the radiologist to improve their own decision[17,18]. Additionally, such systems interrupt the traditional radiological workflow[19]. We posit that *improving the radiologist's report during reporting time* mitigates both of these issues and is the ideal time to deliver effective decision-support.

The mammography report is of crucial importance since it documents the radiologist's imaging observations, interpretation of those observations in terms of likelihood of malignancy, and suggested patient management, such as follow-up imaging or biopsy. Studies have shown the importance of good reporting practices and identified several key traits of good reports: correctness of findings, completeness of the description of significant clinical findings, consistency of report language and findings, and timeliness of the report's completion[20-22]. There are numerous efforts to improve the mammography report with respect to these traits. The Breast Imaging-Reporting and Data System (BI-RADS) provides a standard lexicon of descriptors and interpretation guidelines to improve consistency in language and correctness of findings[3]. Furthermore, structured reporting systems have been designed to improve clarity of presentation and reduce variability of reports between readers[23]. Despite these benefits, structured reporting is generally more time-intensive and can impair the traditional radiological workflow, directly interfering with timeliness[20]. Moreover, current approaches aim mainly to improve upon reporting language and clarity rather than report content and decision-making.

In this study, we propose a system that evaluates the content of the report and links it to errors in diagnosis. We do this by quantifying and measuring the incompleteness of the report findings with respect to abnormalities seen in images. We define incompleteness to be the sensitivity of the radiologist's decision to new information. Should gathering more data about a mammographic abnormality potentially change the radiologist's decision about clinical

management, a report is considered incomplete, and the radiologist can be alerted to provide more information to disambiguate report elements found to be inconsistent..

Mammography Diagnosis Problem

Radiologists presented with mammograms are tasked with two problems: detection and interpretation. Detection is the task of visually inspecting the mammogram and identifying abnormalities. Interpretation is evaluating whether detected abnormalities are suspicious for breast cancer. We will focus on the interpretation problem in this paper.

Formally, the interpretation problem is defined as follows: A radiologist is presented with a lesion in a mammogram, patient history and demographics, and possibly prior mammograms. The radiologist must decide whether this lesion warrants no action or follow-up (either imaging or biopsy) based on their suspicion of malignancy. This suspicion of malignancy is quantified as the BI-RADS assessment category, which is an ordinal value ranging from 1 to 6. An additional assessment category of 0 is used to indicate there is not enough information in the mammogram to make a decision. These assessment categories were designed to have probabilistic interpretations, where each value has a range of posterior probabilities of malignancy as shown in Table 1. A BI-RADS assessment of 1, 2, or 3 indicates the recommendation is no immediate follow-up (a negative assessment). A BI-RADS assessment of 4 or 5 indicates a recommendation for follow-up imaging or biopsy should be considered (a positive assessment). An assessment of 0 *should* not count as either positive or negative, but the fact that it necessitates immediate follow-up imaging means that it is treated as a positive finding [24]. BI-RADS 6 is a non-diagnositc category used to indicate that the images reflect a known cancer diagnosis being evaluated for treatment planning. These assessment categories implicitly mean that any lesion with a posterior probability of greater than 2% should be considered as a positive finding. Recent work has shown that this 2% threshold rule is justified via epidemiological risk analysis[25]. In addition to providing an assessment, radiologists must provide a report that justifies their decision. This report has a set of categorical descriptors standardized by BI-RADS, which can be interpreted as evidence for their decision.

BI-RADS Assessment	Probability of Malignancy	Description
0	N/A	Additional Imaging Needed
1	0%	No Abnormality
2	0%	Benign Finding
3	< 2%	Probably Benign Finding
4	2-95%	Suspicious Abnormality
5	> 95%	Highly Suggestive of Malignancy
6	100%	Biopsy Proven

Table 1: The BI-RADS assessment categories and their probabilistic interpretations.

Though BI-RADS assessments have objective probabilistic underpinnings, mammography interpretation is inherently subjective. Modern practice traditionally does not include quantitative estimates of these probabilities. Rather, radiologists provide the assessment categories based on training and experience. The use of BI-RADS assessment categories allows us to evaluate radiological performance as if radiologists are binary classifiers. We can measure their true positives (TP), false positives (FP), true negatives (TN), and false negatives (FN) as well as all associated statistics (e.g. positive predictive value, sensitivity, specificity). Moreover, the use of categorical descriptors allows us to build joint models of their decision given evidence.

Measuring Incompleteness

Missing descriptors in mammography reports do not necessarily mean that the report does not have all the information to make a correct and justified diagnosis. Conversely, there are cases when most of the descriptors are

reported, but the report still reaches an ambiguous diagnosis. Incompleteness of reports needs to be sensitive to the context of the information already given as well as the effect of missing information on the diagnosis.

Given that the final result of a mammogram is a decision whether to follow-up on patients with mammographic lesions, this decision should be the primary driver of determining whether enough information has been provided in the report. Early approaches to measuring whether medical diagnostic tests were necessary involved calculating thresholds for posterior probabilities that would warrant more testing or treatment [26]. Such methods required that the practicing physician provide the posterior probability. The Pathfinder system used a value of information calculation to repeatedly request more information for diagnosis until there was only one possible diagnosis left [27]. This did not provide a flexible framework for stopping if there was more than one possible diagnosis outside of physician judgment. The STOP criteria provide a quantitative algorithm for when to stop requesting information and make a decision, but this is formulated only to measure whether the probability of an event exceeds a certain threshold [28].

In response to these shortcomings for decision support systems, the same-decision probability (SDP) has been proposed [29]. This is defined to be the probability that a diagnostician will make the same decision they are currently considering given the unobserved information in a system. This metric has a nice intuitive meaning; only collect more information if it will change a decision. The SDP is defined for systems that make binary decisions based upon a posterior probability of an event being above a threshold. Formally, given a system with a decision function *D*, observed variables ***O***, unobserved variables ***U***, and a decision threshold *T* the SDP is defined as:

$$SDP = \sum_{u \in U} \mathbb{I}\left[D(\mathbf{O}; T) = D(\mathbf{u},\mathbf{O}; T)\right] Pr(\mathbf{u}|\mathbf{O})$$

Where I[•] is an indicator function that outputs 1 if true and 0 if false.

In the context of mammography, *D*(•) = diagnosis, ***O***= report data, ***U*** = Unobserved descriptors, and *T* = BI-RADS 2% threshold.

Though this is a well-defined metric, it is intractable to compute [30]. The summation requires iterating over all possible combinations of missing data which is an exponentially large search space. Despite this challenge, there are algorithms to approximate it based on statistical bounds on its value [29]. The drawback here is that such bounds can be weak under a variety of non-trivial cases. There is also an exact algorithm that can take advantage of certain Bayesian network structures to compute it in tractable time [30], but this method may break down for extreme value thresholds and Bayesian networks that do not have highly independent sets of unobserved nodes.

Here we propose a new method to compute an approximation of the SDP based on monte-carlo simulations. The difference between our approximation method and previous ones[29] is that they compute and exact value for an approximate bound on the SDP whereas we compute an approximation to the exact value of the SDP. This follows the advice of John Tukey, “It is far better an approximate answer to the right question, which is often vague, than the exact anwer to the wrong questions, which can always be made precise.” [31] Moreover, our approximation can be made arbitrarily accurate given more monte-carlo sampling steps.

For sake of convenience, we compute the complement of the SDP which is simply 1-SDP. This is the probability that our decision will *change* given new information. We will refer to this value as the *incompleteness score*. In this context, a *lower* value of the incompleteness score means the report is *more* complete.

Algorithm 1 Compute incompleteness score in Bayesian network

Input:
B: a Bayesian network
D: a diagnosis node
T: a decision threshold
N: an integer number of samples to use
O: a set of observed nodes
U: a set of unobserved nodes
Output: an incompleteness score value
Main:
d ← Pr(D=Malignant | **O**) > T
s ← 0
for i = 1:N **do**
u ← junction_tree_sample(B,**U**)
d_{new} ← Pr(D=Malignant|**O,u**) > T
if d_{new} != d **then**
s = s + 1
end if
end for
incompleteness_score ← s/N

Where join_tree_sample is the standard algorithm for sampling from a Bayesian network that has been compiled into a join-tree.

Experimental Methods

Study Design

Data used for this project were de-identified prior to analysis, and our work was thus not considered human subjects research. We acquired mammography report data from two teaching hospitals. Both of these institutions captured mammography findings using a structured reporting system (Mammography Information System, versions 3.4.99–4.1.22; PenRad, Buffalo, MN). Five attending radiologists read the mammograms at Institution 1. They reviewed 52,943 findings, of which 421 were malignant. These data were collected between April 5, 1999 and February 9, 2004. Eight attending radiologists read the mammograms at Institution 2. They reviewed 59,490 findings, of which 793 were malignant. These data were collected between October 3, 2005 and July 30, 2010. These datasets only contain 1 radiologist in common (though no interpreting radiologists were identifiable due to anonymization), the remainder of the radiologists in the two practices were distinct.

Analysis was done at the "finding" level, where a finding is defined as a set of observations about an abnormality in a mammogram, or the record for a mammogram with no abnormalities. Each finding can include patient demographic risk factors, BI-RADS descriptors characterizing an abnormality, BI-RADS assessment category, and pathologic findings from biopsy. Pathological ground truth was determined via matching patients with state cancer registries. By comparing the radiologist assessment to the pathological ground truth, we assessed whether a finding was a false positive (FP), false negative (FN), true positive (TP), or true negative (TN).

The structured reporting system separates masses, calcifications, and general findings. There is ambiguity in assessing when these three types of findings are associated with each other. In general, model builders can ignore the possible correlations since they do not seem to hamper performance of computer-aided diagnostic systems [14,15,32]. Unfortunately, we cannot make such relaxations of the model since we require that all descriptors provide meaningful information. As an example, descriptors specific to calcifications would spuriously affect incompleteness scores on mass findings. We chose to focus on analyzing mass findings to mitigate this issue. The resulting data set had 24,645 mass findings, 672 of which were malignant.

Masses were randomly split into two sets, 85% training and 15% testing. Training and testing groups were stratified by malignancy and care was taken to ensure patients with multiple masses were not represented in both groups. The training set was used to learn a tree-augmented naïve bayes (TAN) model for mammography diagnosis as described

by Burnside[32,33]. The incompleteness score was calculated for all masses in the test set using 5,000 monte-carlo samples with a decision threshold of 2% in concordance with BI-RADS recommendations. All model learning and classification was done in Norsys Netica 5.14.

Statistical Analysis

We stratified resultant incompleteness scores by radiological predictive categories (FP, FN, TP, and TN) to assess how the incompleteness scores differentiated between correct and incorrect evaluations. We quantified this difference by comparing the scores for errors (FP, FN) to the scores for correctly diagnosed findings (TP, TN) with a one-tailed Mann-Whitney U Test (aka Wilcoxon rank-sum test) [34]. The test was performed using the `wilcox.test` function in R version 3.0.2 (2013-09-25) -- "Frisbee Sailing."

Results

We trained a Tree-Augmented Naïve Bayes network on 20,950 training cases and measured the incompleteness score on 3,695 test cases. The resulting incompleteness scores were heavily right-skewed distributions. 83% of the incompleteness scores were equal to zero, meaning no new information would have changed the follow-up decision. Hence, both the median and mode incompleteness scores were zero. The mean incompleteness score was 0.021, but this is not a good indicator of group tendency since the large tail distribution has a disproportionate effect on the mean.

In order to verify that the incompleteness score can be used to predict mammographic error, we plotted its histogram and density estimate stratified by radiological predictive categories: true negative (TN), false negative (FN), true positive (TP), and false positive (FP) [Figure 1]. The graphs show that there are a large number of false positive and false negative cases that have non-zero incompleteness scores. Intuitively, this shows that incomplete reports have a higher likelihood of containing errors. The difference between error (FP,FN) and non-error (TP,TN) incompleteness scores was statistically significant ($p < 2.2*10^{-16}$).

An issue with this data is that there are a small number of false negative findings compared to false positive findings. This could skew results since positive findings may contain descriptors more prone to noise in the model. To account for this, we compared false positive to true positive results since both groups would have similar descriptors. The analysis showed that they were still statistically significantly different ($p<0.0026$).

We then tested how well the incompleteness score could predict error in mammography reading. Figure 2 shows several performance metrics for different cutoffs of the incompleteness score. The maximal accuracy with respect to cutoffs was 0.826 at a cutoff of 0.018. This means that > 1.8% probability of changing decisions when given new information should warrant describing more observations. The precision associated with this cutoff was 0.713 meaning 71.3% of cases classified as errors via the incompleteness score with cutoff 0.018 will actually be errors. Finally, we measured the percentage reduction in total mammography error if each error marked for revision was corrected. Using the given cutoff, we saw a potential 21.7% decrease in total errors.

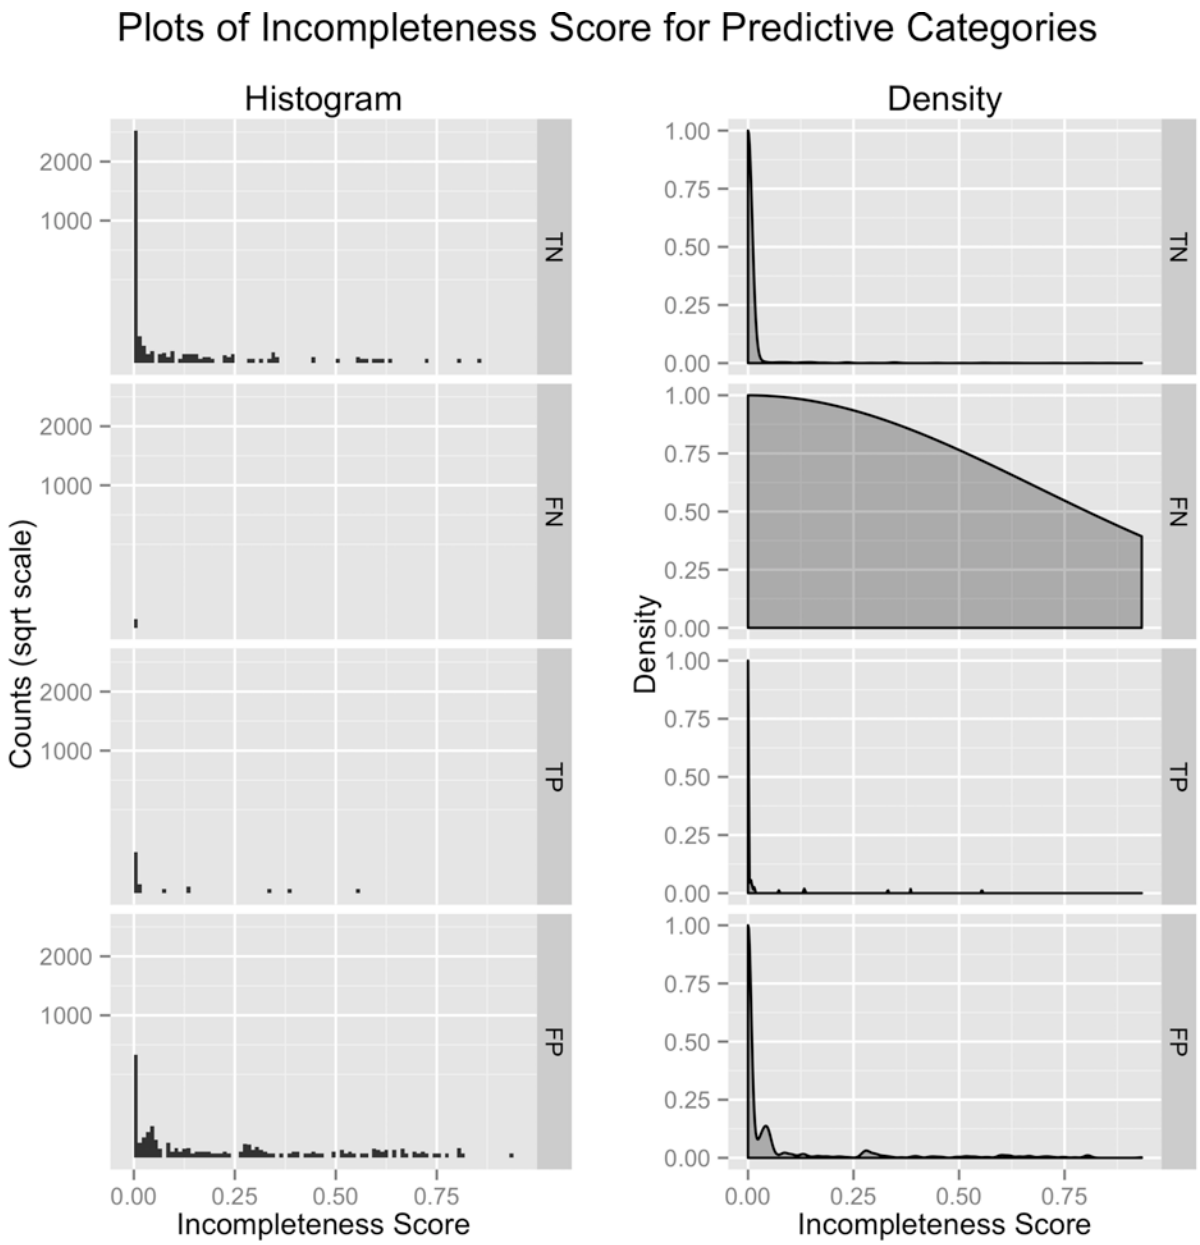

Figure 1: Plots of the histogram and density of incompleteness scores, stratified by radiologist performance on their respective cases. True Negative (TN) findings have the lowest incompleteness scores (indicating they are **most** complete) while false positive (FP) findings have higher incompleteness scores (indicating less completely reported findings). Joining (TN,TP) and (FP,FN), we can compare cases that were correctly assessed to cases with errors. Note that the false negative density graph has a nearly uniform distribution. This is an artifact due to the small amount of false negatives in the data set that skew density estimation.

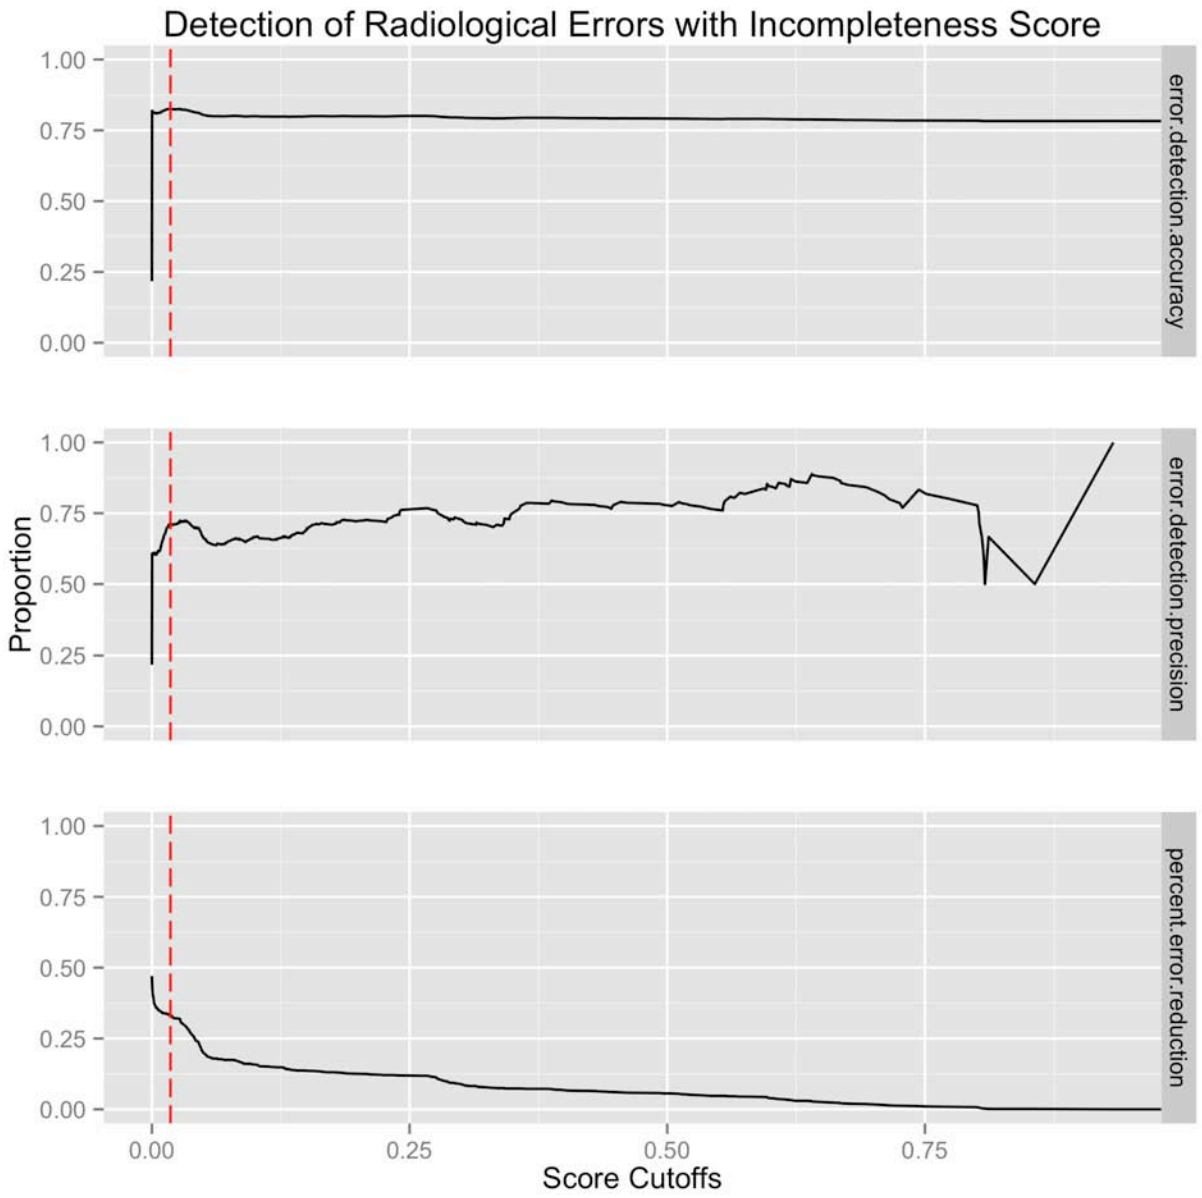

Figure 2: Improvement in radiological performance for difference incompleteness cutoffs. First row shows the incompleteness score accuracy in predicting radiological errors. Second row shows incompleteness score positive predictive value in predicting error. Third row shows the percent reduction in error if identifying error at the specified cutoff. The red-dotted line shows the cutoff point that maximizes error classification accuracy (first panel).

Discussion

We described a method to quantify how incomplete the content is in a mammographic report. We then presented an algorithm to measure this value in a computationally tractable manner. Finally, we showed that this *incompleteness score* is a strong indicator of errors in mammography interpretation. Implementation of this metric during mammography reporting time could provide a useful real-time feedback to radiologists to indicate possible errors.

Reporting in mammography is a labor intensive but critically important task for results communication. Though there is pressure for radiologists to expend their efforts efficiently, we show that poor report quality (measured by

our incompleteness score) is a marker for interpretation errors. This result might stem from a few different causes. The causal explanation is that poor interpretation leads to poor reports. In this case, a radiologist might have not seen a relevant descriptor in the image or neglected to highlight its importance. Another possibility is that incomplete reporting is a function of available time. When required to read large volumes of images, speed may decrease accuracy. In this case, a practitioner producing brief or incomplete reports may also be spending less time interpreting the image. A third possibility is that the process of reporting improves diagnosis by requiring radiologists to reason about their diagnosis. Thus, individuals who do not spend as much time on their reports do not go through the same formal thinking process. For future work, we will consult breast imaging radiologists on cases that were correctly classified as erroneous to see if humans can also identify when poor reporting leads to mis-diagnosis. If this is the case, we can begin to discover reporting practices that reduce error rates.

Though the system we present shows promising results with regards to predicting radiological errors, it does have some shortcomings. The use of an approximate algorithm to estimate the incompleteness score allows for some degree of error. We correct for this by using a large number of samples with respect to the number of hidden variables, but unfortunately, it is difficult to empirically evaluate our system as calculating the exact incompleteness score is prohibitively expensive with regards to computational time. For future work, we will evaluate alternative approaches for measuring incompleteness. Another issue with our system is that it does not actually correct the errors in interpretation or give any constructive feedback. So although the system can *potentially* reduce the amount of errors by ~20%, we have not shown which of these reports would actually be corrected. We plan to incorporate this into a clinical setting to measure the true impact of this decision-support system. Finally, this study was designed to be descriptive rather than predictive, so we did not measure classification results with an optimal cutoff in a third held-out test set. Thus, the results will be overly-optimistic in terms of error-prediction. In the future, we plan to implement our algorithm on faster cluster computers, which will allow us to perform a thorough cross-validation analysis to obtain better accuracy measurements.

Though we developed this system for mammography reporting, this methodology could be extend to any domain that uses expensive information to make threshold-based decisions. All this system requires is a generative model linking descriptors to diagnosis and a method to sample from this model. It is straightforward to implement this in any medical domain where testing can be a costly and/or risky task. Not only can this method improve diagnostic accuracy, but it inherently rewards good, thorough reporting practices. This is beneficial for patients and researchers alike.

How do Interruptions Impact Nurses' Visual Scanning Patterns When Using Barcode Medication Administration Systems?

Ze He, MS[1], Jenna L. Marquard, PhD[1], Philip L. Henneman, MD[2,3]
[1]College of Engineering, University of Massachusetts, Amherst, MA; [2]Baystate Medical Center, Springfield, MA; [3]Tufts University School of Medicine, Boston, MA

Abstract

While barcode medication administration (BCMA) systems have the potential to reduce medication errors, they may introduce errors, side effects, and hazards into the medication administration process. Studies of BCMA systems should therefore consider the interrelated nature of health information technology (IT) use and sociotechnical systems. We aimed to understand how the introduction of interruptions into the BCMA process impacts nurses' visual scanning patterns, a proxy for one component of cognitive processing. We used an eye tracker to record nurses' visual scanning patterns while administering a medication using BCMA. Nurses either performed the BCMA process in a controlled setting with no interruptions (n=25) or in a real clinical setting with interruptions (n=21). By comparing the visual scanning patterns between the two groups, we found that nurses in the interruptive environment identified less task-related information in a given period of time, and engaged in more information searching than information processing.

Introduction

Medication errors are common and can adversely affect patients' health levels[1], with the medication administration process accounting for about one third of serous medication errors[2]. Health information technology (IT) has shown some promise in reducing medication errors[3,4,5]. Barcode technology, for instance, can be used during medication administration to help verify a patient's identity and the medication to be administered. Nurses can use the barcode medication administration system (BCMA) in conjunction with an electronic medication administration record system (eMAR) to automatically document the administration of medications. Because eMAR systems can retrieve records from either provider order entry or pharmacy systems, they may also reduce transcription errors[6], thereby improving patient safety.

Despite their benefits, BCMA systems can introduce errors, side effects, and hazards into the medication administration process[7,8,9], with previous studies identifying many contributing factors leading to undesirable outcomes[7-10]. As Harrison, Koppel, and Bar-Lev pointed out in their Interactive Sociotechnical Analysis framework, unintended consequences of health IT are often the result of interactions between health IT use and health care organizations' sociotechnical systems, including technical and physical infrastructure, social interaction, culture, and workflow[11]. For example, an organization overemphasizing the need for "complete" information may cause cognitive overload during health IT use[12].

Care providers' cognitive processes (for instance, visual scanning patterns) and external interruptions are important factors leading to medical errors[13,14]. However, the interactions between these factors during health IT use remain relatively underexplored. Grundgeiger and Sanderson (2009) reviewed research examining the nature of the relationship between interruptions and medical errors, and noted that much of the research in this area is descriptive. They suggest that future research use cognitive theories as a basis for empirical research[14]. Using an eye tracking device in an intensive care unit, Grundgeiger, Sanderson, MacDougall, and Venkatesh (2010) employed two cognitive theories – memory for goals and prospective memory theories – to empirically investigate how long it takes nurses to resume interrupted critical care tasks[15]. This work is important because it is one of the few studies to explicitly link nursing cognitive processes with an environmental factor (i.e. interruptions).

In our study, we similarly use data from an eye tracking device to study how interrupting factors impact nurses' cognitive processes, specifically their visual scanning patterns during medication administration. We use eye tracking data because visual scanning patterns are an important proxy for information intake and attention allocation. Additionally, Marquard et al. (2011) have shown that visual scanning patterns may be related to an individual's ability to identify patient identification errors[16].

In our study, we attempt to identify the impact of interruptions on nurses' visual scanning patterns. Our study builds off of a large body of work exploring how to measure and evaluate visual scanning patterns.

Researchers in this domain have developed a common set of definitions for visual scanning behaviors. An eye *fixation* occurs when the eye-in-head position is stable and focused on a specific reference point for at least 100-200ms. A *saccade* is the rapid shift of the eye from one point of fixation to another, typically lasting less than 50ms. Jacob & Karn (2003) provide a comprehensive review of tested methods to analyze visual scanning data[17].

Two studies analyzing individuals' visual attention to specific information in an environment are presented in Fitts, Jones, & Miton's (1950) pioneering work addressing pilot-aircraft interaction and in Goldberg and Kotval's (1999) work addressing human computer interaction[18,19]. Fitts et al. (1950) analyzed pilots' frequencies of eye fixations and lengths of fixations on each aircraft instrument. Goldberg and Kotval (1999) used a fixation/saccade ratio to capture individuals' time spent processing (fixations) computer interface components to their time spent searching (saccades) for the components. Higher fixation/saccade ratios indicated that individuals tended to do more information processing than searching for information when using the interface components.

In our study, we use Fitts et al.'s measures to capture which artifacts nurses fixate on *most frequently* while administering medications, and which artifacts nurses fixate on *longest* while administering medications. We use Goldberg and Kotval's measure to capture whether nurses have *different patterns of processing and searching for information* across artifacts during the medication administration process. With this knowledge, we may be able to design corresponding cognitive strategies to minimize the impact of interrupting factors, revise current health IT workflow protocols, and design simulated training experiences to better prepare nursing students for real clinical settings.

Methods

To study the impact of interrupting factors on visual scanning patterns, we compared nurses' visual scanning patterns in their typical interruptive environment (i.e., real clinical setting) with those patterns in a simulated setting, which was controlled to be free from interruptions (i.e., controlled setting). By comparing the visual scanning patterns of these two groups, we can start to distinguish how visual scanning patterns change in response to interruptions.

Settings and Participants

We conducted two experiments at a 600-bed, urban, level 1 trauma, pediatric and tertiary referral center in Western Massachusetts with an annual emergency department (ED) census > 100,000. During each experiment, we observed ED nurses as they completed the medication administration process while wearing an eye tracking device. Study A was conducted in a controlled setting[5], and Study B was conducted in a real clinical setting.

Participants in the studies volunteered to participate during one of their day or evening shifts. We told participants that the purpose of the study was to evaluate how expert nurses use visual cues to perform common patient care processes. The hospital's institutional review board approved the study. All participants read and signed an informed consent form, and had any questions answered by a study researcher.

Study A

Each nurse participant (n=25) performed a common patient care process – administering a medication – to a researcher acting as a patient. The patient only engaged in conversations with the participant when asked questions. Researchers asked each participant to perform the process the same way he or she does every day in the ED except for giving an actual medication. The patient had an ID Band on his right hand wrist, with the patient's name, date of birth (DOB), and medical record number (MRN) printed on the ID Band. A researcher led each participant to a computer with an electronic medication administration record system and a barcode scanner tied to the computer system. The user interface and functions of the system were the same as the hospital's actual system, but the computer did not connect to the hospital database and used local simulated patient data. The researcher also gave the participant an intravenous medication. The medication bag was labeled with the patient's name, DOB, MRN, medication name, medication dose, and a barcode.

Study B

Each nurse participant (n=21) performed the same patient care process as in Study A – administering a medication using barcode technology – but in a real clinical setting. All participants performed the processes on one real patient. Each participant was asked to perform the process in exactly the same way he or she did every day. The context for each process was different for each participant, yet in each case the participant had to perform some kind of medication administration process.

All participants performed the medication administration process using a standalone computer and either a portable tablet computer integrated with a barcode scanner (3/21) or a barcode scanner wirelessly connected to a computer (18/21). The medications each participant administered also varied, including intravenous medication, pills, and liquid medicines; most medications had a barcode on the bottle or bag.

Procedure

In both studies, participants wore an eye tracking device while completing the medication administration process. The ASL Mobile Eye (Figure 1; Applied Science Laboratories, Bedford, MA) is a tetherless eye tracking device that can be worn by participants who must move freely through a study environment. The eye tracking device weighs 76 grams, includes a scene camera, optics, and reflecting mirror all mounted on safety glasses. This eye tracking device can record both video and audio. To calibrate the eye tacking device for each participant, participants looked at twelve specific reference points in their field of view, with marks of their fixation adjusted to correspond to the reference points. After calibration, the software program for the eye tracking device overlays crosshairs (plus signs) at the exact locations in a scene where the individual is fixating throughout the scenario. With the head stable, the device is accurate to within 0.5 degrees of visual angle, with a resolution of 0.10 degrees of visual angle; the visual range of the eye tacking device is 50 degrees horizontally and 40 degrees vertically with respect to the head. The eye tracking device's scene camera records a video of the area in front of the wearer and uses pupil–corneal reflection to measure the position of the eye – sampled at 25 Hz.

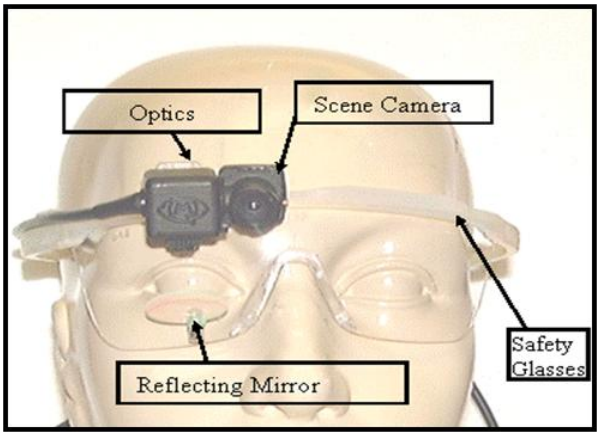

Figure 1. Eye tracking device

Two research team members independently reviewed all eye tracking videos, using standardized step names to code the steps each participant took to complete the medication administration process. The reviewers developed a standard coding policy and focused on the participants' medication administration related visual steps (i.e., fixations on artifacts including the ID band, medication labels, and computers) and interrupting events. The research team members determined a fixation occurred if the cross hairs on the video were within a one-centimeter squared box that covered a medication administration related information section on the pre-defined artifacts for 120 milliseconds. Another researcher resolved disagreements between the two initial coders. A shortened sample process execution is shown in Figure 2; a typical trial included about 20 to 30 steps.

We removed eye tracking data with insufficient quality to judge what artifacts the participant was looking at, e.g., the red crosshair did not show up to indicate where the fixations was located (n=3 in study A and n=2 in study B). We excluded data from one participant in study A who violated experimental protocols by changing the designed procedures of the experiment. We analyze his data separately because this change in the procedure may have affected his visual scanning process. We also removed two participants' data in study B from comparisons because they received a system warning message, but overrode the BCMA system; we analyze their data separately because we were specifically looking at the impact of external interruptions on the 'typical' process. Therefore, the numbers of participants included in our analysis are 21 in study A and 17 in study B.

Gave Medication to Patient

Figure 2. Example shortened process execution

Analysis of Visual Scanning Patterns

a) We measured how many medication administration-related fixations each participant completed per minute, calculated by their total number of fixations over the course of the trial divided by the duration of the trial in minutes. This measure approximates how much medication administration-related information a participant intakes in a given period of time.

b) Eye Fixation Distributions: Each nurse's eye fixation distribution is defined by the following formula:

$$\text{Eye Fixation Distribution on artifact A} = \frac{\text{\# of Eye Fixations on artifact A}}{\text{\# of Total Eye Fixations}}$$

This quantifier helps us to understand how nurses' visual attention is allocated across different artifacts (i.e., ID Band, Medication, Computer) throughout the process. This method is comparable to Fitts' frequency of eye fixation measure[18] and Jacob & Karn's number of fixations on each area of interest[17].

c) Eye fixation/saccade ratio: Each nurse's fixation/saccade ratio is defined by the following formula:

$$\text{Fixation/Saccade Ratio} = \frac{\text{\# of Total Eye Fixations}}{\text{\# of Saccades}}$$

This ratio quantifies how often a participant engages in information processing versus information searching between artifacts. If a participant engages in more fixations on one artifact before a saccade (a transition to another artifact), it implies the participant may do less searching for information across artifacts, instead dwelling on artifacts for longer periods of time for information processing. This method is comparable to Goldberg and Kotval's fixation/saccade ratio method[19], but in Goldberg and Kotval's work, they used durations of total fixations and saccades, while we used numbers of fixations and saccades.

d) Maximum Consecutive Eye Fixation: Each nurse's maximum consecutive eye fixation is calculated for each artifact. Similar to the eye fixation distribution measure, the artifact with the highest number of maximum consecutive eye fixations might be more heavily used, and thus may be a primary information source in the medication administration process. This method is comparable to Fitts' length of fixation[18].

Analysis of Interrupting Factors

We categorized interrupting events into three categories: a) completion of other tasks (e.g., transit between physical locations, other medication-related tasks such as ordering, transcribing, dispensing, etc.); b) unexpected artifact-related events (e.g., lost ID Band, barcode scanner failing to scan); and c) off-topic conversations with patients or colleagues (e.g., plans for the weekend). We measured the total durations of these interrupting events over the duration of the trial. Durations were recorded as the time from the start of a participant attending to the interrupting event to the time (s)he returned to the medication administration process.

Results

Figure 3 shows average number of fixations per minute completed by participants in the two settings, with the error bars representing the 95% confidence intervals for the values. We observed a significant difference between the two groups using a one tailed t test ($p<0.001$).

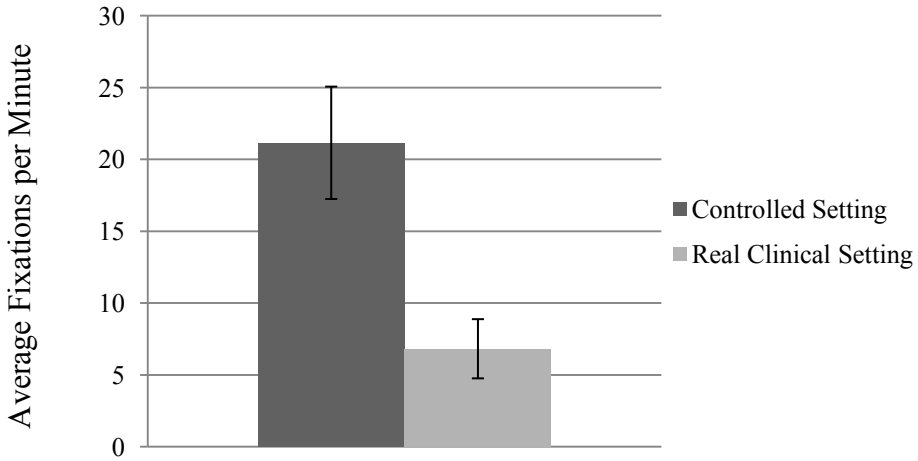

Figure 3. Average medication administration-related fixations per minute

Figure 4 displays the eye fixation distribution for each group. Both groups fixated on the computer most often, but nurses in the controlled setting fixated on the computer (77% of fixations) even more than nurses in the real clinical setting (64% of fixations) ($p=0.015$). Nurses in the controlled setting fixated on the ID band less (8% of fixations) than nurses in the real clinical setting (18% of fixations) ($p<0.001$). The two groups fixated on the medication label with similar frequency, with the percentages of fixations being of 15% for those in the controlled setting and 17% for those in the real clinical setting.

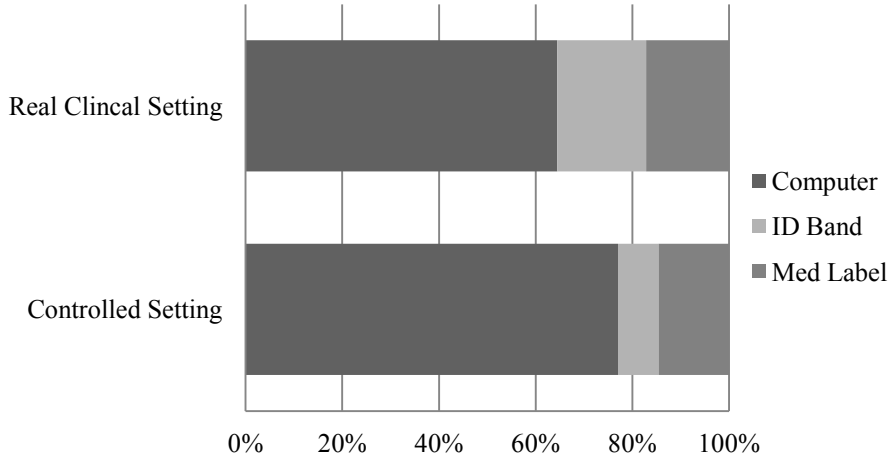

Figure 4. Eye fixation distribution for each group

Figure 5 shows the average number of fixations per saccade completed by the two groups, with the error bars representing the 95% confidence intervals for the values. There is a significant difference between the two groups using a one tailed t test (p=0.026).

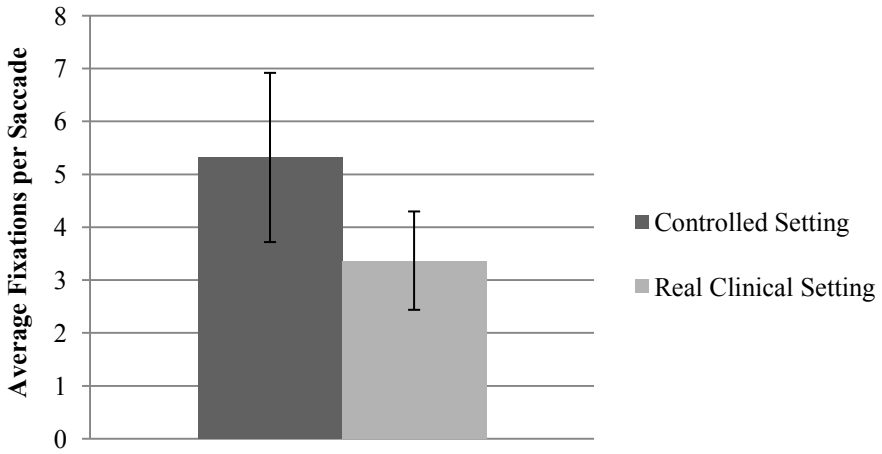

Figure 5. Average fixations per saccade for each group

Table 1 shows the average numbers of maximum consecutive fixations on each artifact for each group. Both groups had their longest average maximum consecutive fixation on the computer, but the nurses in the controlled setting had a much longer average maximum consecutive fixation on the computer (13.1 fixations) than the nurses in the clinical setting (5.2 fixations) ($p<0.001$). The nurses in the controlled setting also had a longer average maximum consecutive fixation on the medication label (1.8 fixations) than the nurses in the clinical setting (1.2 fixations) ($p = 0.04$). The average maximum consecutive fixations on the ID Band (1.4 fixations for nurses in the controlled setting; 1.6 fixations for nurses in the clinical setting) are relatively close for the two groups.

Table 1. Average maximum consecutive fixations on each artifact (confidence interval)

	Computer	ID Band	Medication Label
Controlled Setting	13.1 (9.0-17.1)	1.4 (0.9-1.9)	1.8 (1.4-2.2)
Real Clinical Setting	5.2 (3.6-6.8)	1.6 (1.2-2.0)	1.2 (0.7-1.7)

We identified 16 separate occurrences of interrupting events for 10 participants (59% of total participants) in the real clinical setting, summarized in Table 2. We recorded the durations of each interruption, but some interrupting events overlapped. For example, when completing another medication-related task (e.g., dispensing), a participant may also engage in off-topic conversations with his/her colleagues. In these cases, we count both types of interruptions but combined them into a single interruption time. The durations of each interruption ranged from 10 seconds to 164 seconds, with a mean value of 42.4 seconds (SD=34.5). In total, there were 12 times where nurses completed of other medication-related tasks, 2 times when unexpected events occurred with process artifacts (1 lost ID Band and 1 barcode scanner failure), and 7 off topic conversations with patients or colleagues.

Table 2. Summary of interrupting events in the real clinical setting

Interruption Category	Number of Nurses	Total Number of Occurrences	Description of Interruptions
Other tasks	8	12	• 8 nurses had to transit from the patients' bedside to the computer to complete the medication administration process, e.g., scanning barcode, documenting information • 4 nurses retrieved medications from the medication dispenser after they started the medication administration process
Unexpected artifact-related events	2	2	• One nurse had a medication that the scanner failed to scan, so she had to manually enter the medication administration information. • One nurse had a patient who lost their ID band, so she had to order a new one before she could continue to administer the medication.
Off-topic conversations	6	7	• 6 nurses engaged in off-topic conversations with their colleagues and/or patients.

Discussion

While previous studies made attempts to identify what contextual factors may be potentially interruptive, we used eye tracking video data to quantify how those factors may impact nurses' visual scanning patterns.

Participants in the real clinical setting tended to complete fewer fixations on medication administration-related artifacts in a given time period, therefore collecting less task-relevant information in the same time period. This may be attributed to the impact of various contextual factors that interrupt the participants' attention from attending to medication administration-related information. In our observation, we found that the medication process was non-linear in some cases, with overlap between steps. For example, we observed that some nurses engaged in medication dispensing during the medication administration process, which lengthened the primary task of medication administration. In addition, information sources were often more physically distant from one another in the real clinical setting as compared to the controlled setting, meaning nurses had to scan across larger distances in order the glean the same information.

Participants in the real clinical setting tended to allocate more fixations to the ID band and fewer to the computer. This may be due to the fact that in real clinical settings participants engaged in more direct interactions with patients. Yet, the bulk of fixations for participants in both groups (over 60%) were directed toward the computer. Therefore, special attention should be paid to the layout of the patient and medication information on this artifact, so that in real clinical settings, nurses can retrieve this information more efficiently. For instance, the patient identification information on the computer should be prominently displayed, whereas in many current systems they are in small print at the top of the computer screen.

Participants in the real clinical setting had fewer fixations on one artifact before making a saccade to another artifact than those in the controlled setting. Nurses in the controlled setting had significantly longer

maximum consecutive fixations on the computer, while both groups had similar consecutive fixations on the ID band and medication label. This may imply that the participants in the clinical setting engaged in more information search and less information processing when using the computer than those in the controlled setting, or that they were more likely to be distracted or interrupted while using the computer than at other times in the process.

This study suggests several possibilities for future research that could better determine mechanisms for process and technology redesign. For example, some nurses interrupted the medication administration process in a variety of ways (e.g., to dispense medications), making their visual scanning patterns more fragmented. Determining ways to reduce this type of fragmentation may allow nurses to more efficiently gather and use the information needed to complete their primary process. Technology-related changes may also significantly influence nurses' visual scanning patterns. Future studies could determine the effects of placing technologies physically close together so that nurses do not have to visually scan across large distances, or designing computer interfaces to better support nurses' visual scanning patterns. Finally, future studies may be able to identify especially effective visual scanning patterns, and train nurses to use those patterns.

Limitations

There are several limitations to this study. We could not fully control the variability in the real clinical setting (e.g., differing patients, differing medications) so cannot separate out the contribution of each factor on the differences in visual scanning patterns. Though our sample size was relatively small (n=21-25), there were statistically significant differences in our measures of interest. Additionally, this study was conducted at a single hospital, whereas participants at other institutions may exhibit different visual scanning patterns and follow different protocols. In this analysis, we did not account for verbal steps in the medication administration process, though auditory channels are also related to medication-related administration process. It is reasonable to think that if a nurse used a verbal method to verify a patient's identification, for instance, the nurse might conduct less visual information search. Finally, the coding of the eye tracking videos is somewhat subjective. To address this limitation, we had two independent evaluators review the videos, with another evaluator reconciling discrepancies between the initial evaluators' coding of the process steps. Yet, absolutely objective judgments are difficult to achieve.

Conclusions

This study showed that, on a variety of measures, nurses administering medications in a real clinical setting exhibited different visual scanning patterns than did nurses in a controlled setting. We assessed the nature and lengths of interruptions faced by nurses in the real clinical setting, to assess how these interruptions might be at least partially responsible for these differences.

A Method for Analyzing Commonalities in Clinical Trial Target Populations

Abstract

ClinicalTrials.gov presents great opportunities for analyzing commonalities in clinical trial target populations to facilitate knowledge reuse when designing eligibility criteria of future trials or to reveal potential systematic biases in selecting population subgroups for clinical research. Towards this goal, this paper presents a novel data resource for enabling such analyses. Our method includes two parts: (1) parsing and indexing eligibility criteria text; and (2) mining common eligibility features and attributes of common numeric features (e.g., A1c). We designed and built a database called "Commonalities in Target Populations of Clinical Trials" (COMPACT), which stores structured eligibility criteria and trial metadata in a readily computable format. We illustrate its use in an example analytic module called CONECT using COMPACT as the backend. Type 2 diabetes is used as an example to analyze commonalities in the target populations of 4,493 clinical trials on this disease.

Introduction

An important area for clinical research standards development is participant selection for clinical studies. Many clinical studies are designed to emphasize internal validity, and some design decisions may compromise external validity, which is also referred to as generalizability. When a clinical trial has limited generalizability, the study results can be difficult to translate to the real-world population to which the study results are meant to apply. This is a concern of both the public and the clinical research community [1-3], and has significantly impaired the cost-benefit ratio of many clinical studies. Meanwhile, many clinical investigators prefer to reuse existing participant selection methods [4]. However, there is no well-accepted standard for participant selection.

To supplement the top-down model of traditional research standard development, we propose to use a data-driven approach to analyzing commonalities in participant selection for clinical trials. Leveraging the timely information on the Web, community-generated information has been shown to facilitate public health, e.g., real time prediction of epidemic disease [5]. We hypothesize that this method can identify frequent eligibility features that are in use in the clinical research community and represent *de facto* standards for reusable eligibility features. Understanding these practices can help the design and adoption of standards derived "from researchers and for researchers".

The official public registry of clinical trials and a valuable resource created by the National Library of Medicine of the United States [6], ClinicalTrials.gov presents a great opportunity for identifying frequently used criteria for research participant selection without expensive knowledge engineering by domain experts. Since September 2007, all clinical trials sponsored or conducted in the United States must be registered in ClinicalTrials.gov. As of 01/27/2014, 159,891 clinical trials with sites in more than 180 countries are registered, including 129,193 interventional studies and 29,061 observational studies. Strictly speaking, only interventional studies are called "clinical trials". In this paper, we use the term "clinical trials" to represent both interventional and observational studies. Trial summaries are semi-structured so that descriptive characteristics such as study title, sponsor, and target populations' ethnicity and gender are organized in structured fields, whereas eligibility criteria are written in free text, separated into inclusion criteria and exclusion criteria sections.

We have used ClinicalTrials.gov to identify common eligibility features for clinical research participant selection [7, 8]. As an extension to our previous work, this study integrated our previously developed parsing methods [9-11] to analyze commonalities in clinical trial participant selection. In particular, we designed and built a database called "Commonalities in Target Populations of Clinical Trials" (COMPACT) with searchable information for ClinicalTrials.gov's 159,891 entries as of 1/27/2014. COMPACT enables analysis modules, such as the CONECT (Commonalities in Target Populations in Eligibility Criteria) module described in this paper, to surface commonalities in clinical trial target populations from COMPACT. A use-case driven approach was employed to demonstrate how commonalities in clinical trial target populations can be derived from disease specific trials' inclusion and exclusion criteria and be leveraged to inform future clinical trial designs. This paper contributes to the research community (1) a novel method for analyzing commonalities in clinical trial target populations on the fly,

and (2) a new database to inform knowledge reuse for future clinical trial eligibility criteria designs. Both resources will be made open source in the near future.

Methods

In our design for COMPACT, we formulated the commonalities of target populations as common eligibility features, including numeric features, categorical features, and their attributes. Numeric features are eligibility criteria with a numeric value range requirement for participants, such as "HbA1c > 7%". Categorical features are eligibility criteria that accept one of a set of value options, such as "past history of stroke" (yes or no). We treat dichotomous (binary) criteria as a case of categorical criteria. To demonstrate the analytic utility of COMPACT, we developed an example analytic module called CONECT, which enables a user to mine contextual common eligibility features for trials on a certain disease from COMPACT. Next we will describe the details of both.

1. The Conceptual Design of COMPACT

The database Commonalities in Target Populations of Clinical Trials (COMPACT) includes four entities: *metadata of clinical trials*, *structured clinical trial eligibility criteria*, and *common eligibility features* (i.e., *numeric* and *categorical features*) *and their properties indexed by disease topics*.

Metadata of trials defines indexing characteristics of clinical trials provided by ClinicalTrials.gov, such as study type, intervention, medical condition, and study design (i.e., intervention model for interventional studies, allocation of participants to intervention group for interventional studies, and time perspective for observational studies).

Common eligibility features can be numeric or categorical. Each *common numeric feature* has five properties: numeric feature concept (e.g., HbA1c, BMI), the Unified Medical Language System (UMLS) semantic group [12] for the feature, the collective permissible value ranges derived from all the trials using this feature (e.g., [6.5%-7%] for HbA1c), the width of distinct mutually exclusive value intervals (e.g., 0.5 for [6.5%-7%] for HbA1c) and a salient modal boundary value if applicable (e.g., more diabetes trials use HbA1c of 7% as either a lower or an upper bound than any other threshold so that 7% is the modal boundary value).

Each *common categorical feature* has two properties: categorical feature concept and its UMLS semantic group. For example, the semantic group of "malignant neoplasm" is "Disorders". According to the NLM document [13], all 133 semantic types of the UMLS are grouped into 15 general semantic groups. "Disease or Syndrome" and "Neoplastic Process" along with 10 other semantic types are grouped into the semantic group "Disorders".

Figure 1 illustrates the information flow for a user, who can be a policy researcher, a clinical investigator, a trial sponsor, or others interested in such a system to interact with the COMPACT database. In this figure, the rectangle blocks represent data input and output when interacting with COMPACT. The round-corner blocks represent properties of input and output. The arrow lines represent processes when interacting with COMPACT.

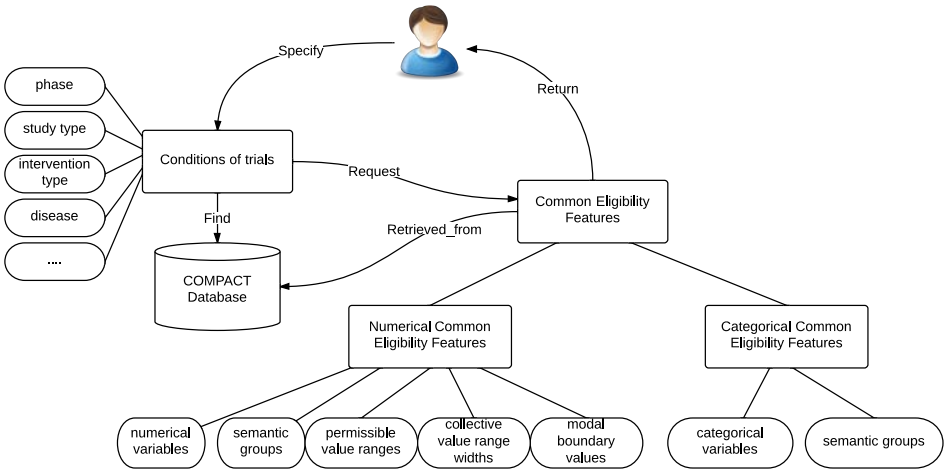

Figure 1. The information flow for a user to interact with the COMPACT database.

For example, when a user specifies certain queries of trials when interacting with the COMPACT database, e.g., *Type 2 diabetes trials recruiting patients with HbA1c >= 7.0 %*, he or she will retrieve the common eligibility

features with their attributes for these trials. Contextual attributes for common eligibility features present to a user how the clinical research community uses the feature HbA1c collectively in Type 2 diabetes trials. From COMPACT, three attributes for numeric features can be generated: collective value ranges, collective value range widths, and modal boundary values. Note that the data set for analyzing these three attributes comprises all the clinical trials of the given disease in the query.

Collective value ranges give the frequently used value ranges of a numeric eligibility feature for all the trials on a certain disease. We itemize all the permissible value ranges of a numeric feature in all the trials of a certain disease and count the number of trials that use a specific value range to get the collective value ranges. For example, in the inclusion criteria of the trial NCT00035984, the criterion "HbA1c value between 7.5% and 11%" gives the value range of HbA1c in this criterion: [7.5, 11.0], in which "[ ]" means being inclusive.

Collective value range widths present the distribution of value range widths of a numeric eligibility feature for all the trials on a certain disease. To get the collective value range widths, we counted the number of trials of a certain disease with the same value range width of a numeric feature. For example, the value range width of HbA1c derived from the same criterion "HbA1c value between 7.5% and 11%" is: 11 – 7.5 = 3.5.

Modal boundary values are defined as the "most-used boundary values" for a numeric feature for eligibility determination. For example, because more diabetes trials use HbA1c of 7% as either a lower or an upper bound, "7.0%" is the modal boundary value of HbA1c for Type 2 diabetes trials. Similarly, "140 mm Hg" is a modal boundary value for systolic blood pressure in the same data set. Note that for some numeric features, there might not be a modal boundary value.

2. COMPACT Database Construction

Figure 2 presents the workflow for constructing the COMPACT database. To enable agile discovery of common eligibility features, we downloaded all the trial summaries in ClinicalTrials.gov as of January 2014, excluding those with no or non-informative eligibility criteria text, such as "please contact site for information". The trial summaries were parsed and saved in the relational database (RDBMS) MySQL. For each trial, using previous developed parsing methods [9-11], we extracted, parsed, and stored the metadata of the trial (e.g., title, location, type, etc.), numeric features, and categorical features in three database tables "Metadata", "Numeric_features", and "Categorical_features", respectively. Ross *et al.* found that approximately 23% of eligibility criteria in ClinicalTrials.gov entries are numeric [14], such as for HbA1c, BMI, blood glucose, and creatinine. To unify these criteria, we negated the meaning of exclusion criteria and converted them to inclusion criteria without changing or losing meaning by replacing "<", "<=", ">", ">=" with ">=", ">", "<=", "<", respectively. The rationale of this conversion is that the complement of a numeric expression in an exclusion criterion indicates an inclusion criterion.

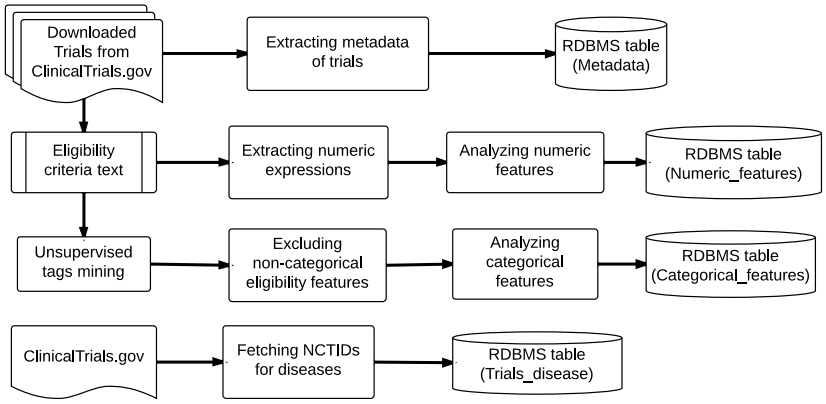

Figure 2. The pipeline for constructing the COMPACT database.

We applied unsupervised text mining on free-text eligibility criteria to automatically extract all frequent (i.e., appearing in at least 5% of all trials) eligibility features [9]. In this step, n-grams were generated for each criterion after noise reduction by a part-of speech (POS) tagger. The n-grams can be identified as eligibility features if they contain a substring that can be annotated using a UMLS concepts assigned one of 27 semantic types relevant to the clinical trial domain [15]. We excluded all the features whose UMLS semantic type was "Body Part, Organ, or

Organ Component". For example, in the inclusion criteria of trial NCT00934414, from the sentence "Smoking: BMI of = 40 kg/m2", two eligibility features "smoking" and "body mass index" were extracted and retained.

Valx, a numeric expression extraction and normalization tool [10, 11] developed in our lab, was employed to extract and parse complex numeric expressions in free-text eligibility criteria. For example, from the inclusion criterion "*type 2 diabetes mellitus diagnosed at least 3 months with fpg level <=240mg/dl and hba1c between 6.5% and 10% inclusive"*, Valx extracted two numeric features "glucose" ("fpg" is short for "fasting plasma glucose") and "HbA1c", and generated the expressions "[["Glucose", "<=", 240, "mg/dL"], [HbA1c, ">=", 6.5, "%"], [HbA1c, "<=", 10.0, "%"]]". For each numeric feature, the permissible value range, the width of the value range, and the boundary values were calculated to support common eligibility feature attributes mining. The value range of the numeric feature "HbA1c" in the criterion above is "[6.5, 10.0]" ("[ ]" means being inclusive, while "( )" means being non-inclusive). Its value range width is 10.0 – 6.5 = 3.5. Its boundary values are 6.5 and 10.0 since they both appear once in this criterion. Heterogeneous semantic representations for the same numeric feature were recognized. For example, HbA1c can be written as "hemoglobin A1c" or "A1c". Using synonyms in the UMLS and manually defined heuristics, we mapped these different representations to the same concept, HbA1c. Also, a rule-based algorithm was employed to recognize different representations for common comparison operators in eligibility criteria statements, such as ">" and "greater than", or ">=" and "greater or equal to". Various measurement units were harmonized. For example, blood glucose can be quantified by mg/dL or mmol/l.

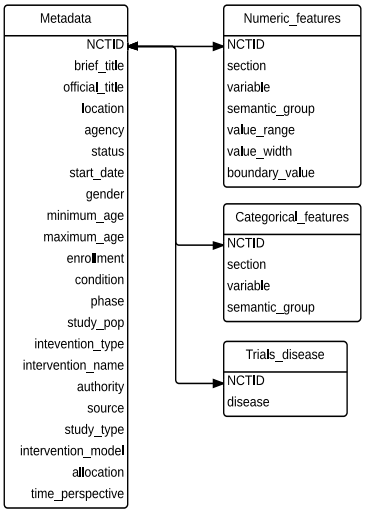

Figure 3. The database schema for COMPACT.

Figure 3 illustrates the database schema for COMPACT. For the table "trials_disease", we used all medical conditions defined by ClinicalTrials.gov (http://www.clinicaltrials.gov/ct2/search/ browse?brwse=cond_alpha_all) and created trial indexes for the selected conditions that were each studied by at least 50 clinical trials. The four tables in Figure 3 can be joined by a common attribute "NCTID", which is the unique identifier for a trial in the ClinicalTrials.gov. This knowledge base supports the mining of common eligibility features and their attributes in trials with various characteristics, e.g., a certain disease, a certain study design, recruiting patients of a certain gender, etc.

3. An Example Use of COMPACT

COMPACT enables flexible queries of sets of clinical trials for exploring the participant selection patterns in ClinicalTrials.gov. To illustrate such a use case, we developed an example common eligibility feature analytic module CONECT, leveraging RDBMS' capability of handling a wide range of queries to mine common eligibility features from COMPACT. **Figure 4** shows the workflow of CONECT using a concrete query example. The light blue rectangle boxes represent steps in the process. The ovals represent the output of each step.

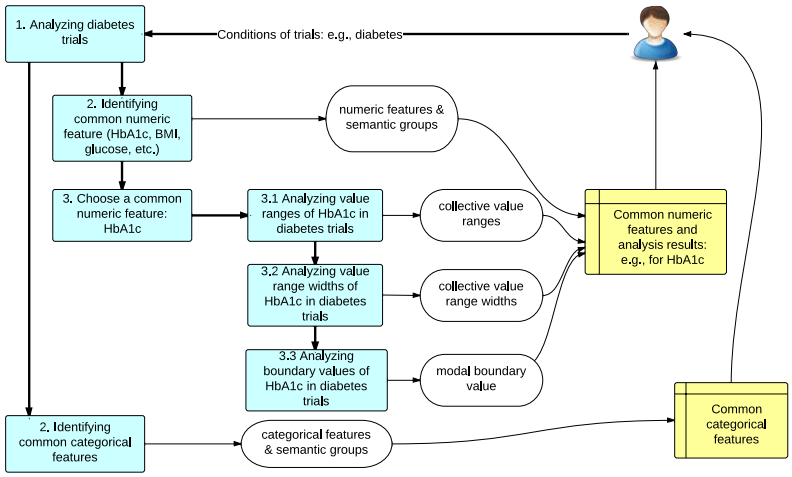

Figure 4. Workflow of CONECT with a concrete example of HbA1c patterns in diabetes trials.

In the example shown in **Figure 4**, a user may submit a query specifying the condition of trials to be "diabetes". In Step 1, CONECT will retrieve all the diabetes trials from COMPACT using the "trials_disease" table. In Step 2, CONECT will identify common numeric features (e.g., HbA1c, BMI, and glucose) and common categorical features in diabetes trials. In Step 3, the user may choose a numeric feature "HbA1c" for further analysis. Then all the pre-computed value ranges, value widths of the intervals, and boundary values of HbA1c in diabetes trials will be retrieved from COMPACT and aggregated upon the number of trials with the same value ranges, value widths, and boundary values. The output of the analysis including common numeric features, common categorical features, and the detail analysis of HbA1c in diabetes trials will be visualized and returned to the user.

Results

1. The Descriptive Statistics of COMPACT

To build the COMPACT database, we downloaded all 159,891 clinical trial records in XML format in ClinicalTrials.gov as of 01/27/2014. After excluding trials with no or non-informative eligibility criteria text, 159,187 trials were retained. The metadata fields of these trials were extracted and saved in the "Metadata" table. In order to quickly identify trials of a certain disease, we also created indexes for trials for 1,543 diseases with more than 50 trials in ClinicalTrials.gov. 229 out of these 1,543 diseases are listed as condition in more than 1,000. The trials of uncommon diseases can be retrieved by querying on the "condition" field using ClinicalTrials.gov's API. Valx extracted 1,045,893 numeric expressions for 176,986 unique features from 429,551 sentences in the inclusion criteria and 283,885 sentences in the exclusion criteria.

2. The Sample Query

In this section, we will use "Type 2 diabetes trials that recruit patients with HbA1C >= 7.0%" as a sample query to illustrate how common eligibility features are discovered from COMPACT. HbA1c is "a lab test that shows the average level of blood sugar (glucose) over the previous 3 months. It shows how well you are controlling your diabetes" [16]. In this paper, HbA1c refers to the test result. WebMD gives the normal ranges of HbA1c. For people without diabetes, the normal value range for HbA1c is between 4% and 5.6%. HbA1c levels between 5.7% - 6.4% indicate increased risk of diabetes, and 6.5% or higher indicate diabetes [17]. The American Diabetes Association recommends a HbA1c goal of less than 7.0% [18]. In COMPACT, 4,370 trials specify the value range of a patient's HbA1c in their eligibility criteria.

3. Common Eligibility Features and their UMLS Semantic Groups

In COMPACT, there are 4,493 Type 2 diabetes trials, out of which 700 trials (15.6%) are recruiting patients whose HbA1c must be >= 7.0%. According to the result of the analysis, five numeric features are used in the inclusion criteria of more than 50 such trials, whereas seven numeric features are used in the exclusion criteria of more than 50 such trials. Due to space limitations, **Table 1** shows the top five numeric features for each section, the semantic group, the number of trials, and the percentage of the qualifying trials (700 trials for the sample query) using the numeric feature. "HbA1c" is the only feature listed as one of the top five for both inclusion criteria and exclusion criteria of such trials, which conforms to the literature [18]. "HbA1c" and "Creatinine" are the most frequently used common numeric features in the inclusion and exclusion criteria of the qualifying trials, respectively.

Table 1. Top five numeric features frequently used in inclusion and exclusion criteria of Type 2 diabetes trials that recruit patients whose HbA1c >= 7.0%.

Numeric features used in the inclusion criteria				**Numeric features used in the exclusion criteria**			
Numeric features	**Semantic group**	**# Trials**	**Perc.**	**Numeric features**	**Semantic group**	**# Trials**	**Perc.**
HbA1c	Physiology	663	94.7%	Creatinine	Chemicals & Drugs	114	16.3%
BMI	Physiology	370	52.8%	Systolic blood pressure	Physiology	85	12.1%
Age	Physiology	327	46.7%	Diastolic blood pressure	Physiology	84	12%
Glucose	Chemicals & Drugs	114	15.9%	ALT	Chemicals & Drugs	73	10.4%
C-peptide	Chemicals & Drugs	56	8.0%	HbA1c	Physiology	71	10.1%

For common categorical features, nine are used in inclusion criteria of more than 50 trials, whereas 46 are used in exclusion criteria of more than 50 trials. **Table 2** shows the top five categorical features for each section, their sematic group, their use in inclusion or exclusion section, and their frequency. "Diabetes mellitus non-insulin-dependent" (Type 2 diabetes) and "diabetes mellitus insulin-dependent" (Type 1 diabetes) are the most frequently used categorical features in the inclusion and exclusion criteria, respectively. This is reasonable because usually Type 2 diabetes trials exclude Type 1 diabetes patients.

Table 2. Top five categorical features frequently used in inclusion and exclusion criteria of Type 2 diabetes trials that recruit patients whose HbA1c >= 7.0%. The names of categorical features are UMLS terms.

Categorical features used in the inclusion criteria				**Categorical features used in the exclusion criteria**			
Categorical features	**Semantic group**	**# Trials**	**Perc.**	**Categorical features**	**Semantic group**	**# Trials**	**Perc.**
diabetes mellitus non-insulin-dependent	Disorders	520	74.3%	diabetes mellitus insulin-dependent	Disorders	236	33.7%
sulfonylurea compounds	Chemicals & Drugs	118	16.9%	pharmacologic substance	Chemicals & Drugs	229	32.7%
antidiabetics	Chemicals & Drugs	94	13.4%	allergy severity - severe	Disorders	224	32.0%
pharmacologic substance	Chemicals & Drugs	91	13.0%	gravidity	Disorders	223	31.9%
contraceptive methods	Procedures	83	11.9%	malignant neoplasm	Disorders	190	27.1%

4. Collective Value Ranges of Numeric Eligibility Features

Among the top 5 numeric features discovered for the sample query, we chose the two most frequently used numeric features "HbA1c" and "BMI" to illustrate collective value ranges, collective value range widths, and modal boundary values. **Table 3** shows the five most frequently used value ranges of HbA1c and BMI in Type 2 diabetes trials. "[ ]" means being inclusive, while "( )" means being non-inclusive; -∞ refers to negative infinity, whereas +∞ refers to positive infinity. Out of 4,493 Type 2 diabetes trials, 2,058 trials (45.8%) use HbA1c, whereas 1,859 trials (41.4%) use BMI in their eligibility criteria. According to the analysis (after unifying inclusion and exclusion criteria), the most frequently used permissible value range for HbA1c is [7.0, 10.0], while the most frequently used value range for BMI is (-∞, 45.0].

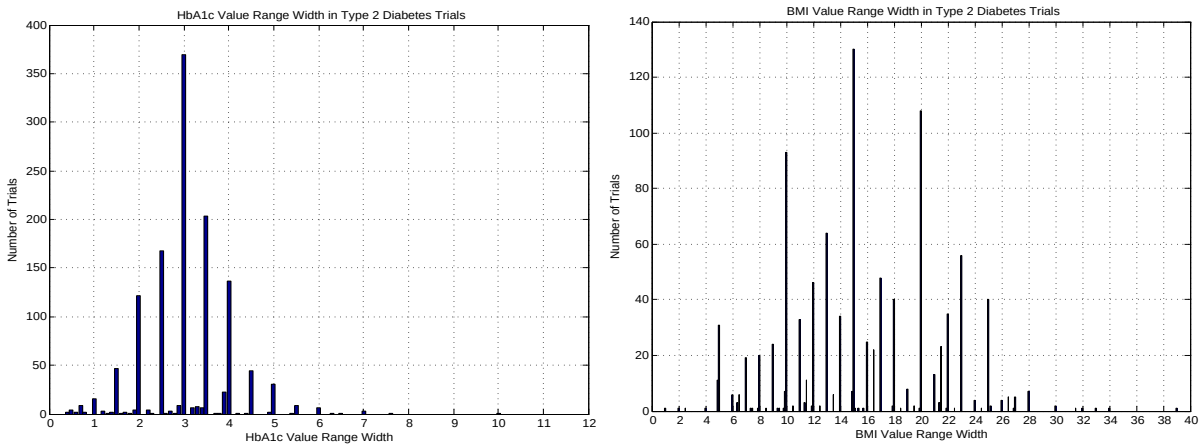
Table 3. Top five collective value ranges of HbA1c and BMI in Type 2 diabetes trials.

HbA1c value ranges	**Number of trials**	**BMI value ranges**	**Number of trials**
[7.0, 10.0]	228	(-∞, 45.0]	113
(7.0, +∞)	97	(-∞, 40.0]	104
(-∞, 7.0]	88	[25.0, 40.0]	72
[7.0, 11.0]	75	(-∞, 40.0)	61
[7.0, +∞)	57	(-∞, 35.0]	58

5. Collective Value Range Widths of Numeric Eligibility Features

In this study, when analyzing the collective value range widths of numeric features, we excluded all the numeric features without an upper bound or a lower bound and defer their analysis to future work.

Out of 2058 Type 2 diabetes trials with HbA1c in their eligibility criteria, 1156 trials (56.2%) specify a bounded value range for HbA1c, i.e., with both an upper bound and a lower bound. **Figure 5 (a)** shows the distribution of collective value range widths of HbA1c in Type 2 diabetes trials. We can see that the value range width "3" is used by 370 Type 2 diabetes trials for HbA1c. Out of 1859 Type 2 diabetes trials using BMI as a numeric feature, 981 trials (52.8%) specify a bounded value range for BMI. **Figure 5 (b)** shows that "15" is the most frequent value range width of BMI used by 130 Type 2 diabetes trials.

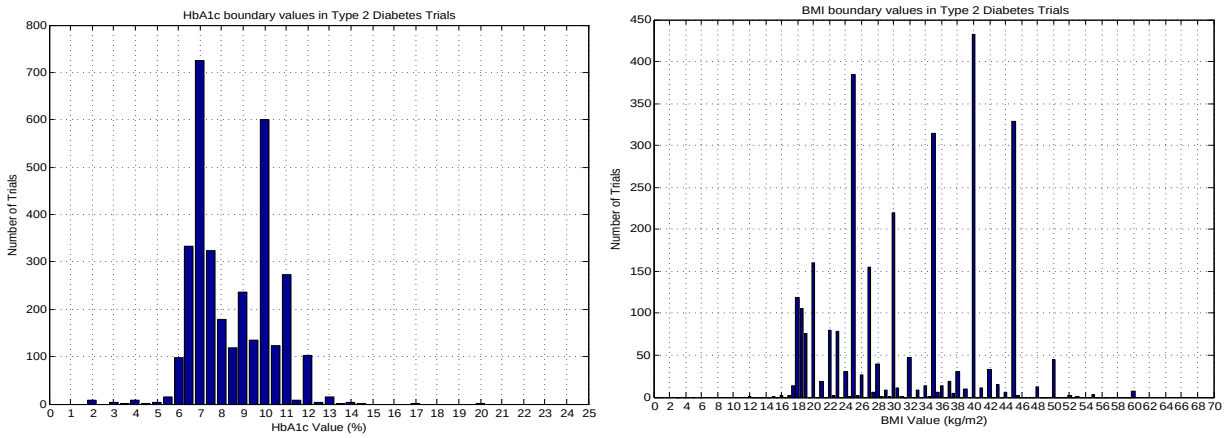


(a) (b)

Figure 5. Collective value range widths for (a) HbA1c and (b) for BMI in Type 2 diabetes trials.

6. Modal Boundary Values of Numeric Eligibility Features

For analyzing the modal boundary value of a numeric feature in trials of a certain disease, we aggregated the number of trials using a certain value for eligibility determination. **Figure 6 (a)** below shows the distribution of Type 2 diabetes trials using a specific HbA1c value in the eligibility criteria, i.e., below or above this value. The peak in **Figure 6 (a)** corresponds to the modal boundary value of HbA1c, which is 7.0% for Type 2 diabetes trials, whereas this modal boundary value of BMI is 40 kg/m^2, as shown in **Figure 6 (b)**.



(a) (b)

Figure 6. Collective boundary values for (a) HbA1c and (b) BMI, respectively, for Type 2 diabetes trials.

7. The Interface Design of CONECT (Commonalities in Target Populations in Eligibility Criteria)

We designed an interface for CONECT so that clinical investigators will be able to utilize the COMPACT database to inform the design of new trials. **Figure 7** shows the interface of the CONECT prototype. In this interface, an investigator can specify various characteristics of trials, e.g., disease, study type, study design (including intervention model, allocation, and time perspective), status, intervention type, phase, permissible values for specific numeric eligibility criteria features, and the number of common eligibility features to be retrieved. Based on the query of the investigator, CONECT will retrieve common eligibility features grouped by their semantic groups. When an investigator clicks on a certain numeric feature, its attributes, i.e., collective value ranges, collective value widths, and collective boundary values with a modal value if applicable, will be visualized in the lower space. CONECT informs the investigator what threshold other investigators have defined for the same variable in similar contexts. The analysis for contextual attributes for the categorical features is still under construction.

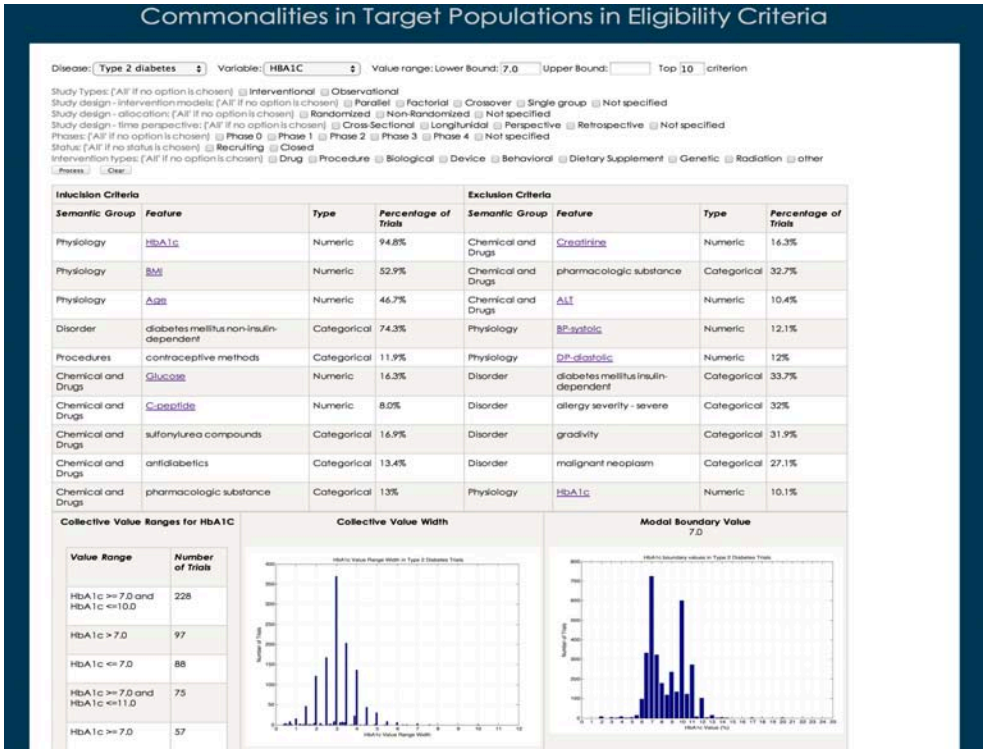


Figure 7. The interface of CONECT (Commonalities in Target Populations in Eligibility Criteria) prototype.

Discussion

This paper introduces a method for analyzing commonalities in eligibility criteria and a new data-driven approach to supporting actionable knowledge reuse for clinical trial eligibility criteria design. The COMPACT database built using this method should enable its target users to learn from the distributed clinical research community. Since its launch in 1997, ClinicalTrials.gov has accumulated about 160,000 studies, among which 48.6% are completed, and 27.3% are enrolling participants. With the large amount of information about clinical trial designs available, there is a compelling need to examine the commonalities in patient selection in this repository to inform the development of new clinical trials. Previously, there was no method going to this level of detail to parse the attributes of frequent eligibility features, e.g., their permissible value ranges, modal boundary values, etc. By coupling this information with descriptive characteristics of clinical trials, our method presents a new way for clinical trial sponsors and investigators to analyze fine-grained commonalities in clinical trial target populations and understand design patterns of eligibility criteria. Leveraging existing clinical trial records, our method intends to discover popular content used in the research community to facilitate future clinical trial design.

Utility of the COMPACT Database

The most important two design principles of the COMPACT database are generalizability and extensibility. In this paper, we demonstrate the utility of the COMPACT database with an example analytic module that supports disease-specific trial design. Analytic modules can be developed for other purposes. COMPACT has additional data such as drug name and location that have not been used by CONECT. Thus, one may develop a module to find common eligibility features in trials of a certain drug. COMPACT enables flexible selection of clinical trials of various characteristics, e.g., randomized or non-randomized, starting after a certain date, with a certain eligibility feature, recruiting only male patients, etc. For example, a clinical trial designer may be interested in discovering common eligibility features for breast cancer trials starting after January 2009, or for heart disease trials that recruit patients with systolic blood pressure greater than 140 mmHg, etc. The normalization of different units of the same numeric feature enables their aggregate analysis among different clinical trials.

Comparison with Other Databases Derived from ClinicalTrials.gov

The most notable effort related to our method is a database called Aggregate Analysis of Clinical Trials (AACT). It was developed by Tasneem *et al.* using descriptive characteristics, e.g., conditions and intervention, to aggregate

clinical trials from ClinicalTrials.gov [19]. Our method and AACT both use RDBMS to store clinical trial summaries from ClinicalTrials.gov. However, AACT does not analyze eligibility criteria in detail. In contrast, our method derives commonalities in participant selection from parsed eligibility criteria. Another database LinkedCT transformed the data of clinical trials on ClinicalTrials.gov into RDF to discover semantic links between clinical trial records [20]. However, it does not contain discrete eligibility features and hence does not support the analysis of eligibility criteria as COMPACT does. Thus, COMPACT can potentially make important contributions by facilitating knowledge reuse during eligibility criteria designs for new clinical trials.

Difference between Common Eligibility Features and Common Data Elements

Luo *et al.* used unsupervised machine learning to identify disease-specific Common Data Elements (CDEs) from clinical trial eligibility criteria [7]. Common eligibility features and CDEs can be both disease specific, but are different in the following three aspects: (1) CDEs are generated in a semi-automated fashion whereas common eligibility features generation is interactive and contextual, depending on the query; (2) Common eligibility features can be generated for trials of various characteristics on the fly, e.g., trials in a certain phase, eligibility criteria with a certain numeric feature in a certain range, etc., while CDEs are usually identified for a specific disease domain, and (3) Common eligibility features have contextual attributes. Numeric features have disease-specific value ranges, disease-specific value range widths and disease-specific modal boundary values. Investigators will get contextual knowledge on how these numeric features are used to define eligibility criteria for participant selection. This method overcomes the following limitations in traditional knowledge base development, including (1) centered around one or a small group of domain experts, (2) limited to one or few disease domains, (3) laborious and costly knowledge management processes, and (4) lack of scalability.

Limitations

This study has limitations. The accuracy of the commonalities in the target populations depends on the accuracy of the parsing of the eligibility criteria text. In a preliminary evaluation of the parser Valx, the precision, recall, and F-measure for extracting numeric expressions with the feature "HbA1c" were 99.6%, 98.1%, 98.8% for Type 1 diabetes trials, and 98.8%, 96.9%, 97.8% for Type 2 diabetes trials, respectively. The results of the measures for extracting numeric expressions with the feature "Glucose" were 97.3%, 94.8%, 96.1% for Type 1 diabetes trials, and 92.3%, 92.3%, 92.3% for Type 2 diabetes trials, respectively [10]. In the future, a comprehensive evaluation of Valx is necessary to assess its performance for other numeric features for their uses in clinical trials of various medical conditions. Our text mining method serves our goals presented here, but still has significant room for improvement. It currently does neither exhaustively recognize all the abbreviations nor normalize all the measurement units for every numeric feature in eligibility criteria text. Categorical features without contextual information (e.g., *within 12 hours of the onset of chest pain*) are sometimes not specific enough for direct reuse. Therefore, further collaborative research on natural language processing of free-text eligibility criteria is desired. In this study, we used one sample query on a common disease (i.e., Type 2 diabetes) for demonstration purposes. More studies are warranted to test how this method works for other eligibility features and other diseases.

Future Work

The COMPACT database needs to be updated on a regular basis. We will develop CONECT as a Web-based system and formally assess its value for clinical research stakeholders. To provide acceptable user experience when interacting with the system, it is imperative to improve the performance of our query processing method, which requires costly table join and value aggregation for numeric features. The current long waiting time, i.e., two minutes, to retrieve common eligibility features for some queries would impair the user experience of the system. We will create a repository to store common eligibility features for popular queries. When a popular question is asked again, the saved results can be returned to the user promptly. We will also analyze the queries submitted by the users, which may reveal new trends in trial design. With continuously improving natural language processing techniques, we will provide finer-grained common eligibility features. Temporal usage patterns will also be explored to show how commonalities in participants evolve over time and across disease domains. In the future, to enhance the analytic utility of COMPACT, we will add a table containing real world patient data and perform comparative analysis between clinical trial target populations and real world patient populations [21].

Conclusions

We introduced a novel data resource for analyzing common numeric and categorical features in eligibility criteria from public clinical trials records. We designed and built a database called COMPACT using all the clinical trial records on ClinicalTrials.gov. CONECT was introduced to illustrate example visualization of the COMPACT

content and the interactions between users and COMPACT. The query “Type 2 diabetes trials that recruit patients with HbA1c >= 7.0%” was used to illustrate the method. This research can potentially help clinical investigators understand frequently used eligibility criteria and how they have been shared across studies and can inform the design for participant selection for new clinical trials. Our future work includes further improvement of visual queries using COMPACT and user evaluation of this new decision aid for clinical research stakeholders.

Acknowledgments

We thank Dr. Riccardo Miotto for contributing parsed clinical trial summaries for building the COMPACT database. This study was sponsored by the National Library of Medicine grant **R01LM009886** (PI: Weng) and National Center for Advancing Translational Science grant **UL1 TR000040** (PI: Ginsberg).

Abstract

Several models have been developed to predict stroke outcomes (e.g., stroke mortality, patient dependence, etc.) in recent decades. However, there is little discussion regarding the problem of between-class imbalance in stroke datasets, which leads to prediction bias and decreased performance. In this paper, we demonstrate the use of the Synthetic Minority Over-sampling Technique to overcome such problems. We also compare state of the art machine learning methods and construct a six-variable support vector machine (SVM) model to predict stroke mortality at discharge. Finally, we discuss how the identification of a reduced feature set allowed us to identify additional cases in our research database for validation testing. Our classifier achieved a c-statistic of 0.865 on the cross-validated dataset, demonstrating good classification performance using a reduced set of variables.

1. Introduction

Stroke is a major cause of mortality and disability in the United States, with over 20% of affected individuals succumbing to the condition, and only one-fourth of surviving adults returning to normal health status [1-3]. There exist a variety of treatments for stroke, including intravenous and intra-arterial tissue plasminogen activator (tPA), as well as clot retrieval using mechanical devices (i.e. mechanical thrombectomy). However, the relationship among a patient's stroke presentation, treatment options, and functional outcomes is not well defined. To inform treatment, work in the literature has focused on building models to predict a patient's functional status given initial presentation, in hopes of detecting cases that need to be treated more or less aggressively.

To build a predictive model that may be used in practice and which generalizes to multiple institutions, it is important to determine an informative feature set that is collected in the course of normal clinical care. More importantly, the distribution of data and associated class labels is also important. Recently, the problem of imbalanced data has received increased attention as it has been shown to decrease model performance and lead to biased prediction [4-6]. While previous work has been focused on using logistic regression models to predict stroke outcomes [7-10], alternative machine learning techniques are less studied, but potentially useful.

In this work, we present a comparison between six models for predicting stroke mortality at discharge that includes methods for data balancing. We calculated the c-statistic for each classifier, following a systematic approach to identify the optimal set for each classifier by sequentially adding informative features until performance no longer increased.

2. Previous Work

There are many models for predicting acute stroke outcomes, which in general apply multivariate logistic regression techniques. Counsell *et.al.* [7] developed a six simple variable (SSV) multivariate logistic regression model to predict survival rate 30 days and 6 months after stroke using a 530 patient dataset. The six variables used were age, living alone, independence in activities of daily living before the stroke, the verbal component of Glasgow Coma Scale, arm power, and the ability to walk. The model was validated using two external independent cohorts of stroke patients with c-statistics from 0.84 to 0.88. Teale *et. al.* [8] reviewed different literature databases (e.g., MEDLINE) and concluded that the SSV model demonstrated statistical robustness, good discriminatory function in external validation, and comprised clinically feasible variables that were easily collected; it performed well among all prognostic models for predicting outcome after acute stroke.

Konig *et. al.* [9, 10] developed a multivariate logistic regression model to predict three month survival rate after acute ischemic stroke using age and the National Institutes of Health Stroke Scale (Pre-NIHSS) [11]. They showed

that Pre-NIHSS is a strong predictor variable that has significant impact on model accuracy. Further analyses [12, 13] have supported the effectiveness of Pre-NIHSS in 30-Day mortality prediction after acute ischemic stroke.

Saposnik *et. al.* [14-16] considered the utility of a predictive model in a clinical setting and developed an algorithm to predict mortality risk in ischemic stroke patients after hospitalization based on information routinely available in hospital, such as demographics, clinical presentation (diplopia, dysarthria, and aphasia, etc.), and patient comorbidities. The model, called iScore, was developed from multivariate logistic regression models by using a regression coefficient-based scoring method based on β coefficients. The iScore model is now available online [17].

In contrast to more general models, which attempt to predict an outcome based on a patient's presentation, additional algorithms are under development that attempt to predict response to a specific therapy. Examples include the DRAGON score for intravenous thrombolysis therapy [18], and HIAT2 score for outcomes after intra-arterial thrombolysis [19].

While significant work has been done in predicting outcomes after acute stroke, there is little work regarding the problem of between-class imbalance, which is common in binary prediction tasks when one class (the majority) is more common than the other class (the minority). We address this problem by using a sampling method, called the Synthetic Minority Over-sampling Technique (SMOTE) [20]. We compare the performance of various models (logistic regression, support vector machines, naïve bayes, decision tree, and random forest) for balanced and imbalanced datasets and determine the best model for predicting discharge mortality. We then identify the best six features that appear to be critical for good model performance.

3. Methods

This section describes the stroke dataset used, the imbalanced dataset problem, and the modeling methods compared for mortality prediction.

3.1 Dataset

UCLA maintains a REDCap [21] database that stores acute stroke patients who have been treated with one or more of the following treatments from 1992 to 2013: intra-arterial tissue plasminogen activator (IA tPA), intravenous tissue plasminogen activator (IV tPA), or mechanical thrombectomy. There are 778 patients in this study cohort, each with more than 500 features, including demographic information, laboratory results, and medications. Our goal is to predict patient mortality at hospital discharge, which is indicated by the discharge modified Rankin Scale (discharge mRS) [22, 23]. Discharge mRS is a commonly used scale for measuring the degree of disability or dependence in the daily activities of patients who have suffered stroke. The scale runs from 0-6, with 0 indicating perfect health and 6 indicating death. Our binary prediction model collapses this scale to two groups: alive (0-5) and dead (6).

Using this dataset, we defined a cohort subset for analysis in this study using inclusion criteria (Table 1). The features are summarized in Table 2. The continuous features are patients' demographics information and time-related information while the binary features are patients' presentation, and medication. This subset was used to build the model.

Table 1. Inclusion criteria for cohort subset.

Original dataset	778 patients; >500 features
Patients' inclusion criteria	• Only patients with discharge mRS recorded. • Only patients with ischemic stroke (excluding patients with subarachnoid hemorrhage). • Only patients who received treatment solely at UCLA. • Only patients who with hospital stays less than 20 days (patients who stay longer are more likely to have other conditions in addition to stroke). • Only patients without missing any features' values after using features inclusion criteria
Features inclusion criteria	• Only features that were available in over 90% of patient cases after the first four patients' inclusion criteria.
Cohort subset	190 patients (156 alive, 34 dead); 26 features

Table 2. Feature distribution of alive and dead patients in dataset before and after SMOTE.

		Alive	Dead (Before SMOTE)	Dead (After SMOTE)
Size		156	34	156
Continuous features		Average(SD)	Average(SD)	Average(SD)
	Age	67.91(17.05)	81.29(9.45)	81.41(8.06)
	Pre-NIHSS	12.16(7.20)	18.24(5.93)	18.16(4.84)
	Systolic blood pressure	151.03(28.20)	147.32(30.96)	145.54(27.54)
	Diastolic blood pressure	82.42(17.71)	79.12(19.12)	77.88(16.30)
	Blood glucose	131.72(48.14)	164.82(74.66)	160.81(61.98)
	Blood platelet count	224.99(75.63)	181.47(54.86)	179.43(50.50)
	Hematocrit	39.60(5.33)	38.66(5.37)	38.38(4.77)
	Time difference between first MRI image and time of symptoms (minute)	178.77(152.89)	166.15(109.27)	171.39(96.26)
	Time difference between first MRI image and admission (minute)	44.67(27.66)	49.35(34.73)	48.89(30.66)
Binary features		Percentage of true(%)	Percentage of true(%)	Percentage of true(%)
	Gender (Male)	44.87	52.94	37.82
	Hypertension	66.67	82.35	84.62
	Diabetes	16.67	20.59	6.41
	Hyperlipidemia	27.56	35.29	17.95
	Atrial fib	30.13	55.88	41.67
	Myocardial infarction	12.18	38.24	25.00
	Coronary artery bypass surgery	7.69	11.76	2.56
	Congestive heart failure	3.21	26.47	8.33
	Peripheral vascular disease	0.00	2.94	0.64
	Carotid endarterectomy angioplasty/stent	1.92	5.88	1.28
	Brain aneurysm	0.00	2.94	0.64
	Active internal bleeding	0.00	0.00	0.00
	Low platelet count	0.00	0.00	0.00
	Abnormal glucose	0.00	0.00	0.00
	Diabetes medication	14.74	32.35	10.90
	Hypertension medication	53.21	82.35	86.54
	Hyperlipidemia medication	16.67	23.53	7.69

3.2 Imbalanced Learning Problem

The cohort subset is imbalanced (156 alive vs. 34 dead). Previous research has shown that imbalanced learning can cause prediction bias, leading to inaccurate and unreliable results [4, 6]. In our case, models would predict all patients as alive to achieve high accuracy, but with low precision and recall. The imbalanced learning problem has received attention in both theoretical and practical application [5]. Most machine learning algorithms do not deal with imbalanced datasets during the training process [4]. In some cases, the minority are scattered in the feature space and the decision boundary is too specific. We addressed this issue by using Synthetic Minority Over-sampling

Technique (SMOTE) [20], a sampling technique combining under-sampling of the majority class with over-sampling of the minority class.

There are two parts to the SMOTE algorithm. In the first part, the minority class is over-sampled by taking each minority class sample and introducing new synthetic samples joining any or all of the *k* minority class nearest neighbors (by Euclidean distance). Neighbors from the *k* nearest neighbors are randomly chosen depending upon the amount of over-sampling required. Synthetic samples are generated in the following way:

1. Find the difference between the normalized feature vector (sample), F_{orig}, and a randomly selected normalized nearest neighbor, F_{near}.
2. Multiply the difference by a random number between 0 and 1.
3. Add the product to the feature vector to generate a new feature vector.

This approach essentially creates a random point along the line segment between two specific features and effectively forces the decision region of the minority class to become more general. The new feature vector, F_{new}, is defined as follows:

$$F_{new} = F_{orig} + rand(0,1) * (F_{near} - F_{orig}) \quad (1)$$

The above step is used for continuous features. For binary features, the new value is obtained by the majority vote (0 or 1) of all the neighbors. In our training process, the second part of the SMOTE algorithm, under-sampling, was not performed because the dataset was small and all data should be considered. We applied the SMOTE algorithm using MATLAB, denoting this new dataset as SMOTE-dataset. Five neighbors (*k*) were used and one of them was randomly selected to generate a synthetic sample. The synthetic step was repeated until the number of minority is equivalent to the number of majority.

3.3 Model comparison and feature selection

Early research has emphasized using logistic regression models [24] to predict stroke outcome [7-10]. To the best of our knowledge, none have compared the performance of different machine learning methods in stroke outcome prediction, particularly with a balanced dataset. Therefore, we compared the performance of five common machine learning methods: Naïve Bayes (NB), Support Vector Machine (SVM), Decision Tree (DT), Random Forests (RF), and Logistic Regression (LR). In addition, we compared the performance of a combined method: principal component analysis followed by support vector machine (PCA+SVM).

Briefly, NB is a probabilistic classifier algorithm based on Bayes' Rule that makes a conditional independence assumption between the predictor variables, given the outcome [25]. SVM is a supervised learning classification algorithm that constructs a hyperplane (or set of hyperplanes) in a higher dimensional space for classification [26]. DT is a tree-like prediction model in which each internal (non-leaf) node tests an input feature and each leaf is labeled with a class [27]. RF is an ensemble learning method in which a multitude of decision trees are constructed and the classification is based on the mode of the classes output by individual trees [28]. LR is a probabilistic classification model in which label probabilities are found by fitting a logistic function of feature values [29]. Principal component analysis is a statistical procedure that uses orthogonal transformation to reduce the dimensionality of the feature space containing only principal components (principal features) [30]. Yang *et. al.* [31] and Gumus *et. al.* [32] have shown the effectiveness of using PCA to extract principal components for SVM classification. We also used this combination of methods and determine whether PCA is beneficial before SVM on stroke patient mortality classification.

It is time-consuming to collect a comprehensive set of features for every patient, and not all the features are relevant. In addition, using all the features to construct a classifier may lead to decreased performance due to over-fitting, especially on small, imbalanced datasets, which are not uncommon in stroke. Thus, we sought a minimum feature set to mitigate these clinical and modeling challenges, and that could also be externally validated more easily.

Different machine learning methods may not perform equally on the same feature set. Therefore, optimal feature sets for each machine learning method were defined systematically, with the top performing method determined using the c-statistic. First, chi-square tests were used to weight the association between features (categorical variables/binned continuous variables) and discharge mRS in the original dataset. Then, the feature with the highest weight was used to construct a single-variable classifier and the c-statistic was calculated. The feature with the second highest weight was then added, and c-statistic was re-calculated. This process of adding features was repeated until an optimal feature set for a machine learning method was obtained. The optimal feature set (the first

optimum) was defined as the point at which adding any additional features did not increase the performance of the classifier. All methods were compared and the best one was chosen for stroke patient mortality at discharge. A summary of steps is shown in Figure 1. Models were fitted and compared using RapidMiner (RM) [33], an open-source software platform which provides an integrated environment for machine learning, data mining, and predictive analytics [34, 35].

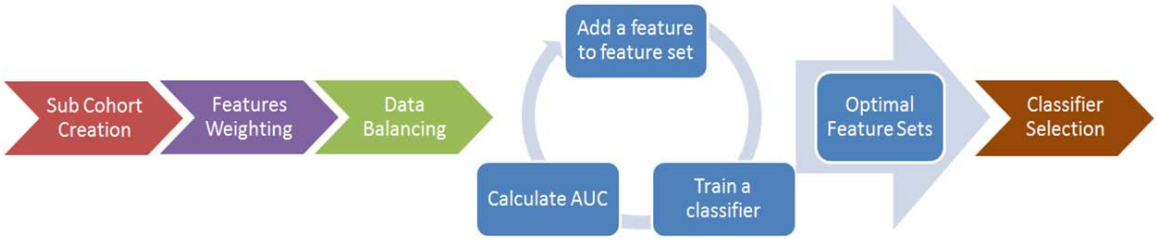

Figure 1. Summary of building classifier for predicting stroke patient mortality at discharge. A sub-cohort based on clinical and missing data factors was first created. Then, the relevance between features and the classes were weighted by chi-square statistics, and then the dataset is balanced by SMOTE. The fourth step was an iterative process in which the highest weighted feature was first used to build classifiers and AUC was calculated. Features were added to the training feature set sequentially in the order of weighting and classifiers were trained. After several iterations, optimal feature sets for all classifiers were obtained. Finally, performances were compared (SVM, PCA&SVM, DT, RF, NB, and LR) and the best classifier was selected.

4. Result and Discussion

4.1 SMOTE over-sampling

There were 190 patients in the training cohort with 156 class-1 patients (alive) and 34 class-2 patients (dead). The final SMOTE-dataset had 156 class-1 patients and 156 class-2 patients. Age and Pre-NIHSS have been shown to be two important features for stroke outcome prediction [9, 10, 12, 13]. Figure 2A shows the data distribution (x-axis: Pre-NIHSS; y-axis: age) between two the classes before SMOTE sampling and Figure 2B showed the distribution after SMOTE sampling. The original class-2 distribution was scattered, and it was hard to determine where the decision boundary should be. After oversampling by SMOTE, it was easy to observe that class-2 patients clustered in the region of high age and high Pre-NIHSS.

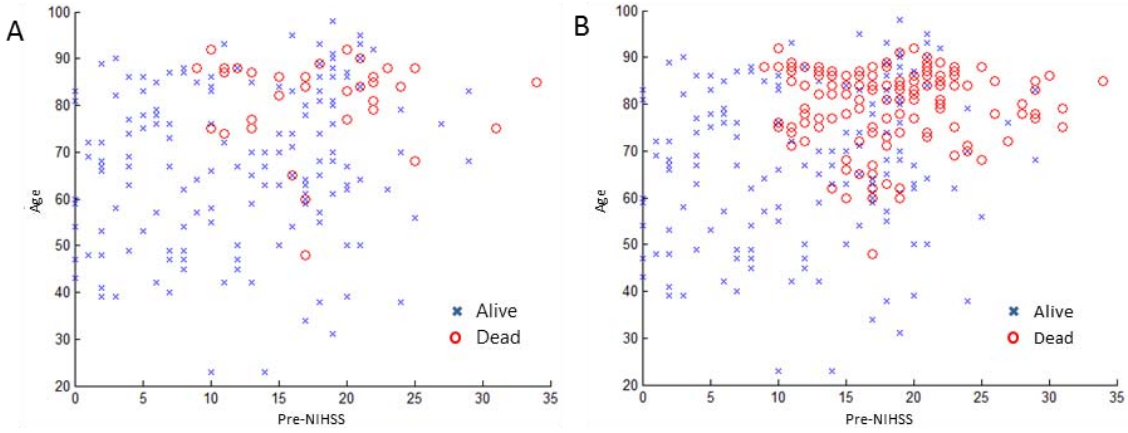

Figure 2. Two classes distribution before and after SMOTE sampling. (A) Before SMOTE, (B) After SMOTE. Two datasets for classifications: (A) original dataset with 156 class-1 patients and 34 class-2 patients), (B) SMOTE-dataset with 156 class-1 patients and 156 class-2 patients.

4.2 Feature Selection

Chi-square tests were used to weight the relevance between a feature and the classes in the original dataset. As our goal was to obtain a ranking of features (rather than finding statically significant features), we calculated the chi-squared statistics (weight) and normalized them for comparison. Continuous variables were discretized into ten bins. The top ten normalized weights are shown in Table 3.

Table 3. Top ten normalized weights by chi-squared statistic.

Feature	Weight
Pre-NIHSS	1.000
Age	0.631
Patient history of congestive heart failure	0.565
Platelet count	0.450
Patient history of myocardial Infarction	0.346
Serum glucose	0.325
Patient on hypertension medication	0.249
Time difference between the first MRI image and admission	0.243
Systolic blood pressure	0.223
Patient history of atrial fibrillation	0.209

4.3 Model Comparison

Ten-fold cross-validation was used to compare different models on the datasets, measuring the model performance via c-statistic and model bias via F1-score [36]. In each validation, nine groups of original data were used to train the classifier and one group of data was classified. For the SMOTE-dataset, nine folds of data were balanced using SMOTE and then used to train the classifier. The held-out unbalanced dataset was then classified.

Features were added sequentially to train a classifier in order of largest weight to smallest weight. The c-statistic of each classifier is shown in Figure 3, with its distribution shown in Figure 4. The enlarged markers represent the size of the optimal feature set for each classifier. With only one feature (Pre-NIHSS), all classifiers performed poorly. The performance gradually increased as more features were added. Each classifier reached to the first maximum c-statistic at a different number of features, with performance for each leveling off with additional features. This validated our hypothesis that more features might not necessarily improve the performance. The size of each optimal feature set is summarized in Table 4.

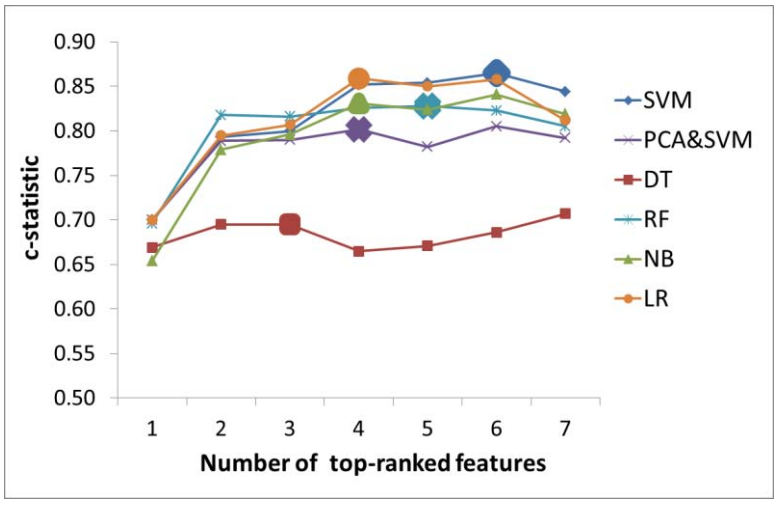

Figure 3. The c-statistics of classifiers with different number of top-ranked features based on Table 3. The size of the optimal feature set for each classifier was indicated by the enlarged marker. Each classifier has different size of optimal feature set. Among all classifiers, SVM has the highest c-statistic with 6 features being used.

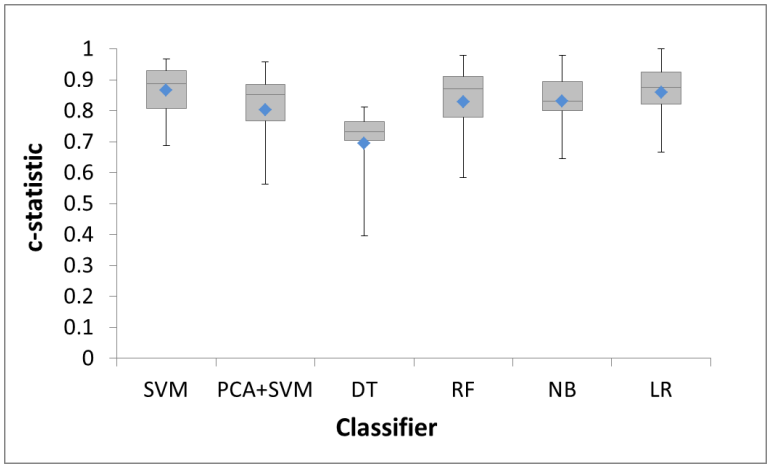

Figure 4. c-statistic distributions for classifiers with optimal feature set (means are represented by blue diamonds).

Table 4. The size of the optimal feature set for each classifier and the cross-validation result.

		SMOTE-dataset		Original dataset	
Classifier	**Optimal feature set size**	**c-statistic**	**F1-score**	**c-statistic**	**F1-score**
SVM	6	0.865	0.594	0.868	0.336
PCA&SVM	4	0.802	0.488	0.856	0.368
DT	2	0.695	0.441	0.709	0.061
RF	5	0.828	0.401	0.789	0.249
NB	4	0.831	0.560	0.839	0.354
LR	4	0.859	0.582	0.867	0.226

Among all the classifiers for the SMOTE generated dataset, SVM performed the best with a c-statistic of 0.865 and an F1-score of 0.594. PCA+SVM did not perform well, which could be due to a scenario where two classes overlapped more after projection [37]. RF and NB both generally performed more poorly than SVM in all feature sizes. DT had the worst performance with the first optimal c-statistic at 0.695. This is mostly because more features were required to build a good classifier based on the nature of DT. LR had the closest performance to SVM. However, previous research has shown that SVM performs better than LR in the case of multivariate and mixture of distributions with a better (or equivalent) misclassification rate [38, 39]. Therefore, SVM was determined to be the most suitable classifier.

The size of the optimal feature set for SVM was six: Pre-NIHSS, age, platelet count, serum glucose, congestive heart failure, and myocardial infarction. These features are routinely collected in acute stroke patients. Pre-NIHSS is a standard measure of impairment caused by a stroke, with most patients receiving Pre-NIHSS assessment immediately after hospital admission. Pre-NIHSS, age, platelet count, and serum glucose level have also been shown to be relevant to stroke outcomes [9, 40, 41]. Therefore, it is reasonable to expect other institutions may maintain these variables and could validate our model. Moreover, the c-statistic was nearly optimal (0.854) with only four features (Pre-NIHSS, age, congestive heart failure, and platelet count), suggesting the possibility of using even less information.

After identifying the top six features for the SVM model, we revisited the database and obtained an additional 39 patients that were not included in the initial filtering due to missing data, but had all six important features. These data were then used as an independent testing dataset to test the classifier. We compared the performance of six-variable SVM classifier trained with balanced and imbalanced testing dataset, and both c-statistic and F1-score were higher when the training dataset was balanced (Table 5). We also performed Mann-Whitney U tests to verify that both SVM1 and SVM2 are statistically better than random ($p=0.020$ and $p=0.011$, respectively), and used a weighted Wilcoxon signed-rank test to verify that the performance difference between SVM1 and SVM2 is

statistically significant (p=0.039). These results suggest that balancing data (i.e., SMOTE) yields an improved classifier for predicting mortality at discharge in acute stroke patients.

Table 5. Performance comparison of six-variable SVMs.

	SVM 1	**SVM 2**
Number of testing data	32 alive, 7 dead	
Number of features	6	
Applied SMOTE?	No	Yes
Number of training data	156 alive , 34 dead	156 alive,156 dead
c-statistic	0.750	**0.781**
F1-score	0.400	**0.500**

5. Conclusion and Future work

In this paper, we compared the performance of SVM, PCA-SVM, DT, RF, NB, and LR models for predicting stroke patient mortality at discharge and determined SVM was the best based on relative c-statistic and F1-score. We then developed an SVM predictive model with six common variables (Pre-NIHSS, age, platelet count, serum glucose level, congestive heart failure, and myocardial infarction) and predicted mortality on the testing data, achieving a 0.781 c-statistic. In addition, we demonstrated the importance of balancing the stroke dataset before training and illustrated the use of the SMOTE algorithm as a solution. We also discussed the benefits of identifying an optimal feature set for building the classifier.

There are a few limitations in our work. First, there are roughly 800 patients available in our dataset, but nearly half of them were missing discharge mRS or other feature values, reducing the size of available data. Our next step will be collecting this information via chart review. Also, we plan to seek independent external datasets on which to validate the proposed models. Second, the distributions of binary features became more imbalanced after SMOTE (Table 2). A possible solution to this problem would be to assign values to binary features by sampling the probability distribution of nearest neighbors, rather than a majority vote.

Lastly, mortality is a standard measure that most existing stroke models aim to predict. However, patients have different degrees of disability even though they are still alive. One clear difference is whether a patient can live independently or dependently [42]. We plan to investigate and improve existing methods in multi-class prediction [43-45] and extend our prediction ability to more classes (independent, dependent, and death), rather than just survival/non-survival.

Abstract

Clinical decision support (CDS) systems can support vaccine forecasting and immunization reminders; however, immunization decision-making requires data from fragmented, independent systems. Interoperability and accurate data exchange between immunization information systems (IIS) is an essential factor to utilize Immunization CDS systems. Service oriented architecture (SOA) and Health Level 7 (HL7) are dominant standards for web-based exchange of clinical information. We implemented a system based on SOA and HL7 v3 to support immunization CDS in Iran. We evaluated system performance by exchanging 1500 immunization records for roughly 400 infants between two IISs. System turnaround time is less than a minute for synchronous operation calls and the retrieved immunization history of infants were always identical in different systems. CDS generated reports were accordant to immunization guidelines and the calculations for next visit times were accurate. Interoperability is rare or non-existent between IIS. Since inter-state data exchange is rare in United States, this approach could be a good prototype to achieve interoperability of immunization information.

Introduction

Health information technology systems support clinical decision-making, providing access to information or suggesting diagnostic strategies (1, 2). However, clinical information is usually scattered among several independent systems that may be syntactically or semantically incompatible. This incompatibility prevents providers' access to patients' comprehensive medical history and makes the exchange of information very challenging (3).

Standards in the healthcare domain play crucial role in facilitating health information exchange and interoperability. However, information systems today are developed based on different technologies and various proprietary protocols and communication standards are not good solutions for inter-organization interoperability (4). Interoperability between systems is one of the key aspects of enterprise solutions, but because of semantic heterogeneity between applications it is very difficult to achieve (5).

To address interoperability, HL7 works as one of the leading standards for exchange of clinical and administrative data among healthcare information systems. HL7 is a syntactic lingua franca used by healthcare computers to talk to other computers and provide information when and where needed (6). Version 2.x of this standard is largely adopted in immunization information systems (IISs) which are confidential, population-based, computerized information systems that attempt to collect vaccination data about all children within a geographic area (7). IISs can be more efficient if they are improved by immunization decision support system (DSS). Immunization DSS can generate reminder and recall vaccination notices regarding each child's immunization history. Also they can provide official vaccination reports and vaccination coverage assessments for caregivers (8).

To date, IISs are usually isolated systems and querying other systems in order to assemble immunization history is barely possible (9). Service-oriented architecture (SOA) provides a way for these isolated systems to remain viable and responsive to increasing demands for information and analysis (10). By overcoming interoperability limitations, SOA allows existing systems to be integrated by exploiting the pervasive infrastructure of the internet and offers a new chance to continue to use and reuse the business functions provided by legacy systems (11).

Currently in Iran, immunization records are captured on paper records and the information is not stored electronically. Accordingly, providers in Iran's immunization centers do not have access to complete records of an individual's hitherto received vaccines, making it difficult to forecast needed vaccines or schedule the next

immunization event. In this paper, we describe the development of two IISs and provide a solution to achieve interoperability between them. Our goal is to facilitate complete immunization history management and Immunization DSS to help providers in Immunization decision making.

System Development

Immunization Information System

To communicate with other systems, an IIS should be able to capture necessary immunization data into a local database and exchange this information with other systems. Our three main objectives for developing IIS are:

- Support basic business requirements of immunization information system according to immunization guidelines for Iran's vaccination centers (12) such as small clinics.
- Ability to interoperate with other systems through standard healthcare web services.
- Ability to send/receive HL7 v3.0 messages based on standard terminologies.

To meet these objectives, business and system requirements were analyzed and necessary use cases were specified. Then an Immunization Minimum Data Set (MDS) was designed and information model was developed in compliant with the HL7 Reference Information Model (RIM). Afterwards, the local IIS's database was designed and implemented using Microsoft SQL Server.

The HL7 RIM specifies the grammar of v3.0 messages of HL7 standard, specifically, the basic building blocks of the language (nouns, verbs etc.), their permitted relationships and Data Types. These messages are all based on XML. All of the XML tags and attributes used in v3.0 messages are derived from the HL7 RIM and the HL7 v3.0 Data Types (6).

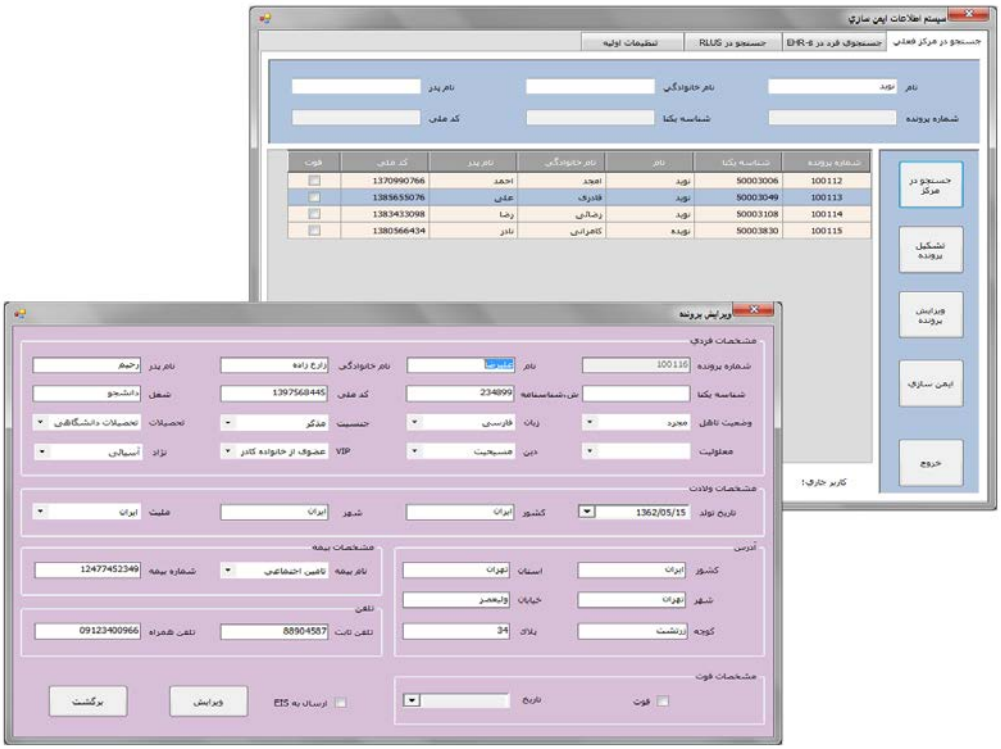

Figure 1. Patient registration forms of implemented IIS

Required vocabularies for concept exchange was extracted from various terminologies like LOINC, ISO 3166, ISO 639-1 and HL7 vocabularies. The system was developed based on three-tier architecture and for transmission of data between these layers we used Data Transfer Object component. Data transfer object (DTO) is an object that carries data between processes in order to reduce the number of method calls. When you are working with a remote interface, each call to it is expensive. The solution is to create a Data Transfer Object that can hold all the data for

the call (13). The system was built in C# language over Microsoft Visual Studio. Figure 1 demonstrates two patient registration forms of implemented IIS which fulfills the required information for HL7 RIM domain model.

EIS and RLUS web services

When a mother takes her child to an immunization center, healthcare providers want to know when and what vaccines has the child received up to now. In other words, they are interested in knowing the child's immunization history. If the entire history is contained in the local center's IIS, there is no need to communicate with other systems to get further information. However, in many cases a child receives vaccines in other locations and data must be retrieved from multiple IISs, making interoperability an important feature for IISs. Deciding if it is required to deliver a vaccine to child, providers need to know what vaccines were previously administered at the other centers. Service Oriented Architecture can help streamline data exchange and promises interoperability between heterogeneous information systems. By using specific web services available in a network, caregivers can retrieve the most current immunization records. SOA environment allows different IISs in heterogeneous platforms and architectures, to negotiate and interoperate with web services without any need to change their architecture.

When there is no information about the current patient in the local system, the first thing the provider needs to know about the child is an identifier which specifies the child as a unique individual among multiple organizations. It is common that the information system of each organization or even department often assigns its own ID that uniquely identify the individuals for its own purposes, with the result that these ID values are meaningless outside that system or organization. These autonomously managed IDs suit the purposes of recording and retrieval of information for the single department or organization, but interoperability requires an ID or matching process to identify an individual uniquely among multiple IISs and then retrieve required information.

In this regard, HSSP recognizes the need for service specifications to support healthcare IT. HSSP is a collaborative effort between HL7 and the Object Management Group (OMG) standards group to address interoperability challenges within the healthcare sector. The activity is an effort to create common "service interface specifications" that ultimately can be tractable within a Health IT context. The stated objective of the HSSP project is to create useful, usable healthcare standards that define the functions, semantics, and technology bindings supportive of system-level interoperability (14).

The Entity Identification Service (EIS) is one of the services recommended by HSSP which is charged with defining the functional specifications of a set of service interfaces to uniquely identify various kinds of entities (e.g. people: patients, providers etc., devices) within disparate systems within a single enterprise and/or across a set of collaborating enterprises(15). EIS defines 'generic' interfaces that would allow name-value pairs to be associated with an entity. EIS is based upon the creation and maintenance of an index consisting of a linked set of Source ID/Entity ID pairs representing the same Real World Entity (RWE). A Source ID and Entity ID are supplied in pairs in order that they may uniquely identify an Entity with the Domain of the EIS. An Entity ID alone uniquely identifies an Entity within the Domain of the Source (16).

By exchanging HL7 messages between IIS and EIS web service we can obtain the child's Unique ID and his/her demographic information. In this effort EIS was implemented according to the service specifications which are published by OMG and HL7 (15, 16). Communicating with this web service, our IIS was able to search using the child's traits in web service and get respective unique ID and demographic information to register a new record in its own local data base.

After resolving the child's identification, the next step is retrieving individual's immunization history based on this unique ID. The Retrieve, Location, and Updating Service (RLUS) is another service specified by HSSP which provides a set of interfaces through which information systems can access and manage information. RLUS allows health data to be located, accessed and updated regardless of underlying data structures, security concerns, or delivery mechanisms (17).

This service is designed for general purposes in the healthcare domain, so we implemented a customized RLUS web service according to (17, 18) with constrained functions to retrieve individual's immunization information. For integrating immunization information of different IIS systems, each IIS sends the information of every Immunization event occurred in the local center to the web service through HL7 v3.0 XML based messages. Figure 2 shows a high level picture of SOA-based interoperability between IISs and web services. In the picture, HL7 messages are wrapped inside SOAP messages and they are exchanged though internet. Also it demonstrates the two immunization DSSs which are embedded in IISs.

Our EIS and RLUS Web services, were built based on Microsoft WCF technology in C# language and the protocol used to exchange XML-based HL7 messages is SOAP and the location of the services and their operations are described through the web services description language (WSDL). The service layer in both web services (EIS and RLUS) is very thin and does not include any business processes or service implementations. Service, data and operation contracts were exposed just in service layer. Regarding the security of interoperability we take advantage of WCF security. Microsoft WCF provides several security features such as transfer security, authorization, and auditing by default, which are responsible for providing message confidentiality, data integrity, and authentication of communicating parties.

Each web service took advantage of multi-tier architecture and has its own independent data base in Microsoft SQL Server. Operations in both of the web services are practically equivalent to HL7 v3.0 interactions specified in HL7 universal domains and Input parameters and return values of the operations are HL7 messages. When a remote IIS invokes one of these operations, depending on operation and its input message, the processes are performed in the web service and the results are returned in the form of an HL7 message. If any error occurs during the message processing, the error code and its description will be returned to the calling IIS. Messages are validated once received by the web service. Message validation is performed locally in EIS and RLUS servers for the pilot system. Messages are checked for both syntax (e.g., Is the message conformant with HL7 message structure?) and semantics (e.g., is valid information from standard terminologies used?). For improper messages, an error message with appropriate error description is returned to the sender.

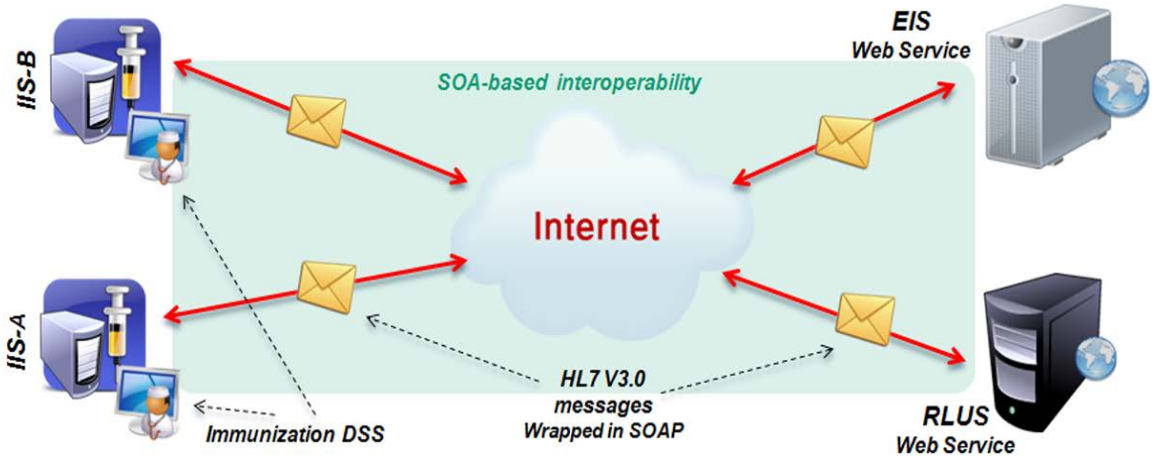

Figure 2. High level picture of SOA-based interoperability between IISs and web services

HL7 v3.0 Messages

The HL7 standard represents the foundation of many healthcare information management systems (19). Version 2.x of this standard is extensively adopted in health care domain and usually IISs use version 2.x rather than v3.0. Immunization information systems which are exchanging HL7 v3.0 messages are rare or non-existent. The reason is that the structure of messages completely changed in version 3.0 and it is cumbersome to upgrade systems from older version to newer one. However, version 2.x enables some optionality in message generation that makes it very hard to apply conformance tests and forces implementers to investigate whether the messages coming from different parties have the same structure of optional fields for a single message (6). This optionality provides multiple ways for generating the same message, therefore when you get one implementation of version 2.x it is likely that you get another one and that is different because of many optional fields and segments in message structure (20).

By presenting RIM data model and using “rigorous analytic and message building techniques”, HL7 addressed the issues of version 2.x and provided messages without optionality issues in version 3.0 (6). By adoption of RIM in this study as information model of IISs and exchanging HL7 v3.0 messages, we tried to improve immunization information interoperability.

Figure 3. Localized HL7 message in XML format with Father Name and customized home address

According to EIS and RLUS specifications, messages are defined to cover universal needs; however the structure of universal messages does not meet Iran's needs for message exchange. For example, "Father Name" is mandatory in patient's demographic information in Iran, which is not considered in universal messages. Also the structure of patients' address is totally different in Iran. Each universal message includes plenty of classes and attributes that are not in the scope of our work. We solved these problems in two steps. First the messages were customized according to our business requirements and then an intermediary component was developed as an API which isolates the complexity of messages inside of itself and presents very simple operations for message generation. Working with this component is much easier because it plays as a mediator between operations and HL7 complicated classes and data types.

HL7 messages have many data types which are added into the web service's data contracts and by exposing the services through WSDL the local IISs can access to all of HL7 data types in order to massage making. The localized HL7 message in XML format with Father Name and customized home address is shown in Figure 3.

Immunization Decision Support System (DSS)

Timely vaccinations decrease a child's risk of contracting vaccine-preventable disease and prevent disease outbreaks. Reminders and comments generated by immunization DSS can advise providers on which immunizations are needed for a particular patient and provide valuable information for caregivers to deliver better vaccination services to individuals and help people to live healthy. Moreover, Clinical DSS can improve the adherence of providers to clinical guidelines (21).

In this study, the immunization DSS is designed as a guideline based rule engine and embedded into local IISs by which the system can forecast immunization events and give appropriate alerts and recommendations to providers. All of the information needed for rule engine component is provided through communicating with EIS and RLUS.

It is important for providers to know when and what vaccines were administered to patients up to now and whether they were delivered on time or late. Also, they need to know where a patient received the vaccines and who the caregiver was or what vaccines are required to be administered in future and what would be the accurate schedule for next immunization events according to guidelines. Identifying individuals uniquely by exchanging messages with EIS and retrieving integrated immunization history from RLUS web service, the rule engine can apply standard immunization rules on retrieved comprehensive immunization history and generate useful information for providers to address their requirements. Also system can alert the provider that what vaccine is not allowed to be administered or what is needed.

Figure 4 is translation of a sample report from Persian language to English generated by the immunization DSS. This report is based on fake immunization scenario with many delays in attending at immunization center which shows the DSS detects late delivery of vaccines to child. Also, it schedules the future events considering the information from previous events. Moreover, the implemented DSS warns the provider that the Diphtheria, Tetanus and Pertussis (DPT) Vaccination is already recorded for five times and is not allowed to be administered any more when a provider tries to add a new immunization record into system. For each immunization event, the report informs the location of vaccine delivery, provider and some necessary comments. The rules of DSS component have been extracted from guideline of immunization approved by national immunization committee of Iran (12).

Immunization Forecasting Report

Patient Demographics

Patient ID: 30005046 **Name:** Homayoun **Last Name:** Asadi **DOB:** 07/23/2011

Vaccine type: Diphtheria, Tetanus, and Pertussis (DPT)

Vaccine Schedule	Encounter Date	Delay (day)	Next Dose Date	Center	Provider	comments
1st time 2 month old	10/03/2011	10	11/23/2011	IIS_A	Reza Ahmadi	This dose should be delivered to baby between 2 months old to 2 months and 29 days old
2nd time 4 month old	01/31/2012	69	02/29/2012	IIS_A	Reza Ahmadi	Next dose in 1 month
3rd time 6 month old	03/04/2012	4	01/23/2013	IIS_A	Reza Ahmadi	Next dose at the age of 18 months
4th time 18 month old	02/25/2013	33	07/23/2017	IIS_B	Kazem Nabavi	Next dose at the age of 6 years
5th time 6 year old	08/06/2017	14	N/A	IIS_B	Kazem Nabavi	Administration is not allowed after this dose
6th time	07/29/2019	Warning	Warning	IIS_B	Kazem Nabavi	Administration is not allowed!

Figure 4. Sample report in Farsi language generated by the immunization DSS

Results

In order to explore the feasibility of our approach, we conducted a system test and deployed two independent IISs connected to internet without any direct connection to each other and published the EIS and RLUS web services. Then approximately 1500 immunization records for roughly 400 infants from Alzahra Education and Treatment Center in Iran were collected. These records are collected on paper and didn't include any identifying information, so the fake demographic data and ID for children were generated.

The data were randomly entered into two IISs. Considering that each child has more than one immunization record, by random data insertion we guaranteed that immunization information of each individual is scattered in different IISs. During the registration of patients' demographics and immunization records in a random way, the information automatically were sent to EIS and RLUS web services based on HL7 v3.0 messages and integrated in databases located in web services. Then we randomly selected 50 patients and searched their immunization records in both IISs. Based on received immunization history we got and immunization forecast from DSSs embedded in systems.

The HL7 v3.0 messages are specialized from abstract RIM data model to carry domain specific concepts. These messages are converted to large XML documents to transmit between IISs and web services. Although XML messages are large and complex, however, the systems' turnaround time is less than a minute for synchronous operation calls and there was no delay even when the HL7 XML messages are very large.

Due to communication in SOA environment, information is gathered from both IISs and consolidated in web services so the immunization history of patients are always identical in different systems. Systems can update their local data base by synchronizing with web services.

The reliable information supports DSS to generate reliable reports and alerts which is very important in health care sector. For the 50 individuals that we retrieved immunization history, generated warnings or forecasts for the next vaccines were completely accordant to Immunization guidelines and the calculations for next visit dates were 100% accurate. Also the result of DSS was the same in both IISs and there was no difference in generated reports.

Discussion

It has been more than a decade since Iran's government invested in Electronic Health Record (EHR) systems to overcome the challenge of data exchange between Health Information Systems (HIS). However, there has been little progress in computerization of Immunization registries and vaccination information is still captured in traditional methods in Iran. In the United States, minimum functional standards for the operation of immunization information systems were developed by the U.S. Centers for Disease Control and Prevention (CDC), however, currently IIS systems are usually state-centric and there is significant need to data exchange among states and improve data quality and interoperability of systems. Given that residents travel between facilities and across states, healthcare providers require access to comprehensive immunization history of individuals across fragmented EHR, HIS, and IIS. We present a novel prototype for integration and exchange of immunization information based on localized HL7 v3.0 messages for Iran and which takes advantage of SOA specifications. This same approach could be applied in the U.S. for integrating individuals' immunization records by exchanging data in SOA environment and accessing valid and up-to-date information in all of the states. For example, the Nationwide Health Information Network (now referred to as the eHealth Exchange) uses a SOA-based framework for the exchange of HL7 v3.0 continuity of care documents (CCDs) among health information exchanges and federal agencies (22, 23).

To date, v2.x of HL7 standard has been more popular than v3.0 in U.S., mainly due to inertia among commercial EHR companies to move away from legacy platforms. However, the implementation of CDA-requirements in compliance with the 'meaningful use' initiative has resulted in several commercial EHR vendors adopting v3.0 web services, even if they are simply wrappers (24) built on top of existing messaging endpoints. Therefore the U.S. market may see increased availability of v3.0 services in the coming years, and the pilot work in Iran might be useful for EHR vendors that wish to implement interoperable interfaces between various IISs among the various state health departments. Furthermore, given Europe's broader adoption of HL7 v3.0 messaging, the prototype described here might also be useful for sharing immunization records across nation borders.

Our system is built upon standard profiles and technical specifications that will help to be translated by US audience. IHE is one of leading organizations that tries to improve the utilization of computer systems in healthcare to support optimal patient care. EIS web service developed in this study, has many overlaps with IHE Patient Identifier Cross-Referencing (PIXV3) and IHE Patient Demographics Query HL7 V3 (PDQV3) which are presented in IHE IT Infrastructure Technical Framework (25). Both our study and IHE profiles use HL7 RIM model for design of messages and are corresponding with HL7 interactions for message calls. Also, in this study we adopted service profiles and specifications from HSSP and OMG, which are prominent organization in standard developing. Although there are some difference between our work and IHE profile such as service or message customization, however, we believe vendors can use presented model in this work along with IHE profiles which will not necessarily bad thing and they can reproduce this method.

Because of the inherent complexity in HL7 v3.0 messages, it can be confusing to extract and map all of the required IIS information into specific message fields when generating a message. We therefore encapsulated all message generation complexities inside an API component and, by exposing some simple operations to external software developers, better facilitated the process of message generation. This API can be re-used in other systems where the data model is based on the HL7 RIM.

When developing CDSSs, knowledge engineers try to use expression languages like GELLO to represent knowledge in a shareable format among other CDSSs. However, expression languages require an Object Oriented information

model to work efficiently. In this study, we designed information model based on HL7 RIM which is Object Oriented. This model enables our system to use expression languages for defining immunization knowledge and make this knowledge available for any other IIS. Furthermore, CDSSs are also moving towards SOA-based frameworks to enable distributed knowledge delivery across a range of clinical guidelines to improve health care quality, safety, and efficiency (26).

Conclusion

Providers require up-to-date access to information to accurately forecast vaccines as well as make other clinical decisions. EHR, HIS, and IISs have generally been developed and deployed as silos enabling fragmented, cumbersome access to patient information. Greater deployment of health information exchange technologies like SOA and HL7 make it possible to engineer distributed IIS and CDSS. We describe an approach for Iran that has potential for the U.S. and other nations. Future research and development is promising to incrementally advance health information technologies towards meeting provider and patient needs for real-time access to information wherever it may be located.

Syndromic surveillance in an ICD-10 world

Achala Jayatilleke MBBS, MSc, PhD, Jeffrey Kriseman MS, PhD, Lisa H Bastin MA, Umed Ajani MBBS, MPH, Peter Hicks MA, MPH

Centers for Disease Control and Prevention, Atlanta, GA, USA

Abstract

The Centers for Disease Control and Prevention's BioSense program is an integrated national public health surveillance system that uses electronic medical record (EMR) data to provide situational awareness for all-hazard health-related events. Because the system leverages International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) coded data from EMRs for syndromic surveillance, the upcoming Health and Human Services-mandated transition from ICD-9-CM to ICD-10-CM will have a significant impact. To translate across the two encoding systems, we developed a Mapping Reference Table (MRT) for the ICD-9/10 transition. We extracted ICD-9-CM codes binned to predefined syndromes and mapped each to its corresponding ICD-10-CM code(s). Then, we translated the output ICD-10-CM codes back to ICD-9-CM through a reverse translation validation process. Throughout the translation process, we examined outputs manually and incorporated annotated results into the MRT. The resulting MRT can be used to refine and update each existing syndromic surveillance definition in BioSense to be compatible with ICD-10-CM and consistently classify or bin any given emergency department visit into the correct syndrome regardless of coding system.

Disclaimer

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention (CDC).

Introduction

The Public Health Security and Bioterrorism Preparedness and Response Act of 2002 mandated the establishment of public health surveillance systems for early detection and rapid assessment of potential bioterrorism-related illness. As a response to that mandate, the Centers for Disease Control and Prevention (CDC) launched the BioSense Program in 2003 to establish an integrated national public health surveillance system.(1) BioSense began receiving data feeds in 2003 from outpatient clinics maintained by the Department of Veteran Affairs (VA) and Department of Defense (DoD).(2, 3) In 2005 BioSense began to receive data from non-federal civilian hospitals as well. Initially, BioSense defined 11 broad major syndromes (botulism-like, fever, gastrointestinal, hemorrhagic illness, localized cutaneous lesion, lymphadenitis, neurological, respiratory, rash, severe illness or death, and specific infection) and more-specific sub-syndromes based on chief complaint and final diagnosis data.(4) Although BioSense was initially launched as a surveillance system for early event detection and rapid assessment of potential bioterrorism-related illness over time, it has transformed to a public health surveillance system that provides situational awareness for all-hazard health-related events.(5)

CDC started redesigning BioSense in 2010, and the system was launched as BioSense 2.0 in 2012. The latest iteration of BioSense is a streamlined collaborative data-exchange system that enables its users to share health-related data, quickly track adverse or anomalous health issues, and share this information rapidly among other public health jurisdictions participating in the system.(5–7) Currently, as of July 2014, BioSense receives data feeds from 3,377 (1,920 non-federal and 1,457 federal) facilities and tracks approximately 130 pre-defined syndromes.(8)

Leveraging data from electronic medical records (EMRs) is a modern cornerstone for public health surveillance activities.(9) BioSense uses EMR data (such as chief complaint and final diagnosis codes) to provide national, regional, and local situational awareness for all-hazard health-related events and to inform a wide range of public health activities. Within the BioSense program, International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM)-coded data are extracted from EMR data provided by participating healthcare facilities.(4,8) These ICD-9-CM codes are binned and classified into syndromes and used to create temporal and geographic indicators and trend-lines for injury, disease, conditions, healthcare utilization, and adverse or anomalous event monitoring.(4,5)

In 2009, the Department of Health and Human Services mandated that a transition from ICD-9 to ICD-10 will occur on October 1, 2014 (now extended to October 1, 2015), for all entities covered under the Health Insurance Portability Accountability Act (HIPAA) and for healthcare systems that submit reimbursements to the Centers for Medicare and Medicaid (CMS) in the United States.(10) As many other secondary users of final diagnosis-coded data, public health surveillance systems will be significantly affected by this transition. To receive, analyze, interpret, and report upon ICD-9 and ICD-10 encoded data, public health surveillance systems that used ICD-9-CM codes must modify the existing database structure, modify data extraction rules, and create well-defined Mapping Reference Tables (MRT) to bridge the gap across the two encoding systems.

The most challenging aspect of the ICD-9/10 transition for public health surveillance systems will be to develop flexible and standardized solutions to accommodate analysis across two different code sets in 2015 and beyond. In addition, a meaningful baseline must be developed that can be used for benchmarking after the transition. Public health surveillance systems should expect to receive ICD-9-coded data for the first nine months of 2015 and ICD-10-coded data for the last three months of 2015; in addition, public health surveillance systems should plan for the possibility of receiving and analyzing a

mixture of both ICD-9 and ICD-10-coded data for some period of time following October 1, 2015, which will make the situation more complicated. In this context it is essential to have a method to identify the type of original codes received by public health surveillance systems and to have the compatibility to seamlessly map across the two code sets.

We carried out this project to describe the process of developing an MRT for ICD-9/10 transition to be used to translate across the code sets and to propose a methodology for a meaningful baseline to be used in the BioSense system after October 1, 2015.

Methods

We extracted ICD-9-CM codes binned to all predefined BioSense syndromes from the list of syndromes developed by the BioSense community, which includes federal, state, and local public health partners.(8) We updated each of the extracted codes to 2014 ICD-9-CM codes by using the Code Translation Tool (CTT) developed by 3M for the translation process. (11) By using CTT, we translated the resulting ICD-9-CM 2014 codes to ICD-10-CM 2014 codes. Then, we translated the output ICD-10-CM codes back to ICD-9-CM by using a reverse translation validation process to ensure that the appropriate codes were correctly identified at the onset of the translation process. Throughout the translation process, outputs were individually examined manually and annotated results were incorporated into the MRT by an epidemiologist and a clinician. We used ICD-9 and ICD-10 complete official code sets for the manual process.(12, 13)

By using the resulting MRT, we computed ICD-9-CM codes for use cases of ICD-10-CM codes and vice versa. Computed ICD-9-CM codes were then binned to existing BioSense syndromes. Similarly, we attempted to bin computed ICD-10-CM codes to the existing BioSense syndromes. During this process, we also developed an algorithm that can identify whether the original code belongs to ICD-9-CM or ICD-10-CM. In addition, we used the resulting MRT to refine and update each of the existing syndromic surveillance definitions used in the BioSense program to be ICD-10-CM compatible.

Results

The output MRT comprises four columns: 1) the original ICD-9-CM, 2) the updated 2014 ICD-9-CM codes, 3) corresponding ICD-10-CM codes, and 4), lastly, a value to indicate the level of confidence for each individual mapping in regards to a specific syndrome. Table 1 depicts a section of MRT for syndrome asthma as an example. We indicated the level of confidence by using four values (Table 2).

In some instances where a single ICD-9-CM code is insufficient to represent the relevant ICD-10-CM codes, we introduced an additional column in the MRT named *Supplementary ICD-9-CM Code*. Similarly, we introduced supplementary ICD-10-CM codes where a single ICD-10-CM code is insufficient to represent some concepts represented by ICD-9-CM.

Table 3 shows the level of confidence of ICD-10-CM codes for five selected syndromes. Figure 1 illustrates the number of ICD-9-CM and ICD-10-CM codes binned to five selected syndromes.

Leveraging the MRT, we computed ICD-9-CM and ICD-10-CM codes for hypothetical use cases and binned them to the existing BioSense syndromes. Table 4 shows the computed codes and binning of codes to the syndromes asthma and chronic obstructive pulmonary disease (COPD).

Figure 2 shows the algorithm we used to identify the type of original code. This algorithm describes how an ICD-9-CM diagnosis code can be differentiated from that of ICD-10-CM.

Discussion

The ICD-9-CM to ICD-10-CM transition will have a significant impact on the BioSense program. Due to the complexity and higher level of specificity in ICD-10-CM codes, ICD-9-CM codes pertinent to syndromes within BioSense cannot be automatically translated into ICD-10-CM codes. Existing translation tools are insufficient and frequently provide results that are either inaccurate or incompatible with the syndromic surveillance concept under review. Therefore, we developed an MRT to be used by the BioSense program with manual expert review and input based on General Equivalence Mappings (GEMs) files prepared by CMS.(14)

By leveraging the developed MRT, ICD-10-CM codes can be down-coded and translated into ICD-9-CM codes. The resulting ICD-9-CM codes can be binned to existing BioSense syndromes. Similarly, ICD-9-CM codes can be up-coded and translated to ICD-10-CM by using the MRT. The output (the resulting ICD-10-CM codes) can then be incorporated into new syndromic surveillance visit (case) definitions that can be incorporated into the overall BioSense system or appended to a given record to allow a given event to be analyzed in either code set. The developed MRT can be used to refine and update each of the existing syndromic surveillance definitions used in the BioSense program to be ICD-10-CM compatible. However, due to the higher specificity of ICD-10-CM codes, existing BioSense 2.0 syndromes should be reviewed based on ICD-10-CM codes to achieve syndromic surveillance objectives more effectively.

Syndromic surveillance data are of limited use without a reliable and interpretable referential baseline. The BioSense program uses the past two years of data to define a referential baseline. However, after October 1, 2015, it will be impossible to compute a referential baseline unless there is a platform to accommodate both ICD-9-CM and ICD-10-CM codes. Referential base lines can be computed for both ICD-9 and ICD-10 code sets by using our developed MRT. These calculated referential baselines can be used until all healthcare facilities providing data to the BioSense program fully transition to the ICD-10 coding system or until a complete two-year referential baseline is computed (October 2017).

After October 1, 2015, public health surveillance systems may receive a mixture of both ICD-9 and ICD-10 codes. Because ICD-10-CM diagnosis codes begin with an alpha character (e.g., J45.30, J45.20), a majority of ICD-10-CM codes can be differentiated from ICD-9-CM codes that begin with a numeric character (e.g., 493.0, 493.1). However, there are similarities in ICD-10-CM codes and ICD-9-CM codes starting with an alpha character (E and V).(15) To address this issue, we developed an algorithm for this project that can be used to validate and differentiate ICD-10 codes from ICD-9 codes after the transition. However, in some occasions where ICD-10 codes are identical to ICD-9 codes, additional information will be required for the differentiation.

The lack of ICD-10-CM-based data to test the developed MRT is a limitation of this project. Currently, we are developing a synthetic ICD-10-CM data set by using probability theories based on historical ICD-9-CM data. This data set can be used to test the developed MRT several months before the real transition occurs.

In conclusion, the developed MRT can be used as a common language and reference to receive, integrate, and classify healthcare visits to syndromic surveillance definitions and develop computed referential baseline data regardless of ICD code set. However, to receive the benefit of the more specific ICD-10 codes, existing BioSense syndrome definitions should be revised based on ICD-10-CM codes to achieve syndromic surveillance objectives more effectively. The MRT and the code set identification algorithm can be leveraged beyond the BioSense program and will be made available to state and local partners for potential inclusion in their specific syndromic surveillance systems.

Table 1. Mapping Reference Table (MRT) for selected codes of asthma syndrome

Original ICD-9 CM	2014 ICD-9 CM	Corresponding ICD-10 CM	Level of Confidence
493	493.00	J45.20	A
493	493.00	J45.30	A

Abstract
Type 2 Diabetes Mellitus is a progressive disease with increased risk of developing serious complications. Identifying subpopulations and their relevant risk factors can contribute to the prevention and effective management of diabetes. We use a novel divisive hierarchical clustering technique to identify clinically interesting subpopulations in a large cohort of Olmsted County, MN residents. Our results show that our clustering algorithm successfully identified clinically interesting clusters consisting of patients with higher or lower risk of diabetes than the general population. The proposed algorithm offers fine control over the granularity of the clustering, has the ability to seamlessly discover and incorporate interactions among the risk factors, and can handle non-proportional hazards, as well. It has the potential to significantly impact clinical practice by recognizing patients with specific risk factors who may benefit from an alternative management approach potentially leading to the prevention of diabetes and its complications.

Introduction

Type 2 Diabetes Mellitus is one of the fastest growing chronic diseases in the United States, with a profound influence on public health quality and cost[1,2]. It is a progressive disease, associated with an increased risk of developing serious cardiac, vascular, renal and ophthalmological complications, and it is one of leading causes of death[2]. With no cure per se, prevention and management are of paramount importance. As effective preventive measures such as lifestyle change and drug therapy exist[3,4], early identification and management of patients at high risk is an important healthcare need.

Numerous diabetes risk indices aimed at early identification of patients at high risk have been developed[5]. Arguably, the most popular such index is the Framingham score[6], which has gained wide acceptance in clinical practice. The Framingham model assigns a risk to a patient based on the risk factors the patient presents with and the resulting score can be used to stratify patients into low, moderate, or high-risk groups. Almost all indices, the Framingham score included, estimate the risk of diabetes in an additive fashion, assuming that the risk factors act independently.

Interactions among risk factors are known to exist[7–11]. Recent work[7–10] aimed to address interactions, most prominently through the application of association rule mining (ARM)[12–15]. ARM was specifically designed to discover sets of associated risk factors, along with the affected subpopulations. While association does not always translate into (non-additive) interaction, it often does. Given its ability to seamlessly incorporate interactions, ARM has successfully identified patient subpopulations that face significantly increased or decreased risk of diabetes[7,11]. Another beneficial characteristic of the ARM model lies in the straightforward interpretability of the individual rules. Thus the ARM model does not just provide a risk estimate, but it also offers a "justification" in the form of the associated risk factors in the rule.

ARM has its own shortcomings. While interpretability is one of the hallmarks of the ARM modeling approach, ARM algorithms tend to extract combinatorially large sets of redundant rules, which quickly erodes interpretability. Under these conditions, it is necessary to offer fine control of the amount of details the ARM model extracts; however, this is precisely where ARM falls flat. When ARM discovers a manageable number of rules, they tend to be too general to be useful; when the model is sufficiently detailed to give the user new insights, the sheer number of rules impedes interpretation. There is a reason for this phenomenon. The ARM rule set is highly redundant: the same subpopulation is described by an exponential number of rules, each rule associating the subpopulation in question with a different set of risk factors. This unfortunate property obfuscates the disease mechanism.

In this work, we propose the use of a novel divisive hierarchical clustering[16] technique, which retains most of the advantages of ARM, while it alleviates the interpretability issues. From a hierarchical clustering, depending on the desired amount of detail, many clusterings can be extracted. Each clustering consists of a varying number of clusters, is complete (they include all patients) and non-overlapping (each patient belongs to exactly one cluster).

Our proposed approach retains all advantageous properties of ARM and alleviates its primary shortcoming: interpretability is enhanced through the elimination of redundancy and through lending the user fine control over the amount of details the clustering should incorporate.

Methods

Data

In this study we utilized a large cohort of Olmsted County, Minnesota, residents identified by using Rochester Epidemiology Project resources. The Rochester Epidemiology Project (REP)[17] is a unique research infrastructure that follows residents of Olmsted Co., MN over time. The baseline of our study was set at Jan. 1, 2005. We included all adult Mayo Clinic patients with research consent, who are part of the REP, resulting in a study cohort of 69,747 patients. From this cohort, we excluded all patients with a diagnosis of diabetes before the baseline (478 patients), missing fasting plasma glucose measurements (14,559 patients), patients whose lipid health could not be determined (1,023 patients) and patients with unknown hypertension status (498 patients). Our final study cohort consists of 52,139 patients (overlaps between the groups exist) who were followed until the summer of 2013.

We collected demographic information (age, gender, body mass index BMI), laboratory information (primarily fasting plasma glucose and lipid panel), vital signs (blood pressure and pulse), relevant diagnosis diagnoses (obesity, hyperlipidemia, hypertension, renal failure and various cardiac and vascular conditions), aspirin use, and medications used to treat hypertension and hypercholesterolemia. Additional known risk factors for diabetes (such as tobacco usage) were also included.

Features

To enhance the interpretability of our results, the variables were transformed into binary variables to indicate the presence and severity of risk factors. These variables are typically constructed as a meaningful combination of diagnoses, abnormal vital signs, abnormal laboratory results, and use of medications by drug class. Laboratory results were considered abnormal when they exceeded the cutoffs published in the American Diabetes Association (ADA)[18] guidelines. Table 1 shows the definitions of the variables used henceforth.

Table 1. Predictors and their definitions

Predictors	Definitions
Demographics	
age.18+	Age > 18 and < 45
age.45+	Age ≥ 45 and < 65
age.65+	Age ≥ 65
genderM	Male
Comorbidities	
obese	Obesity (BMI ≥ 30 or diagnosis)
tobacco	Current smoker
renal	Renal disease
chf	Congestive Heart Failure
ihd	Ischemic Heart Disease
Major risk factors and their severities	
ifg.no	Normo-glycemic patients: fasting plasma glucose (FPG) ≤ 100
ifg.pre1	Impaired Fasting Glucose level 1: FPG > 100 and ≤ 110
ifg.pre2	Impaired Fasting Glucose level 2: FPG > 110 and ≤ 125
htn.no	No indication of Hypertension: no diagnosis of HTN, no hypertensive drugs are described and blood pressure results (if present) are normal.

htn.any	Indication of Hypertension exists in the form of either a HTN diagnosis or abnormal blood pressure measurement
htn.tx	Hypertension required therapeutic intervention; however, at most 3 HTN drugs were prescribed.
htn.pers	Persistent Hypertension. Patients present with abnormal blood pressure measurements despite having been prescribed 3 or more drugs; or they are prescribed 4 or more drugs (regardless of blood pressure results).
hyperlip.no	No indication of Hyperlipidemia: no diagnosis of hyperlipidemia, no cholesterol drugs and no abnormal lipid panel results are present.
hyperlip.any	Indication of Hyperlipidemia exists in the form of diagnosis or abnormal laboratory results.
hyperlip.tx	Hyperlipidemia with therapeutic intervention: a diagnosis code or abnormal laboratory result indicates hyperlipidemia and a single cholesterol drug is prescribed.
hyperlip.multi	Hyperlipidemia requiring multi-drug intervention: multiple cholesterol drugs are prescribed.

Patient Clustering

The purpose of clustering is to partition patients into groups (clusters), such that patients within the same cluster are more similar to each other than to patients in a different cluster. Formally, in our application, a **cluster** is a set of patients, who share risk factors relevant to diabetes progression and have similar diabetes risk. A **clustering** is a non-overlapping complete set of clusters. A clustering is *complete* in the sense that all patients in the population are assigned to a cluster, and it is *non-overlapping*, as each patient is assigned to a single cluster in a clustering. Our goal is to create a patient clustering, where the clusters correspond to clinically meaningful patient subpopulations.

To identify such subpopulations, we applied bisecting divisive hierarchical clustering. The algorithm iteratively constructs a hierarchy of clusters in a top-down (divisive) fashion, in each iteration bisecting a cluster into two new (child) clusters. A cluster is bisected using a *splitting variable*. One of the two child clusters contains all patients from the parent cluster for whom the splitting variable is true, and the other child contains all patients for whom the splitting variable evaluates to false. For example, if the parent cluster (cluster to split) consists of patients with hypertension (htn is true) and the splitting variable is ifg.pre2 (fasting plasma glucose FPG > 110), one of the child clusters is comprised of hypertensive patients having high FPG (ifg.pre2=true) and the other cluster is comprised of hypertensive patients with lower FPG (ifg.pre2 is false).

The algorithm proceeds by recursively bisecting each cluster into two child clusters starting with a cluster that represents the entire population. The algorithm terminates when no cluster can be bisected without having insufficient number of patients in the resultant child clusters; or when the patients in the cluster are sufficiently similar to each other.

The splitting variable is selected on the basis of how much variability in the diabetes outcome it can explain; bisections that explain a large amount of variability are preferred. Let t_j denote the follow-up time (in days) and δ_j the diabetes status at the end of follow-up for patient j. This patient is censored when the diabetes outcome is negative ($\delta_j = \text{false}$) at the end of follow-up. The martingale residual $M_j(t)$ for a patient j at time t_j is computed as the difference between the observed number $\delta_j(t)$ of event (1 if a patient j had developed diabetes before (or exactly at) time t_j, 0 if censored) and the estimated number $H_j(t)$ of events (cumulative hazard)

$$M_j(t) = \delta_j(t) - H_j(t).$$

To calculate the cumulative hazard, we use the Nelson-Aalen estimator,

$$H_j(t) = \sum_{t_i \le t} h_j(t_i) = \sum_{t_i \le t} \sum_k \frac{dN_k(t_i)}{Y_k(t_i)},$$

where $h_j(t_i)$ denotes the (non-cumulative) hazard of patient j at time t_i, k iterates over all patients, $dN_k(t_i)$ denotes the number of diabetes incidents that patient k suffers exactly at time t_i (0 or 1) and $Y_k(t_i)$ indicates whether patient k is at risk at time t_i. The formula for the non-cumulative hazard can be thought of as the number of events

occurring exactly at time t_i divided by the number of patient at risk at that time. When multiple patients suffer events at exactly the same time, these events are arbitrarily serialized.

Suppose we have a cluster C_1, which we need to bisect into clusters C_{11} and C_{12} using a particular splitting variable. Further, let SSR(C) denote the sum of squared martingale residuals for any cluster C. Bisecting C_1 will decrease the total SSR by

$$G = SSR(C_1) - [SSR(C_{11}) + SSR(C_{12})].$$

Each splitting variable produces a different G value. Among the possible splitting variables, we select the one that reduces the SSR the most, or equivalently, maximizes G. This is the splitting variable that explains the diabetes outcome in C_1 the best, thus it can be thought of as 'most relevant' to diabetes in the subpopulation corresponding to cluster C_1.

Once the cluster hierarchy has been constructed, the final clustering can be extracted. A **leaf cluster** is a cluster that is not bisected. Our hierarchical clustering algorithm ensures that each patient falls into exactly one leaf cluster, thus the collection of leaf clusters form a non-overlapping complete clustering of the patient population.

We wish to make two notes. First, our clustering algorithm is similar to the survival tree construction algorithm[19]; in fact, one can think about it as an adaptation of the recursive partitioning algorithm[20] for censored outcomes to a clustering application. Indeed, we follow Therneau et al.[21] in broad strokes and adapt their ANOVA criterion for censored outcome: we use sum squared martingale residuals instead of sum squared error. Second, the analogy between recursive partitioning and our algorithm goes deeper. The martingale residual can be rescaled into a deviance residual. Just as the sum squared error relates to the "deviance" of two nested Gaussian models, the sum squared deviance residuals relate to the deviance of two nested survival models, enabling the use of likelihood ratio tests for significance testing. Since our purpose is to construct the full hierarchy of clusters, we do not perform significance testing and use the martingale residuals instead of the deviance residuals.

Clustering and statistical analysis were conducted with the use of R version 3.0.1.

Results

In what follows, we demonstrate that our clustering algorithm successfully identified potentially interesting clusters that consist of patients with substantially higher or lower risk of diabetes than the general patient population. The clustering (the collection of leaf clusters) assigns each patient to exactly one leaf cluster and each leaf cluster possesses a cumulative hazard curve (specific to the subpopulation that the leaf consists of). Thus the clustering can be used to estimate a patient's risk of diabetes and can hence serve as a diabetes index. We will also demonstrate that our clustering used in this fashion outperforms the popular Framingham score. Thirdly, we will also show by constructing the entire hierarchy of clusters, that we can extract clusterings that encompass varying amounts of detail. Finally, we will demonstrate that our clustering can model non-proportional hazards as well as interactions among the risk factors.

Identifying high and low risk subpopulations

We performed hierarchical clustering of our patient population under the user-defined constraint that clusters with less than 50 patients are not bisected further. We identified 275 leaf clusters. From these leaves, we selected two: one indicative of very high risk and one indicative of very low risk. We then compared these leaves with the general population.

In Figure 1, we display the Kaplan-Meier survival curve and the cumulative hazard curve for the entire population (blue dotted line) and for the above two clusters: red solid line is used for the high-risk cluster and green dotdash line for the low-risk one. The patients (n = 61) in the high-risk cluster have fasting plasma glucose greater than 110 mg/dL (ifg.pre2), hyperlipidemia that requires therapeutic interventions (hyperlip.tx), and are current smokers (tobacco). The low-risk cluster consists of the patients (n = 498) characterized by fasting plasma glucose level equal to or lower than 100 mg/dL, no indication of hypertension, no indication of hyperlipidemia, no obesity, no renal disease, no congestive heart failure, no ischemic heart disease, no aspirin use, male non-smokers being between 45 and 65 years of age.

From Figure 1, the difference in diabetes progression among these three subpopulations is obvious and the risk factors for these patients are consistent with our clinical expectation.

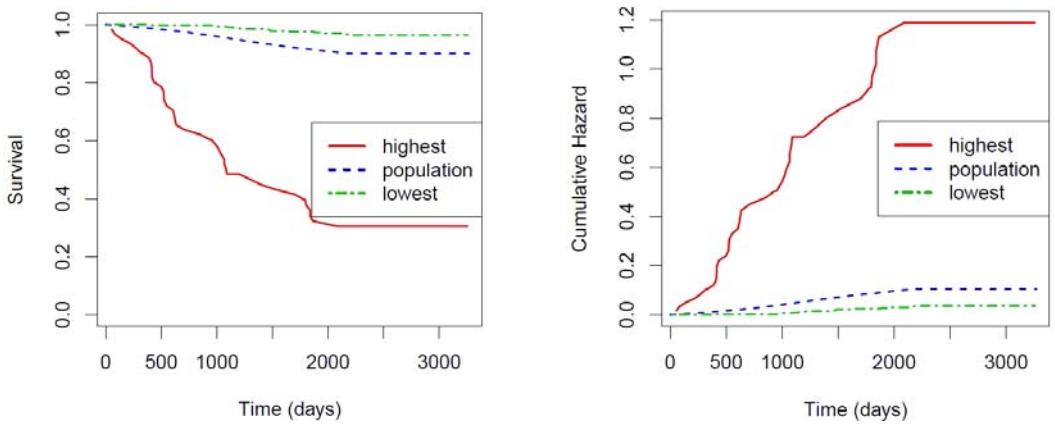

Figure 1. Kaplan-Meier survival curve (Left) and Cumulative incidence of diabetes (Right) for two pre-diabetic subpopulations (red sold and green dotdash) and the entire population (blue dotted)

Clustering as a diabetes index

As we described earlier, the leaf clusters form a non-overlapping clustering, where each patient belongs to exactly one leaf cluster. Since each leaf cluster contains a survival function of the corresponding subpopulation, it is possible to use the clustering as a diabetes index, providing a risk estimate for each patient. In this section, we compare the clustering as a diabetes index against the popular Framingham score, an actual diabetes index in clinical use. Specifically, we use concordance as our evaluation measure. Concordance is the probability that for any two patients where one progressed to diabetes earlier than the other, the one that progressed earlier has a higher predicted risk. The clustering achieved a concordance of 0.78, while the Framingham score achieved a lower concordance of 0.70, signifying the clustering has imporved discriminatory power.

Controlling the amount of detail

An important advantage of the proposed clustering technique over alternative methods, such as association rules, is that it offers fine control over the amount of detail it presents to the user. This control can be achieved by **cutting** the hierarchy at a particular level. To illustrate this point, we depict the entire cluster hierarchy in Figure 2. The leaf clusters are listed along the horizontal axis and the vertical axis indicates the SSR of the cluster. The hierarchy is represented by a dendrogram, which can be interpreted as follows. The root of the dendrogram is at the top (SSR=4645) and it represents a cluster that includes all patients. The root is split into two clusters (on ifg.pre2; not shown) one with SSR 730 (ifg.pre2=true) and one with SSR 3914 (ifg.pre2=false). The subpopulation having ifg.pre2=true is split on htn.pers into two clusters, one with SSR 41 (persistent hypertension present) and one with SSR 688 (htn.pers=false). In short, the dendrogram allows us to trace the bisections our algorithm performed and it also depicts the SSR of the resultant clusters.

We can cut the dendrogram at any SSR of our choice. Cutting the hierarchy produces a new set of leaf clusters, which in turn forms a non-overlapping complete clustering of the patient population. For example, if we cut the dendrogram at SSR of 4000 (which is very close to the top), we obtain only two leaf clusters: ifg.pre2=true with SSR of 730 and ifg.pre2=false with SSR of 3914. If we cut the dendrogram at a lower SSR, say at 500, we will obtain a larger set of leaf clusters (26 in this example) each having lower SSR. This particular cut is shown in Figure 2 as a magenta line. Larger number of leaf clusters offers a larger amount of detail. Selecting an SSR for cutting the dendrogram is what allows us to control the amount of detail (number of leaf clusters) in a predictable fashion. The SSR of the resulting leafs also shows the within-cluster similarity of the patients.

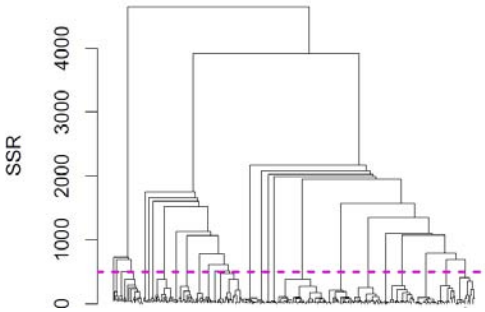

Figure 2. Dendrogram of the entire hierarchy of clusterings

Naturally, a tradeoff exists between the amount of detail and the predictive capability of a clustering. In Figure 3, we visualize this tradeoff. The horizontal axis represents the SSR at which the dendrogram was cut and the vertical axis represents the resultant clustering with the number of clusters depicted in left pane and the predictive capability (as measured by concordance) in the right pane. The figure shows that as we increase the SSR (move right on the horizontal axis), we decrease the amount of detail (number of clusters) and along with the decreased amount of detail, the predictive capability of the clustering decreases, as well.

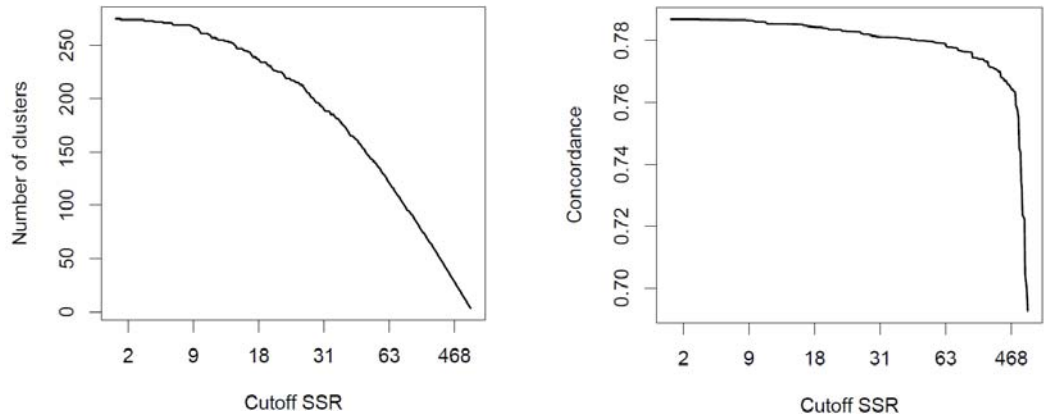

Figure 3. Tradeoff between the amount of detail (number of clusters) and the predictive capability (concordance)

Non-proportional hazard

We plot the cumulative hazard functions for the 26 clusters we extracted earlier (by cutting the hierarchy at SSR 500) in Figure 4. To avoid overcrowding the image and preserve good visibility of the lines, we separated the 26 clusters into four panes essentially at random. The IDs in the legend refer to their original IDs (IDs before cutting), thus they can exceed 26. Cumulative hazards across the clusters are not proportional because the LOGLOGS plots of the 26 clusters (shown in Figure 5) do not appear as parallel lines, indicating interactions between time and subpopulations. This non-proportionality was correctly captured by our approach. To show these clusters are clinically relevant, we selected the 12 highest risk clusters out of the 26 and described in Table 2.

Interactions among risk factors

Cluster 4 consists of patients who have ifg2.pre2 and htn.pers, and the estimate of the cumulative hazard at the end of the study is 1.02. To estimate the hazard under the assumption that the two risk factors are additive (act independently), we fit a Cox regression model to the entire population using only the above two variables as predictors. We used this Cox model to make a prediction for the subpopulation represented by cluster 4 and their cumulative hazard is 1.44. The difference between this prediction (of 1.44) and the prediction of 1.02 by the clustering strongly suggests that an interaction between these two risk factors (FPG and HTN) exists. While we do not know the exact risk of diabetes (true value for the cumulative hazard) in this subpopulation, it is between the observed prevalence of diabetes in this subpopulation, which is 0.57, and 1.0 (each patient can only experience at most one event of diabetes). 1.02 is closer to this range than 1.44, thus the additive Cox regression model overestimated the risk

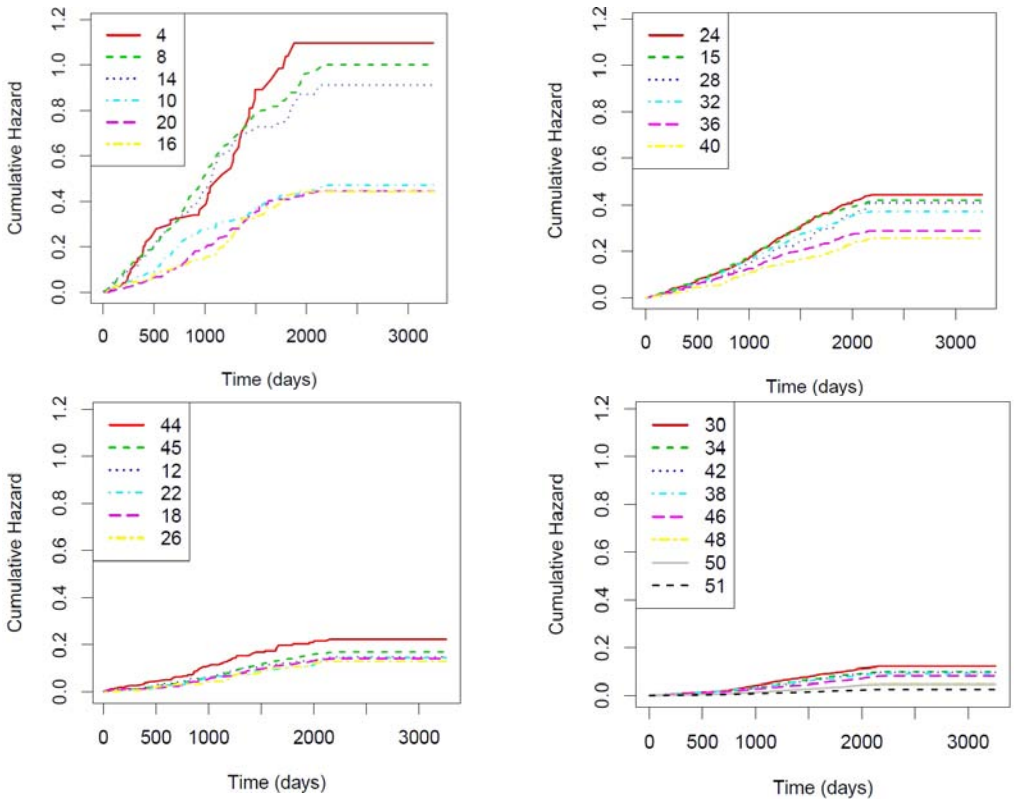

Figure 4. Identified pre-diabetic subpopulations based on cumulative hazard after infinite follow up time

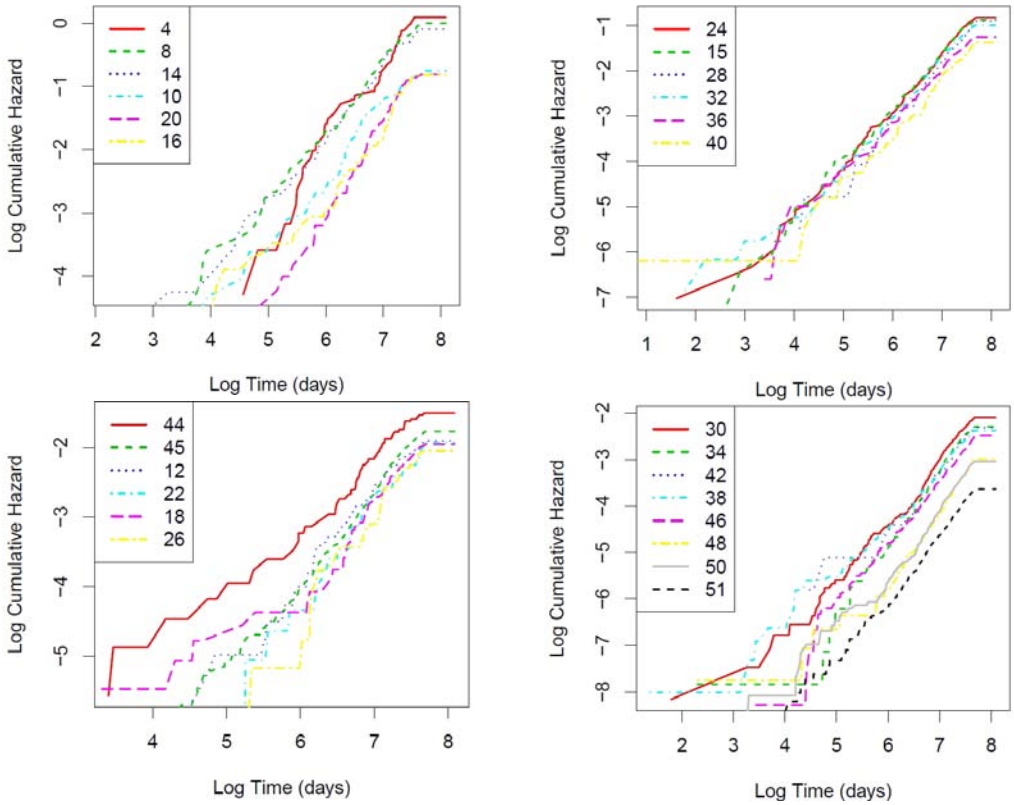

Figure 5. LOGLOGS plot of cummulative hazard

Table 2. Subpopulation summarization in terms of cumulative hazard at the end of the study.

Cluster ID	Patient Count	SSR	Cumulative hazard	Risk factors
4	74	40	1.02	ifg.pre2=true, htn.pers=true
8	297	180	1.00	ifg.pre2=true, htn.pers=false, obese=true
14	212	121	0.91	ifg.pre2=true, htn.pers=false, obese=false, hyperlip.tx=true
10	227	81	0.47	ifg.pre2=false, ifg.pre1=true, hyperlip.multi=true
20	280	88	0.45	ifg.pre2=false, ifg.pre1=true, hyperlip.multi=false, renal=false, htn.pers=true
12	736	88	0.15	ifg.pre2=false, ifg.pre1=false, htn.pers=true
24	1130	380	0.44	ifg.pre2=false, ifg.pre1=true, hyperlip.multi=false, renal=false, htn.pers=false, hyperlip.tx=true
15	1276	384	0.42	ifg.pre2=true, htn.pers=false, obese=false, hyperlip.tx=false
28	241	68	0.41	ifg.pre2=false, ifg.pre1=true, hyperlip.multi=false, renal=false, htn.pers=false, hyperlip.tx=false, ihd=true
32	949	277	0.37	ifg.pre2=false, ifg.pre1=true, hyperlip.multi=false, renal=false, htn.pers=false, hyperlip.tx=false, ihd=false, obese=true
36	735	166	0.28	ifg.pre2=false, ifg.pre1=true, hyperlip.multi=false, renal=false, htn.pers=false, hyperlip.tx=false, ihd=false, obese=false, htn.tx=true
40	493	102	0.25	ifg.pre2=false, ifg.pre1=true, hyperlip.multi=false, renal=false, htn.pers=false, hyperlip.tx=false, ihd=false, obese=false, htn.tx=false, aspirin=true

Discussion

In this paper, we presented a novel bisecting divisive hierarchical clustering algorithm to identify clinically relevant patient subpopulations using type 2 diabetes as the endpoint. In a good clustering, patients within the same cluster are more similar to each other than to patients in a different cluster. Patients in our clusters are similar to each other because they share the same risk factors that are most relevant to diabetes and also have similar risk of developing diabetes. We have shown that our clustering can be used as a diabetes index: when the clustering is sufficiently detailed, it outperformed the Framingham score in terms of concordance (ability to distinguish high-risk patients from low-risk patients). While ARM models have also shown excellent predictive performance, their high level of redundancy leads to unnecessary computational cost. In the following discussion, we examine the beneficial properties of the clustering particularly compared to ARM models and the potential of overfitting.

Comparison to Association Rule Mining

Recent developments of ARM[22], including survival association rule mining[9] have demonstrated its applicability in the EHR mining domain and its appropriateness to serve as a diabetes index. The key advantage of the ARM methodology lies in its interpretability: individual rules are straightforward to interpret and the interpretation provides a context around the risk estimate (e.g. the high risk is due to persistent hypertension and severe hyperlipidemia). As previously discussed, the disadvantage of ARM is that it generates an exponentially large, redundant rule set. With many rules applying to the same patient, making prediction for an individual becomes non-trivial[7,9], making a direct comparison between ARM and clustering leave room for arguments. Just to show that the predictive performance of ARM and clustering are similar, we performed a simple, albeit admitted imperfect, comparison. We largely followed the methodology outlined in the studies using ARM to assess the risk of type 2 diabetes[7,14]: we built a Cox model with age and gender as the predictors, and extracted distributional association rules[7,15] indicating an association between the martingale residual and the major risk factors (IHD, hypertension and hyperlipidemia as defined in Table 1 that covered at least 50 patients (same coverage as used for clustering). For each patient, we made a prediction using the most specific rule. The concordance of the resultant model was .7601 with a standard error of 004. This is comparable to the performance of the clustering model. Additionally, both the ARM-based models and our clustering have the ability to automatically discover interactions among risk factors and seamlessly incorporate them into the model or clustering.

Our proposed method goes beyond the state of the art by allowing the user to control the amount of details the clustering should incorporate. This is particularly beneficial, because the amount of detail can be adjusted to the needs of the consumer of the model. For example, when the user of the clustering is an automated clinical decision support system, a highly detailed clustering may be desirable. Computational systems can handle complex models, even as complex as the ARM models, and thus a clustering that incorporates a large amount of details (without overfitting) can be most appropriate.

Another potential use of the clustering produced by our method concerns clinical investigation, where clinicians, rather than computers, view the clustering results. Presenting excessively detailed complex models to investigators can be more distracting than useful, thus a moderately complex clustering may be most desirable. Our method constructs the entire cluster hierarchy upfront allowing investigators to drill down for further details. This can be achieved through further clustering a specific subpopulation (leaf), as needed.

Overfitting

Models as flexible as the clustering-based model or the association rule set are susceptible to overfitting the data. In this application, we were not particularly concerned with the predictive performance of the model as it is secondary to its interpretability. To avoid overfitting, we required the presence of at least 50 patients in each node (or association rule), which is sufficient to reliably estimate their risk. Also, Figure 3 shows no sign of overfitting: increased number of nodes have consistently led to improved performance on a validation set. Nonetheless, when the clustering is used as a predictive modeling tool, the number 50 needs to be tuned more carefully and attention must be paid to the potential overfitting.

In summary, we have demonstrated that our clustering method retains the benefits of existing diabetes risk models and adds its own advantage through allowing for fine control of detail that is presented to the user. This promises great potential of contributing to clinical practice.

Abstract

Natural language processing has been successfully leveraged to extract patient information from unstructured clinical text. However the majority of the existing work targets at obtaining a specific category of clinical information through individual efforts. In the midst of the Health 2.0 wave, online health forums increasingly host abundant and diverse health-related information regarding the demographics and medical information of patients who are either actively participating in or passively reported at these forums. The potential categories of such information span a wide spectrum, whose extraction requires a systematic and comprehensive approach beyond the traditional isolated efforts that specialize in harvesting information of single categories. In this paper, we develop a new integrated biomedical NLP pipeline that automatically extracts a comprehensive set of patient demographics and medical information from online health forums. The pipeline can be adopted to construct structured personal health profiles from unstructured user-contributed content on eHealth social media sites. This paper describes key aspects of the pipeline as well as reports experimental results that show the system's satisfactory performance in accomplishing a series of NLP tasks of extracting patient information from online health forums.

Introduction

Natural language processing (NLP) has been widely leveraged in the biomedical domain in recent years. It has been shown effective in extracting biomedical information from free-structured text data [1, 2, 3]. Many applications have been developed to enhance the performance of clinical information retrieval. The extracted information is sometimes restructured or encoded in a special machine-friendly format for automatic computer processing. Most biomedical NLP applications focus on specific areas and thus extract information from text data in single clinical application areas such as radiology reports [4], discharge summaries [5], medication instructions [6, 7] and nursing narratives [8]. Typical input to these text extraction tasks is formal medical reports that contain precise clinical information about patients. However these reports do not comprehensively reveal the overall health conditions of a patient because of their narrow focus, definitive purpose, and limited scope of information collection aimed at by a single medical report in a specific area. To better understand patient conditions with more depth and breadth, we need to extract health-related information of patients more richly and diversely. A good class of information sources useful for this purpose is the increasingly emerging and popular online health forums, which contain posts in large numbers written by a variety of patients, caregivers, and supporters. Many of these posts voluntarily offer, through narrative text, a board range of information regarding the personal background and medical conditions of patients, including patients' demographic and health-related information, such as patients' living habits, working circumstances, and family history. Such an enriched body of information is typically not included in formal clinical reports. Having access to the personal medical information through the non-traditional communication channel can be a valuable additional resource for clinical and epidemiological research. By extracting the comprehensive scope of patients' health-related information from the relevant posts on online health forums, this study exploits a new opportunity to access patient information that differs from traditional information extraction approaches relying on formal and specialized clinical reports.

*Correspondence can be addressed to S. Xu through songhua dot xu at njit dot edu.

It is noted that many existing studies have attempted to extract information from online forums. For example, Ritter and Mausam propose a method to extract open domain event information from Twitter [9] through topic modeling. Jung propose a name entity recognition method for microtexts in social networks such as Twitter [10]. In [11] Sondhi and Gupta use support vector machine and conditional random field to classify sentences in health forums into two medical categories, including physical examination/symptoms and medications. However they neither extract detailed attributes from those sentences nor attempt to structure or restructure the extracted information. In this paper we propose an algorithmic pipeline that automatically extracts a comprehensive set of patient demographic and health-related information about their posts on online health forums. The goal is to construct structured patient health profiles from unstructured user-contributed content on eHealth social media sites. The derived structured patient health profiles are encoded in the XML format, containing structured and categorized patient information that is easy for computer to read, process, retrieve, and analyze. Such output format can also be easily transformed into different representation models and formats for automated consumption by various third-party systems, e.g. Entity-Relationship (ER) and UML models.

Methods

System Framework

The proposed system comprises a sequence of modules, each responsible for a type of NLP function, which collectively composes our overall application pipeline. The initial input to the pipeline is a corpus of webpages downloaded from a collection of online health forums. The system output is a set of structured patient health profiles. Each module transforms its input data according to its functional role and then subsequently passes the intermediate output to its following module until the final form of the target structured patient profile is generated. The first module is a preprocessor, which extracts the text content of all posts written by or about a user and then merges the result into one user profile. This module also detects and segments the post text into individual sentences for further processing. The second module is a classifier. It assigns each sentence a set of class labels that specify the particular category of patient information delivered by the sentence. The next module is a parser, which utilizes multiple NLP tools to extract health-related attributes from each category of sentences. The last module is an encoder. It generates the final form of the profile of patient information in the XML format. Figure 1 illustrates the overall framework of the proposed system pipeline.

Preprocessing

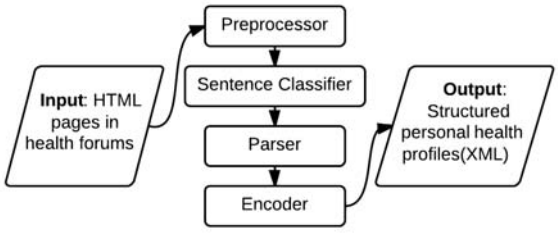

Figure 1: The overview framework of our system pipeline.

The raw data downloaded from the Internet is a corpus of HTML webpages collected from a range of online health forums. These raw HTML files cannot be directly fed into the text mining modules of our pipeline since they carry lots of text irrelevant to our text mining purpose such as HTML tags and Javascripts codes. To address this problem, we develop an HTML parser to filter out such irrelevant content from the raw webpage downloads. The remaining text is retained for the subsequent analysis. The parser has different parsing rules according to different HTML patterns exhibited by various health forums. To identify and gather all posts written by or about a specific patient in the cyberspace, we perform link analysis on each online forum. All analysis results derived for the same user are then merged into a single file for the person. When identifying a user, we also use the HTML parser to detect the user's name according to different tag patterns exhibited in HTML pages downloaded from different forums. For example, posts on the American Cancer Society forum express a user's name through the following string pattern: " .* ", where ".*" means a character string of arbitrary letters and of any length. If we encounter a string in the pattern of " mxperry ", we can parse this string and extract the user name as "mxperry". Each forum adopts its own source code pattern. We respectively explore each site's particular encoding pattern for string parsing when extracting user names. For the tracking purpose, each user is assigned with a unique patient ID number. As mentioned earlier, all detected content corresponding to a common user is then consolidated into a single text file for the user, which we call the user's *online content file*. For each resultant online content file corresponding to a specific user, we then apply a sentence splitter to segment the consolidated post content into its constituent

Class	Description	Subclass	Example
DMO	Demographic information	AGE (age)	11 years old
		GEN (gender)	male, female
		ETH (ethnic)	Asian, Hispanic
BVR	Patient's behavior	WOK (work)	I was a teacher at 2009
		LIF (living habit or behavior)	I have been smoking for 8 years
		STU (study)	I studied for my master degree
		CLI (clinical response)	My back pain relieved after the therapy
FMA	Family information		My father died of cancer
SPM	Symptom		chest pain, cough
ETR	Exam/Test and Results	TES (test)	chest x-ray
		RES (result)	Blood pressure is normal
DIG	Diagnosis		I was diagnosed with stage IV lung cancer
PRO	Medical Procedure /Treatment		surgery, chemotherapy
MED	Medication		I took Lisinopril one time a day
PHY	Physical State		tired, sleepy
PSY	Psychological State		sad, stressed
NOC	Not belonging to any class		

Table 1: The list of sentence classes and subclasses on eHealth forums supported in this work.

sentences. Overall, the preprocessing module transforms the original unorganized collection of webpages downloaded from the Internet to a corpus of personal information files. Each online content file of a user contains the user's patient ID, name or nickname, followed by a list of sentences written by or about the user on online health forums.

Extracting and Classifying Sentences Containing Patient Demographic and Health-Related Information

Our classification procedure regards each sentence in a user's online content file as the basic processing element. By classifying every such sentence, the method offers a finer granularity for information access and processing. For example, different researchers may be interested in different aspects of a patient's information for knowledge discovery and pattern mining. Our method recognizes 11 basic classes of sentences for those appearing on online health forums. Some classes also have sub-classes. The 11 classes are selected based on the medical concepts from the Medical Entity Dictionary (MED) [12], Unified Medical Language System (UMLS) [13], and some extension recommended by the domain experts we consulted with for the project. These resources collectively cover nearly all categories of health-related information supplied by online health forums that are encountered in this study. Table 1 lists all supported classes and sub-classes in this study.

Every sentence in the training set is manually labeled with one or multiple applicable class labels and their corresponding subclass labels, if the latter type of finer-level sentence classification is available. Each sentence may have multiple labels since these sentence classes are not necessarily mutually exclusive, given that a sentence may convey one or more information classes simultaneously. We explore a number of text classification methods such as Naive Bayesian, Bayesian Net, Adaboost, K-Nearest Neighbor, Support Vector Machine (SVM), Sequential Minimal Optimization (SMO), Logistic Regression, Neutral Network, and Decision Tree. Multiple types of text features such as TF-IDF, unigram, bigram, trigram, and words sequence are extracted for input to each candidate classification method. Our implementation chooses the Naive Bayesian classifier as its multi-class sentence classifier in the end because of its robustness and efficiency for short text classification according to empirical evidence. Note that the sequence of sentences may bear an important impact on sentence labeling outcome. For example, a sentence that states a patient's medical test results (RES) is very likely to follow a sentence that states the patient's medical test (TES). According to this observation, we utilize the Hidden Markov Model (HMM) to boost our basic Naive Bayesian classifier. Our implementation utilizes the HMM boosting procedure proposed in [14]. The states in the HMM model correspond to the 11 classes of sentences recognized in our method. Experimental results show that our Naive Bayesian classifier boosted by HMM outperforms other candidate classifiers explored. Using the multi-label classifier mentioned in the above, the method can automatically assign one or multiple class labels for each sentence in the patient's online content file. Those sentences labeled with "NOC," which stands for "not belonging to any class," are filtered out.

Parsing Sentences using NLP Tools to Extract Detailed Patient Information

After we extract sentences that contain a patient's demographic and health-related information using the Naive Bayes classifier, the method can further extract detailed attributes of patient information from each sentence. For sentences of different classes, different natural language processing toolkits are adopted for the parsing task. The patient information extraction result is formatted following the inline XML schema.

Extracting Patient Demographic Information

We use and extend DIVER, a tool developed by Hsieh and Doan [15] that identifies and standardizes demographic variables, to extract patient demographic information from sentences belonging to the class of Demographic information (DMO). In particular, we extract three types of attributes: age, ethnic, and gender. An example is as follows:

Input: <DMO:AGE>I am 35 years old now.</DMO:AGE>
Output: <DMO:AGE>I am <Age>35 years old</Age>now .</DMO:AGE>

Extracting Heath-Related Patient Information

We use MedLEE [1], a medical natural language processing system, to parse sentences that belong to the classes of SPM, ETR, DIG, and PRO. MedLEE has been proved to yield satisfactory performance in processing free-structured clinical text, such as X-ray reports, discharge summaries, sign-out notes, and nursing narratives [2, 8]. MedLEE covers a broad range of concepts and semantic rules in the medical domain such as medication, procedure, body measurement, and laboratory test. The output of MedLEE is represented using a frame-based format. Each frame contains the frame type, frame value, and several modifier slots, which are also represented following a frame-based format. We show an example below that demonstrates how MedLEE structures a sentence that belongs to the symptom class.

Input: severe pain in back
Output: [problem, pain, [degree, severe, [bodyloc, back]]

We can easily transform the frame-based output of MedLEE into its corresponding XML format by extracting each value of the frame as an attribute with the type of the frame used as the tag name. An example is shown below on the transformation process.

Input: <SYP>I suffered from a severe pain in my back.</SYP>
Output: <SYP>I suffered from a <Degree>severe</Degree> <Problem>pain</Problem> in my <Bodyloc>back</Bodyloc>.</SYP>

As medical information is often related to time, organization, and location, we also need to extract those attributes. For such purpose, we adopt the Stanford Core NLP toolkit [16]. It contains a named entity recognition tool that can tag seven types of entities, including Time, Location, Organization, Person, Money, Percent, and Date. Leveraging this tool, we can extract and tag the time, date, organization, and location attributes from a sentence. Below is a parsing example on a sentence that discusses a medical procedure:

Input: <PRO>I received chemotherapy at CTCA in Oklahoma in 2009.</PRO>
Output: <PRO>I received <Procedure>chemotherapy</Procedure> at <Organization>CTCA</Organization> in <Location>Oklahoma </Location> in <Date>2009</Date>.</PRO>

Extracting Medication Information

For sentences that discuss medication information, we use the MedEX, a medication NLP tool introduced in [6], to extract concrete attributes involved, such as drugName, strength, route, frequency, form, dose amount, intake time, duration, and dispense amount. MedEx can extract more detailed attributes than MedLEE in the above area. Below is an example:

Input: <MED>I was discharged on Lopressor 50 mg, take 1 Tablet by mouth two times a day.</MED>
Output: <MED>I was discharged on <DrugName>Lopressor</DrugName> <Strength>50 mg</Strength>,

take <Dose>1 Tablet</Dose> <Route>by mouth</Route> <Frequency>two times a day<Frequency>.
</MED>

Extracting Patient Behavior

For sentences that describe patients' behaviors, physical and psychological states, as well as family information, the involved information often does not fall into any single domain. To extract those attributes, we need a general-purpose parsing tool. In this subsection, we are concerned with the method for extracting patient behaviors. Our system implementation utilizes the part-of-speech parser provided by the Stanford Core NLP toolkit, which can generate a parse tree for each input sentence. This parser has a good reputation in processing text in the biomedical domain [17]. An example of the generated parse tree is as follows:

Input: <BHV:LIF>I smoked very often in the last 10 years</BHV:LIF>.
Parse Tree: (ROOT (S (NP (PRP I)) (VP (VBD smoked) (ADVP (RB very) (RB often)) (PP (IN in) (NP (DT the) (JJ last) (CD 10) (NNS years))))))

We first identify the subject of the sentence by finding the noun phrase (NP) that appears immediately before the verb phrase (VP), where both phrases are in a simple declarative clause (S), which must be the child node of the sentence root. In this example, we identify "I" as the subject following the above heuristic. For sentences that describe patient behaviors, our approach assumes that the verb phrase in a predicate usually contains the direct description of patient behavior. Such verb phrase usually locates at the right sibling of the sentence subject. After identifying the verb phrase, we then filter out the descriptive words in it, including the adverb phrase (ADVP) and preposition phrase (PP), so that only verbs would remain. We then tag each remaining verb as a patient behavior attribute. We also use the Stanford named entity parser mentioned in the previous section to label the time, date, organization, and location appearing in an input sentence. An example output is shown below for the same input displayed in the above:

Output: <BHV:LIF>I <Behavior>smoked</Behavior> very often in the <Date>last 10 years</Date>
</BHV:LIF>.

Extracting Patient Physical and Psychological States

To extract patient physical and psychological states, we use the same parse tree method mentioned in the above. The difference is that this time the main focus is on extracting adjective phrases in an input sentence instead of verb phrases because adjective phrases are generally more descriptive of patients' physical and psychological states. In particular, by identifying the adjective words (JJ) in adjective phrases (ADJP), we can extract attributes regarding patient states. An example is as follows:

Input: <PYS>I feel scared and stressed in the first two weeks.</PYS>
Parse Tree: (ROOT (S (NP (PRP I)) (VP (VBP feel) (ADJP (JJ scared) (CC and) (JJ stressed)) (PP (IN in) (NP (DT the) (JJ first) (CD two) (NNS weeks))))))
Output: <PSY>I feel <Psy-state>scared</Psy-state> and <Psy-state>stressed</Psy-state> in the first two weeks.</PSY>

Extracting Patient Family Information

For those sentences that contain family information (FMA) such as family medical history, we extract any mentioning of family member(s) in the sentences. We first use the parse tree to find the subject of an input sentence. We then search the appearance of any subject word according to a vocabulary list regarding different roles of family members according to English Grammar Online [18]. The list contains 45 words. If the subject word appears in the list, we then label it using the tag "Member." An example is as follows:

Input: <FMA>My father died of lung cancer at the age of 83. </FMA>
Output: <FMA>My <Member>father </Member> died of lung cancer at the age of 83. </FMA>

Results

Data

We downloaded a total of 11274 webpages from a number of US health forums and hospital association websites, such as American Cancer Society's Cancer Survivors Network, eHealth Forum, PatientsLikeMe, etc. After the pre-processing stage, we constructed 3196 patients' personal online content files using the pipeline discussed earlier. After segmenting these content files into individual sentences, we obtained 9730 unique sentences as our full experimental data set. We then invited 4 researchers in the domain of medical informatics to manually assign sentence class labels for all these sentences with the help of MED and UMLS. Table 2 shows the 10 online health forums where we collect our data and their size of patient population respectively.

Forum Name	URL	Population

Sentence Classification

To explore the effectiveness of the new pipeline, we tested the overall performance of different classifiers mentioned in Section 3. We use Weka [19], a widely used machine learning software, to run our experiments. From the whole dataset we randomly chose 7000 sentences as the training data and the rest 2730 sentences as the testing data. We adopted the cross-validation schema to benchmark the learning performance. After we train our sentence classifier through the training dataset, we measured its performance on the testing dataset. We performed ten-fold cross validation to measure the precision, recall, and F-rate of the method.

Table 3 shows that in terms of the sentence classification performance, the Naive Bayesian classifier boosted by HMM outperforms all other classifiers. Although the rest of the classifiers may be more effective for tackling certain text classification tasks, for the particular sentence classification task concerned in this study, we adopted Naive Bayes as the optimal learning device for our implementation. Table 4 shows that the sentence classification module implemented in our pipeline yields generally satisfactory performance in terms of its precision, recall, and F-rate, especially in the medically related areas. In such areas, text tends to be written using more medical terms and formal language than those in the non-medical areas. This particular language characteristic may affect the choice of the optimal text classifier. Figure 2 shows the percentages of sentences in each class. According to the statistics, each sentence class has enough samples for training the corresponding classifier.

Classifier	Precision (%)	Recall (%)	F-rate (%)	Classifier	Precision (%)	Recall (%)	F-rate (%)
NB-HMM	93.2	90.9	91.7	SVM	82.2	70.3	75.8

Table 5: Performance of information extraction in different sentence classes.

Extracting Detailed Patient Information

For the 9730 sentences analyzed in our experiments, those labeled with "NOC" are first excluded. We then utilize a set of NLP tools integrated in our prototype system implementation to extract attributes containing detailed patient information for different classes of sentences respectively. For the evaluation and benchmarking purpose, the information extraction accuracy is manually verified by four domain experts according to MED, UMLS, and some extensions made by them based on the sentence classes not related to MED and UMLS directly. Since the demographic information usually requires more precise extraction, we further report the information extraction performance for each demographic attribute. To further demonstrate the effectiveness of the information extraction module, we compare its performance with that of another peer concept extraction tool—BioTagger-GM [20]. The peer tool uses machine learning techniques to train semantic taggers for extracting medical concepts from clinical documents. We apply both our method and the peer method to extract ten classes of information concerned in this study, i.e. all sentence classes except for the "NOC" class. The results yielded by both methods are then compared. Figure 3 shows that our proposed information extraction pipeline, which collaboratively leverages multiple NLP tools, consistently outperforms the peer method.

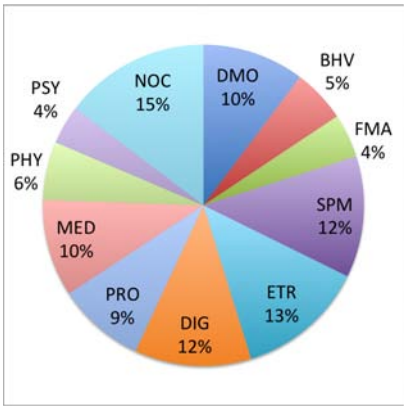

Figure 2: Percentage of sentences in each class.

Table 5 shows that the information extraction module of our implemented pipeline performs satisfactorily for all sentence classes. Some categories received relatively low F-rates such as life behavior. A potential reason was due to the more complex language and ambiguous vocabularies often used for conveying information of these categories.

Table 6: Coverage of different classes of information on top ten most popular online health forums in this study.

Coverage of Patient Information on Different Health Forums

We examine the distributions of different categories of patient information on different online health forums and websites. The amount and range of demographic and health-related patient information available on a forum indicate the forum's richness of information on certain patient conditions. We measure the information coverage of a forum using the ratio of the users on the forum whose extracted health profiles contain the desired class of information. Table 6 shows the respective sizes of patient populations on top ten most popularly encountered health forums in our study. We can see that although the information coverage varies among different domains and health forums, our system can extract a relatively comprehensive set of patient information since the information coverage ratios for all classes on each of the top ten forums consistently exceed 60%.

Distribution of Patient Demographic Information on Different Forums

By extracting patient's demographic information we can further analyze the demographical composition of different patient groups, which can help medical researchers more insightfully analyze the common characteristics and behavior features of the group of the patients. For this need, the implemented prototype system also aims to extract comprehensive patient demographic information from online health forums. Figures 4 and 5 respectively present the age, gender, and ethnic distribution of users on the top ten most popular health forums concerned in this study. Figure 4 shows the age curves of patients extracted from the ten forums respectively. Their peaks

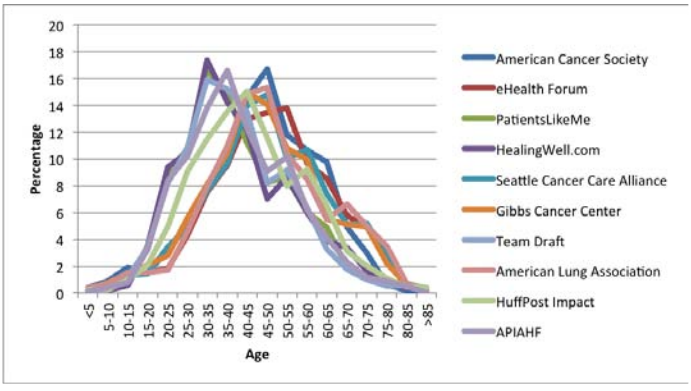

Figure 4: Patient age distributions on each of the ten most popular forums analyzed in this study.

fall into the range of 30 to 55 years old. We assume that the sparse presence of old patients might be partially caused by the inability of those people in accessing and participating on online health forums. We also find that the average age of patients on cancer forums is greater than that on general health forums, which indicates cancer may be more likely to affect older people than young people. In general, the patient demographic statistics extracted can provide valuable clues for analyzing online patient content in an age-adjusted manner.

(b) Ethnic distribution

Figure 5: Patient gender and ethnic distributions on each of the ten most popular forums analyzed in this study.

Discussion

The proposed biomedical NLP pipeline and its prototype system implementation extract patients demographic and health-related information in a wide range of categories from online health forums. For each category of patient information present on health forums, a corresponding set of NLP procedures are applied to extract values of detailed category attributes. The set of supported information categories is also adaptive, which can be adjusted and expanded over the time to extract more comprehensive patient information. One potential limitation of this work is that a patient may register on mutiple health forums and possibly using different user names or nicknames, none of which may be their real names. How to detect and merge different profiles of the same patient into one consolidatd record is a meaningful algorithmic problem deserving immediate future studies.

Conclusion

We proposed and developed a software pipeline for extracting and structuring patient's personal and health related information from online health forums. Our experimental results demonstrated the usability and effectiveness of the prototype implementation. The automatically acquired health profiles of online patients can provide valuable informational aid for cyber-mining based eHealth research.

Abstract

Practitioner guidelines simultaneously provide broad overviews and in-depth details of disease. Written for experts, they are difficult for patients to understand, yet patients often use these guidelines as a source of information to help them to learn about their health. Using practitioner guidelines along with patient information needs and preferences, we created a method to design an information model for providing patients access to their personal health information, linked to individualized, relevant supporting information from guidelines within a patient portal. This model consists of twelve classes of concepts. We manually reviewed and annotated medical records to demonstrate the validity of our model. Each class of the model was found within at least one patient's record, and seven classes of concepts appeared in over half of the patients' records annotated. These annotations show that the model produced by the method can be used to determine what guideline information is relevant to an individual patient, based on concepts in their health information.

Introduction

Patient portals are web-based applications designed to allow patients direct access to content from their medical record. Portals can also provide patients with general content relevant to their health, similar to what they would find at MedlinePlus[1], the Mayo Clinic website[2], or other consumer health websites. While not yet commonplace, large healthcare institutions are beginning to design and implement patient portals. Compelling reasons to do so include: the potential for an informed patient population, government endorsements via policy and funding, and ubiquitous digital infrastructure that allows patients easy access to information. Portals have the potential to empower patients; accessing personal health information encourages patient involvement, enabling them to make decisions based on the information they have received[3]. Applications that promote patient empowerment have also been shown to improve clinical outcomes and health statuses[4].

Searching for health information is now the third most popular task completed online[5]. However, the content available to consumers spans a wide array of quality in their accuracy and completeness of information[6]. In addition, not all accurate sources regarding health and disease will be relevant to an individual. Here, we define "relevance" as how well the information meets the information needs of the user, based on the idea that information that satisfies the information need will fill the knowledge gap of the user[7]. Searching for health information, patients are left to mull content, attempting to determine what is applicable to their personal health and often having difficulty doing so[1,8]. Medical content intended for patient consumption lacks personal context; while letting individuals view information on subjects that concern them, such content does not provide a contextual overview or specific details regarding their diagnosis and the process of their care. Professional medical guidelines also lack a tailored view of the healthcare process relative to a given patient, often enumerating a spectrum of medical concepts (symptoms, test, diagnoses, etc.) that requires an expert to make logical inferences. As such, a lay patient looking at a guideline may be overwhelmed with information, and may not properly comprehend or appreciate the nuances within the guideline.

Motivation

A model for personalized patient guidelines can provide consumers with supporting information regarding their health, presented in a fashion that provides context and chronology, and allowing them to see how individual concepts and processes relate together and to their health. The design of this information model should tailor the content of guidelines to the content of individual medical records in order to support the understanding of relevant information and to lessen cognitive overload. In this work, we address the issue of developing a methodology to model relevant supporting information to medical record content. The construction of the model was defined by the overlap between patient information needs and preferences, relevant professional clinical guidelines, and medical record content. More specifically, content from each of these three domains was examined to determine shared concepts to be included in the model. Examples of each information source area may be seen in Figure 1. Using this model creation method, we were able produce a model that matches relevant supporting content from guidelines to those concepts patients are interested in within their medical records.

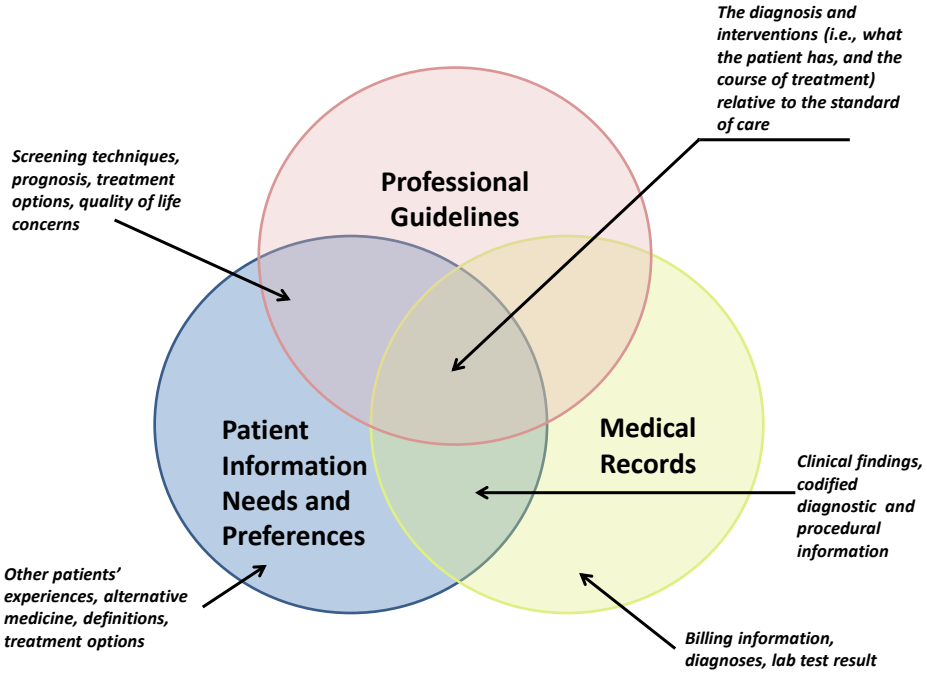

Figure 1. Venn diagram illustrating cross section of information areas of interest, which falls in the overlap of the three domains.

Patients undergoing diagnostic tests have numerous sources of traditional supporting information including pamphlets, informational clinics, and support groups. The provision of electronic health information is also widely available, as noted above, in the form of consumer health information sources[1,2,9-11], and personal health records (PHRs). Even before a diagnosis is made, data is collected on symptoms, procedures and test results. The testing process is often a stressful time for patients, with new information being introduced, both via the healthcare setting and what patients find themselves online. Yet, there is a lack of a consistent, reliable linkage between personal health information, information found within a portal, and other online supporting content. Patients now have ensured access to their medical record via the Health Insurance Portability and Accountability Act, (HIPAA). If such content is to be ultimately comprehensible to patients (e.g., to make informed decisions about their own care), online methods such as patient portals should not simply display medical record content verbatim, but instead make the content understandable to consumers with changes in visual presentation, abstraction level, and vocabulary as necessary to accommodate the lay person.

Professional clinical guidelines provide views of multiple granularities on disease-specific information. However, like individual health records, the content of these guidelines contain medical jargon and typically require the lens of clinical experience and/or knowledge to properly understand the information. By way of illustration, a lung cancer

screening patient with a history of smoking and additional symptoms (e.g., cough, unexplained weight loss) may consult an online professional guideline (e.g., National Collaborating Center for Cancer[12], Figure 2) to learn more about his risk factors and the diagnostic procedures. Yet, as such guidelines outline all possibilities, not just the relevant pathway to the individual's circumstances, the lay reader may become more confused (if not anxious) about his condition. Indeed, professional guidelines take multiple potential symptoms and findings into consideration, and do not represent a patient-specific series of events. For example, while some patients being assessed for non-small cell lung cancer (NSCLC) have an x-ray, others do not. Professional guidelines, although appropriate for practitioners, present information that is sometimes irrelevant, redundant or too complex for the information needs of an individual patient. Given this consideration, patient records cannot simply be linked to professional guidelines as a whole. Depending on the patient, only parts of the practitioner guidelines are applicable. Therefore, guidelines presented to a patient need to be tailored to the individual based on concepts present in their medical record.

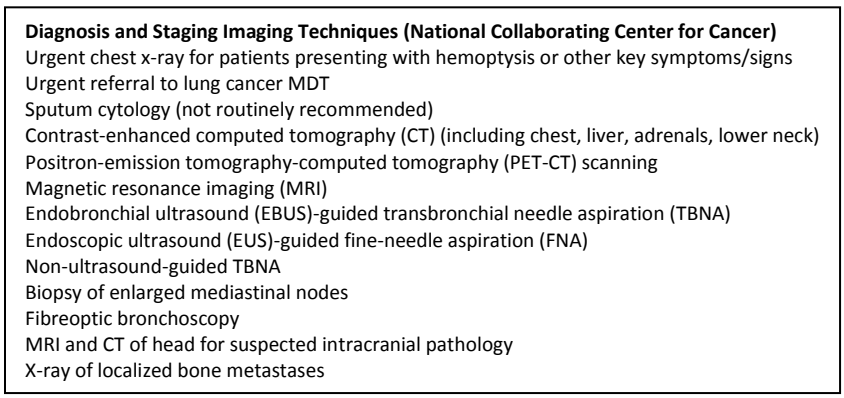

Figure 2. List of imaging techniques from National Collaborating Center for Cancer page on lung cancer screening.

Background

Linking medical record content to supporting information has become commonplace for clinicians, with numerous electronic health record (EHR) systems providing decision support. It has been proposed that patients may be provided with additional information via their PHR in a similar manner[13]. However, the linkage of supporting information for patients via hyperlinks and embedding content is relatively new. MedlinePlus Connect is a web service that accepts ICD-9 codes and returns links to health information[14]. To use this service, institutions must opt in and provide concept unique identifiers (CUIs) from reports. This process also requires the patient to leave the content of their health portal and visit pages from the MedlinePlus website. Numerous healthcare organizations are now using this web service, including Columbia University Medical Center, Sutter Health System and the University of Utah. This system is dependent on correct CUIs in order to retrieve relevant information. However, this pairing of supplemental information can be hindered by incorrect or inexact matches, exclusion of appropriate child matches (e.g., choosing "cough" instead of "chronic cough"), and context dependent definitions[15].

Kaiser Permanente has designed an in-house encyclopedia for patients using their portal[16]. Patients can access the encyclopedia pages while onsite. Each page contains specific information on a medical concept. Yet, the content accessible is not specific to the patient. While patients should not be prevented from viewing additional content that is not necessarily related to the patient, neither MedlinePlus Connect nor the Kaiser Permanente encyclopedia directs patients towards information that focuses on the concepts that have a positive occurrence in their record. In other words, patients can be directed toward information on a biopsy, even if it was decided not to do a biopsy but the word "biopsy" is mentioned in a report. Moreover, while online resources like MedlinePlus Connect can direct patients to relevant supporting information, they do not fully demonstrate how concepts may relate within the framework of a patient's encounter and the narrative of the PHR.

Although there are numerous information models for health information (Heath Level 7's [HL7] Clinical Document Architecture [CDA], Digital Imaging Communications in Medicine [DICOM], etc.), the majority are standards created to support interoperability among healthcare institutions, with practitioners as the end users[17]. To the best of our knowledge, none focus solely on the patients' information needs and how to link patient record content with supporting content. Often, patient information models are the product of using an information model designed for clinicians and then implementing it for a patient view of the information[18-20]. Little study has been done on how patient information needs and preferences should inform information models for patients.

In prior work, we conducted a survey of 41 patients who were undergoing screening or treatment for lung cancer at a clinic in UCLA, regarding their information needs and preferences[21]. Question topics were the result of a literature review of patient information needs and preferences. Results demonstrated that patients were particularly interested in concepts that were important to their diagnosis (90%) and imaging (90%). This earlier work and insight helps guide the development of the proposed information model.

Material and Methods

Class Definition: Literature Review

To test the process of designing the model, the domain of lung cancer screening was chosen. To create an explanatory information model that links guideline information with clinical data for the patient, we first defined a set of classes through a literature review of patient information needs. This literature review is the same utilized to design the survey in McNamara et al. 2014[21] and was performed in March 2013. To conduct this literature review, we used Google Scholar and PubMed search engines to find articles on patient information needs, using the terms "patient information needs", "patient portal" and "patient information preferences". Approximately 5 million articles were returned; however after manually reviewing several pages of ranked results, we observed that the relevance of articles to our study diminished. For example, large numbers of articles focused on other groups' information needs or medical procedures involving the portal vein, both subjects are outside the scope of this study. We reviewed the first 100 articles returned by PubMed and the first 50 returned by Google Scholar ranked by relevance. To be included, an article had to discuss patient information needs and preferences, and be published in the last twenty years. Articles were deemed to discuss patient information needs and preferences based on the content of their title and abstract. In total, 26 pertinent articles were identified. We choose to specify our class set from this literature review, as defining a model relevant to patient information needs is our overarching goal, rather than deriving classes from clinical guidelines, which may be irrelevant to patients. We then analyzed the subset of documents that met our criteria of content and publication years and noted themes that occurred throughout. If a theme was noted in at least three separate articles, the articles in which it was included were added to our focused annotated bibliography. This process resulted in thirteen articles within the focused annotated bibliography[22-34]. Each theme from the bibliography was included as a candidate class. This literature review resulted in the five candidate classes of: Diagnosis[23, 24, 28, 29, 31, 33, 35, 36], Treatment[22-24,28-31,33,35], Common Side Effects of Treatment[22, 23, 29, 35], Symptoms[22, 29, 37, 38], and Diagnostic Test[24,30,34]. As made evident by the literature review, these classes of concepts appear to be popular across patient populations, as such information helps patients to understand their diagnosis and cope with prognosis and treatment. These initial candidate classes could thus serve as the basis for class creation across domains of cancer screening.

Concept Definition: Guideline review

To generate a candidate list of clinical concepts (e.g., normalized instances of nouns found within the diagnosis guidelines) with associated contextual explanations, we reviewed the lung cancer diagnosis guidelines from the National Collaborating Center for Cancer and UpToDate[12, 39]. As seen in Figure 3, these guidelines were visualized as a flowchart, composed of connected nodes.

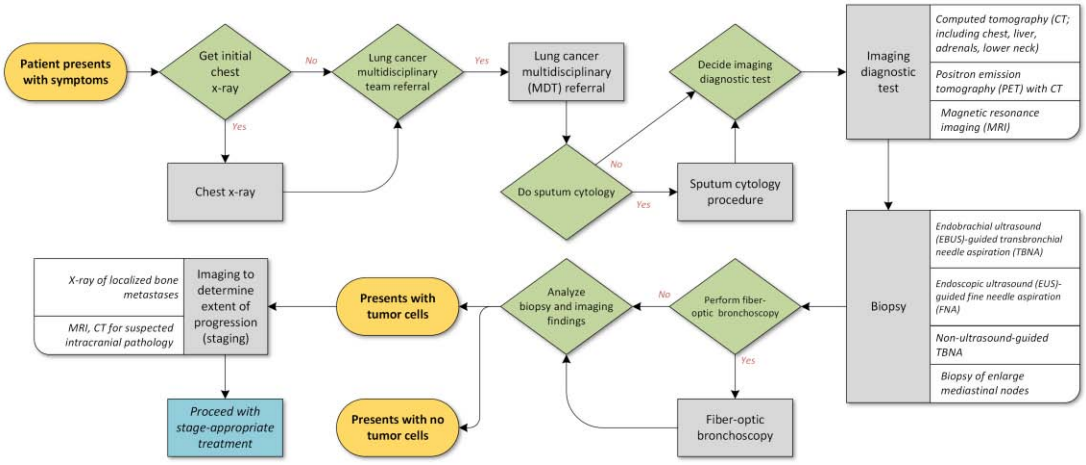

Figure 3. Simplified version of practitioner guidelines for lung cancer diagnosis.

Each node was then considered a candidate concept for the model. With this candidate list, we began to organize the data model, with the constraint that concepts included in the model were representative of classes seen in our literature review on patient information needs, and that the classes included were indicative of the screening process as made evident in our review of the professional guidelines. Table 1 shows our initial model structure of patient information need classes and corresponding concepts.

Table 1. Initial model of concepts and classes.

Class	Tumor	Symptoms	Diagnostic Test
Number of Sources Citing Information Need	8[23,24,28-30,33,35,40]	4[22,27,29]	3[24,30,34]
Guideline Concepts mapped to Class	Tx, T0, Tis, T1, T2, T3, T4	Weight Loss, Fatigue, Chest Pain, Lung Infection, Breathing Trouble, Cough, Hoarse Voice	Sputum Test, Bronchoscopy, Thoracentesis, LDH, PET Scan, Albumin, Chest X-ray, Computed Tomography , Video Assisted Thoracoscopy, Pulmonary Function Test, MRI, Thoracotomy, Fine Needle Aspiration, Mediastinoscopy, Blood Test, Bone Scan

Manual Annotation of Medical Reports

After this initial linking of candidate concepts to classes, we manually annotated pathology, laboratory, oncology, and radiology reports from ten patients to determine the presence of these candidate concepts in reports. We then revised the working list of concepts based on the actual content of reports. This process helped to ensure that the smallest units of information within the model – the concepts – were indeed reflective of the content of reports. During this process, we found that there were concepts indicative of indeterminate nodules, which had not been previously included in the model. This finding required enumeration of several new concepts concerning an indeterminate nodule. We also found that sometimes instead of reporting a TNM stage, a Roman numeral stage was instead reported. Additionally, we found that a patient's smoking history is frequently mentioned in their reports. As smoking history information is relevant to understanding the application of a lung cancer guideline, we decided that these concepts should be incorporated into the model. However, it was found that these concepts were not well-represented by any of the existing classes. Thus, we revised the list of classes to add the classes of Nodule, Stage and Smoking Status. All concepts and classes were then manually matched to their Unified Medical Language System (UMLS) concept unique identifiers (CUIs).

Revision Based on Survey Results

Based on survey results from McNamara et al. 2014[21], we revised the model one more time to include concepts pertaining to the imaging process and concepts relevant to diagnosis. To provide for more detail regarding imaging, the Diagnostic Test class was broken into five classes (Imaging, Biopsy, Excision, Pulmonary Function, and Other Diagnostic Test). To focus on concepts relevant to diagnosis, the Comorbidity class was added. The Comorbidity class contains concepts that are lung disease comorbidities common in smokers.

Manual Annotation of Medical Records

To determine the overlap between the model's concepts and those within patient records, the first author manually annotated an additional unseen 60 patients' oncology, pathology, radiology and laboratory documents. First, a combination of report types (e.g., imaging, pathology, radiology, oncology) and keywords (e.g., "tumor", "smoking", "diagnosis", etc.) were used to filter documents that contained a concept of interest. These reports were then manually reviewed to determine if the concept was present. If, after reviewing these documents there remained unobserved concepts, a patient's entire report set of documents was reviewed to ensure no concept present in a history was unaccounted for.

Results

The finalized information model consists of twelve classes, as seen in Table 2. Nodule is the class that captures the presence of an indeterminate nodule, as well as its location and size. Tumor, while referencing the same nodule, is only utilized when there is confirmation of cancerous cells. Related to this, the class of TNM contains concepts of individual stages of tumor progression, as taken from the TNM staging system of lung cancer[41]. As made evident by

annotations, sometimes Stage I-IV is reported instead of TNM, so the Stage class contains concepts to account for this method of staging. The Smoking class contains a concept that confirms a smoking habit (yes/no), and once confirmed, quantifies it with the concept of pack year history. The Symptom class does not contain every symptom a patient with lung cancer might experience. Rather, it contains only those symptoms commonly experienced by patients as noted in Corliss et al.[9].

The first revision of the model produced a single Diagnostic Test class containing a wide range of diagnostic tests (pulmonary function, imaging, biopsy) that can be used in the diagnosis of lung cancer, as indicated by the National Comprehensive Cancer Network and UpToDate[12, 39]. However due to surveyed patients' interest in imaging, it was decided that the Diagnostic class should be divided into five new classes to allow for a finer granular representation of concepts pertaining to imaging. The five classes are: Biopsy, Imaging, Excision, Pulmonary Function, and Other Diagnostic Test. The Biopsy class is meant to cover all likely types of biopsies associated with the screening process, with the concept "Other Biopsy" to accommodate all other types of biopsy. Similarly, the Imaging, Excision, and Pulmonary Function classes contain concepts reflective of the most common types of concepts associated with them. The Other Diagnostic class contains those concepts that didn't fit into any of the other Diagnostic classes, but were found in the guidelines and reflective of patient information preferences. The Comorbidity class is concerned with smoking related comorbidities, as the majority of lung cancer patients either have smoked or were exposed to second hand smoke.

Out of the 60 patients records annotated for the concepts within these twelve classes, 33 contained the class TNM, 49 contained the class Tumor, and 21 had concepts from the class Stage. 57 patients had concepts from the class Nodule, 35 had concepts from the class Smoking, 56 had concepts from Biopsy class. The Comorbidity class was found in 24 patients' records, 5 patients had concepts from the class Excision. 58 patients had concepts from the class Imaging. Only one patient exhibited concepts from the Pulmonary Function class, one patient had concepts from the Excision class, and one patient had a concept from the Other Diagnostic class. 37 patients had concepts from the Symptoms class.

Table 2. Revised Model of Classes and Concepts.

Symptoms	TNM	Tumor	Stage	Nodule	Smoking Status	Comorbidity	Excision	Imaging	Biopsy	Pulmonary Function Test	Other Diagnostic Tests
Weight Loss	TxNxM*x*	Tumor Present (Y/N)	I	Nodule Present (Yes/No)	Smoker (Yes/No)	COPD	Video-Assisted Thoracic Surgery (VATS)	X-ray	CT-Guided Lung Biopsy	Spirometry	Sputum Test
Fatigue		Tx	II	Nodule Location	Pack Year	Pulmonary Fibrosis	Mediastinoscopy	Computed Tomography	Brochoscopy	Body Plethysmograph	Bone Scan
Chest Pain		T0	III	Nodule Size		Chronic Obstructive Asthma	Thoracotomy	PET Scan	Fine Needle Aspiration	Gas Diffusion	
Lung Infection		Tis	IV	Ground Glass		Chronic Bronchitis		MRI	Thoracentesis		
Breathing Trouble		T1		Multiple Ground Glass		Emphysema			Other Biopsy		
Coughing Blood		T2		Solid							
Hoarse Voice		T3									
		T4									
		Metastases									
		Tumor Location									
		Tumor Size									

Discussion

Based on a literature review of patients' information needs, we designed a method to create an information model for patients that links medical record concepts with guideline content. This method consisted of looking at patient information needs and preferences, and determining which of those also fell within the domains of practitioner guidelines and medical record content. The model is intended to aid in patients' information comprehension. Screening for any disease is complicated and detailed, and can be stressful for the patient, as they encounter and process new information. By providing classes of concepts relevant to the information needs of patients that can be linked to guideline content, the model promotes directing patients to contextualized information relevant to their health. We demonstrated the application of this model within the domain of lung cancer screening by manually annotating 60 lung cancer patient records. While no one class' concepts were present in every record, every class was represented in at least one patient's record. The model's concepts can therefore be used to annotate a patient's record and collect

a set of domain specific concepts. These concepts can then be used to determine what guideline content is relevant to a particular patient's record, based on the concepts within the record. For example, if the concept "CT Guided Lung Biopsy" is found within a patients' record, additional supporting information on the process of getting a CT lung biopsy can be provided to the patient within the same application (i.e. a portal), in which they are accessing their record.

In a prior study, we surveyed 41 patients at a lung cancer clinic at the University of California Los Angeles, to determine how accurately this information model reflected their perceived needs[21]. The survey results support the relevance of our model. 66% wanted information about their health problems, and 90% wanted to know about information on their diagnosis. While less than half (32%) agreed that it was difficult to find information, 61% would like to see terminology from their medical reports defined. This alludes to patients having information available to them, but not necessarily being able to understand it, reaffirming a need to make medical record content more accessible to patients.

Although the concepts of the model are specific to the domain of lung cancer, this method of reviewing patient information needs and preferences, guideline review, and medical record annotation can be used to create an information model for patients undergoing screening in another domain of cancer. In addition, the model produced by the method will likely be similar across cancer domains. Many of the classes produced by this information model method, with perhaps the exception of smoking, would likely be reproduced when the method was implemented in another domain, for instance that of breast cancer. The classes of Nodule, Tumor, and Stage are applicable within breast cancer, as unknown phenomena can be captured by the concept "nodule", and malignant findings are referred as a "tumor" and staged using the same hierarchy of staging. Likewise, while the type of imaging most common varies by type of cancer (mammogram for breast cancer), the Imaging class can easily to altered to focus on those methods most prominent with a particular diagnosis.

Implemented within a portal, this model may allow patients to more effectively learn about concepts within their medical record. While users can currently read their records and then search for information online on concepts found within the record, the proposed model facilitates the automatic linking of record content to educational content by filtering content for an individual patient based on disease presentation within their record. To realize this, natural language processing (NLP) tools may be trained to mine model concepts from patient records, and links from the records to the educational content can be provided via a patient portal. For example, if a patient were to see the concept "CT scan" within their record, they could be provided with links to the definition of a CT scan, images of a CT scanner, example CT scan results, and information on why a CT scan is used in lung cancer screening. This provision of educational content is similar to the personal health record level three as presented in Krist and Woolf 2011[43].

Limitations of this work include: a limited sample size from one institution was used to learn concepts for the model, the assumption that patients' perceptions of what they want to see from their record aligns with their actual information needs, and that annotations in this work were created by one researcher. These limitations may have biased our results to make the model appear to fit better than it will with records from other institutions, or for other annotators.

Our future work includes using this model within a portal as the basis for an information visualization that links patient medical information to guideline content, thus creating personalized guidelines. User studies will be conducted to determine the extent to which the model is successful in helping patients to understand information regarding their lung cancer diagnostic process. We are currently in the process of designing a patient portal that utilizes this model. Once this program is finalized, we will recruit patients from a UCLA lung cancer screening clinic to use the portal and complete a survey based on their perceptions of how well the model meets their information needs. Additional future work may also include the automation of the annotation process using NLP.

Conclusion

We designed and implemented a method to create an information model that links concepts from medical records to relevant information from practitioner guidelines indicative of patient information needs and preferences. Classes for the model were derived from a literature review on patient information needs and populated with concepts found in professional guidelines. Here the application focused on the domain of lung cancer, but is anticipated to be applicable across cancer domains. The revised model was used to annotate 60 patients' records, were it was found that each class was present in at least one patient's record, and that seven of the twelve classes were present in over 30 patients' records.

Identification and Management of Information Problems by Emergency Department Staff

Alison R. Murphy, BS, Madhu C. Reddy, PhD
The College of Information Sciences and Technology,
The Pennsylvania State University, University Park, PA

ABSTRACT

Patient-care teams frequently encounter information problems during their daily activities. These information problems include wrong, outdated, conflicting, incomplete, or missing information. Information problems can negatively impact the patient-care workflow, lead to misunderstandings about patient information, and potentially lead to medical errors. Existing research focuses on understanding the cause of these information problems and the impact that they can have on the hospital's workflow. However, there is limited research on how patient-care teams currently identify and manage information problems that they encounter during their work. Through qualitative observations and interviews in an emergency department (ED), we identified the types of information problems encountered by ED staff, and examined how they identified and managed the information problems. We also discuss the impact that these information problems can have on the patient-care teams, including the cascading effects of information problems on workflow and the ambiguous accountability for fixing information problems within collaborative teams.

INTRODUCTION

Hospitals are highly collaborative, information-intensive environments where patient-care teams rely on the accuracy and availability of information to provide safe and effective patient care. However, hospital staff frequently encounter information problems. In this paper, information problems are defined as any wrong, outdated, conflicting, incomplete, or missing information that may interfere with the ability of hospital staff to do their work. Although these information problems have always existed in paper records,[28] there is an increasing need to focus on information problems in electronic records due to the tremendous growth in the use of electronic health record (EHR) systems.

Due to recent U.S. government legislation, there has been an acceleration in the transition from paper-based records to EHR systems. These electronic systems also include the use of other information technology systems that can be integrated with EHRs, such as computerized provider order entry (CPOE) systems.[25,26] Although these EHRs can provide a number of benefits,[3,7,11,24] the use of EHRs do not necessarily eliminate information problems, such as wrong, outdated, conflicting, incomplete, or missing information.[3] In some cases, EHRs can actually introduce new types of information problems,[3,7] such as the unintentional selection of default values[2] and the truncation of data entry fields resulting in the loss of patient data.[23] These information problems can lead to issues among the patient-care team including ambiguity about what treatments/procedures were done to a patient,[3] medical decisions being made based on wrong or outdated information,[16] and even the occurrence of medical errors that could harm patients.[3]

Current medical informatics research focuses primarily on what causes these information problems within hospitals[2,3,6,7,11,16,23,24,29] and the impact that the information problems have on the workflow of hospital staff.[1,3,4,8,9,21] However, there is still limited research that explores how these information problems are identified and managed by the patient-care teams who encounter them during their daily work. If they are not properly identified and managed, there may be serious consequences such as medical errors that harm the patient. Therefore, the goal of this paper is to provide a better understanding of the types of information problems encountered by emergency department (ED) staff, and how the staff identified and managed information problems within a highly collaborative emergency department. We will also discuss the impact that information problems have on collaboration, including the cascading effects of information problems on workflow and the ambiguous accountability for fixing information problems in collaborative teams.

BACKGROUND

Information problems have been extensively studied in the medical informatics community because of the serious impact that they can have on medical errors in patient care. These existing studies primarily focus on the *causes* of information problems, which include information problems caused by the *design* of EHR systems[3] and by the *users*

of EHR systems.[7] Additionally, researchers also discuss the impact that information problems can have on the workflow of hospital staff.

Information Problems Caused by EHR Design

It is a challenge to build information systems for the fast-paced and information-intensive environment of hospitals. Researchers describe how EHR systems tend to be overly structured and designed with rigid rules that encourage data standardization (e.g., drop-down menus, text entry restrictions), which can lead to information problems caused by the design of the EHR.[3] Koppel et al. [11] discuss how system design can cause problems with medication ordering, including: fragmented displays that prevented a coherent view of patients' medications, inflexible ordering formats that led to wrong orders, and separation of system functionality that resulted in double dosing or incompatible orders. Abramson et al.[2] also describe how a medication ordering system automatically selected the default dosing in medication order forms resulting in inaccurate medication requests.

Additionally, Dillion & Lending[6] also identify information problems caused by systems preventing users from entering descriptive data into a record and, instead, forcing them to select values from drop-down menus that are not considered intuitive to the user. EHR design can also prevent the entry of important psycho-social information about patients, which nurses argue, "*provided continuity of care…[and] a richer picture of the patient's situation*" (p. 2065).[29] Furthermore, EHR researchers describe system bugs that cause information problems. This includes EHR systems that truncate data entry fields resulting in lost patient data and EHR systems where two buttons on a screen have the same label but different functionalities, which caused information problems within the system.[23] These studies highlight how EHR design can lead to information problems that users must manage.

Information Problems Caused by EHR Users

Users are also the cause of certain information problems within EHRs. These problems can include information entry errors, delayed information entry, and discrepancies between multiple sources of information. Researchers have often described how users tend to copy-and-paste information from prior notes in the system in order to cut down on their data entry efforts.[3,7,22] However, as Embi et al.[7] highlight, this can lead to outdated or incorrect information being proliferated throughout the system. Siegler & Adelman[22] also discuss how the copy-and-paste function leads to, "*reducing the credibility of the recorded findings, clouding clinical thinking, limiting proper coding, and robbing the chart of its narrative flow and function*" (p. 495).

Other researchers describe how delayed information entry occurs when clinicians are too busy or tightly scheduled to enter patient data into the system directly after seeing the patient, which leads to information in the EHR being outdated or incomplete for extended periods of time.[16] This negatively affects any other patient-care team member who needs access to updated, accurate patient records. As Ash et al.[3] describe, delayed information entry could result in the patient being given the same medication twice by another member of the patient-care team who relies on the patient record for information. Furthermore, information discrepancies are another issue that can occur during the use of EHR systems. Turchin, Shubina, & Goldberg[24] discuss how EHR users encountered situations where medication information provided in the system's structured fields (e.g., medication name, dosage) contradicted information found in the free-text description field. Therefore, these studies highlight how information problems can also be caused by the users themselves.

Impact of Information Problems on Workflow

Within a hospital, a number of clinical and non-clinical staff members must work together to gather, document, and share information in order to provide effective patient care. This workflow of activities is highly collaborative, complex, and prone to interruptions. This is especially true in fast-paced hospital environments like the emergency department where patients require immediate attention. However, it is important that whatever can negatively affect the hospital workflow is minimized in order to reduce impacts to the patient-care process. Medical informatics researchers have studied how information problems can have a negative impact on the hospital workflow.

Researchers discuss how the design of EHR systems can increase the time it takes to perform workflow activities. Holden[8] discusses how issues with information accessibility (e.g., system login, system response time) can negatively impact the workflow of physicians. Additionally, Shachak et al.[21] describe how there are communication interruptions when physicians try to navigate EHR systems to find or enter patient information while also talking with their patients. This can lead to inaccurate information being entered into the system. Other researchers also describe the additional time and effort spent finding and updating information in multiple systems or on different screens.[1,9] The time and effort that users often do not have.

The existing medical informatics literature on information problems describes what causes information problems and the impacts that information problems can have on workflow. In this paper, we seek to extend this understanding to include how patient-care teams *identify* and *manage* the information problems that they encounter during their daily work.

METHODS

Research Site

We conducted this study in the emergency department of a large teaching hospital in northeastern United States. The ED has approximately 55,000 visits per year. The first author conducted 54 hours of observations and 4 hours of semi-structured interviews with 7 clinical and non-clinical staff in the ED. We observed approximately 85 ED staff members (Table 1).

Table 1. Observed ED Staff

ED Staff Role	***Number Observed***
Nurses (including Charge Nurses)	18
Registration Assistants	14
Physicians	12
Residents	10
Emergency Medical Technicians (EMTs)	6
ED Technicians	4
Transporters	4
ED Volunteers	4
Chaplains (spiritual advisors)	3
Sanitation/Cleaning	3
Care Coordinators	2
Social Workers	2
Maintenance	2
Pharmacists	1
TOTAL	**85**

The ED staff communicated and received information using a variety of sources, including: verbal communication, cell phones, pagers, desktop computers, laptops, computers-on-wheels (COWs), paper documents, white boards, and mounted electronic screens that displayed the "tracking board" (i.e. a chart of ED rooms with patient information and the assigned ED staff). The ED staff primarily used an electronic health record (EHR) system to document patient information. This system included the patients' medical records, laboratory and medication orders, laboratory results, clinical team narratives, registration information, and tracking board. One group of users, registration assistants, also used an Admissions Discharge and Transfer (ADT) system that was integrated with the EHR to document information when patients first arrived in the ED. This ADT system created the patients' unique identification number and included their name, date of birth, social security number, zip code, and complaint (i.e. symptoms, why they were there).

Data Collection

In this study, we used qualitative data collection methods including observations and semi-structured interviews. We used this methodological approach because qualitative research includes an immersion into a field site, which allows the researcher to observe the naturalistic processes and activities of the participants.[12] Our ED observations resulted in detailed descriptions of participants' behaviors and interactions related to information problems. These problems were situated within the context of the participants' busy ED setting and everyday work activities.[13] These qualitative methods have also been used in other informatics studies for a similar purpose.[3,4,19]

The first author conducted 54 hours of observations in two ED areas that had the largest amount of communication and information exchange among the staff: the registration area and the main nurses' station. We also observed the ED staff in hallways and at smaller nurses' stations. Detailed field notes were taken about the workflow,

communication, collaboration, and technology used by both clinical and non-clinical staff. During the observations, the first author also had short, informal discussions with participants in order to clarify assumptions or gain additional information about specific situations. The field notes were then transcribed into an electronic document for analysis (Table 2).

The first author also conducted 7 semi-structured interviews in order to better understand the ED staff's roles and responsibilities, as well as their use and perceptions of the EHR system. The first author interviewed 1 physician, 1 registered nurse, 3 registration assistants, 1 care coordinator, and 1 social worker. The interview data was then transcribed into an electronic document for analysis (Table 2).

Table 2. Data Collection Method, Participants, and Data

Method	***Focus***	***Hours***	***Participants***	***Transcribed Data***
Observations	ED Workflow	54 hours	85 staff	175 pages
Semi-structured Interviews	ED Staff	4 hours	7 staff	28 pages

Data Analysis

The transcriptions resulted in 203 pages of data. This data was analyzed by the first author using Braun & Clarke's[5] six-phase thematic analysis approach (Table 3). This approach facilitates the process of becoming familiar with the data, systematically identifying codes and themes, and then defining and naming the common themes found across the entire data set. The analysis resulted in three main themes, as described in the results section.

Table 3. Braun & Clarke Six-Phase Thematic Analysis Approach

Phase	***Description***
(1) Familiarizing ourselves with the data	Transcribe the notes taken during observations/interviews and read through the transcriptions to ensure a general understanding of the data.
(2) Generating initial codes	Label segments of data in a systematic way across all of the data.
(3) Searching for themes	Review individual codes and identify preliminary themes.
(4) Reviewing themes	Review preliminary themes to ensure that they make sense across the entire data set.
(5) Defining and naming themes	Continuously refine each theme, identify a specific name for each theme, and define the boundaries of the theme.
(6) Producing the report	Present themes with interesting examples from the data that illustrate the individual themes.

RESULTS

Through our data analysis, we identified three main findings: the types of information problems encountered by ED staff, how the staff identified the information problems, and how the staff managed the information problems.

Types of Information Problems

We identified the following information problems in the ED: wrong, outdated, conflicting, incomplete, and missing information (Table 4). These information problems identified in the ED are similar to information problems described by other researchers.[3,11,16,29]

Table 4. Types of Information Problems in the ED

Information Problem Type	***Description***	***Example from Data***
Wrong	Information is not accurate.	"*For example, if you put allergies in the wrong spot, they're put in the problems list instead of the allergies list – which happens – [and it led to] another physician making patient care decisions off of the wrong information.*" [physician interview]
Outdated	Information is no longer accurate and has not been updated.	"*We had a patient who was in here because of abuse injuries and the boyfriend was listed as the emergency contact from a previous visit. The boyfriend was called, but the boyfriend was the abuser. So this created a potentially dangerous situation for the patient and the hospital because the information was not updated.*" [social worker interview]
Conflicting	Information that should be the same but it is not the same.	*In the check-out area, a physician tells the registration assistants that his patient's insurance had been stolen. He says that while scanning the patient's registration information he realized something was wrong because the record said the patient's race was listed as African American and the man was Caucasian. The patient then confirmed that the [EHR] record did not have his correct social security number.* [observational field notes]
Incomplete	Only part of the information is provided.	*"Some of my information about my patient does not get into the patient's record because I can't edit [in the system]. And there's no place for me to put some of my notes about the patient, which could help others, like the next shift."* [social worker interview]
Missing	Information is not available.	*In the registration area, a doctor is talking to an EMT and the family of his patient. He says that the patient is refusing to tell him anything about his medical conditions, medications, and what happened in his accident. The doctor says there is no existing record for this patient and he needs any information they can provide so he can proceed with his patient care plan.* [observational field notes]

These information problems occurred quite frequently in the ED. Even though participants discussed the importance of ensuring information accuracy in their work, they also stated that certain problems, such as data entry errors or incompleteness, are often an inherent aspect of the highly dynamic hospital environment. A participant described this: "*There's always the possibility of errors, that's just the nature of entering information. And you only know what you know. Sometimes you don't have the whole story*" [social worker interview].

Identification of Information Problems

The ED staff recognized the information problems when the problems interfered with their ability to do work, and they were subsequently identified as information problems. Any of the information problems described in the previous section could have persisted within the EHR system if no one had identified the problem. Therefore, it is important to understand how ED staff identifies information problems because the information problem must first be identified before it can be managed or fixed by the team. The ED staff identified information problems in two ways: comparing the EHR system's information to other information sources, and trying to make sense of information that did not "look right."

Comparing Sources: The ED staff frequently identified information problems when they were comparing the EHR system information to other sources of information. These other sources included other ED staff members, patients, visitors, or paper records. For example:

A registration assistant identifies that a patient's first and last names are switched in the system while she is talking with a visitor who requested to see the patient [observational field notes].

The registration assistant was comparing the EHR system to the information that the visitor was verbally providing about the patient when she identified this as an information problem. Additionally, a social worker identified an information problem when comparing the information in the EHR system to a patient's statement:

> *"The other problem with the system is people checking the wrong information. So the nurses will ask [patients] questions, like "has anyone ever forced you to have sex against your will?" One time a nurse checked the wrong box for that question, then I am called in [through a notification in the EHR system] to talk to the patient about it. When I addressed them about the sensitive topic, the patient became irate saying that they never said that and demanding that their record be changed"* [social worker interview].

Furthermore, the participants also identified information problems when comparing the EHR information to something they were physically seeing. For instance, the care coordinator identified an information problem when she noticed that the patient's pill color was not the same color that the patient normally received:

> "*I had a patient who was elderly that had an INR of 16 and it should have been 3.5 at most. I went in to talk to the patient and she said, "the color changed" in reference to her pills. So I looked in the records and found that the drug she was taking was 5 times the amount she should have been taking. So [comparing the pill to] the record in the system helped me identify that there was an issue*" [care coordinator interview].

***Sensemaking*:** Participants also described identifying information problems when they encountered information that did not look right, which then caused them to think about why that information did not look right – or to make sense of the information. Sensemaking is "*the process of encoding information into external representations to answer task-specific questions*" (p. 322).[17] When the ED staff tried to make sense of information that did not look right, they were questioning the accuracy of information based on their previous experiences, medical knowledge, or other training or skills that they have. The staff described this as a "*gut instinct*" or simply that the information just "*didn't look right*." The following two examples illustrate the identification of information problems while making ED staff was trying to make sense of the information:

> The care coordinator described a time when the EHR system showed that the diabetes patient was using a glucometer, but noticed that her "*[glucose] numbers were off.*" The care coordinator stated: "*A lot of times I have a gut instinct, you know? It didn't look right. So I talked to the patient and she said, 'I had a glucometer but my son stepped on it' so she wasn't using one at home, even though her record said she was [using a glucometer]*" [care coordinator interview].

> *A registration assistant (RA) questions another RA about something she had entered into the EHR system. The second RA said she could not read her handwriting from her notes when she was transcribing the information into the system, so the information in the system may be wrong. The first RA said: "Yeah, it just didn't look right. So I had to check with you"* [observational field notes].

In both of these examples, the social worker and the RA identified the information problem by making sense of the information and discussing it with a patient or other ED staff member.

Management of Information Problems

After the ED staff identified information problems, they then had to respond to the problem. The participants managed information problems in one of three ways: by fixing the problem, finding the right person to fix the problem, or finding a way to work around the problem.

***Fixing the problem*:** When the participants identified an information problem and knew how to correct the problem, they typically just fixed the issue in the EHR system themselves. This is exemplified in the following two scenarios:

> *In the check-out area, a physician tells the registration assistants that his patient's insurance had been stolen. He says that while scanning the patient's registration information he realized something was wrong because the record said the patient's race was listed as African American and the man was Caucasian. The patient then confirmed that the [EHR] record did not have his correct social security number. The physician says he then asked the patient for his correct information and entered it into the EHR system so that the patient could be billed correctly for the visit"* [observational field notes].

A registration assistant identifies that a patient's first and last names are switched in the system while she is talking with a visitor who requested to see the patient. She then asks the visitor additional questions about the patient (date of birth, home address) to verify the patient's identity and asks other registration assistants about the patient's correct name. The registration assistant realizes that the first and last names of the patient are mistakenly switched, so she fixes the information error in the system [observational field notes].

***Finding someone to fix the problem*:** There were other times where the participant who identified the information problem did not have the knowledge or the editing rights to fix the problem in the EHR system. For instance, in the previous example, a social worker realized that a nurse had checked the wrong box in the system after the patient verified that the system was incorrect. However, the social worker could not change the error in the system so she had to find the nurse to fix it:

"And the issue with the system is that the person who entered it has to change it. So I have to track down the nurse to change it" [social worker interview].

Additionally, the social worker also described a time when the patient's contact information was outdated and she needed to find someone who could fix the problem:

"Since I can't update it as a social worker, I try to call others to update it…I talk to registration, but they say that it's the nurse's responsibility, but when I talk to the nurse, they say it's not their responsibility." When asked if it was unclear whose responsibility it was to fix the problem, the social worker responded: "*Well, it's clear to them that it's* ***not*** *their responsibility [laughs]! But it's not clear whose responsibility it is"* [social worker interview].

This highlights how the participants managed the information problem by finding someone who could fix the problem since the EHR system restricted her from being able to fix it. This example also highlights the ambiguity or conflicting opinions around who is accountable for the accuracy and completeness of patient information in an environment where information is collectively managed by a patient-care team.

***Working around the problem*:** The participants also found ways to work around the information problem so that they could continue with their task without having to fix the problem in the EHR system. For example:

A registration assistant (RA) discusses with another RA how she reads the "comments" field before letting a visitor back to see a patient, since the nurses occasionally write notes in this field about whether a patient can have visitors. However, she also mentions that the field is not always reliable, so they usually call the nurse to double-check [observational field notes].

By calling the nurse, the registration assistant found a way to work around the unreliable "comments" field in order to continue with her task of directing visitors to patient rooms. In addition, the social worker described how the system does not allow her to enter all of her notes about the patient, so she described using a paper-based workaround:

"Some of my information about my patient does not get into the patient's record because I can't edit [in the system]. And there's no place for me to put some of my notes about the patient, which could help others, like the next shift. So I usually just write it on the [paper] face sheet or the next shift takes notes during our hand-off." [social worker interview].

Therefore, these workarounds allowed the ED staff to continue with their work, even though it did not fix the information problem in the system.

DISCUSSION

The results describe the various types of information problems that ED staff encountered during their work activities, as well as some of the approaches that they took to identify and manage those information problems. Given the highly collaborative nature of hospital work, it is important to consider how these information problems affect the collaboration of patient-care teams. In this section, we discuss how the management of information problems can have a serious impact on collaborative hospital teams including the cascading workflow effects of information problem management and the ambiguous accountability for fixing information problems in collaborative teams.

The Cascading Workflow Effects of Information Problems

Patient-care teams are highly collaborative and team members rely on each other to provide accurate and up-to-date information about a patient. EHR systems provide a centralized view of a patient's history and current status, which creates a shared awareness of that patient across the patient-care team. Therefore, when there is an information problem – wrong, outdated, conflicting, incomplete, or missing information – it does not just affect the one team member who identifies the problem. It affects the entire patient-care team who relies on that information to do their work. Therefore, the way in which hospital staff manage information problems can affect the entire team's collaborative understanding of a patient.

After identifying an information problem, hospital staff may manage the information problem by using a workaround.[15] These workarounds are temporary solutions that allow users to adapt technologies or processes in order to minimize interruptions.[27] Our study's results describe how ED staff used workarounds as one way to manage information problems that they encountered during their work. Other researchers have also described how clinicians frequently perform workarounds when the EHR design interferes with their work[18,20,30] or when there is a problem with the information in the system (e.g., missing, incomplete, outdated).[2,10,11,23] Since the primary concern of patient-care teams is to take care of patients, the staff will find ways to perform their activities by working around EHR design or information problems. Additionally, the user may not go back to the system and fix the known issue.[10] Not fixing the problem results in an information problem persisting in the record for an extended period of time. This is common for hospital staff to not immediately fix an information problem in the system because they are responsible for a number of patients and have a variety of urgent tasks.[3,16] However, this can cause problems in highly collaborative environments because the effects of workarounds can directly impact other members of the patient-care team. This is especially true if the known information problem is not fixed and other members of the team are not made aware that the information problem exists.

Kobayashi et al.[10] discuss the "cascading effects" of workarounds where working around one issue can lead to the need for other workarounds. The authors' discussion of cascading effects describes the impact that one person's workaround can have on other team members' work. Similarly, Saleem et al.[20] state that the use of EHR workarounds, "*introduces the potential for gaps in documentation as well as the unintentional propagation of errors*" (p. 662). Therefore, the persistence of an information problem and lack of making others aware of the problem can affect the next team member who uses that information for his/her own work. So, although there may be perfectly valid reasons for hospital staff to enact workarounds to complete their own patient-care tasks, the effects of the workaround on the overall collaborative team should also be considered. For example, our study's results described how the system restricted a social worker from editing the patient's record, so she created a workaround by writing her patient notes on a printed patient report. Although the workaround allowed the social worker to record patient notes for herself, it also prevented any of the other patient-care team members from being able to see her notes in the EHR system. Her notes could help provide a more comprehensive view of the patient's condition to other members of the clinical team, as seen in prior studies.[29]

Ambiguous Accountability When Managing Information Problems in Collaborative Teams

In hospitals, patient information is co-owned and co-managed by multiple members of the patient-care team. This means that there is a shared responsibility for entering, updating, and maintaining the accuracy of the information. However, members of a collaborative patient-care team may have an ambiguous understanding and, at times, a conflicting opinion about who is responsible for managing the information. This can lead to the persistence of information problems because the team members either assume or believe that someone else is responsible for entering the information or fixing information problems.

To help address this issue, collaborative organizations frequently enact formal policies to address accountability. Hospitals create formal policies to outline accountability guidelines for how staff should handle a variety of situations, such as managing information problems. Hospital staff are required to complete training on these policies and comply with the policies during their daily work. However, while some of the formal policies include very specific instructions, others are more general or vague in order to account for variances across different areas of the organization.[14] The issue with these general policies is that the staff may have different interpretations of the policies when conducting their daily work. This can lead to an ambiguous understanding or a conflicting opinion about responsibilities, as discussed in the study's results. Researchers have described how individuals interpret formal policies in their everyday work practices can vary from person-to-person, which causes conflict or tension within

highly collaborative teams.[14] Therefore, understanding how well aligned the formal policies are to the everyday work activities of collaborative teams may provide insight into the persistence of information problems.

RESEARCH LIMITATIONS

A limitation of this study is that the data was collected and analyzed by a single researcher. One researcher in a large ED setting is not able to observe all instances of information problems that occur. Being a single observer required the first author to make choices about who to observe and where to focus when many different activities were occurring simultaneously. However, since the goal of this work was not to present an exhaustive list of information problems, but rather to identify common information problems in the ED and how they were identified and managed by the hospital staff, we believe that we still were able to collect and analyze the data appropriately.

CONCLUSION

Information problems frequently occur in hospitals and can negatively impact the patient-care workflow and potentially cause harm to patients. This study classifies and describes the types of information problems that ED staff encountered during their work activities. Additionally, the paper addresses a limitation in existing medical informatics research by discussing how collaborative patient-care team members identify and manage these information problems. By better understanding and addressing the challenges of identifying and managing information problems within complex collaborative patient-care teams, hospitals could reduce the negative impact that information problems can have on hospital workflow and the patient-care process.

Furthermore, as hospitals transition from paper records to EHR systems, it is important to consider the impact that EHR design has on information problems. EHR systems dynamically display the most recent patient information in a digital format that can be viewed from a variety of distributed locations (e.g., computers, laptops, mobile devices). This differs from paper records that include static information with visual cues indicating who updated the record (e.g., signature, initials, handwriting) and when it was updated (e.g, date, change in ink, new sheet of paper).[28] This shift from paper to electronic documentation changes the way that patient-care teams enter, view, and share information and how they do their work. Therefore, given the serious effects that information problems can have on patient care, it is important to more closely examine the design of EHR systems and the impact that they can have on the identification and management of information problems.

ACKNOWLEDGEMENTS

We would like to thank the hospital's ED staff for their willingness to participate in this study, as well as the AMIA reviewers for their informative feedback. This work is supported by the U.S. National Science Foundation under grant IIS-1017247. Any opinions, findings, and conclusions or recommendations expressed herein are those of the researchers and do not necessarily reflect the views of the National Science Foundation.

An Evaluation of Two Methods for Generating Synthetic HL7 Segments Reflecting Real-World Health Information Exchange Transactions

Abstract
Motivated by the need for readily available data for testing an open-source health information exchange platform, we developed and evaluated two methods for generating synthetic messages. The methods used HL7 version 2 messages obtained from the Indiana Network for Patient Care. Data from both methods were analyzed to assess how effectively the output reflected original 'real-world' data. The Markov Chain method (MCM) used an algorithm based on transitional probability matrix while the Music Box model (MBM) randomly selected messages of particular trigger type from the original data to generate new messages. The MBM was faster, generated shorter messages and exhibited less variation in message length. The MCM required more computational power, generated longer messages with more message length variability. Both methods exhibited adequate coverage, producing a high proportion of messages consistent with original messages. Both methods yielded similar rates of valid messages.

Introduction

Health information is gathered within and among different organizations and technical systems, stored in different formats with different identifiers. This situation requires technology that integrates disparate data, and such technology must be validated through testing. To validate software's ability to meet industry standards including interoperability with pre-existing software, the use of real world data during the testing phase is necessary.

Access to real world data for testing software is however very challenging for various reasons.[1] First, technology developers often lack rights to access identifiable protected health information (PHI). Second, when such access is permitted, strict regulations governing the use of PHI may impose de-identification and data management burdens limiting the efficiency and effectiveness of the testing process. Further, when representative data is unavailable, software developers may substitute simplistic test data that lacks the vagaries, complexities and idiosyncrasies of real-world data. Subsequently, the lack of access to representative transactional testing data may hinder software development and testing, potentially impacting software quality.

The work in this paper was motivated by a real world problem. OpenHIE is a global, open-source collaborative initiative emerging to assist in the strengthening of national health information exchanges for underserved and resource poor settings.[2] It combines several open source components necessary to accommodate large volumes of health information exchange transactions. To test OpenHIE's integrative functionality, we require representative HL7 messages from 'real-world' settings that must be made available to the multiple open source development communities that comprise OpenHIE.

Although general approaches for generating synthetic data have been published.[3-5] Specific methods for generating large volumes of representative synthetic messages approximating real world HL7 transactions are currently not well-described, nor are we aware of any freely available tools to support this need. The HL7 Messaging Workbench tool allows an array of functionality most prominently allowing creation of conformance profiles and standards conformant message segments based on HL7 version 2.[6] However, functionality to insert synthetic content into HL7 version 2 messages is pending.

Consequently, we sought to evaluate the feasibility, efficiency and effectiveness of two methods that generate synthetic HL7 messages using de-identified HL7 data from the Indiana Network for Patient Care, the nation's largest and longest running health information exchange. We chose these two methods based on their ability to generate new data from the original messages.

Our process for creating synthetic messages involved specific phases. First, we create a message segment framework consisting of valid HL7 message segments. Once the message segment framework is created, we then inject instance data (simulated patient data, clinical data, etc.) into the appropriate fields in the message. We focus our analysis in

this paper on the first phase, message segment creation. We compare the two methods using various metrics, in order to determine the most effective method for generating synthetic HL7 message segment frameworks that accurately approximate the original real-world messages. The comparison metrics included computational effort, level of compliance with the HL7 messaging standard, variability of messages generated, and conformance to the original 'real-world' data.

Segment generation in this paper is focused on HL7 version 2. This was largely dictated by the fact that both the HIE source transaction data (from the INPC) is HL7 version 2, and the target software to be tested (OpenHIE) consumes HL7 version 2 messages. HL7 version 2 is one of the most broadly used messaging standards across the world, and in developing countries where OpenHIE is likely to have widespread use, HL7 version 2 offers the advantage of small data footprint, which is well adapted to slow network infrastructures. For this reason, HL7 version 2 has a big role to play and will likely co-exist with other newer standards like HL7 version 3 and Clinical Document Architecture.

Methods

Source Data

We extracted HL7 messages received by the Indiana Network for Patient Care (INPC) during a continuous 24-hour period. The messages were de-identified and stripped down to include only HL7 segments together with the timestamp, source facility, and the message header components including the message type and event type. The figure below illustrates the example source HL7 message segment framework data from the INPC.

Figure 1: Example HL7 message segments extracted from source messages exchanged within the INPC.

We developed a python script to analyze the proportion of HL7 event types in the dataset. The event-type proportions were used to ensure a similar proportion of messages in the synthetic output. We implemted two methods for synthesizing new HL7 message segment frameworks, labelled the Markov Chain Model[7] (MCM) and the Music Box Model (MBM), respectively.

Two Approaches to HL7 message synthesis

Markov Chain Model: A python script was written based on the principles of the markov chain model[7], which is an approach that models nodes (states within a system) and transition probabilities among nodes. In our HL7 segment framework generating process, nodes represent HL7 segments and the transition probabilities represent the probability of transitioniing from one HL7 segment to the next. We developed a transition matrix using the original HL7 source messages. The transition matrix defined the probability of each segment transitioning to the next segment. Transition matrices were generated for each specific HL7 message event type. We then used the transition matrix to generate random HL7 message frameworks that approximated the original messages.

Music Box Model: This model's name was derived from the music box, a 19th/20th century music instrument that produces sound using a set of pins placed on a revolving cylinder so as to pluck the tuned teeth in what would seem like random plucking movement. For this method we generated HL7 message segment frameworks by choosing messages from the original de-identified source data using simple random sampling with replacement and then adding the chosen message segment to a new generated pool. Using the precalculated proportions for each event type HL7 messages matching the event type were picked at random from the original messages until a desired number of messages were generated.

The two models were evaluated using several parameters to determine the most suitable model that can be used to generate data that were consistent with messages from INPC. These were the parameters of interest:

1. Time required to generate message segment frameworks.
2. Number of segments generated per message.

3. Proporation of message segment frameworks that conform to the HL7 messaging standard rules.
4. Proportion of message segment frameworks that match original messages.

Determining conformance with HL7 standard rules: In order to validate the segment transitions that were generated, we developed a collection of valid segment transitions based on the HL7 message specification. Each HL7 message type contains an abstract message with a collection of segments including rules describing features such as optionality and repetition. Below is an example of an incomplete ADT^A01 abstract message with its rules.

```
MSH             Message Header
EVN             Event Type
PID             Patient Identification
 [PD1]          Additional Demographics
[ { NK1 } ]     Next of Kin / Associated Parties
PV1             Patient Visit
[ PV2 ]         Patient Visit - Additional Info.
[ { DB1 } ]     Disability Information
```

Figure 2: ADT^A01 abstract message with rules

We used a python script to generate all possible valid segment transitions from the information contained in the abstract messages of each trigger event. The above ADT^A01 abstract message would generate the following valid segment transitions separated by commas and so on.

`MSH|EVN,EVN|PID,PID|PD1,PID|NK1,PID|PV1,PD1|NK1,PD1|PV1,NK1|PV1,NK1|NK1,PV1|PV2,PV1|DB1,PV2|DB1,DB1|DB1…`

Using the set of valid segment transitions, we could then determine the percentage of valid segment transitions generated by each of the two models.

Results

Our original INPC data source contained 627,329 representative HL7 messages. The proportion of each message type stratified by trigger event is shown below.

Table 1: Original HL7 message proportions per event type

	TYPE	FREQUENCY		TYPE	FREQUENCY		TYPE	FREQUENCY
1	ORU^R01	0.669666	**12**	ADT^A06	0.001153	**23**	ADT^A13	0.000072
2	ADT^A08	0.148348	**13**	ADT^A09	0.000607	**24**	ADT^A38	0.000056
3	ADT^A04	0.063141	**14**	ADT^A18	0.000575	**25**	ADT^A25	0.000032
4	ADT^A03	0.026297	**15**	ADT^A16	0.000561	**26**	ADT^A28	0.000018
5	ADT^A31	0.023431	**16**	ADT^A44	0.000453	**27**	ADT^A23	0.000014

The most frequent message triggers in the source data set were ORU^R01, ADT^A08, ADT^A04, ADT^A03 and ADT^A31, which comprised 93.1% of the total messages. These proportions were maintained when generating message segment frameworks.

The two models were used to generate increasingly larger number of HL7 message segment frameworks – from 100 to 1,000,000. The two models were compared with respect to the amount of time required to generate messages, total

segments generated and the number and percentage of valid segment transitions in all the messages generated. Table 2 below shows the results.

Table 2: Markov Chain vs Music Box model in generating sequential increasing HL7 messages

	Markov Chain Model vs Music Box Model in generating sequentially increasing messages					
	Markov Chain Model			Music Box Model		
Number of HL7 Messages	Time (sec)	Total Segments	Valid Segments (%)	Time (sec)	Total Segments	Valid Segments (%)
100	0	784	741 **(94.5)**	9	742	718 **(96.7)**

On average the Markov chain model generated more segments per message when compared with the Music box model. The percent of valid HL7 segment transitions in both models were comparable ranging between 94% and 98%. In both models the proportion of valid message segments generated was independent of the number of messages generated.

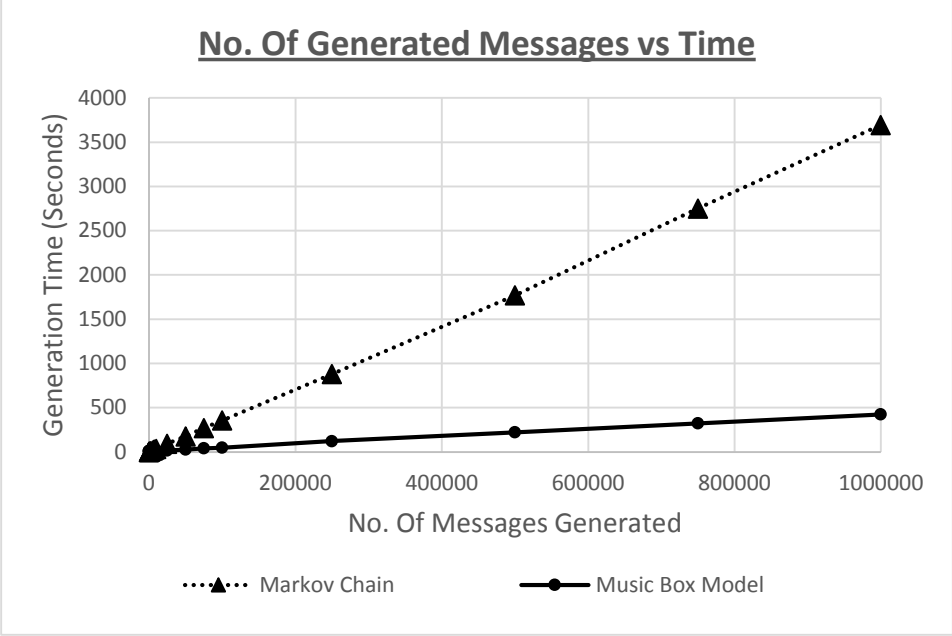

Figure 3: Comparisons of time taken to generate increasing no. of messages by the two models

Because the Music Box method must load all source messages into memory before generating new messages, the Markov Chain method was faster when generating a small numbers of messages (< 2,500). Overall, the music box method was faster. The Markov Chain method generated 270 message segment frameworks per second and the Music Box method generated 1,100 message segment frameworks per second. The message generating rates were nearly constant, as shown in Figure 3.

Comparing coverage of the two models: We assessed the degree to which each method generated message segment frameworks corresponding to one or more of the original source messages, a measure we defined as "coverage". Table 3 below shows the data obtained when the two models generated sequentially increasing number of messages.

Table 3: Comparisons of the two models in terms of coverage of original messages

	Markov Chain Model vs Music Box Model Coverage Of Original HL7 Messages		
	Markov Chain Model		**Music Box Model**
Number of HL7 Messages	**No. of messages identical to original HL7 messages (%)**		**No. of messages identical to original HL7 messages (%)**
100	281,630 **(44.8)**		350,997 **(55.9)**
250	312,527 **(49.8)**		388,518 **(61.9)**
500	356,187 **(56.8)**		418,368 **(66.7)**
750	361,454 **(57.6)**		431,500 **(68.8)**
1,000	396,876 **(63.3)**		456,437 **(72.8)**
2,500	427,513 **(68.2)**		502,382 **(80.1)**
5,000	453,976 **(72.4)**		519,882 **(82.9)**
7,500	463,736 **(73.9)**		527,091 **(84.0)**
10,000	470,447 **(75.0)**		549,014 **(87.5)**
25,000	496,201 **(79.1)**		570,735 **(91.0)**
50,000	506,989 **(80.8)**		584,566 **(93.2)**
75,000	522,169 **(83.2)**		590,466 **(94.1)**
100,000	530,474 **(84.6)**		595,614 **(94.9)**
250,000	540,282 **(86.1)**		606,252 **(96.6)**
500,000	553,554 **(88.2)**		612,750 **(97.7)**
750,000	560,124 **(89.3)**		615,214 **(98.1)**
1,000,000	566,515 **(90.3)**		616,733 **(98.3)**

Overall the Music Box method exhibited greater coverage than the Markov chain method. Both models showed that with an increasing number of HL7 message segment frameworks generated, there was a corresponding increase in coverage of the original messages. The rate of coverage increase plateaued after 75,000 messages. The graph below reflects the data above. Note that the initial 100 messages in both methods corresponded with a more than 40% coverage:

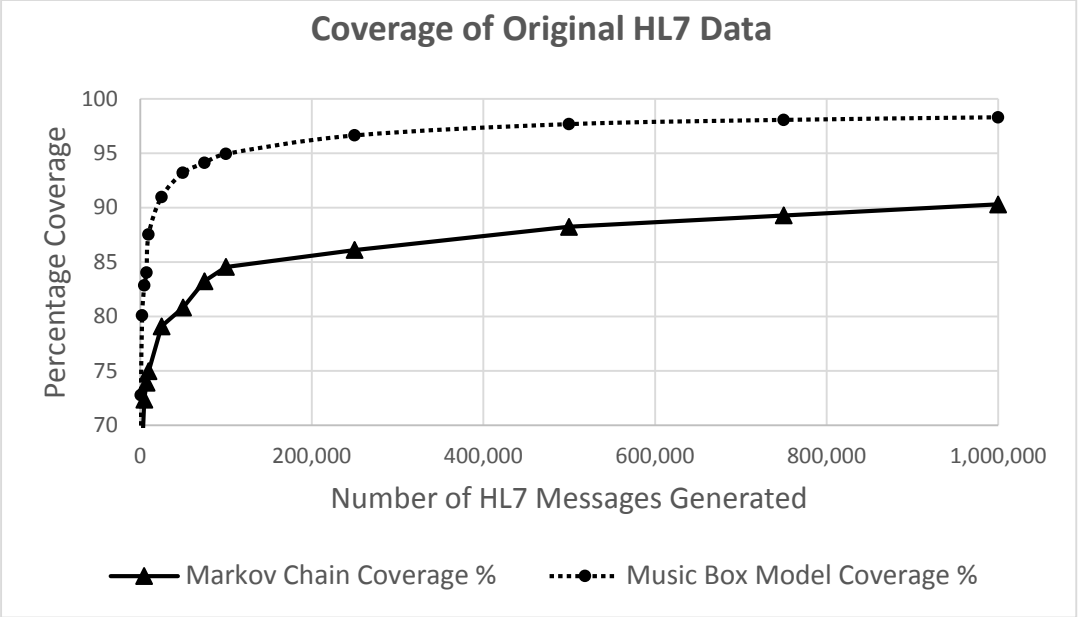

Figure 4: Graph of percentage coverage of original HL7 messages with increasing number of messages generated

The Music Box model had a higher coverage than the Markov Chain for every level of any number of HL7 messages generated. The Music Box model increased to 98.3% compared with Markov Chain at 90.3% when both generated 1 million messages.

Shown below is the comparisons based on segment length per message:

Table 4: Analysis of the number of segments per HL7 message of the two models

	Original Data	Music Box Model	Markov Chain Model
No. of HL7 Messages	627,329	750,000	750,000
Mean	15.67	12.65	14.66
Median	10	10	10
Mode	9	9	9
Std. Deviation	28.24	17.91	34.92
Skewness	14.62	21.32	26.39
Std. Error of Skewness	.003	.003	.003
Minimum	6	6	6
Maximum	1,145	980	3,612

We compared the average number of segments per message in the original 627,329 source messages to 750,000 messages generated by the Markov Chain model and the Music Box model. The most common number of segments per message (mode) generated was 9 in both the original data and both methods. All the data in the three arms were positively skewed with a median of 10 segments. Mean segment length was 15.67 in the original data closely matched by the Markov Chain model at 14.66 segments per message. The spread of segment length per message was also closely correlated between the original data and the Markov Chain as shown by the standard deviation in comparison to that of the Music Box mode. However, the Markov Chain model was prone to generating messages with significantly large number of segments (up to 3,612) compared to the largest number of segments in the original data (1,145).

Discussion

Overall the Music Box model required less time to generate messages when compared with the Markov Chain model. The Music Box model was 5 times faster than the Markov Chain model in generating the same number of messages. This is primarily explained by the fact that the Markov Chain model uses a complex algorithm based on transitional matrix probabilities, which require more computational effort. The Music Box model, on the other hand, implements a straight forward simple random sample of messages, and is therefore preferable when messages must be generated with maximum speed.

Both models generated messages with similar rates of valid segments as gaged by compliance with the HL7 standard rules for each message trigger type. Both topped 97% which reflected to proportion of valid message segments in the Indiana Health Information Exchange source. This rate of valid messages was independent of the number of messages to be generated.

There was a high proportion of identical message segment frameworks in the original dataset. This was reflected by the high coverage by the generated messages. As few as 100 messages generated by both models corresponded to approximately 300,000 (50%) of the original messages. Overall, the Music Box model generated a higher proportion of message segment frameworks corresponding original messages. This is explained by the fact that this method was randomly selecting from the pool of original messages. The Markov Chain method attained a coverage of 90.3% after generating a million messages.

The Markov Chain model generated relatively longer messages when compared to both the original messages and the Music Box model. The Markov Chain also generated greater variability with respect to the number of segments per message compared to the Music Box model. In most situations where software is being tested, this wider variability of messages may be desirable.

Alternatively, the Music Box model generated relatively shorter messages compared with the original messages. This is not necessarily a reflection of the weakness of this method but more a reflection of selecting the most common messages out of the original data. The messages with the largest number of segments were much less common and therefore were less likely to be selected by the Music Box model. However, since these messages are used in generating the transition matrix, the Markov Chain model did reproduce these messages.

Using the mean and standard deviation, the Markov Chain model appeared to more closely correlate with the original data than the Music Box Model. The pattern of the length of messages generated by both models was skewed to the right. Both models showed a statistically significant standard error of skew at 0.03. This means most messages were short with a median segment length of 10. However, messages of up to 3,000 segments per message existed on the Markov Chain model compared to the maximum segment length of 1,145 in the original data. This may have contributed to the Markov Chain method's higher mean and larger standard deviation that correlated more closely with the original data. It is possible that if we constrained number of segments allowed by the Markov Chain method, and thus minimized its outliers, the MCM may have less closely correlated with the original data.

Either method can be used to generate HL7 segments in other settings tailored to the local context. In this paper, we used source data from the Indiana Network for Patient Care. The source data was in the form of de-identified HL7 data stripped down to segment level. Informaticians interested in generating segments using either method in their local context can user our software (made available upon request) to analyze the proportion of HL7 message types in their dataset and then generate transition matrices for each message type. Synthetic message segments for each message type can then be generated according to the transition matrices. For the MBM method, new segments can be generated by randomly selecting each message type in keeping to the analyzed proportions.

There are limitations in making conclusions about HL7 message generation from this study. The synthetic process in this paper focused on generation of HL7 message segment frameworks only and doesn't involve generation of individual field-level data within the segments. Our future work includes developing pragmatic methods for populating fields in each segment with synthetic data that reflect underlying characteristics of the original data. The two methods used to generate message segments can be similarly applied to generate data for individual fields in each segment. The MBM method is being used to randomly select simulated patient identifiers to complete the HL7 patient ID (PID) segment. The MCM will be used to generate simulated address data by first generating transition matrices based on real-world address data. Therefore, both methods are useful not only for generating the segments but also for generating the entire HL7 message.

The MCM's use of transitional matrices introduces additional complexities beyond simple random sampling that require more computational cycles regardless of the language of code or optimization level, thus we believe that the fundamentally different characteristics of the two approaches accounted for much of the difference observe time to completion. However implementation-specific software inefficiencies also likely contributed to a portion the observed time differences. Thus, different implementations of these approaches may yield different computational efficiency results.

Conclusion

In summary, both methods represent effective approaches to generating message segment frameworks, which are necessary precursors to creating fully realized synthetic HL7 messages. The Music Box model was faster, generated shorter message segment frameworks and had less variability in message segment framework length. The Markov Chain required more computational power, generated longer message segment frameworks with some outliers and had more variability in message segment framework length. Both models demonstrated adequate coverage, generating message segment frameworks corresponding to a high proportion of the original messages. The data generated by both models also had a high compliance with the HL7 standard rules.

The work in this paper forms an important first phase in evaluating important models that can be used to generate HL7 messages that reflect real-world data.

Scalable and High-Throughput Execution of Clinical Quality Measures from Electronic Health Records using MapReduce and the JBoss® Drools Engine

Kevin J. Peterson, MS[1,2] and Jyotishman Pathak, PhD[1]
[1] **Dept. of Health Sciences Research, Mayo Clinic, Rochester, MN**
[2] **Dept. of Computer Science & Engineering, University of Minnesota, Twin Cities, MN**

ABSTRACT

Automated execution of electronic Clinical Quality Measures (eCQMs) from electronic health records (EHRs) on large patient populations remains a significant challenge, and the testability, interoperability, and scalability of measure execution are critical. The High Throughput Phenotyping (HTP; `http://phenotypeportal.org`) project aligns with these goals by using the standards-based HL7 Health Quality Measures Format (HQMF) and Quality Data Model (QDM) for measure specification, as well as Common Terminology Services 2 (CTS2) for semantic interpretation. The HQMF/QDM representation is automatically transformed into a JBoss® Drools workflow, enabling horizontal scalability via clustering and MapReduce algorithms. Using Project Cypress, automated verification metrics can then be produced. Our results show linear scalability for nine executed 2014 Center for Medicare and Medicaid Services (CMS) eCQMs for eligible professionals and hospitals for >1,000,000 patients, and verified execution correctness of 96.4% based on Project Cypress test data of 58 eCQMs.

1 INTRODUCTION

Secondary use of electronic health record (EHR) data is a broad domain that includes clinical quality measures, observational cohorts, outcomes research and comparative effectiveness research. A common thread across all these use cases is the design, implementation, and execution of "EHR-driven phenotyping algorithms" for identifying patients that meet certain criteria for diseases, conditions and events of interest (e.g., Type 2 Diabetes), and the subsequent analysis of the query results. The core principle for implementing and executing the phenotyping algorithms comprises extracting and evaluating data from EHRs, including but not limited to, diagnosis, procedures, vitals, laboratory values, medication use, and NLP-derived observations. While we have successfully demonstrated the applicability of such algorithms for clinical and translational research within the Electronic Medical Records and Genomics (eMERGE)[1] and Strategic Health IT Advance Research Project (SHARPn)[2, 3], an important aspect that has received limited attention is scalable and high-throughput execution of electronic Clinical Quality Measures (eCQMs) using EHR data. Briefly, eCQMs are Center for Medicare and Medicaid Services (CMS) defined quality measures for eligible professionals and eligible hospitals for use in the EHR Incentive program for electronic reporting[4]. The e-specifications include the data elements, logic and definitions for that measure in an Health Level Seven (HL7) standard - Health Quality Measures Format (HQMF) - which represents a clinical quality measure as an electronic XML document modeled using the Quality Data Model (QDM). While significant advancements have been made in the clarity of measure logic and coded value sets for the 2014 set of eCQMs for Meaningful Use (MU) Stage 2, these measures often required human interpretation and translation into local queries in order to extract necessary data and produce calculations. There have been two challenges in particular: (1) local data elements in an EHR may not be natively represented in a format consistent with HQMF/QDM including the required terminologies and value sets; and (2) an EHR typically does not natively have the capability to automatically consume and execute measure logic. In other words, work has been needed locally to translate the logic (e.g., using an approach such as SQL) and to map local data elements and codes (e.g., mapping an element using a proprietary code to SNOMED). This erodes the advantages of the eMeasure approach, but has been the reality for many vendors and institutions in the first stage of MU[5].

In our prior work[3], we have devised solutions for EHR data normalization and standardization, including generation of structured data templates using natural language processing. In this work, we address the second challenge for scalable and high-throughput execution of eCQMs using MapReduce, the open-source JBoss® Drools Rules engine, and Common Terminology Services 2 (CTS2)[6, 7]. Specifically, we have developed a set of architectural principles that guide the functional and non-functional requirements of our proposed system that supports interoperability, testability, and scalability for automated execution of eCQMs. To evaluate and test our system for performance, scala-

bility, and correctness of measure result calculations, we leveraged test datasets from Project Cypress which provides a rigorous and repeatable testing tool of EHRs and EHR modules in calculating MU Stage 2 CQMs, and is the official testing tool for the 2014 EHR Certification program supported by the Office of the National Coordinator for Health IT (ONC). Our evaluation results show that the system implemented can not only replicate Cypress benchmarks for calculated measure results (accuracy of 96.4%), but also linearly scales to a large number of patient records (>1,000,000 patients). The source code of our system, released under Apache License Version 2.0, is available via: `http://api.phenotypeportal.org`.

2 MATERIALS AND METHODS

In order to evaluate a candidate architecture, we first present a series of Architectural Quality Attributes that outline the critical high-level functional and non-functional requirements of the system. These guide design decisions and technology choices, and must hold for the candidate architecture to be viable. Next, we examine the individual components of the system and their interconnections, along with an examination of the general architectural style. To reinforce the system architectural goals, we will investigate one of the eCQMs, CMS MeasureID CMS163v1 (*Diabetes: Low Density Lipoprotein (LDL) Management and Control*), as a use case at various stages of transformation and ultimately computation. Finally, to test our architecture and implementation viability, we quantitatively measure system performance in terms of measure computation time and execution "correctness," or verification of the results.

2.1 Tools, Standards, and Models

Project Cypress. Project Cypress[1] is a testing and verification framework for eCQMs and is the official testing tool for EHR measure calculation provided by the ONC. It provides a set of 36 de-identified test patients, along with expected execution results for each quality measure calculation. Both the patient dataset and the expected results are distributed in JSON format[8], which is easily parsed and analyzed for testing. Project Cypress also includes several table-based graphical views of expected results, along with in-depth debugging information.

QDM/HQMF. The Quality Data Model (QDM)[9, 10] is a standardized electronic model for representing quality criteria. These models are represented using the Health Quality Measures Format (HQMF)[11] specification, which is an HL7 Version 3 Draft Standard for Trial Use (DSTU). For any given eCQM, the QDM defines, via logical operators and temporal comparisons, criteria used to classify patients into several categories, or *Populations*. These include the *Initial Patient Population* (IPP), *Numerator* (NUMER), *Denominator* (DENOM), *Denominator Exclusion* (DENEX), and the *Denominator Exception* (DENEXCEP)[12].

CTS2. Common Terminology Services 2 (CTS2) is an Object Management Group® terminology services standard[6], as well as an accepted HL7 Normative Service Functional Model.[2] The CTS2 standard defines a common data model and interface for interacting with a terminology service, including read/write access and various maintenance, content loading, and querying functionality.

2.2 Architectural Quality Attributes

In order to better understand the intent and function of the system, we have identified several guiding concepts, or Architectural Quality Attributes[13], that are necessary for a successful system.

Quality Attribute 1: Interoperability
Statement: Communications, interfaces, and data exchanges should be based on industry standards and specifications.
Rational: Standards-based design allows for effective componentization of the system, as component interfaces and data contracts can be linked to published specifications. This promotes low coupling and improved separation of concerns. A standards-based approach also enables implementation and information hiding[14], which allows greater opportunities for substituting component implementations based on use case.

[1] http://projectcypress.org/
[2] Publishing pending at time of writing.

Implications: First, a standardized measure definition format is needed. This will enable interoperability and provide a common, shared grammar for communicating measure intent. Second, as structured vocabularies play a major role in the measure logic, a standard terminology service interface is required. Finally, standard protocols are needed to integrate these components and to interact with the system.

Quality Attribute 2: Testability
Statement: System results should be verifiable, repeatable, and comparable to benchmarked and curated datasets.
Rational: The identification of patient cohorts in many instances remains a manual, human-driven process[15]. This presents a system testing problem, as it may be difficult to determine acceptable system outputs without significant effort. It is important, therefore, that a subject matter expert curated test dataset be available, and that the system architecture incorporate such datasets in order to allow for automated and repeatable testing.
Implications: Testing infrastructure will need to accommodate the automation of benchmarked and curated test datasets. This also will require reporting processes to clearly demonstrate test results.

Quality Attribute 3: Scalability
Statement: System architecture will allow for increasing workloads and expanding datasets.
Rational: As shown in the eMERGE[1] project, efficiently processing large datasets is important to research. High scalability is necessary for both present and future viability.
Implications: Processing algorithms and deployment models must enable horizontal scalability and parallel execution.

2.3 Architectural Style

The architectural style of our platform is a combination of *pipe and filter* transformations and a *MapReduce* computational algorithm. In the pipe and filter phase, input data is transformed via several discrete components in a streaming fashion, creating an information flow through the system which ultimately leads to the desired output[16]. Output of this phase is a machine-executable representation of the quality measure. One of the main benefits of this style is loose coupling, as components need not know implementation details of each other. This approach is possible via our Architectural Principle 1 – *Interoperability* and standards-based design – as components will have explicit and standardized contracts. These contracts are implemented as Representational State Transfer (REST) based services wherever possible, giving them a consistent interface[17]. Measure execution logic is then partitioned by the MapReduce computational algorithm, allowing for parallelization and horizontal scalability.

2.4 System Components

The overall system architecture and scope is shown in Figure 1. Functional software modules of the execution system are enumerated below, while other components or infrastructure shown can be assumed to be external dependencies.

HQMF/QDM XML to JSON Transformer. The HQMF/QDM XML to JSON transformation component parses the HQMF/QDM XML representation and transforms it into easily parsable JSON. This functionality is exposed via a REST service wrapping the Project Cypress health-data-standards[3] project. This component is Ruby[4] based, and represents the only non-Java Virtual Machine (JVM) component of the architecture.

JSON to JBoss® Drools Compiler. The QDM JSON representation is then programmatically transformed into executable JBoss® Drools Rules via a compilation process. The result of this transformation is a single Drools Rule file per measure that is executable by the *Drools Execution Engine* or other JBoss® Drools environment. The compilation component is based on the Groovy[5] language, as Groovy provides templating and string interpolation functionality that is difficult to replicate in Java.

Drools Execution Engine. Utilizing the JBoss® Drools Rule engine, the generated Drools Rules are executed given an input patient set. The result of this execution is the classification of patients into populations (such as NUMER,

[3] https://github.com/projectcypress/health-data-standards

[5] http://groovy.codehaus.org/

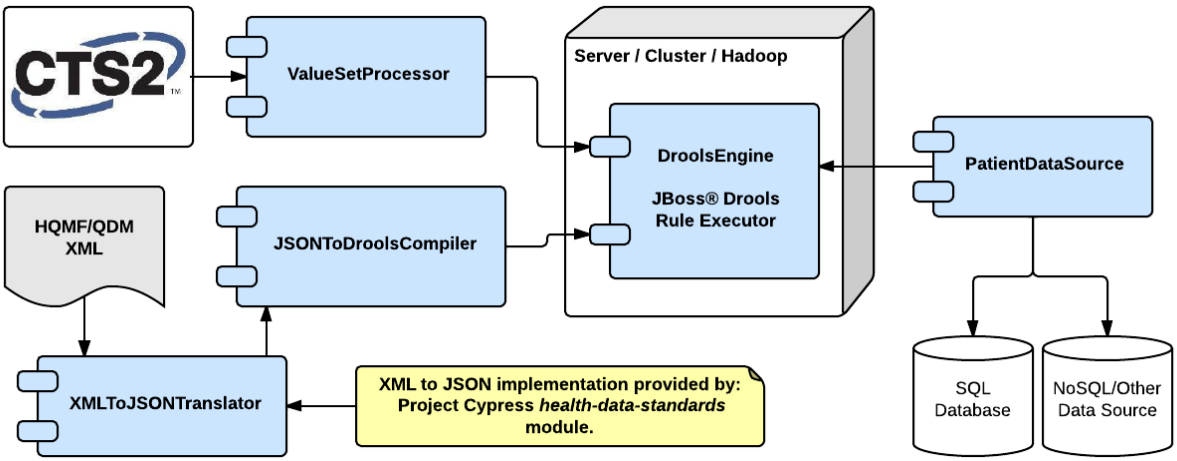

Figure 1: Scalable and High-Throughput Phenotyping Architecture for Clinical Quality Measure Calculation

DENOM, etc). A thin interface façade was created over the "JBoss® Drools version 5.6.0.Final" library, hiding the implementation details of the engine. There are, in fact, no Drools-related interfaces exposed to the client – meaning the Drools-based implementation is decoupled from the user-facing contracts.

Patient Data Source. Data is provided to the execution engine via an abstraction layer utilizing the Iterator pattern[18]. This approach neither provides nor specifies a specific data source, but facilitates custom data extraction implementations tailored to the specific database and environment.

Value Set Processor. QDM Data Elements semantically define their intended criteria using *Value Sets*, or enumerated sets of coded concepts from standard vocabularies. Take, for instance, the criteria: *"Diagnosis, Active: Acute Pharyngitis" using "Acute Pharyngitis Grouping Value Set (2.16.840.1.113883.3.464.1003.102.12.1011)."* In this example, in order for the QDM Data Element to be satisfied, a patient record must contain a Diagnosis entry coded with concepts contained in the Value Set uniquely identified by the given HL7 Object Identifier (OID)[19].

To facilitate this, a mechanism for resolving the concepts of a Value Set is required. This functionality is described in two procedures shown in Algorithm 1, and defines the capability of the *Value Set Processor*. The procedure `EXISTS_IN_VALUESET` defers explicit full resolution in favor of an *exists*-type functionality, which tests membership of a given $coded\_entry$ within a Value Set. In this procedure, the set of concepts C denotes each concept c defined by the Value Set identified by the given OID. The boolean existence of $coded\_entry$ in C is returned. Furthermore, it often is necessary to find the subset of coded entries that align semantically with a defined Value Set. In the procedure `FIND_MATCHES`, instead of checking existence in C as above, the intersection of C and the $coded\_elements$ set is returned. In both procedures, the function $resolve(oid)$ returns the set of all concepts in a Value Set given an OID.

Algorithm 1 Value Set Processor Functionality

1: **procedure** EXISTS_IN_VALUESET(oid, coded_entry)
2: $C \leftarrow \{c | c \in resolve(oid)\}$
3: **return** $coded\_entry \in C$
4: **end procedure**
5: **procedure** FIND_MATCHES(oid, coded_elements)
6: $C \leftarrow \{c | c \in resolve(oid)\}$
7: **return** $C \cap coded\_elements$
8: **end procedure**

2.5 Processing Algorithms and System Deployment

MapReduce. MapReduce is a computational abstraction designed to allow for easier parallelization and distribution of large datasets for processing[20]. The computation is a two-step process, consisting of a *map* function followed by a *reduce* function. The *map* function, given an input, divides this input into smaller sub-problems which then are consolidated by the *reduce* function.

We can apply this concept in the context of patients and populations. In the *map* function, each patient is classified into the appropriate populations given an eCQM. We then *reduce* each population (and its given set of patients) into some analytic result – for instance, analyzing demographic characteristics or creating patient lists for the quality measure.

Algorithm 2 MapReduce for Clinical Quality Measures

```
1: map(String measure, List patients)
2:     for each patient in patients:
3:         for each population in getPopulations(measure, patient):
4:             emit(population, patient)
5: reduce(String population, Iterator patients)
6:     emit(postprocess(population, patients))
```

Algorithm 2 illustrates the general flow of information through the measure execution logic. The *getPopulations* function encompasses the actual measure execution logic – in our case, the *Drools Execution Engine* component. The *postprocess* function in the *reduce* portion is left to be implemented by the client, as this will be use case dependent. Note that the current code base includes a basic demographics analytics post processor, but it is expected that clients will extend it to meet their needs, or substitute their own processing entirely.

2.6 Measure Execution using the JBoss® Drools Rules Engine.

The JBoss® Drools Rule Engine provides the execution framework for the clinical quality measures. Given the input HQMF/QDM XML, the intermediary JSON representation is then compiled into Drools Rules. Figure 2 shows a representation of CMS MeasureID CMS163v1 and the translation of one example criteria to a Drools Rule. In a Drools Rule execution, decisions are made based on data elements, or *Facts*, that have been placed into working memory either from an external data source or as the result of other rule executions. In this example, a `MeasurementPeriod` is first checked – this is a parameter that controls the valid start/end date range of the measure. A `Patient` is then retrieved from the working memory, and the `Encounters` of that patient are examined for a *semantic* match (a match in Value Set 2.16.840.1.113883.3.464.1003.101.12.1001), and a *temporal* match (expressed by the `during` operator in reference to the `MeasurementPeriod`). Finally, if this result is satisfied, a `PreconditionResult` is inserted into working memory. The Drools execution engine, using the Rete[21] algorithm, assures that dependent rules will then fire, as the new `PreconditionResult` is now available in working memory.

2.7 Quantitative Evaluation Methods

Performance (Execution Time). Scalability and performance are important aspects of the architecture, and the ability to efficiently process large patient sets is critical. Examining the architecture for these aspects requires several components - first, a large de-identified patient set (>1,000,000 patients with EHR data) is needed. Next, a mechanism to verify the execution results is required to ensure a valid test environment. Finally, as shown in our prior work[22], computational complexity is variable across different quality measures, with examples ranging from simple logical comparisons, to large nested decision trees with temporal relationships between events. We must account for this variability by measuring complexity of the measures under study.

To meet these requirements, the previously mentioned Project Cypress test dataset was re-purposed for execution time performance testing. In order to simulate >1,000,000 patients, the Project Cypress' 36 patients were "cloned"

Initial Patient Population =

- AND: "Diagnosis, Active: Diabetes" starts before or during "Measurement Period"
- AND: "Patient Characteristic Birthdate: birth date" >= 18 year(s) starts before start of "Measurement Period"
- AND: "Patient Characteristic Birthdate: birth date" <= 75 year(s) starts before start of "Measurement Period"
- AND:
  - OR: "Encounter, Performed: Office Visit"
  - OR: "Encounter, Performed: Face-to-Face Interaction"
  - OR: "Encounter, Performed: Preventive Care Services - Established Office Visit, 18 and Up"
  - OR: "Encounter, Performed: Preventive Care Services-Initial Office Visit, 18 and Up"
  - OR: "Encounter, Performed: Home Healthcare Services"

```
rule "EncounterPerformedOfficeVisit_precondition_21"
   dialect "mvel"
   no-loop
when
   $measurementPeriod : MeasurementPeriod()
   $p : Patient ( )
   $event : edu.mayo.qdm.patient.Encounter(
       this during $measurementPeriod
   ) from droolsUtil.findMatches("2.16.840.1.113883.3.464.1003.101.12.1001"), $p.getEncounters())
   then
       insertLogical(new PreconditionResult("EncounterPerformedOfficeVisit_precondition_21", $p, $event ))
   end
end
```

Figure 2: Drools Rule Representation of Initial Patient Population for CMS MeasureID CMS163v1

and re-created to form a larger cohort. Execution time was then measured for 12 different patient set sizes, each set size equaling the Project Cypress test patient set size multiplied by an increasing multiple of 2500. Specifically, given the Project Cypress test patient set P, we can define each test patient multiset T_j as $T_j = P \otimes (2500j)$ where $1 <= j <= 12$. For each set of test patient data T_j, the execution time necessary to compute the test set was measured and recorded.

The complexity of eCQMs under study is an important criteria to quantify, especially when comparing execution times. Several efforts provide guidance in this area[12, 23], from which we derive our complexity attributes: *Max Depth, Boolean Operators, Negations,* and *Temporal Operators*. *Max Depth* measures the maximum amount of nesting in the boolean clauses. If thought of as a boolean decision tree, this measurement would equal the longest path length to the root node. *Boolean Operators* is a count of every `AND`/`OR` operator in the measure, while *Negations* measures how many of these operators include a negation. Finally, *Temporal Operators* counts the number of temporal logic calculations specified in the measure – either as relative temporal comparisons between events, or comparisons to the start and/or end time of the measurement period.

Due to brevity, a subset of the complexity measurements is shown in Table 1 (See full details at: `http://docs.phenotypeportal.org/figures/htp_complexity.png`). To test the computation time of the execution engine under a variety of complexity scenarios, 9 measures representing different complexities were executed. The chosen measures represent a broad spectrum of complexity, ranging from the most complex to relatively straightforward. Execution tests were performed on an Amazon 2xlarge EC2 instance with 8 vCPUs and 30 GiB RAM.

Table 1: CMS Clinical Quality Measure Algorithm Complexity Metrics

CMS ID	Max Depth	Boolean Operators	Negations	Temporal Operators
CMS159v1	8	41	16	56
CMS160v1	6	46	12	63
CMS153v1	4	110	27	112
CMS145v1	4	84	14	114
CMS126v1	3	57	9	64
CMS134v1	3	26	6	29
CMS163v1	2	10	1	12
CMS127v1	2	8	0	10
CMS148v1	2	4	1	8

Performance (Verification). Automating the verification of the measure is in many ways as important as the automation of the execution itself. Quality Attribute 2 describes the need for a robust testing environment, and the ability to measure verification performance is key to our architectural evaluation. Verification was performed using the Project Cypress verification framework, following guidance from the *Test Procedure for §170.314© Clinical Quality Measures* document[24]. Project Cypress was used as the testing oracle for the verification process, providing a curated test dataset along with expected outcomes. Automation of this verification process also allowed for Test Driven Development[25] practices to be used. To automate this verification process, first the Project Cypress JSON Patient Data was transformed into the target HTP data representation format. Next, the HQMF/QDM XML representation of a given eCQM was selected, and execution of that measure against the test dataset was started. When complete, the results were compared against the expected outcomes, which were loaded from a provided Project Cypress results file.

3 Results

Performance (Execution Time). Execution times, shown in Figure 3, show the total elapsed execution time over the test patient sets. Execution times tended to scale linearly as the patient set size increased. The execution time of CMS MeasureID CMS145v1 *Beta-Blocker TherapyPrior Myocardial Infarction (MI) or Left Ventricular Systolic Dysfunction (LVEF* $< 40\%$*)* was anomalous, as shown in the results. Although similar in measured complexity compared to other executed measures, it exhibited a significantly higher execution time.

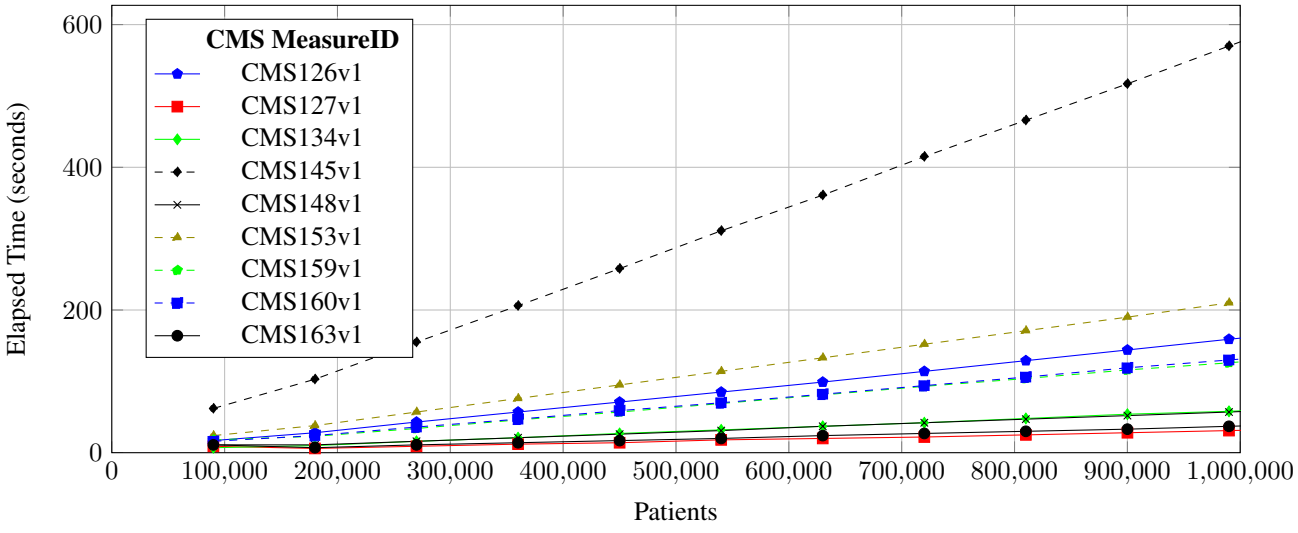

Figure 3: CMS Clinical Quality Measure Algorithm Execution Time

Table 2: Project Cypress Verification Results - Patients Classified per Population *(actual/expected)*

CMS ID	IPP	NUMER	DENOM	DENEX	DENEXCEP	Result
CMS122v1	**2/2**	**2/1**	**2/2**	**0/0**		**Failure**
CMS126v1	3/3	1/1	3/3	1/1		Success
CMS127v1	5/5	1/1	5/5			Success
CMS134v1	2/2	1/1	2/2	0/0		Success
CMS145v1	2/2	1/1	2/2		0/0	Success
CMS148v1	2/2	1/1	2/2	0/0		Success
CMS153v1	4/4	1/1	4/4	1/1		Success
CMS159v1	**2/2**	**0/1**	**2/2**	**0/0**		**Failure**
CMS160v1	3/3	2/2	3/3	0/0		Success
CMS163v1	2/2	1/1	2/2	0/0		Success

Performance (Verification). A subset of the Project Cypress validation results are shown in Table 2. For each measure, results are displayed in the form of *(actual/expected)* patients classified for the given population. Of the 58 total measures analyzed, 56 matched the expected results, while 2 measures failed to match the expected results in one or more of the population criteria. The two anomalous measures, CMS MeasureIDs CMS159v1 and CMS122v1, both failed to correctly identify the *Numerator* (NUMER) population. Due to brevity, see detailed results here: `http://docs.phenotypeportal.org/figures/htp_cypress.png`.

4 Discussion

Summary. The evaluation of the candidate architecture begins with ensuring that the Architectural Quality Attributes still hold. By using standards such as QDM/HQMF and CTS2, along with the uniform interface of REST, we were able to achieve a degree of *Interoperability* in the system. Also, as shown by the Project Cypress integration, the architecture was able to achieve a high degree of *Testability*, while the MapReduce processing algorithm enables a solid platform for high system *Scalability*. Our quantitative analysis results also verify that the Quality Attributes hold. Achieving 96.4% Cypress verification (56 out of 58 measures) shows high system "correctness," while the execution time results show predictable and scalable results for the selected measures given datasets of $>$1,000,000 patients.

Anomalous Results. CMS MeasureIDs CMS159v1 and CMS122v1 both failed to produce the correct results when executed against Project Cypress test data. For CMS159v1, the numerator population is defined by *"Risk Category Assessment: PHQ-9 Tool (result $<$ 5)" $<=$ 13 month(s) starts after end of "Occurrence A of Risk Category Assessment: PHQ-9 Tool."* Cypress verification results identify test patient `BH_Adult_D` for inclusion, and test data for this patient shows two qualifying assessments, the first on *Sat, 24 Sep 2011 12:30:00 GMT* and the second on *Thu, 01 Nov 2012 12:30:00 GMT*. Our results exclude this patient via the $<=$ 13 month(s) temporal constraint. It is unclear as to whether this is a misinterpretation of the temporal constraint or an otherwise unknown system defect.

With regard to the verification failure of CMS122v1, the test patient `Diabetes_Adult_A` was erroneously added to the numerator population due to a miscalculation of the the constraint: *"Occurrence A of Laboratory Test, Result: HbA1c Laboratory Test (result $>$ 9 %)."* This patient does have an HbA1c Laboratory Test result, but with a value of only 8%. Inclusion of this test patient indicates a system defect in analyzing the value of this laboratory test result.

The anomalous execution time of CMS145v1 is not sufficiently explained by complexity calculations in Table 1, as it does not differ significantly from other observed measures. One possible explanation could be the large number of individual Drools Rules produced by the compilation process of this measure. To explore this further, Figure 4 shows the number of generated Drools Rules as compared to execution time for each analyzed measure. The results indicate a possible correlation between the two, and shows the execution time of CMS145v1 degrades predictably given the large number of discrete Drools Rules needed to express it.

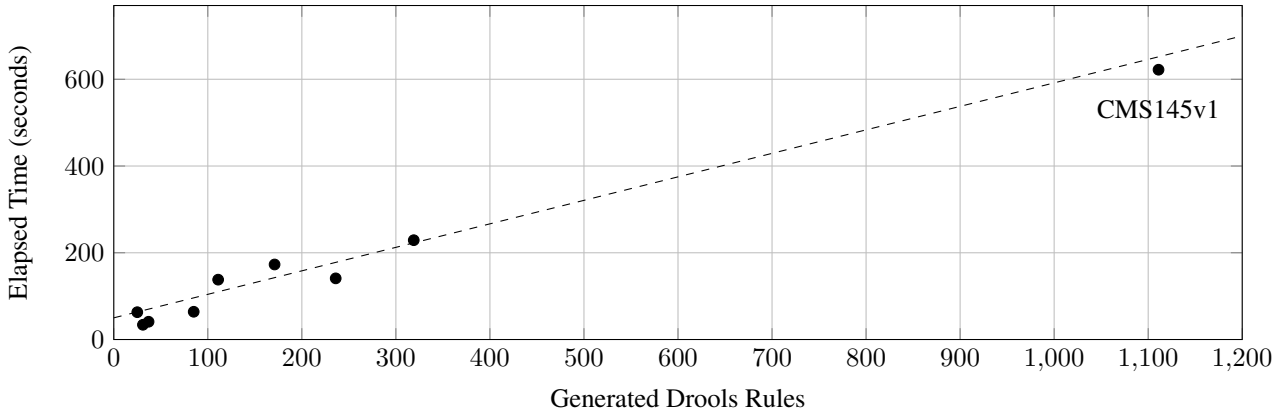

Figure 4: Measure Execution Time per 1,000,000 Patients vs. Number of Generated Drools Rules

Limitations. Compilation of the QDM XML into JBoss® Drools Rules has several significant opportunities for improvement. First, Drools Fusion and Complex Event Processing[7] was only partially utilized for the temporal relationships. Utilizing these modules would cause a significant increase in rule readability and conciseness. Next, the generated rules are prone to combinatorial explosions of rule activations – especially in measures that heavily utilize `OR` clauses. The `exists` Drools operator would usually alleviate this, but a unique aspect of the QDM measures called *Specific Occurrences* makes this difficult. A *Specific Occurrence* is the notion of assigning an identifier to a specific event (such as a Diagnosis or Encounter), and referring to that specific event elsewhere in the measure. To account for this, we follow the *Specific Occurrence* processing algorithm proposed by the MITRE Corporation[26]. Execution time performance metrics are also limited by the small Project Cypress patient set size, and as such, a larger test patient set would be more appropriate for scalability and performance evaluations.

Future Work. In general, optimizing the Drools Rule compilation has the potential to increase scalability and performance to even higher levels, as well as to provide more readable and concise rules. Also, the relationship between Complexity in Table 1 and Execution Time in Figure 3 is not fully understood. If a correlation exists, it has not been statistically analyzed. Furthermore, asserting relative complexity rankings between measures is error-prone, as algorithms and metrics for capturing true measure "complexity" are not known. More analysis is needed to explore how this complexity can be measured. Along these lines, Figure 4 suggests that the number of generated Drools Rules – not complexity – may be a more accurate model of execution time. If the correlation does indeed hold, future work in Drools Rule compilation optimizations may be approached with that model in mind.

Knowledge Crystallization and Clinical Priorities: Evaluating How Physicians Collect and Synthesize Patient-Related Data

Ari H Pollack, MD[1,2], Carolyn G. Tweedy, BS[2], Katherine Blondon[3], MD, PhD, Wanda Pratt[2], PhD.
[1]Seattle Children's Hospital, Seattle, WA; [2]University of Washington, Seattle, WA; [3]University Hospitals of Geneva, Geneva, Switzerland.

Abstract

Information seeking and synthesis are time consuming processes for physicians. Although systems have the potential to simplify these tasks, future improvements must be based on an understanding of how physicians perform these tasks during clinical prioritization. We enrolled 23 physicians in semi-structured focus groups discussing simulated inpatient populations. Participants documented and discussed their data gathering and prioritization processes. Transcripts were coded to identify themes and generalized process flows. Results indicate that data are collected to categorize and prioritize patients according to expected clinical course. When data do not support these expectations, or when categorization indicates potential for morbidity, physicians increase efforts to act or re-categorize patients. Unexpected clinical changes have a significant impact on the decision-making and prioritization by clinicians. A modified version of the Knowledge Crystallization Framework helps to frame this work laying a foundation to advance information displays and facilitate information processing by physicians in clinical care environments.

Introduction

As increasing amounts of data become available within the medical record, Electronic Medical Record (EMR) systems need to prioritize and visualize that data to help clinicians process it in their time-constrained schedules. Clinicians perform many different tasks throughout the day—some are urgent and require immediate attention, while others can be postponed. The task of identifying priorities occurs continuously, and clinicians constantly re-evaluate their list of activities as new information surfaces. Ensuring that clinicians have all the data they need to make these decisions is a significant challenge. Today, clinicians must wade through volumes of information to find meaning, assign value, and take action. It has been estimated that physicians use approximately two million pieces of data when caring for patients.[1] This data includes both the acquired scholastic knowledge as well individual data for each patient. Some have said that "much of the art of medicine lies in gathering this information."[2] This practice needs to move away from artistry and self-discovery to a more rigorous process that limits the potential for error. The artistry within medicine should present itself in the interpretation and application of data, not the process of finding it.

It seems clear that access to additional data can lead to more informed prioritization and improved clinical outcomes; however, the costs associated with gathering and processing these data impact both clinicians and patients. The manual processes of searching for information and analyzing it to understand trends or see patterns involves too much time, especially as patients and their problems increase in complexity. Ideally, all the relevant data required to provide clinical care should be available at the time of need. In reality, the most critical data might not be readily accessible. Therefore, a clinician must use their judgment to decide when they have enough data to proceed with analysis and decision-making, as the cost of continual searching becomes too great.[3,4]

In this exploratory study, we examined how physicians collect, process, and utilize data during the clinical prioritization process. We sought to model this process and examine how our model compares to the knowledge crystallization framework previously described by Card et al., which was proposed as a means for understanding and amplifying cognition during information-seeking activities.[5] Our goal was to identify opportunities to improve the delivery and utilization of information in the clinical care environment and future medical information systems.

Methods

Recruitment & Focus Group Structure

This study was reviewed and approved by the Institutional Review Board at Seattle Children's Hospital (SCH). Our target subject enrollment was 16 to 24 physicians. In order to be included in this study, we required that physicians be credentialed at SCH at either the attending (supervising physician) or fellow (sub-specialty trainee) level, and that they provided acute clinical services to hospitalized patients within the four months leading up to their scheduled

focus group session. Resident physicians commonly work in shifts at SCH and their prioritization process is heavily influenced by the handoff from the previous resident on duty, hence they were excluded from our recruitment efforts. We also excluded surgical providers given differences in workflows between the medical and surgical specialties.

Recruitment letters were sent to individual medical staff members. Respondents were scheduled to participate in one of five focus groups, each with 4 to 5 participants. Each subject participated in only one focus group, and we ensured that each focus group had a diverse group of participants, not limited to a single medical specialty.

All participant interactions, with the exception of recruitment, occurred during the focus groups, which took place between September and December 2013. To ensure balanced participation by all participants, each focus group was led by a focus group facilitator from our research team. Each session was 90 minutes in length and leveraged a semi-structured format divided into two parts.

During the first half of each session, participants received a series of six fictional cases (Table 1) which represented common clinical presentations and were designed to simulate a typical inpatient population. Cases were written in purposefully vague language to allow for the potential of a large differential diagnosis. Using the cases to stimulate thought, the participants wrote responses to a series of questions (Table 2) on individual worksheets. Participants were asked to provide basic demographic information on this worksheet, including age, gender, professional level (attending or fellow), medical specialty, and year of completion in medical school and graduate medical education.

Table 1. Focus group cases with admitting or presentation diagnosis

1. **Asthma**: Allison is 3 year old female with a history of 2 days of upper respiratory symptoms, and 1 day of increased work of breathing. At presentation to the emergency department had a significantly elevated respiratory score, and partial response to inhaled bronchodilators.
2. **Hypertension and headaches**: Ben is a 15 year old previously healthy male with 1 month of progressively worsening headaches and general malaise, who is found to have a blood pressure of 192/120 mmHg.
3. **Cellulitis**: Alex is a 6 year old female previously healthy who sustained an insect bite 3 days ago on her lower leg. She presents with 1 day of increasing redness, swelling, and tenderness of her calf and now has streaking extending up to her thigh and a temperature up to 39.5 C.
4. **Gastroenteritis**: Sara is a 3 year old previously healthy female with 4 days of vomiting and diarrhea, afebrile, unable to tolerate any oral intake, and no appreciable urine output over the past 12 hours and lethargy.
5. **Failure to thrive:** Isaac is a 4 week old infant male likely full term (exacts dates unknown, due to little prenatal care) weighing 3.28 kg and at admission weighs only 3.3 kg.
6. **Abdominal pain:** Matt is an 11 year old previously healthy male with acute onset abdominal pain, nausea, and fever.

Table 2. Focus group worksheet writing prompts

1. Describe the process you would use to prioritize this group of patients. In your description please consider the data that is important in the process, where this data comes from, and how you acquire this data. Please do not rank the patients in these cases.
2. Please describe how data in different situations may lead to different prioritizations. For example a fever in a previously healthy 6 year old with upper respiratory symptoms, is different from a fever in a 6 year old on hemodialysis with a central line, which is different from a fever in 6 year old with acute lymphoblastic leukemia and neutropenia. Think about how you contextualize and bundle data elements to help with the prioritization process.
3. Please list any challenges you might experience during the process you described above.

In the second part of the focus group, individual participants presented and discussed their written responses with the focus group. We recorded each focus group session with a digital audio recorder. The audio files and worksheets were transcribed for later processing and analysis.

Data Analysis

All participant data was de-identified prior to analysis. We coded focus group transcripts to identify themes and map out individual process flows described in the focus groups. Coding was done iteratively, and focused on participants' description of their prioritization processes. We made reference to the worksheets to verify patterns and process flows, and sought to explain differences in said flows using the demographic information provided by participants.

Results

Participants

We recruited 23 physicians—19 attending physicians and four fellows—representing six different medical specialties (Table 3). The participants from sub-specialty services provide care to patients on their own medical service and to other services in a consultative fashion, with the exception of five participants who were Infectious Disease physicians that provide only consultative professional services.

Table 3. Provider Characteristics

	Fellow	Attending
Number	4	19
Female n (%)	1 (25)	8 (42)
Age Range	30 -39	30 -59
Average number of years since completing medical school (range)	4.5 (4-5)	18.1 (7-31)
Average number of years since completing graduate medical education (range)	NA	10.3 (0-26)
Medical specialties (n)	General Pediatrics (4) Gastroenterology (3) Infectious Disease (5) Nephrology (7) Pulmonology (1) Rheumatology (3)	

After mapping out the process described by each participant, it became clear that physicians consistently perform the same activities during their prioritization processes. Two distinct, though similar, prioritization workflows emerged from this analysis (Figure 1).

Workflows

The two workflows we identified contain similar elements: categorizing each patient, gathering data, and testing the fit of the collected data with the working diagnosis. The distinction between the workflows seems to correlate with a physician's identification as either one with primary patient responsibilities or one with only consultative services. Both groups employ a tacit understanding of their patients and categorize patients based on this understanding. However, providers with primary responsibility for their patients prioritize their patients based on level of concern, which determines the order of data collection for these patients. Providers collect data, test the fit of that data within their existing mental model, and then reprioritize their work based on this test of fit. It appears as though consulting providers (without primary patient responsibilities) do not prioritize their patients based on their initial clinical categorization, but gather data first, then prioritize patients based upon the fit of data within their working diagnosis.

Here we describe the two workflows using scenarios that capture the essence of participants' processes, followed by a series of representative quotes from the focus groups.

Workflow 1: Primary providers

When I come into the hospital in the morning, I begin with the patients on my service for which I have the most concern. Typically these are the sickest patients, but not always. Sometimes I am most worried about the patients who I just haven't figured out or who are not behaving as expected, based on the information I have at the time I start my day. This data comes from a variety of sources, including communications received from other providers on the care team as well as the medical record. However, at this point I am mostly prioritizing my patients based on my own tacit understanding and categorization.

Once I have identified the patients I am most concerned about, I begin collecting additional data to investigate how that patient has changed since I last saw them. I am less concerned with absolute values (for example, an elevated creatinine level) since many were abnormal in the first place. The new data either confirms my working diagnosis or identifies inconsistencies that need further exploration and explanation. I am reassured by patients who are progressing as expected, even if they are clinically sicker, but receiving appropriate therapy. When I identify a patient who doesn't seem to fit within my mental model or categorization, I become more concerned and this patient escalates on my prioritization list. This leads me to gather additional data for this patient in an attempt to identify the correct diagnosis and ultimately provide appropriately-targeted therapy. Their response to therapy provides additional data that either supports or conflicts with my understanding of their disease process and accordingly affects my level of concern and ultimately my prioritization. Once I believe my patient to be receiving the correct therapy, I usually move on to the next patient.

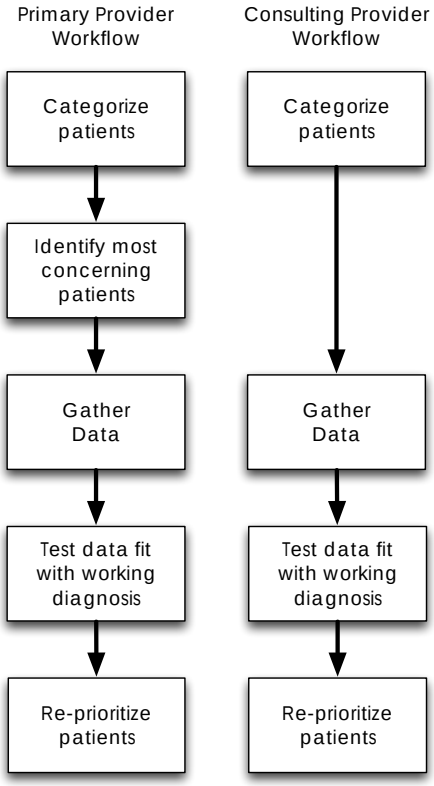

Figure 1. Workflow elements and order for primary and consultant providers.

Supporting examples from focus groups:

Participant 3.2: "…I prioritize first based on if the patient's on my service because then I'm primarily responsible as opposed to just being a consultant, and then if I'm primarily responsible, then I guess I kind of think of … the least stable or the most sick…. [the sickest patient is] unpredictable – the patient has been primarily unpredictable while they've been there, they're not following a course we would like them to follow…"

Participant 3.1: "…we inherently are constantly thinking about the sickest patient more than anybody else, so when I come into the door, I automatically will open their chart up first…"

Participant 4.2: "…if anything catches my eye that would be worrisome, I might do a little bit more investigating."

Participant 5.5: "I usually want to know exactly what interventions have been tried already, because that also modifies my probability of what's going on…and kind of like just how certain we are about things, and certainly there [are] vital sign changes or [as] abnormal lab results come back, then that changes my diagnostic impression."

Workflow 2: Representative of physicians with only consultative service responsibilities

Since I am not the primary responsible provider for the patients I am providing care to, I am less focused on their clinical acuity as I expect their primary service to address any urgent needs. Therefore, I typically begin my day with my list of patients, sorted alphabetically by last name or by location within the hospital, and then start at the top of that list and work my way down collecting new data for each patient, for example microbiology results or fever curves. As I collect these data, I am mentally processing to ensure that it fits with my understanding of the patient. I am reassured when the data fits my mental model, and more concerned when it does not. When the data doesn't fit, I spend time searching for and collecting data to help me identify the correct diagnosis. I am also concerned when I feel that the patient isn't receiving appropriate therapy, and I work with the primary team to explore why.

Supporting example from focus groups:

> *Participant 5.3: "I think a couple of things that are really different about an ID consultant. One is this idea that – ah, someone else will take care of the patient. I'm totally not interested in: "are they coding at the moment"… there's other people to deal with that, so I'm expecting that if they have questions for us, they'll call us. So I'm really more concerned with more bigger picture stuff…And so trying to keep track of all of that can be one of the bigger challenges…What I tend to do when I come in…I look at everything, because what I found was that unless I looked at seven different sources of information, there were gaps."*

Prioritization: Acuity vs. Change

When asked how they prioritize their patients, almost all focus group participants discussed invoking the concept of "sick vs. not sick" during their patient care regimes. This concept is thought to have been first used to quickly triage injured soldiers during the French Revolution, and is widely attributed to Dominique Jean Larrey, a surgeon who attended to Napoleon's Imperial Guards.[6] Participants in our focus groups had a difficult time defining this concept. When pushed to explain what they meant by "sick vs. not sick," participants ultimately agreed

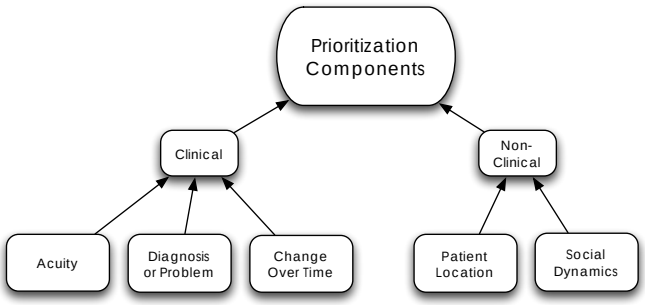

Figure 2. The components used by clinicians in the prioritization process contain both clinical and non-clinical elements.

upon a process rather than a definition; a process performed by experts with expert knowledge. Physicians often use experience and intuition in conjunction with objective data to decide who is sick. Most participants cited clinical acuity as the basis for the distinction, including a variety of data points most commonly including vital signs and laboratory values. Clearly, clinical acuity plays a role in the prioritization process, but changes or trends seem to play a vital role in this process, as well (Figure 2). Changes in either objective or subjective data elements—both expected changes and unexpected changes— appear to facilitate the distinction between patients who are sick, and those who are not. Quotes from the focus group participants explain this best:

> *Participant 2.2: "So I'm looking for patterns that I recognize that I'm supposed to be seeing in patients in general based on experience. I'm looking for how the patterns are not following what I'm expecting based on my knowledge of the type of patient … And I'm looking for a change in the pattern or in the trend which maybe I wasn't expecting…And that stops me in my tracks, why is this not making sense? … That's when everything stops and that's when I really want to be able to have the ability to grab around all the data, the numbers, the written words, the commentary which is hard to find, the imaging, the everything, and just sort of say why does this not make sense?"*
>
> *Participant 2.4: "So if you're sure of the diagnosis and you're sure they're on the right therapy even if they're worse, not such a big deal. If all of a sudden you say, 'Wait, this doesn't make sense anymore.' You have to go back to square one…Are we treating the wrong thing?"*
>
> *Participant 2.2: "… We have plenty of patients who get worse, but sometimes that's part of pattern. And that actually doesn't freak you out anywhere near as much as when somebody gets even just a little bit worse, but that's not what they're supposed to do. It's when they do what they're not supposed to do that you think something is weird going on, you have to regroup."*
>
> *Participant 4.1 "Change, yeah, a new vital sign change, new critical lab value. I'm trying to get at that decompensation potential…"*

Our findings suggest that physicians express elevated levels of concern and anxiety for patients that do not follow an expected clinical course. Upon encountering this scenario, participants indicate a heightened level of concern, which leads to increased vigilance for those patients who have the potential to acutely decompensate. In order to uncover this type of discrepancy, participants indicated that they rely on changes in clinical outcomes and did not find absolute values as helpful.

Challenges

Participants expressed many concerns and difficulties, relating to both data collection and processing, when trying to prioritize their patients (Table 4 and Table 5). Participants identified missing data as a significant problem. A variety of factors contribute to missing data—it might not have been collected in the first place, or it might have been collected but stored in an alternative location (e.g. lab result in an outside record). Many participants echoed this sentiment and expressed frustration with data sources that are inaccessible or hard-to-access, especially data retained by a nurse, consultant, or patient.

In addition to missing data, another major challenge identified during the focus groups related to the time required to collect relevant data. Participants reported the need to search across multiple sources, oftentimes in a variety of physical locations. The need to search through voluminous data sources and ultimately filter out non-relevant segments significantly contributed to the amount of time participants required to complete the data collection process. Other challenges encountered related to data quality as well as technical challenges with interacting with

Table 4. Challenges with Data Collection

1. Missing data
   - Not collected
   - Collected but not resulted
   - Collected but not available or not found
     - Data in outside record
     - Source (i.e. resident, nurse, consultant, patient, care provider) not accessible
     - Most recent results not available
   - Available data not recognized as valuable
2. Communication between care team members did not occur
3. Noise
   - Filtering unimportant data
4. Time Consuming
   - Searching
   - Waiting (related to availability of resources)
   - Need to check multiple sources in a variety of locations
5. Quality concerns
   - Data gatherers have varying skill levels
   - Language barriers
6. EHR
   - Speed
   - Interface

Table 5. Challenges with Data Processing

1. Bias
   - Anchoring
   - Bandwagon
   - Confirmation
   - Premature Closure
   - Presentation
   - Source value
2. Time Consuming
3. Multitasking
4. Different focuses between stakeholders (physician, nurse, patient, caregiver)
5. Unexpected results
6. Discovering trends especially across data types
7. Framing, putting results in context
   - Normal vs abnormal
   - Better or worse
   - Over time

the electronic medical record.

During the focus group discussions, participants also indicated that they encounter difficulties processing information after it has been collected. Many of these challenges concerned cognitive biases that interfere with the participant's ability to appropriately process and interpret available data. For example, some participants expressed challenges with incorporating new data into existing mental models, especially when the new data did not fit or was unexpected. Despite the quantity or quality of data that may be available within the medical record, a clinician may not always think to gather all potentially relevant data, or may even miss an important test result, due to an error in their clinical reasoning or potential retrieval issues.

Other themes that emerged around the discussion of data processing were difficulties with trending data over time, across data types, and putting it in the appropriate context.

Discussion

Clinicians spend much of their time working with information: searching, acquiring, processing, framing, and acting on information with the goal of providing the best patient care. Most clinicians in a hospital setting are responsible for providing care to multiple patients at once. Given the multitude of competing needs, clinicians must constantly re-prioritize their work to ensure the most urgent needs are met first. This process might best be described as a "knowledge crystallization" task, which was first described by Card et al. as a task "in which a person gathers information for some purpose, makes sense of it by constructing a representational framework (referred to as a schema), and then packages it into some form for communication or action."[3]

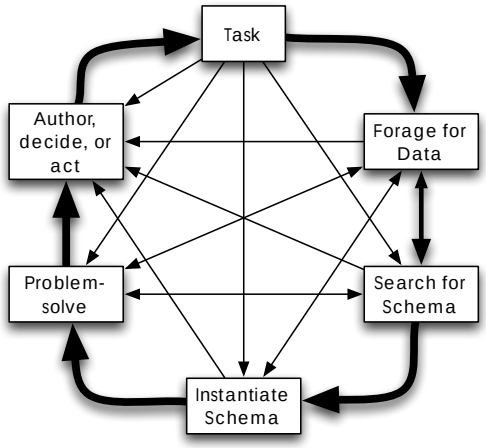

Figure 3. Knowledge Crystallization framework as proposed by Card, Mackinlay, and Shneiderman in 1999. This model aids information seekers by providing structure as well as context to their search process ultimately reducing the cognitive burden needed to accomplish a task. Typically, one moves around the outside in a counterclockwise fashion, but can jump to other steps as appropriate.

Knowledge Crystallization

Within the knowledge crystallization framework (Figure 3), a knowledge seeker typically moves from a task to gathering data to finding and instantiating an appropriate schema that allows the individual to address the task and act appropriately. Card et al. describe this process in detail, and specify three required elements for knowledge crystallization: data, tasks, and schemas.[3] The value of the knowledge crystallization model lies in its ability to improve the efficiency of acquiring and processing data in order to accomplish a stated task. Initially envisioned as a tool to create schemas for information visualization models, use of knowledge crystallization extends to most information seeking activities.

At a high level, the prioritization process used by clinicians during patient care activities seems to model the knowledge crystallization framework. However, the process revealed by physicians in our focus groups indicates a slight—though notable—difference.

When caring for patients, clinicians have a primary task: provide the best and most appropriate therapy in a timely fashion. To accomplish this task, clinicians systematically collect targeted data. To be effective, clinicians begin with a mental model or schema they have deemed appropriate to their current situation, and they ask questions and seek answers that test the validity of this schema (in the field of clinical reasoning, this is analogous to the hypothetico-deductive approach, where experts use co-selection in order to test a hypothesis).[7,8] This process continues until the clinicians reach a point where they are comfortable enough to act and deliver appropriate care.

Therefore, we cannot accept the knowledge crystallization framework wholesale without making modifications. Recognizing and understanding the difference between the knowledge crystallization framework and a physician's prioritization process allows us to propose a new model which highlights the importance of the schema for clinicians while providing patient care. The new model resulting from this research (Figure 4) incorporates the concept of the schema and how the prioritization process is influenced by the collection and processing of data.

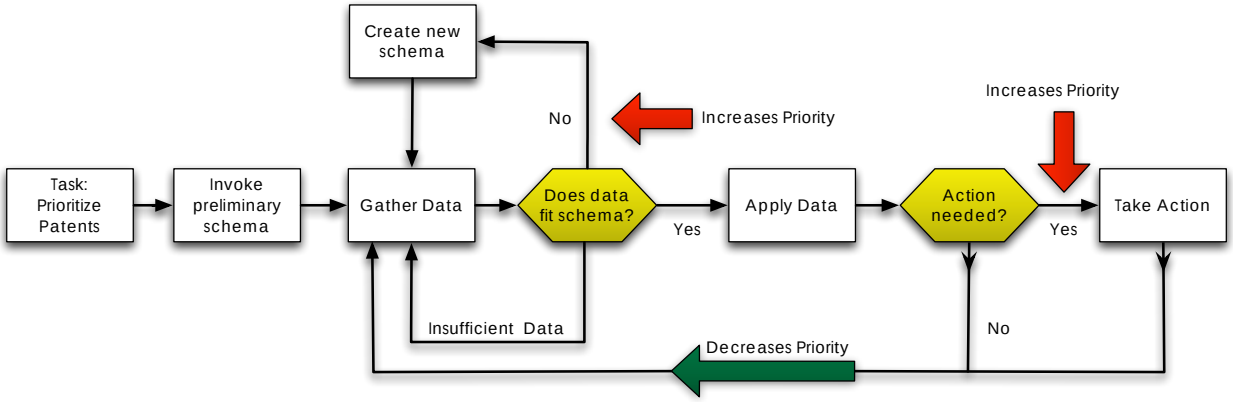

Figure 4. Modified knowledge crystallization model addresses the task of prioritizing patients. Once clinicians have invoked their preliminary schema, categorizing each patient, they gather data and asses the fit of the data with their schema. Poor-fitting data requires a new schema, increasing the priority of that patient.

Beginning with a schema prior to gathering data allows a clinician to proceed with purpose and direction, what some would refer to as the artistry in medicine.[9,10] When a physician determines the need to take action and provide care, therapeutic interventions appear to be based on their diagnostic categorization (i.e. schema). Depending on the acuity and urgency of the situation, clinicians may choose to act with a low level of diagnostic certainty to prevent further clinical deterioration. However, regardless of the degree of certainty with the working schema or diagnosis, instantiating a schema allows for constant evaluation and testing, generating refinements, increasing accuracy, and ultimately leads to the appropriate intervention for the patient.

Our model identifies the value of the schema and how clinicians use data to test its validity. Clinicians place high importance on the validity of their schema: when they uncover data that contradicts that schema, their level of concern for the patient, and therefore the patient's priority increases. We expected clinical acuity (i.e. sick vs. not sick) to be the major driver in the prioritization process; but this research suggests that classification errors leading to poor schema formation have equal, if not greater importance. Recognizing the importance of patient categorization and ultimately schema formation has the potential to influence future information delivery systems.

Implications

Tools designed with this new model in mind will have a greater capacity to dramatically improve a clinician's ability to provide care for their patients, and streamline their work processes. We first propose design principles to help guide the development of new clinical information system tools followed by specific recommendations where use of our model has the potential for positive change: workflow improvements to assist in patient categorization, and potential integrations with the burgeoning field of information visualization.

Design Principles

Our model provides multiple opportunities to improve clinical information systems. Designers should focus their development efforts highlighting information that contradicts the pre-formed schemas utilized by clinicians in the care process. These tools have the potential to highlight subtle and early changes in the clinical course of a patient, perhaps even before a clinician has recognized them. In addition, our research clearly demonstrated the importance and value clinicians put on expected and unexpected changes in the clinical courses their patients follow. Therefore, the development of new tools should focus on highlighting these types of changes, making it easier for clinicians to detect, process and act. Designers have the opportunity to focus their efforts on concepts such as change from expected, change over time, as well as relative changes and absolute changes.

Patient Categorization

Large data repositories—a result of the implementation of electronic health records at many hospitals—have tremendous potential for machine learning applications. Machine learning involves the process of applying an algorithm to accomplish a task, where "learning" is achieved through recursively repeating the task and improving upon an empirical metric. Clustering, a typical machine learning problem, sets out to group objects such that the objects within a group or cluster have similar traits. The process of assigning a diagnosis to a patient is analogous to cluster analysis, in that a physician identifies specific traits of an individual (e.g. fever, cough, chest pain) and identifies potential similar groups or diagnoses for that patient (e.g. upper respiratory infection, pneumonia or asthma). As the physician gains more information she adjusts the grouping to improve the fit, just as we have described in our model. There are examples of using cluster analysis to better understand the variability within a specific disease, but we are not aware of its use in clinical systems to help in real-time patient classification.[11] The physicians we interviewed agreed on the importance of recognizing when patients begin to deviate from their expected course, and it is clear that an automated cluster analysis tool built into the electronic medical record with the potential to highlight these changes would be tremendously valuable to physicians. Furthermore, given the biases that interfere with the medical decision-making process these tools have the potential to provide more objective evidence to providers during times of great need.[12]

Information Visualization

One could argue that the results of cluster analysis achieve their greatest potential when expressed visually. The human visual system quickly allows us to find patterns and associations within data sets when organized in a visual fashion.[13] Cluster analysis exploits this trait to discover patterns and groupings based on specified attributes.

Imagine a clinical system that visually represents groups or clusters of patients based on historical clinical attributes from within the medical record. Patients of an individual physician could be overlaid on this display, allowing the physician to quickly identify appropriate groupings for his or her patients. It would be possible to show how a patient's affinity towards different groupings changes over time as new data becomes available. Our results demonstrate the importance of categorization and schema formation within clinical care, specifically how inaccurate categorization of patients leads to increased concern from medical providers. Visual presentation of cluster analysis has incredible potential to help physicians recognize subtle changes in a patient's clinical course more quickly, reducing this anxiety.

We recognize that this vision for cluster analysis within the medical record will be challenging to implement and may be in the future but information visualization still has great potential with much simpler tools using our model as a basis for presenting information to clinicians. For example, visualizations that identify changes in patient variables over time would be easier to implement, and still offer tremendous benefit to physicians. Wang et al. indicate that tools have been developed to visualize event time sequences that provide clinicians and administrators insight into how the order of events affect overall patient care.[14,15] Leveraging tools to highlight changes in clinical outcomes across different data points, like changes from baseline, changes from normal, or changes from an expected course, support the task of clinical prioritization. Most electronic systems provide this basic capability via result trending over time, but it is easy to imagine how more intricate displays spanning disparate data sources could help physicians identify patients with more urgent needs. As indicated in our focus groups, physicians tend to sort their patient list by demographic information. A patient list with sort options encompassing the degree of change over the last 6 or 12 hours based on vital signs and lab values would help physicians quickly identify patients with the highest degree of change among their population of patients. Combined with a physician's tacit knowledge of the expected course for an individual patient, this tool could help identify patients with unexpected deviations in their clinical course.

These examples leverage Shneiderman's mantra for information visualization: overview first, zoom and filter, and then details on demand, which would provide clinicians with a quick, but highly interpretable snapshot of their patients' statuses.[16] Although clinicians often create mental models to help process this information, visualization techniques could help lighten cognitive processing required by physicians as well as provide new insights into data available within the medical record.[17,18] Chittaro describes a series of techniques and goals for visualizing information and applying them to the medical domain.[19] However, none of these tools help to prioritize information within a single record, nor across multiple patient records. Leveraging information visualization to highlight the points in our model that increase a patient's priority has the potential to dramatically improve physicians' ability to prioritize all of their patients.

Strengths and Limitations

Too often the evaluation of healthcare information technology occurs late in the software development cycle, making changes much more difficult and costly to implement.[20] In addition these late evaluations base their system design on assumptions of stakeholder needs and workflows. Conversely, our work explored understanding the fundamentals of information seeking and processing for practicing physicians. This knowledge should allow clinical information system designers to develop systems that better target the needs of clinicians. Because our study based its findings on a diverse sample of medical providers, the results should be generalizable across a broad population of providers.

Despite the diversity of medical providers within our sample, all of the participants were pediatric providers at a single organization, which might diminish its generalizability. Nonetheless, we would argue that pediatric providers approach the task of clinical prioritization in the same manner that internal medicine or family practitioners do. In addition, the scenarios utilized in the focus groups only included hospitalized patients, excluding the outpatient setting, though most of the participants in the study provide care in both settings. One could easily repeat this study and include an expanded group of clinicians in a variety of settings to ensure the broader applicability, especially for ambulatory patients where care extends over weeks to months and even years.

Conclusion

Physicians expend a significant amount of time and mental effort working with data, finding context, and ultimately transforming information into knowledge, which proves to be a tremendously costly endeavor. Understanding the cost structure of information seeking has broad implications in healthcare information systems. Development of these systems should be based on a thorough understanding of clinical knowledge acquisition and processing as well as the costs of these procedures.

The first step in reducing these costs requires us to understand how physicians approach the journey of knowledge discovery and identify points or situations that have the potential to increase these costs. We present a model that describes the information seeking behavior used by physicians to prioritize patients in a hospital setting, highlighting the importance of accurate clinical categorization in this process. Our goal for this research was to inform the design and creation of novel tools or systems that focus on the data and information required during the prioritization process and improve their delivery. Through machine learning applications and information visualization, our model has great potential to reduce the costs of knowledge acquisition in healthcare settings and as a result improve clinical outcomes.

Acknowledgments

We would like to thank all participants and funding sources (NIH T32 DK007662) and Dr. David Hendry for his support in this endeavor.

Providing Hospital Patients with Access to Their Medical Records

Jennifer E. Prey, MS[1], Susan Restaino, MD[2,3], David K. Vawdrey, PhD[1]
[1]Department of Biomedical Informatics, Columbia University, New York, NY; [2]NewYork-Presbyterian Hospital, New York, NY; [3]Department of Medicine, Columbia University, New York, NY

Abstract

Being a hospital patient can be isolating and anxiety-inducing. We conducted two experiments to better understand clinician and patient perceptions about giving patients access to their medical records during hospital encounters. The first experiment, a survey of physicians, nurses, and other care providers (N=53), showed that most respondents were comfortable with the idea of providing patients with their clinical information. Some expressed reservations that patients might misunderstand information and become unnecessarily alarmed or offended. In the second experiment, we provided eight hospital patients with a daily copy of their full medical record—including physician notes and diagnostic test results. From semi-structured interviews with seven of these patients, we found that they perceived the information as highly useful even if they did not fully understand complex medical terms. Our results suggest that increased patient information sharing in the inpatient setting is beneficial and desirable to patients, and generally acceptable to clinicians.

Introduction

Being in the hospital has been called "one of the most dis-empowering situations one can experience in modern society."[1] Patients often feel isolated, anxious, and that they do not have control over their care. They often do not know what medications they are taking, their treatment plans, or even the names of members of their care teams.[2–4] Therefore, it is important to try to engage hospital patients and facilitate greater participation in their care.

Engaging patients has received significant attention in recent years. In contrast to the traditionally paternalistic doctor-patient relationship, consumers increasingly expect direct and fast access to their health records.[5] This engagement of patients not only helps the patients feel more involved, but also can lead to improved health outcomes.[6,7] The journal *Health Affairs* recently referred to patient engagement as equivalent to the next "blockbuster drug".[8] The Institute of Medicine (IOM) recommended that individuals receive opportunities to have access to medical information and clinical knowledge which will enable the patients to be the "source of control".[9] The U.S. Meaningful Use financial incentive program stipulates requirements for patients having access to clinical summaries, electronic messaging with their providers, patient-specific educational resources and online access to their personal health information (including information like care team members, medication lists and history, laboratory results, and problem lists).[10] Further, the Consumer Assessment of Healthcare Providers and Systems (CAPHPS) Hospital Survey, which collects patients' perspectives of hospital care, impacts hospital reimbursement from the Centers for Medicare and Medicaid.[11]

Despite a growing interest in patient engagement, little work has been conducted to study patient engagement in the inpatient setting.[12–15] As noted in a recent New England Journal of Medicine article, access to information by patients is becoming more common, but providing access in the inpatient setting is particularly complex.[16] To our knowledge, no one has studied the impacts of providing patients in the hospital with full access to their medical record. This includes data like medications, laboratory results, radiology and pathology reports, clinical summaries, operative/procedure reports and progress notes. We wanted to understand the clinician perspective on increased patient access to information as well as study the patient experience in receiving greater access to their information while in the hospital. Our hope was that by providing patients with access to their full clinical chart, they would feel more engaged in their care.

Methods

This research consisted of two parts; a survey administered to clinicians as well as a complementary field study conducted with patients in the hospital. In the field study, patients received daily printouts of their medical chart and then participated in semi-structured interviews to discuss their experiences. The study was conducted at Columbia

University Medical Center (CUMC), a large urban academic center that is part of NewYork-Presbyterian Hospital. This research was approved by the medical center's human subjects institutional review board.

Clinician Survey

A one-page survey was distributed to attendees of a staff meeting in a cardiac step-down unit, mostly comprised of nursing staff and physician assistants. It was also distributed at a monthly meeting of CUMC's Housestaff Quality Council, a group of resident physicians representing each clinical department at the medical center. Additional surveys were collected from clinical staff on the cardiology floor.

The survey consisted of two sections, one that focused on clinicians' perceptions of sharing different types of information with patients (e.g. medication information, clinical notes), and a second section that asked about potential consequences of increased patient access to information. Each of these items was evaluated on a 5-point Likert-type scale from 'Strongly Disagree' to 'Strongly Agree'. Questions used negatively and positively worded stems to guard against acquiescence.[17] The survey also provided additional space for participants to provide comments and encouraged them to elaborate on potential concerns, burdens, or benefits of increased patient access to information.

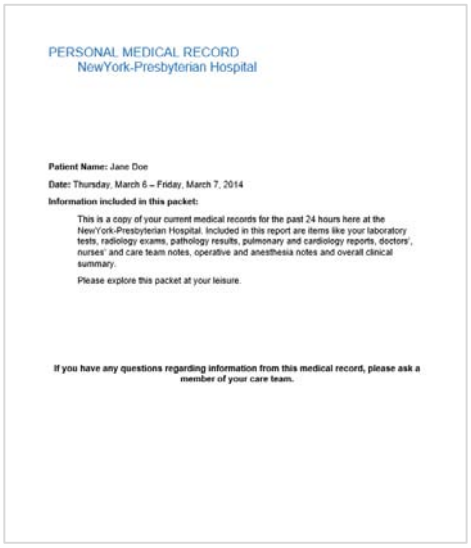
Responses to the survey were tabulated and analyzing using both Microsoft Excel 2010 and the R Statistical package.[18] A descriptive summary of the data consisted of calculating frequencies, medians, and inter-quartile ranges (IQRs). Kruskal-Wallis analysis was completed, and a Bonferroni correction used for post-hoc analysis.[19]

Inpatient Field Study

We provided cardiology patients with a daily printout of their hospital care, printed from the institution's electronic health record (EHR).[20] After four consecutive days of receiving this printout, we conducted in-situ semi-structured interviews with patients to elicit their feedback. Interviews were audio recorded, and transcripts of the audio were thematically coded.

Medically stable patients on a cardiology floor were approached for potential participation based on their ability to speak English and their anticipated date of discharge. In line with our institutional policies, their attending physician described the study and referred interested patients to the primary researcher (JP), who obtained informed consent.

After providing consent, the patient received a daily printout of his/her medical record, which included new information added to the EHR in the previous 24 hours. Specifically, the printout contained: laboratory test results, physician progress and consult notes, radiology reports, pathology reports, cardiology test results, discharge planning materials, operative reports, nutrition notes, the medication administration record, and other nursing documentation.



PERSONAL MEDICAL RECORD
NewYork-Presbyterian Hospital

Patient Name: Jane Doe

Date: Thursday, March 6 – Friday, March 7, 2014

Information included in this packet:

This is a copy of your current medical records for the past 24 hours here at the NewYork-Presbyterian Hospital. Included in this report are items like your laboratory tests, radiology exams, pathology results, pulmonary and cardiology reports, doctors', nurses' and care team notes, operative and anesthesia notes and overall clinical summary.

Please explore this packet at your leisure.

If you have any questions regarding information from this medical record, please ask a member of your care team.

Figure 1. Cover page for patient printout.

Minor editing was performed to remove phone numbers and social security numbers, and to delete unnecessary white space. No additional changes were made to the documents. A cover page describing the potential contents of the printout was added (Figure 1). The report was printed and hand-delivered each morning to each of the participants. The reports ranged from 5–40 pages each; 10–15 pages was typical.

After receiving daily reports for four days, a semi-structured interview was conducted. In addition to basic demographic questions, patients were asked to describe various experiences related to receiving their clinical information. Topics that were discussed included:

- Patients' use of the printout (e.g., frequency, time spent)
- Patients' perceived capacity to understand the information
- Preferences regarding structure/format of the information
- Patients' desire to receive such information in the future
- Behavior changes as a result of having the information (e.g., asking more questions)

Interviews were audio-recorded and transcribed. As done in previous studies by this research team,[13] transcripts were then thematically coded by the primary researcher (JP).[21]

Results

Clinician Survey

Approximately 65 surveys were distributed and 53 clinicians responded: 21 physicians (40%), 20 nurses (38%), 7 physician assistants (13%), and 5 allied health professionals (e.g., nutrition specialists, social workers) (9%). Responses are shown in Table 1 along with frequency, median, and IQRs in ordinal number format (1=Strongly Disagree; 5=Strongly Agree). Only the first question (sharing some information in general) had an IQR equal to zero. Six questions had an IQR of two. The Kruskal-Wallis test analyses differences between the groups (Physicians vs. PAs vs. Nurses vs. Other). Only the question on note-writing behavior was statistically significantly different between groups (p=0.033); however, post-hoc pairwise analysis of between group differences with a Bonferroni correction did not find any significance. The survey results are also presented using diverging stacked-bar graphs in Figures 2–4.[22]

Table 1. Summary statistics for clinician survey on attitudes toward inpatient information sharing.

	Disagree	Strongly Disagree	Neutral	Agree	Strongly Agree	No Response	Range	Q1	Median	Q3	IQR	Kruskal-Wallis
I am comfortable with patients having access to:												
Some information from their EHR (in general)	0 (0%)	0 (0%)	6 (13%)	28 (62%)	11 (24%)	9 (20%)	3-5	4	4	4	0	0.458
Medication Information	0 (0%)	0 (0%)	1 (2%)	23 (45%)	27 (53%)	3 (6%)	3-3	4	5	5	1	0.336
Care Team Profiles	3 (0%)	0 (6%)	8 (15%)	23 (44%)	18 (35%)	2 (4%)	2-5	4	4	5	1	0.419
Lab Results	2 (2%)	1 (4%)	3 (6%)	23 (44%)	23 (44%)	2 (4%)	1-5	4	4	5	1	0.511
Radiology Results	3 (2%)	1 (6%)	5 (10%)	21 (40%)	22 (42%)	2 (4%)	1-5	4	4	5	1	0.088
Pathology Results	2 (2%)	1 (4%)	3 (6%)	24 (46%)	22 (42%)	2 (4%)	1-5	4	4	5	1	0.211
Operative/Procedure Reports	1 (2%)	1 (2%)	6 (11%)	27 (51%)	18 (34%)	1 (2%)	1-5	4	4	5	1	0.345
Progress Notes	10 (6%)	3 (19%)	11 (21%)	19 (36%)	10 (19%)	1 (2%)	1-5	2	4	4	2	0.092
Consultation Notes	7 (4%)	2 (13%)	12 (23%)	20 (38%)	12 (23%)	1 (2%)	1-5	3	4	4	1	0.233
In my opinion, providing patients increased access to their medical information will result in:												
Increased time at bedside	9 (4%)	2 (17%)	15 (29%)	20 (38%)	6 (12%)	2 (4%)	1-5	3	3	4	1	0.970
Increased patient misunderstanding of information	15 (2%)	1 (28%)	11 (21%)	20 (38%)	6 (11%)	1 (2%)	1-5	2	3	4	2	0.541
Increased patient anxiety	14 (10%)	5 (27%)	13 (25%)	14 (27%)	6 (12%)	2 (4%)	1-5	2	3	4	2	0.638
Increased legal liability	11 (2%)	1 (21%)	16 (31%)	16 (31%)	8 (15%)	2 (4%)	1-5	3	3	4	1	0.784
More work for me as a caregiver	16 (0%)	0 (31%)	14 (27%)	18 (35%)	4 (8%)	2 (4%)	2-5	2	3	4	2	0.333
Increase in patient questions	5 (2%)	1 (10%)	17 (33%)	25 (49%)	3 (6%)	3 (6%)	1-5	3	4	4	1	0.198
Improved health behaviors	16 (4%)	2 (31%)	6 (12%)	26 (50%)	2 (4%)	2 (4%)	1-5	2	4	4	2	0.140
Enhanced patient-clinician communication	1 (0%)	0 (2%)	18 (35%)	30 (58%)	3 (6%)	2 (4%)	2-5	3	4	4	1	0.301
Increased patient engagement in decision making	2 (0%)	0 (4%)	16 (31%)	28 (54%)	6 (12%)	2 (4%)	2-5	3	4	4	1	0.570
I would change the way I write my clinical notes if I knew a patient could view them:	15 (4%)	2 (31%)	12 (25%)	15 (31%)	4 (8%)	6 (13%)	1-5	2	3	4	2	0.033*

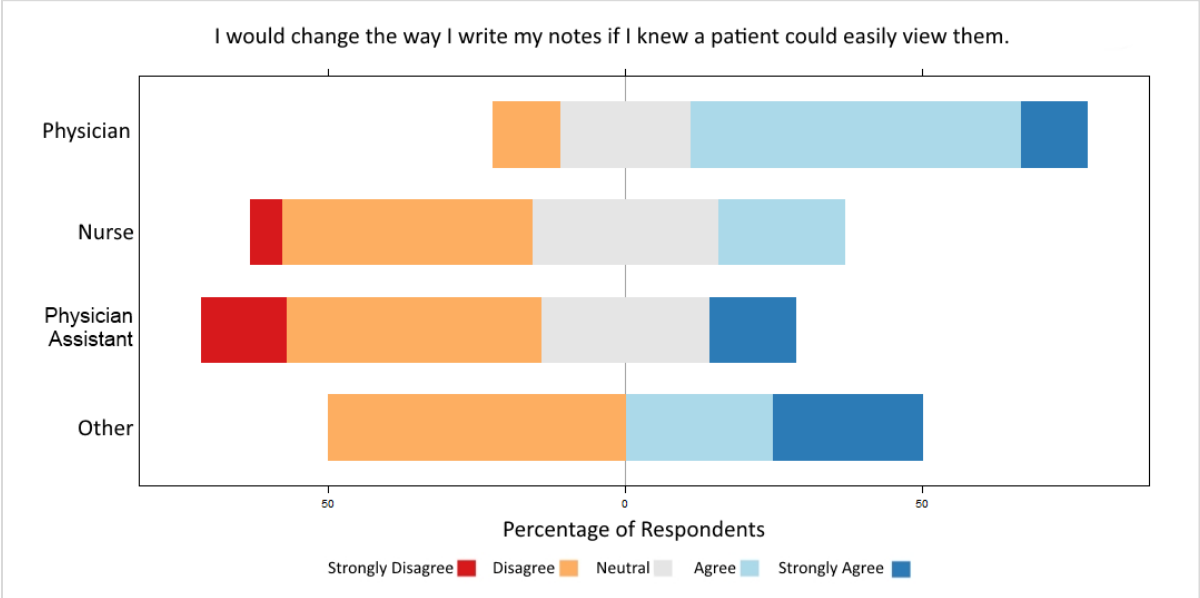

Figure 4. Clinician perspectives on expected changes in note-writing with increased patient information sharing.

Inpatient Field Study

Eight patients participated in the field study (Table 2). Seven completed the follow-up interview after receiving printouts of their hospital record for four days. The eighth patient was discharged prior to completing four days of receiving his records.

Table 2. Participant Demographics of Inpatient Field Study.

	Sex	*Age*	*Admission Reason*	*Presenting Chief Complaint*	*LOS*[*]	*Highest Level of Education*	*Reports Using Internet for Health Information*
P1	Female	87	Congestive heart failure exacerbation	Shortness of breath	6 days	High School	No
P2	Male	56	Diarrhea, atrial fibrillation	Diarrhea, shortness of breath	22 days	Some College	Yes
P3	Male	65	Septic Shock	N/A[†]	8 days	Graduate School	Yes
P4	Male	43	Myocardial infarction	Chest pain	4.5 months	College Graduate	No
P5	Male	35	Hemoptysis	Hemoptysis, shortness of breath	5 days	College Graduate	Yes
P6	Male	54	Awaiting Heart Transplant	N/A[‡]	5 weeks	Associates Degree	Yes
P7	Male	54	Ventricular tachycardia	Shortness of breath	5 weeks	Some College	No

[*]Length of stay at time of interview, [†]Transferred because of fevers from inpatient acute rehab, [‡]Admitted for heart transplant listing

Overall, patients' feedback on receiving the daily printouts was positive. Out of the seven patients we interviewed, six patients indicated that they would want to receive this type of information again if they had to return to the hospital. All six expressed a desire to continue receiving the printouts for the remainder of their current stay. Key themes that emerged from the semi-structured interviews were: variations in use, difficulty understanding medical jargon, appreciation of having the information, suggestions for improvement, changes in interaction with clinicians, and changes in engagement.

Variation in Use

There was a range in use of the printout. Two patients stated that they did not look at the printout (P5 and P7), P4 looked at it on two of the four days, and the remaining patients reported looking at it every day. The scope of use also varied. Some patients reported only skimming the information, while others read it in detail and even added their own annotations. For example, P2 commented: "I take a look, and if I see something that's not [in range], I just mark it."

Difficulty Understanding Medical Jargon

The printouts were created from the EHR without any substantive changes made to the content or format. Patients discussed having particular difficulty with certain medical terms and acronyms. P3 stated, "I read until I found technical stuff, and then I would jump over it…the parts I read, and I understood, were interesting and beneficial." P2 said, "Most of the things I understand, but some of the other things…like letters in combination, 'WT' or whatever… [were] not of use to me."

Several patients reported looking for specific items which they knew about. P1 specifically asked about her creatinine values and searched for the results of a sonogram performed the previous day. P5 expressed difficulty with understanding some material, but was planning to use the Internet to supplement his knowledge: "I'm familiar with some stuff," he said, "but…some of the terms I'm not familiar with, so once I have my laptop I'm probably going to take another look at it."

Appreciation in Having the Information

Patients expressed appreciation for having access to information about their care that they wouldn't normally receive. P7, who did not review the printouts at all, reported that it was important to him to "have a file." P2 said it was "very, very neat…because they give you all the details," and P5 stated: "Notes help a lot too, to see if the doctors are interpreting what I say… and they're pretty right on. And just [to see] what they thought as far as the possible diagnosis."

Suggestions for Improvement

In addition to wanting more explanation around medical terms and acronyms, patients expressed ideas regarding changes to the process that would make the intervention more helpful. For instance, P5 requested that there be a

more clear delineation of the author of notes: "Sometimes I see a bunch of comments, and I don't see exactly which doctor said it." P3 expressed the desire for more descriptive information: "If you could give me more information describing my condition and my situation…more than the technical stuff…more information as far as what the doctors are finding, and what the doctors are doing."

We also discussed the possibility of presenting the information to patients via a computerized interface. Most patients (four of the five who viewed the printouts) expressed an interest in viewing their information on a tablet computer or laptop.

Changes in Interaction with Clinicians

We asked patients if having access to their information prompted them to ask follow-up questions. Only one of the seven patients (P5) mentioned asking anything related to information in his printout. Several patients acknowledged the busy clinical workload of the providers and did not want to further impose on their limited time. P2 said, "[My doctors] have one or two minutes, [then] they're running all the time."

Changes in Engagement

Patients expressed feeling more informed about their health as a result of receiving the daily printouts. P2 mentioned that "if you don't ask, you don't receive [information], but with that paper, I am very on top of the situation." P5 said, "Instead of just listening to the doctor…I should pay attention to myself too" and believed the printouts could help him to do so.

In addition to feeling more informed, multiple patients mentioned the ability to act as a 'fact checker' of the information. P1 reported finding a prior procedure that was recorded with an incorrect date. P5 said it was, "neat to see the notes because sometimes during the interviews with the doctors, they'll write things down that I said, and well I didn't really mean it exactly that way." P5 also said, "I see the hospital medications…that's important I guess, just in case there are any discrepancies…between what stuff I think I should be taking, and [that] which they didn't give me here, and I'm like why, not?" P2 and P6 mentioned noticing discrepancies between when medications were documented as administered and when they believed them to have actually been administered.

Discussion

While patient engagement has recently been a topic of considerable interest[23–29], research in the inpatient setting is lacking.[12,14,15] In *The Patient Checklist*, Elizabeth Bailey observed that "once a patient enters a hospital for treatment of any kind, what he or she needs most of all is knowledge – what is happening to him, and why."[30] We believe our study may be the first to evaluate the effect of providing patients with access to their entire charts, including physician notes, during their hospital stay. The most important findings of our study were that information sharing: 1) was perceived as desirable to patients and acceptable to clinicians, 2) allowed patients to more actively participate in their hospital care, and 3) may impact clinician behavior in terms of workload, communication, and note-writing practices.

Our results suggest that greater information sharing with hospital patients can be beneficial. Of the seven patients we interviewed, six of them requested to continue receiving the daily printouts. Patients appreciated seeing the details of their hospital care even in the raw, unfiltered format that came from our EHR system. We believe that a more tailored format, though difficult to actualize, could have even greater potential to increase patient engagement. The survey results indicated that clinicians also viewed information sharing with patients favorably. For clinicians, the sharing of objective data in particular seemed to provoke little controversy. The sharing of more subjective data, such as progress notes and consultation notes, was less agreeable to survey respondents, but still, the majority were comfortable with sharing this information.

Clinicians' expectations of the consequences of inpatient information sharing were mixed. Most were optimistic that sharing information would enhance communication and increase patient engagement in decision-making. However, some survey responses reflected concerns about increased anxiety and misunderstanding of information. Though our sample was small, none of the patients interviewed expressed that they felt additional anxiety from viewing their records. On the contrary, several patients commented that receiving the daily printout made them feel more informed and better able to understand the details of their care. Additionally, having access to their information allows patients to act as another 'line of defense' to identify incorrect information and potentially decrease medical errors.

In the outpatient setting, the OpenNotes project explored the effects of giving patients the ability to read their doctor's office visit notes.[31] The project has been successful enough that the three institutions involved continued sharing notes with patients after the study ended. Additionally, the project has expanded to other institutions, including the Department of Veterans Affairs (VA).[32] Although further study of information sharing in the hospital setting is warranted, our results suggest that the OpenNotes concept may also be applicable to inpatient care.

OpenNotes investigators reported that increased access to physician notes by patients may change note-writing behavior.[33] Comments from our clinician survey suggested that this was a concern at our institution. For example, patients may be offended by reading certain descriptions in their charts (e.g., "obese", "disheveled"). Moreover, notes often contain expressions of uncertainty, frightening differential diagnoses, and findings that lack interpretation. If notes are readily accessible to patients, clinicians might avoid using certain terms, or omit clinically relevant details to protect patients from unnecessary anxiety. On the other hand, because so much of what clinicians currently document is not easily understandable by patients, they may be inclined to write in a manner that is more intelligible to patients (e.g., by using fewer acronyms).

Design Considerations for Inpatient Engagement

Beyond a pilot study, printing and hand-delivering daily reports as we did in this study is probably not a feasible option for most hospitals. However, a recent study from a neonatal intensive care unit described delivering a one-page paper handout to parents each day of their baby's stay.[34] The handout included information on the baby's care team, respiratory status, nutritional status, medications, most recent lab results, and care plan. Similarly, the VA began providing inpatients with access to limited information through the Daily Plan project, which delivered a daily printout of the patient's medications, appointments and diagnostic tests which nurses would then review with the patients each day.[35] We[13] and others[14,15] are working to deploy online patient engagement solutions for hospital patients. So far, these projects have provided tablet computers to patients in the hospital on a small scale and with limited information—excluding clinical notes, for example.

Future work should investigate how to present patient-specific medical information in a more patient-friendly manner. Appealing to diverse populations of patients, including those with low health literacy, low literacy in general, and non-native English speakers is a particular challenge. Using resources such as the Consumer Health Vocabulary and MedlinePlus may help to make complex medical terminology more understandable.[36,37] Additionally, use of visualizations has been shown to help patients better understand health information, especially for individuals with low health literacy.[38–40] Research on the creation of visualizations that explain inpatient data is warranted.

Another challenge to providing increased access to patient information is addressing privacy and security concerns. A recent article by Bates and colleagues discusses the need for family, caregiver, and care partner access to patient data.[41] Restricting access to certain types of data may be a feature necessary for privacy of sensitive topics like testing for drug use, or pregnancy in teenagers.

Limitations

This study was limited by a relatively small sample size for the clinician survey (n=53), and similarly by a small sample size of hospital patients who participated in the inpatient field study (n=8). Of the eight patients in the inpatient field study, one was discharged prior to the interview and two additional patients had not read through their records. Thus, the sample size was insufficient to achieve thematic saturation. Nevertheless, we believe our results shed light on the understudied topic of engaging hospital patients in their care and provide a foundation for future research. The study was conducted at a single site, an academic medical center in an urban setting, and our findings may not generalize to other settings. More specifically, our study was focused primarily in the domain of cardiology, and different results may be found in other patient populations. For example, patients with cardiac disease may have higher baseline engagement levels than patients with less chronic diseases, and thus may be more interested in seeing their data. Future work should explore whether differences in settings or patient populations exist with respect to inpatient engagement.

Conclusion

Healthcare delivery organizations are moving towards greater sharing of information with patients. Consumers, who are the "sole subject matter expert on themselves,"[42] are increasingly expecting to have access to their data. Our study found that clinicians were mostly comfortable with increased information sharing, and patients benefitted from

receiving daily printouts of their hospital care record. Increased access to information will enable patients to more actively participate in their hospital care.

Acknowledgments

This research was supported by grants from the National Library of Medicine (T15LM007079) and the Agency for Healthcare Research and Quality (R01HS21816). The authors thank our study participants, Dr. Suzanne Bakken for her feedback on creating the survey instrument, and the rest of our departmental colleagues for their continued support.

Improving Clinical Data Integrity by using Data Adjudication Techniques for Data Received through a Health Information Exchange (HIE)

Pallavi Ranade-Kharkar, MS[1,2], Susan E. Pollock, MS[1], Darren K. Mann, BS[1], Sidney N. Thornton, PhD[1,2]
[1]Intermountain Healthcare, Murray, UT;
[2]Department of Biomedical Informatics, University of Utah, Salt Lake City, UT

Abstract

Growing participation in Healthcare Information Exchange (HIE) has created opportunities for the seamless integration of external data into an organization's own EHR and clinical workflows. The process of integrating external data has the potential to detect data integrity issues. Lack of critiquing external data before its incorporation can lead to data unfit for use in the clinical setting. HIE data adjudication, by detecting inconsistencies, physiological and temporal incompatibilities, data completeness and timeliness issues in HIE data, facilitates corrective actions and improves clinical data integrity.

Introduction

Health Information Exchange (HIE) holds the promise of improving the quality and efficiency of health care[1, 2]. Hospital-based HIE grew 41% between 2008 and 2012 as six out of ten hospitals exchanged information with providers and hospitals external to their organization[3]. Another study found three-fold increase in HIE participation from 2010 to 2012 when 10% ambulatory practices participated in 119 operational HIEs[4]. As the capability to exchange health information among healthcare organizations is a mandatory requirement for "Meaningful Use" and certification of electronic health records (EHR)[5], we can expect increased adoption and utilization of HIE in the future.

Growing participation in HIE has created opportunities for integrating data from external sources into an organization's own EHR. The exchange of data for patients served by more than one organization can also lead to uncovering inconsistencies in data. This may open up opportunities for corrective actions on one's own data. However, more data does not always mean better care. Kuperman and McGowan note that a flood of data from external sources can have the unintended consequence of overwhelming clinicians[6]. HIE-related errors can also reduce patient safety[7]. Incoming external data need to be critiqued for duplication, contradiction and physiological compatibilities. Data incorporation done in conjunction with data adjudication has the potential to improve clinical data integrity in the receiving organization's EHR. This manuscript addresses the following types of data integrity issues: the consistency, physiological compatibility, completeness, and timeliness of data.

In a previous study, we analyzed data from Intermountain Healthcare's (IH) Enterprise Data Warehouse (EDW) to identify error patterns, extracted requirements for a data adjudication framework, and designed architecture for an inferencing solution[8]. In this manuscript, we present a study which describes how the data adjudication infrastructure addresses data integrity issues for the use case of a point-to-point HIE between IH and a government trading partner that exchanges death information. Our approach as a partner in the Healtheway collaborative[23] (formerly Nationwide Health Information Network Exchange) has been point-to-point HIE connections rather than to an HIE as a consolidator organization. We believe this approach allows for local decision autonomy for issues of clinical data integrity as opposed to HIE organizations which are limited by consensus decisions and potentially by the lowest quality source of data.

This study is novel for a number of reasons: 1. It addresses the issue of data integrity for HIE data inbound into an organization; 2. It goes beyond passively accepting HIE data and takes it a step further into incorporating that data into an organization's own EHR; 3. It takes into consideration 4 axes of data integrity: consistency, compatibility, completeness and timeliness; 4. It applies a decision support infrastructure to adjudicate HIE data.

Background

Data integrity: EHRs have highly variable levels of data accuracy ranging from 30% to 100% data correctness and completeness[9]. The integrity of data in healthcare information systems affects decision making processes, both manual and automated. Berner et al.[10] report that gaps in patient data can affect the accuracy of the output of the Clinical Decision Support (CDS) tools. Guidance and recommendations provided by CDS systems may not be

trustworthy unless they are based on data with high levels of integrity[11]. Clinician perception of the effectiveness of CDS is dependent on data quality across settings, organizations and types of EHRs[12]. Data integrity issues also affect secondary use of health care data for the purposes of quality improvement, public health, and research[13].

In this study, we address the following types of clinical data integrity: consistency, physiological compatibility, completeness and timeliness of data. Current literature on data integrity in the context of HIE focuses on the data integrity issues surrounding patient identification[14, 15]. In this manuscript, we focus on death information exchanged in an HIE, its consistency and physiological compatibility with other clinical data in the receiving organization's EHR, and its completeness and timeliness.

Data incorporation: While HIE is about moving data from one organization to the other, data incorporation is about integrating appropriate data into an organization's own EHR and workflows. Literature on data incorporation in the realm of HIE is sparse. Frisse et al.[16] describe data incorporation performed in the Memphis HIE which was done at the display level. In another system, a high-tech approach was applied to medication reconciliation where data from a pharmacy system was incorporated into an EHR[17]. Cerner, a commercial vendor of EHR and IH's strategic partner, uses a document-based data model for integration of HIE data. The incoming documents with patient data are stored in a repository and the data in it is transformed for display, transfer, etc., as needed[18]. Data incorporation becomes more challenging if the EHRs on both sides of the exchange are different.

Another way to accomplish data integration at the discrete level is through electronic messaging interfaces between organizations using standards such as HL7 v2.x. However, discrete data incorporation done using document-based exchange is more scalable without incurring the expense of traditional messaging interfaces. We did not find evidence of network exchange based "complete" data incorporation in literature where the incorporated data becomes fully integrated with the EHR and is stored just like other similar data natively captured and stored by the EHR.

Setting for Health Information Exchange: This study was conducted at IH in Salt Lake City, UT. IH is currently participating in multiple HIE projects including the Care Connectivity Consortium (CCC)[19] at the national level, the Clinical Health Information Exchange (cHIE)[20], the Utah Health Information Network (UHIN)[21] and a private exchange with a government trading partner at the state level. IH has developed an infrastructure that processes different types of standards-based documents and can be universally used for any of the various exchanges. The exchanges have had to face administrative, logistical, policy, and other delays. As a result, the exchanges are at different stages of maturity.

We chose the exchange of death-related information between our government trading partner and IH as a convenience sample for this study. This type of data is available for all patients regardless of whether they opted-in or opted-out of HIE. Moreover, death is an important clinical outcome. Having high integrity death-related data is important for secondary uses such as patient outcome, resource utilization and cost analyses.

Previous work: The authors (PRK, DKM and SNT) analyzed 2.2 million Hemoglobin A1C (HgbA1C) result records from IH's enterprise data warehouse (EDW) for potential error patterns[8]. The HgbA1C results records are generated at IH, at point-of-care and external non-Intermountain laboratories. The authors then extracted requirements and designed architecture for a data adjudication infrastructure that integrates into the overall system architecture to detect data integrity issues and facilitate corrective actions[8].

Figure 1 shows the architectural diagram of Intermountain's HIE data adjudication system along with the document processing system used for HIE. External HIE data in the form of a summary of care document in the HL7 Consolidated Clinical Document Architecture format (CCDA) or an HL7 clinical document for reporting death information, inbound into IH, is initially processed to establish positive patient identity and positive consent. Data that pass these criteria are then transferred to the Inbound Message Orchestrator. This component is responsible for managing the workflow marked 2 through 6 in Figure 1. First, incoming data are filtered for new data at the document level to eliminate duplicative processing. Data is then extracted into internal data models and mapped from standard terminologies such as SNOMED and LOINC codes to Intermountain's own terminology using Intermountain's proprietary data dictionary.

Data that has been extracted and mapped to local terminology is fed into the HIE Data Adjudicator where a series of JBoss® Drools rules are run on it. Context-independent rules, i.e. rules that can run solely on the external data are run first for maximizing efficiency. These include data completeness and temporal compatibility rules. Data completeness rules check whether the incoming data meets mandatory data requirements as determined by the analysts at IH. Temporal compatibility rules check whether data are current and relevant. If the data passes the

context-independent rules, the rules processing continues to the context-dependent rules, i.e. rules which infer on external as well as internal data. These include data redundancy and data compatibility rules. Data redundancy rules compare incoming data to the data that is stored in IH's longitudinal patient data repository called the "Clinical Data Repository" (CDR) and determine if the data are duplicative. The data compatibility rules are responsible for detecting inconsistencies and physiological incompatibilities between the external HIE data and data recorded at IH. The HIE Data Adjudicator result statuses include "accept", "accept_as_new" and "reject". The "accept_as_new" status results in new records in the database. The "accept" adjudication status indicates that the new data is an update to existing data. Data in either statuses of "accept_as_new" and "accept" are stored to Intermountain's CDR. Data "rejected" by the HIE Data Adjudicator goes through various data integrity workflows. This architecture is fully implemented and is undergoing verification and validation at the time this manuscript was written.

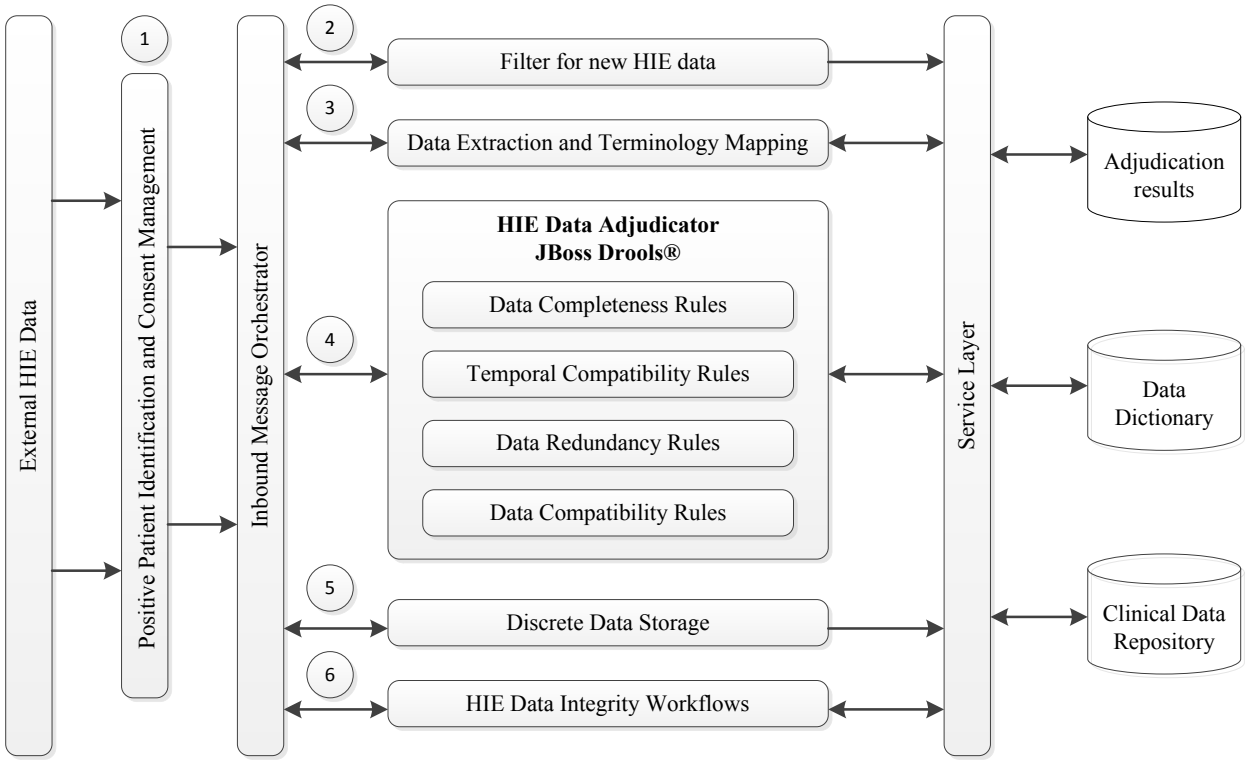

Figure 1. Architecture for HIE Document Processing and Data Adjudication

Methods

The data source (IH's government trading partner) receives death certificate data from multiple sources within the state of Utah. IH maintains the death records for patients who pass away at any of its own facilities. We performed a retrospective, descriptive analysis to compare death information recorded at IH facilities to that received from the data source between January 1, 1996 and August 31, 2013. The patient identities were matched prior to this analysis using research-driven technologies that included a combination of algorithmic and manual processes. Algorithms used for determining positive patient identity included Jaro-Winkler and Levenshtein distance algorithms. We measured the inconsistencies, physiological incompatibilities, completeness and timeliness of the death information. We enhanced the document processing system developed at IH for HIE by implementing the data adjudication architecture. We then ran a sample of the data through the data adjudication infrastructure to validate the errors we found in our analysis.

Data Inconsistencies/Physiological Incompatibility: We first compared the date/time of death in the data generated at IH to that in the data received from the data source. We then analyzed the data to determine if clinical data was recorded for deceased patients to understand the physiological incompatibility issues. We included billed encounters, vital signs, laboratory results, medication orders and problems in our analysis because these were most frequently used data types to record data for all patients at IH. We excluded data recorded for reasons that were

considered appropriate for deceased patients such as encounters for transplants, equipment, and organ and cadaver donors. We also included an allowance of 24 hours after the earliest recorded death date to accommodate for systems that have different ways to record time of death. We did not include data that was marked canceled or error. In the cases where we found multiple recorded death dates, we considered the earliest recorded death date as the death date for our analysis. Finally, we checked for temporal compatibility by looking at date/time of death and determining if it is in the future.

Data Completeness: The analysts at IH determined the criteria for completeness for death information. Death information is considered "complete" at IH if a valid patient identification and date/time of death is recorded.

Timeliness: We calculated the latency of recording of death information as the difference between the actual death date/time and the date/time the information was processed by IH workflows. The Utah State Code (Title 26 Chapter 2 Section 13)[22] stipulates that death certificates must be filed with the health department within five days of death. Our analysis adjusted for this allowance.

We had to simulate the exchange between IH and the government trading partner because of unforeseen administrative and logistical delays. The simulation system translated raw death data from the data source into an HL7 clinical document for the template id: 2.16.840.1.113883.10.20.24.1. This document was then input to and processed by the Inbound Message Orchestrator as shown in Figure 1. Process steps 2 through 6 were identical between the simulated and model systems.

We randomly selected 100 death records which were found to have inconsistencies ("error" records) and 100 death records for which we did not find data integrity issues ("good" records). The simulation system created HL7 clinical documents using this data. These records were run through the adjudication process for two iterations. The first iteration was performed to validate all the rules. We then added a dummy cause of death to half of the "good" records and performed a second iteration of the data through the system with the updated records as well as the records that were not changed. The second run was performed to validate the data redundancy rules (that detect duplicates) in addition to the other types of rules. We further created "empty" documents that did not have either date or time of death ("empty" records). We ran these through the system to validate the rejection logic in the data completeness rules. We also created documents with date/time of death in the future ("future" records) to validate the temporal compatibility rules.

Results

IH received a total of 198,453 death records from the data source between January 1, 1996 and August 31, 2013. A total of 47,175 patient deaths were recorded at IH facilities during the same time period.

Table 1 describes data inconsistencies and physiological incompatibilities with the clinical data recorded for deceased patients at least 24 hours after their death date/time. We found a total of 15,721 inconsistent records for different types of clinical observations. A total of 4483 unique patients were affected by these inconsistencies across all types of clinical observations we analyzed. We did not find any temporal compatibility issues with the data.

Table 1. Death data related inconsistencies and physiological incompatibilities

Type of Clinical Observation	Number of Unique Patients	Number of Inconsistent Records	Comments
Billed encounters	401	819	Data was recorded under 110 different types of billed encounters.
Vital Signs	23	2820	12 types of vital signs were recorded (10 from inpatient and 2 from the outpatient setting).
Laboratory Results	1271	2614	Data was recorded for 704 different test codes.
Medications Orders	2889	9467	Out of all the inconsistent records, 9359 were from the inpatient setting, 96 were from the outpatient setting and 12 were from other settings.
Problems	1	1	

We found that all data met the data completeness criteria decided upon by our analysts. However, we found that some records were missing cause of death. Table 2 details the results of the data completeness analysis.

Table 2. Data completeness profile for death related data

Description	Number of records	Contributes to data completeness
Missing patient id	0	Yes
Missing date/time of death	0	Yes
Missing cause of death	852	No
Missing location of death	0	No

We currently manually process death data from our government trading partner. This is typically done at unpredictable intervals. We had timeliness data for only a subset of the death records (35962 or 18.1% of death records). Table 3 shows the results of the latency calculations for the death data from the data source.

Table 3. Data timeliness profile for death related data

Latency description	Latency value (days)
Minimum	76
Maximum	1051
Mean	549.6304
Median	544

The data adjudication system validation results were as expected. All the data integrity issues were successfully detected and the related records were "rejected". The "good" records were "accepted" or "accepted_as_new" and stored to the test CDR. Table 4 gives the validation results.

Table 4. Validation of the data adjudicator framework for death related data

Iteration Number	Type of records	Number of records	% "Accepted _as_new"	% "Accepted"	% "Rejected"	Reason for Rejection
Iteration 1	"Good"	100	100	0	0	n/a
	"Error"	100	0	0	100	"Failed Data Compatibility Rules"
Iteration 2	"Good" (with dummy cause of death)	50	0	100	0	n/a
	"Good"	50	0	0	100	"Failed Data Redundancy Rules"
	"Error"	100	0	0	100	"Failed Data Compatibility Rules"
Iteration 3	"Empty"	2	0	0	100	"Failed Data Completeness Rules"
Iteration 4	"Future"	2	0	0	100	"Failed Temporal Compatibility Rules"

Discussion

We uncovered inconsistencies and physiological incompatibilities for 4483 patients marked as deceased (2.259% of the HIE inbound data) even after we accounted for the types of data that are appropriate to be recorded on deceased patients (such as encounters for transplants, equipment, and organ and cadaver donors). We augmented our original time criteria for search of 24 hours after death date/time to 15 and 30 days after the death date/time. Although the number of inconsistencies and physiological incompatibilities decreased as we increased our time criteria for search, there appeared to be ongoing data issues that were not picked up by our data integrity workflows. There could be a variety of reasons, both benign and non-benign, for these data integrity issues and may be attributed to either side of the exchange (IH or the data source). An example of a benign reason could be delayed billing by any of the various systems (excluding equipment rentals) involved in a patient's care. A non-benign reason could be the possibility of fraudulent activity, where the identity of a deceased patient is used to procure healthcare services. Further investigation is necessary uncover details about the reasons. Data adjudication applied to HIE data gives us the opportunity to detect such errors and brings us one step closer to facilitating corrective actions and thus improving the data integrity of one's own EHR.

Data completeness and temporal incompatibility were found to be a non-issue with the death information use case. This could be attributed to the mandatory requirements imposed by the Utah State Code at the source system. We think that the timeliness issues we found (mean latency of 549.63 days) are more of a process issue rather than a data issue. We believe the automation of the HIE exchange between IH and the government trading partner for death information will take us closer to solving the problem.

Handling redundant data at the document as well as discrete data level is important to reduce inefficiencies in processing of HIE data. Without the ability to detect duplicate documents, systems may waste resources by re-processing previously processed data that provides no new information. Likewise, the ability to compare discrete data and decide whether the incoming HIE data is new, duplicate or an update to already existing data can greatly improve process and database resource utilization.

The data adjudication framework implemented in this study is highly generalizable and can be extended to handle other clinical data types by adding appropriate data extraction, terminology mapping and data integrity rules specific to the data type. The framework can also be applied to demographic or administrative data. It can be further enhanced to detect more data integrity issues such as clinical data trend incompatibilities. The framework also suggests an approach to integrate HIE data focusing on episodic care details into patient's longitudinal data record. This approach is scalable and has the advantage of inter-organizational electronic messaging interfaces without the overhead associated with such interfaces.

The approach described in this manuscript can be applied bi-directionally. In other words, it can be applied to improve clinical data integrity of the EHR sending the data as well as the one receiving the data. We envision that the data integrity critique (a report of inconsistencies, physiological and temporal incompatibilities and incompleteness of data) can be fed back to the sending system.

We believe that the information gained and lessons learned from our study will inform our national and international collaborators working towards improved exchange profiles, standards-based data adjudication rules and HIE best practices.

Limitations: In order to validate the data adjudication infrastructure we had to simulate the data exchange between IH and the data source for death information because the effort to establish a working exchange faced administrative and logistical delays. Although our verification and validation test cases adequately covered variations in data, we understand that the real working exchange may add some data or system conditions that we did not anticipate. However, should any issues arise, we feel that we will be able to rectify them efficiently because the implementation of the data adjudication framework allows for easy and efficient updates. Another limitation of the study is related to the accuracy of patient identity matching algorithms and processes. Any errors with patient matching can adversely affect the analysis and data adjudication results. However, we feel that because this study has used the patient identity matching workflows that have been implemented and incrementally improved at IH for over a decade, the potential negative effects of this are minimal. Finally, we acknowledge that clinically more complex data models exist as compared to the death data model we have used in this study. We feel that because of our modular approach, our framework can be augmented to use resources such as ontologies to handle hierarchical and complex data models.

Future work: Our next step is to connect the data adjudication infrastructure demonstrated in this study to a working HIE between IH and the government trading partner. We believe that the experience will help us fine tune the data adjudication logic. We plan to expand the data adjudication to include problems, medications, allergies, and other data types, that are exchanged in the HIE domain. Additionally, we want to understand, in more detail, the reasons for data integrity issues we found. This may further inform our effort to enhance the data adjudication logic. Finally, we intend to research ways to translate the data adjudication rules into interoperable and shareable knowledge.

Conclusion

We demonstrated the capabilities of a data adjudication infrastructure integrated into Intermountain Healthcare's HIE architecture. We showed that it can detect data integrity issues related to inconsistencies, physiological and temporal incompatibilities, and completeness. It also addressed new data integrity issues related to redundancy by detecting duplicates external and internal to the organization's EHR. Data adjudication reduces the burden of manual review and resolution of data integrity issues by automatically connecting the data adjudication results to HIE data integrity workflows and facilitating corrective actions.

Acknowledgements

We would like to acknowledge Shannon Hood and Dallin Rogers for providing domain knowledge for the patient identification process at Intermountain Healthcare. We would also like to acknowledge Jeff Duncan for his expertise with death related information.

Abstract

Information systems managing image-based data for telemedicine or clinical research applications require a reference standard representing the correct diagnosis. Accurate reference standards are difficult to establish because of imperfect agreement among physicians, and discrepancies between clinical vs. image-based diagnosis. This study is designed to describe the development and evaluation of reference standards for image-based diagnosis, which combine diagnostic impressions of multiple image readers with the actual clinical diagnoses. We show that agreement between image reading and clinical examinations was imperfect (689 [32%] discrepancies in 2148 image readings), as was inter-reader agreement (kappa 0.490-0.652). This was improved by establishing an image-based reference standard defined as the majority diagnosis given by three readers (13% discrepancies with image readers). It was further improved by establishing an overall reference standard that incorporated the clinical diagnosis (10% discrepancies with image readers). These principles of establishing reference standards may be applied to improve robustness of real-world systems supporting image-based diagnosis.

Introduction

Medical diagnosis has traditionally required examination by a physician. However, advances in imaging technology have affected specialties such as ophthalmology, dermatology, radiology, and cardiology to the point where clinical decision-making in these specialties is based largely on review of these imaging studies. Meanwhile, there have been persistent concerns about the accessibility of health care, particularly in rural and medically underserved areas. As a result, store-and-forward telemedicine strategies have emerged as a potential strategy for improving the delivery and cost of health care by replacing some in-person physician examinations with remote image-based evaluations.[1-2] Real-world implementation of these strategies will require appropriate validation of diagnostic accuracy, as well as agreement among different image readers.

At the same time, institutional and regulatory pressures are placing increased emphasis on quality and adherence to evidence-based practice guidelines.[3-4] Clinical examination by a physician is generally considered the gold standard in medical practice. However, there are often significant variations in diagnosis and management among physicians, even when they are presented with the exact same clinical scenarios.[5-6] Similarly, although image-based diagnosis is made from the appearance of structural and morphological features, numerous studies in ophthalmology have demonstrated that there may be significant discrepancies in image reading, even among experts looking at the same images.[7-9]

This variability among experts creates challenges for the implementation of image-based clinical information systems. For telemedicine systems, an accurate reference standard must be defined for proper validation, yet different remote image readers may disagree with regard to diagnosis. Furthermore, it is often unclear whether the

actual clinical examination or remote interpretation is more correct. For clinical research systems, it is critical to define a reference standard with the highest accuracy, yet there may be discrepancies between the interpretations of clinical examination and imaging data. Understanding the factors contributing to accurate diagnosis, as well as having a clear definition of a reference standard defining the correct diagnosis, is essential for managing image-based data for applications such as telemedicine and clinical research.

The purpose of this paper is to describe the development and evaluation of reference standards for image-based diagnosis, which combines the diagnostic impressions of multiple image readers with the actual clinical diagnoses by expert physicians. Sources of discrepancy will be identified and analyzed. Retinopathy of prematurity (ROP), an ophthalmic disease affecting low birth-weight infants during the first several months of life, is used as the study domain. Results from clinical ophthalmoscopic exams by an expert on a study cohort of infants are compared to results from image interpretation by three readers. In this way, we evaluate the variability among multiple readers performing image-based diagnosis, the impact of integrating diagnoses by multiple readers into an image-based reference standard for telemedicine applications, and the impact of integrating clinical diagnosis into an overall reference standard for clinical research applications.

Study Domain: Retinopathy of Prematurity (ROP)

ROP is diagnosed from dilated fundoscopic examination by an ophthalmologist, and there are established guidelines for identifying high-risk premature infants who need serial screening examinations.[10] When ROP occurs, approximately 90% of cases improve spontaneously and require only close follow-up examinations every 1-2 weeks. However, approximately 10% are at high risk for complications leading to blindness and require treatment.[11-12]

ROP has several characteristics that make it an ideal topic for research in telemedicine, biomedical informatics, and clinical research: (1) Diagnosis is based solely on the appearance of disease in the retina. (2) There is a universally-accepted, evidence-based, diagnostic classification standard for ROP.[13] (3) Although it is treatable if detected early, ROP continues to be a leading cause of childhood blindness throughout the world because of inadequacies in screening.[14] (4) Current ROP exam methods are time-intensive and physiologically stressful to infants. (5) Clinical expertise is often limited to larger academic centers, and is therefore unavailable at the point of care. Therefore, following the establishment of an appropriate reference standard, there should be diagnostic reliability and reproducibility of telemedical diagnosis via the application of objective diagnostic criteria. Furthermore, the physiologic stress on the infants may be reduced[(15), (16)DL, MM] Finally, while the expertise required to diagnose and treat ROP tends to be found only at large academic medical centers, the skill needed to acquire images adequate for diagnosis can be taught and disseminated across myriad practice settings and communities of varying size, thereby increasing access to care.[(17, 18, 19, 20)PC, RW, YM, DW]

Methods

Ophthalmoscopic Examination and Image Capture

This is a multicenter study with eight participating academic medical centers: (1) Oregon Health & Science University (OHSU), (2) Weill Cornell Medical College, (3) University of Miami, (4) Beaumont Health System, (5) Columbia University Medical Center, (6) Children's Hospital Los Angeles, (7) Cedars-Sinai Medical Center, and (8) Asociación para Evitar la Ceguera en México (APEC). Each institution's IRB approved the study protocol. Subject enrollment began in July 2011. All infants admitted to a participating Neonatal Intensive Care Unit (NICU) were eligible for the study if they met published criteria for ROP screening examination, or if they were transferred to the study center for specialized ophthalmic care.[10]

Study infants underwent serial examinations in accordance with the most recent evidence-based ROP guidelines.[10] Dilated ophthalmoscopic examinations were performed by an expert ophthalmologist, and findings were documented according to the international classification standard[13]. Retinal images were captured by a trained photographer after each eye examination using a wide-angle camera (RetCam; Clarity Medical Systems, Pleasanton, CA) using a standard protocol following manufacturer guidelines. De-identified clinical and image data were uploaded to a secure database (ASP.net, C#; State33, Portland, OR).

Image-based Reading

Remote image-based readings were conducted by three study authors (MFC, RVPC, SO) using an SSL-encrypted web-based grading module. In some cases, the image readers were the same ophthalmologists who had performed the ophthalmic examination. To best simulate ophthalmoscopy, where both eyes are examined sequentially before a final diagnosis is made, images from both eyes were displayed side-by-side (**Figure 1**). Demographic information, such as gestational age, postmenstrual age, and birth weight were also visible during image reading. Image readings were graded on an ordinal scale based on criteria from NIH-funded clinical trials: (1) No ROP; (2) Mild ROP; (3) Type-2 (moderate) ROP; and (4) treatment-requiring (severe) ROP,[11-12]

Development and Rationale for Reference Standards

Two reference standards were developed for this study: (1) Image-based reference standard, which was defined as the diagnosis given by a majority of the three readers. The rationale for this definition is that pooling the expertise of multiple image readers may improve the overall diagnosis. (2) Overall reference standard, which integrated the image-based reference standard with the actual clinical diagnosis provided by the examining ophthalmologist. The rationale for this definition is that combining information from clinical and telemedicine data may provide the most accurate diagnosis possible, and that this may be applicable in setting such as rigorous clinical research. In instances when there discrepancies between the image-based reference standard and the clinical diagnosis, all medical records reviewed by the three image readers and a moderator (KJ) to reach a consensus for the overall reference standard.

Data Analysis

Data were analyzed using spreadsheet software (Excel 2011; Microsoft, Redmond, WA). All records that had three image readers as of December 3, 2013 were analyzed. Additional analysis was conducted on the subset of these records that also had a submitted overall reference standard.

Inter-reader agreement in diagnostic classification was calculated for each pair of image readers using absolute agreement, kappa (κ) statistic for chance-corrected agreement, and weighted κ. Agreement was also investigated for the following comparisons: (1) individual readers vs. clinical diagnosis, (2) individual readers vs. image-based

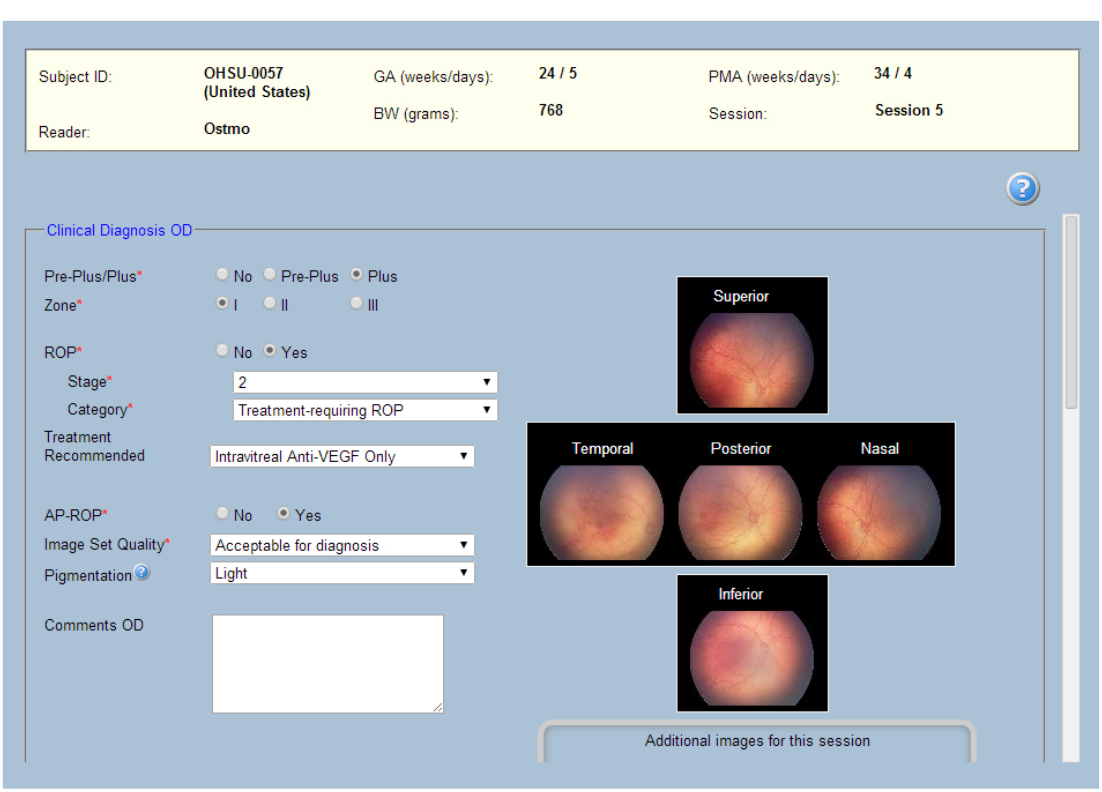

Figure 1. Example of web-based interface used for image evaluation and imaged-based diagnosis of ROP.

Table 1. Inter-reader agreement for ordinal ROP classification expressed as κ, weighted κ, and absolute agreement.

Reader Pair	κ (SE)	Weighted κ (SE)	Absolute Agreement (%)
1 vs 2	0.490 (0.027)	0.586 (0.024)	67%
1 vs 3	0.591 (0.026)	0.668 (0.023)	74%
2 vs 3	0.652 (0.025)	0.723 (0.021)	67%

reference standard, (3) individual readers vs. overall reference standard, (4) image-based reference standard vs. clinical diagnosis, (5) image-based reference standard vs. overall reference standard, and (6) clinical diagnosis vs. overall reference standard.

In all instances where there were diagnostic discrepancies with reference standards, all study data were reviewed by the authors (MCR, SO) and the reason for discrepancy was classified as either: (1) no ROP identified by ophthalmoscopic exam, (2) no ROP identified by image-based exam, (3) disagreement in classification of ROP severity ("stage"), (4) disagreement in classification of ROP location ("zone"), and/or (5) disagreement in classification of blood vessel appearance ("dilation" and "tortuosity").

Results

Characteristics of Study Population

A total of 150 infants who underwent 358 clinical exams met eligibility criteria for analysis. Both eyes of each infant underwent ophthalmoscopic examination at each visit, for a total of 716 study eyes. Based on clinical exam, 335 (47%) had no ROP, 283 (40%) had mild ROP, 67 (9%) had Type-2 ROP, and 31 (4%) had treatment-requiring ROP.

Inter-Reader Reliability and Reader Agreement with Clinical Exam

Table 1 summarizes agreement for each pair of readers based on ordinal ROP classification. Readers 1 & 2 had moderate agreement, while readers 1 & 3 and readers 2 & 3 had substantial agreement. Overall absolute agreement among the three readers was 73%. **Table 2** summarizes agreement between individual readers and the actual clinical diagnosis. Readers 1 and 2 demonstrated moderate agreement with the clinical diagnosis, while reader 3 had substantial agreement with the clinical diagnosis.

Agreement of Image-based Reference Standard with Individual Readers and Clinical Exam

Table 3 displays agreement for individual readers with the image-based reference standard. Reader 1 had moderate agreement with the image-based reference standard, while readers 2 and 3 had near-perfect agreement. Overall absolute agreement between the image-based reference standard and clinical diagnosis was 72%, while the κ (SE) and weighted κ (SE) were 0.551 (0.027) and 0.621 (0.024) respectively, indicating substantial agreement.

Agreement of Overall Reference Standard

Table 4 displays agreement for individual readers with the overall reference standard. There was near-perfect agreement for all three readers. Absolute agreement between the overall reference standard and clinical diagnosis was 81%. The κ (SE) and weighted κ (SE) were 0.679 (0.032) and 0.751 (0.027) respectively, indicating substantial agreement.

Table 2. Agreement between individual readers and clinical diagnosis for ordinal ROP classification expressed as κ and weighted κ statistics.

Reader	κ (SE)	Weighted κ (SE)	Absolute Agreement (%)
1	0.460 (0.028)	0.542 (0.026)	66%
2	0.465 (0.028)	0.556 (0.024)	66%
3	0.553 (0.027)	0.624 (0.024)	72%

Table 3. Agreement between individual readers and the image-based reference standard for ordinal ROP classification expressed as κ, weighted κ, and absolute agreement.

Reader	κ (SE)	Weighted κ (SE)	Absolute Agreement (%)
1	0.713 (0.023)	0.769 (0.020)	80%
2	0.773 (0.021)	0.824 (0.018)	85%
3	0.900 (0.015)	0.920 (0.012)	92%

Comparing the imaged-based reference standard to the overall reference standard, the κ (SE) was 0.911 (0.019) and the weighted κ (SE) was 0.931 (0.015). This signifies near-perfect agreement between the two standards.

Classification of Discrepancies with Reference Standards

Among 434 eye exams in this study with an overall reference standard, there were 14 (3%) discrepancies with the image-based reference standard derived from majority vote among the three image graders. When these medical records were reviewed, it was discovered that 6/14 discrepancies were due to disagreements over disease location, 5/14 were due to disagreements over blood vessel morphology, in 2/14 cases the image-based reference standard did not identify any signs of ROP, and 1/14 was due to a disagreement in disease severity. **Table 5** summarizes the absolute number of discrepancies and discrepancy rates for each study comparison.

Discussion

Summary of Key Findings

To our knowledge, this is the first study to develop and evaluate the accuracy of reference standards in ophthalmology that integrate clinical diagnosis with a consensus image-based diagnosis from multiple image readers. The performance of the reference standard was evaluated against the telemedical ROP diagnosis of three image readers, the clinical exam, and an image-based reference standard. The key findings from this study are: (1) There is imperfect agreement in image-based diagnosis among experts, and between image-based and clinical diagnoses. (2) Using multiple image readers is a potentially useful approach to increase the accuracy and reliability in telemedical diagnosis of ROP. (3) Use of an overall reference standard that integrates information from the clinical exam with image-based diagnoses may be of value in image-based clinical research.

Telemedicine holds great promise for improving the accessibility and quality of health care.[2,21] However, variation in telemedical image interpretation and the lack of definitive reference standards have presented challenges to the implementation of telemedicine systems for the diagnosis and management of retinopathy of prematurity (ROP).[7]

Inter-reader Agreement

This study confirms findings from previously published research showing that inter-reader agreement in image-based ROP diagnosis is imperfect (**Table 1**). For example, a previous study examining interphysican agreement in the telemedical diagnosis of ROP found a weighted κ statistic that ranged from 0.38 (fair agreement) to 0.81 (near-perfect agreement).[22] This prior study's higher maximum value for κ may be a consequence of only using ophthalmologists for image interpretation, whereas one of the image readers in the current study was not a physician.[23] However, inter-reader agreement for the non-ophthalmologist reader (reader 3) was comparable to what

Table 4. Agreement between individual readers and the overall reference standard for ordinal ROP classification expressed as κ and weighted κ statistics.

Reader	κ (SE)	Weighted κ (SE)	Absolute Agreement (%)
1	0.802 (0.026)	0.850 (0.021)	88%
2	0.829 (0.025)	0.877 (0.019)	90%
3	0.839 (0.024)	0.877 (0.020)	90%

Table 5. Summary of absolute number of discrepancies and the discrepancy rate for each comparison in the study.

Comparison	No. of Eye Exams	No. of Disagreements	Disagreement Rate
Individual Readers vs Clinical Exam	2148	689	32%
Individual Readers vs Image-based Reference Standard	2148	269	13%
Individual Readers vs Overall Reference Standard	1302	133	10%
Clinical Exam vs Image-based Reference Standard	716	198	30%
Clinical Exam vs. Overall Reference Standard	434	82	19%
Overall Reference Standard vs. Image-based Reference Standard	434	14	3%

was observed for the two ophthalmologist readers. Interestingly, agreement between the non-ophthalmologist reader and the clinical diagnosis was actually higher than what was observed for the ophthalmologist readers.

The degree of inter-reader agreement noted in the current study is also consistent with what has been observed in non-ROP related ophthalmologic studies investigating image-based diagnosis. In a major multicenter study involving diabetic retinopathy, the weighted κ for intergrader reliability was 0.41 (moderate agreement) to 0.80 (substantial agreement), depending on the type of retinal lesion being observed.[24] In a study examining interobserver agreement in the diagnosis of age-related macular degeneration based on fluorescein angiography imaging methods, the κ was 0.37 to 0.40 (fair agreement).[25]

Additional published literature suggests that this finding is generalizable across other medical domains. In one dermatologic study examining agreement in the evaluation and diagnosis of skin tumors the κ statistic was 0.32 (fair agreement).[26] In a radiographic study comparing expert radiologists and pulmonologists in their diagnoses of upper lobe-predominant emphysema the κ was 0.20 (slight agreement) to 0.60 (moderate agreement).[27]

When considered in conjunction with the existing evidence base, findings from this study suggest that the reliability in the telemedical diagnosis of ROP, while imperfect, is comparable or better than interobserver agreement for other ophthalmic or medical diagnoses. This supports the validity of telemedicine programs for ROP diagnosis.

Image-Based Reference Standard Combining Multiple Readers

While the telemedicine literature examining inter-reader agreement and reader agreement against a gold standard is relatively robust, data investigating the utility of pooling telemedical diagnoses is sparse. A 2010 study investigating the accuracy of "non-expert" graders in diagnosing ROP noted slight improvements in sensitivity and specificity when using the majority diagnosis of the three best non-expert readers, but the results were not statistically significant.[28] They found that sensitivity in diagnosing treatment-requiring ROP increased from 0.82 to 1.00, while specificity increased from 0.92 to 0.94.[28] Similarly, a 2013 teledermatology study investigating the diagnostic accuracy of remote reflectance confocal microscopy found that sensitivity was improved by more than eight percentage points by combining reader diagnoses.[29]

This study confirms and expands upon these earlier findings (**Tables 1 and 3**). By merging the image-based diagnoses of the individual readers to form the image-based reference standard, the reliability of telemedical diagnosis of ROP was significantly improved. The range of individual reader's weighted κ increased from 0.586 – 0.723 for inter-reader agreement to 0.769 – 0.920 for agreement with the image-based reference standard. Importantly, there was little-to-no improvement in the agreement of the clinical diagnosis with the image-based reference standard, with only a 2-percentage point increase in absolute agreement (69% vs. 71%).

Overall Reference Standard Combining Clinical and Image-Based Diagnoses

While the establishment of an image-based reference standard significantly improved the reliability of telemedical diagnosis, the relative lack of improvement in agreement between clinical and the image-based diagnoses suggests the need for further refinement of potential reference standards. A reference standard that allows for direct comparison of image-based and ophthalmoscopic diagnoses would be particularly useful in clinical research, where both diagnostic approaches need to be evaluated simultaneously. We created such a reference standard by

incorporating the clinical diagnosis with the image-based reference standard. The utility of this approach is demonstrated by the increased levels of agreement (**Table 4)** and the decreased levels of discrepancies (**Table 5**). Each time more information was aggregated together to form a new reference standard there were commensurate increases in reliability and accuracy of the telemedical diagnosis.

Limitations

There are several limitations of this study. (1) While the data in this study were analyzed by eye, the classification and diagnosis of ROP in the right and left eyes of the same patient is not independent. At the time of image interpretation, images of both eyes were presented to the study readers simultaneously so as to simulate ophthalmoscopy, where both eyes are examined together. This approach minimizes bias that might favor either examination and allows for the analysis of both eyes of the infant. (2) There was no standardization of image reading conditions, such as resolution, contrast, and luminance. Previous radiographic studies have demonstrated the ability of these parameters to affect diagnostic accuracy.[30] (3) While two of the readers involved in this study have extensive clinical experience with ROP (RVPC, MFC), the third was a research coordinator who was trained to interpret images (SO). While the use of "non-expert" readers is common in the literature, it is unclear what affect, if any, this may have had on the study findings. Future studies examining the influence of reader background on inter-reader reliability and diagnostic accuracy may be revealing. (4) The sample size of three image readers, while consistent with the published literature, is still relatively small. As such, it is difficult to make generalizations to the broader community of ophthalmologists. (5) As some of the ophthalmic examinations included in this study were performed by the image readers, there is the potential for recall bias. However: (a) Study images were collected at eight sites, and readers only worked at two of those sites. (b) Study images were reviewed by readers several months after clinical exams. (c) No clinical data beyond the retinal images and basic demographic information (e.g. birth weight & gestational age) were shown to readers about subjects. For these reasons, we suspect that the impact of recall bias is minimal.

Conclusions

Telemedicine has the potential to improve the quality, cost, and accessibility of medical care, particularly in image-oriented specialties. Previous research investigating the accuracy and reliability of telemedicine systems in ophthalmology has typically compared telemedical diagnosis to the current gold standard of a dilated fundoscopic exam by an ophthalmologist. However, defining absolute reference standards for the diagnosis of ROP has been difficult and has hindered the implementation of image-based clinical information systems. This study demonstrates that the reliability and accuracy of ROP diagnosis can be improved through the implementation an overall reference standard that integrates diagnostic information from the clinical examination and an image-based telemedicine system. Findings from this study have important implications for groups designing and implementing image-based telemedicine systems and for future research aimed at improving the accuracy of ROP diagnosis.

Abstract

Inappropriate medications use (IMU) is a serious issue of global concern that leads to a waste of resources and potentially harms the patients. IMU can usually be identified by extracting information about the patient's conditions and treatments, and comparing them with "medication appropriateness criteria". To enable automation of these criteria, we developed a formal representation for them, which we called Objective Medication Appropriateness Criteria (OMAC). OMAC represents four aspects of the criteria: trigger, rules, action and meta-data. Our evaluation showed that OMAC can completely represent explicitly defined medication appropriateness criteria using links to external knowledge sources. OMAC is the first formal representation for medication appropriateness criteria, and will enable development of structured rules for appropriate use of medications that can be implemented using standards for clinical decision support.

Introduction

Inappropriate medication use (IMU) is a serious issue of global concern that not only leads to a waste of healthcare resources, but also potentially harms patients due to inadvertent side effects [1–3]. Previous studies have shown that several groups of medications are commonly subject to inappropriate use, including antibiotics, antidepressants, antipsychotics, bronchodilators, non-steroidal anti-inflammatory drugs (NSAIDs), proton pump inhibitors (PPIs), and statins [4–8]. Numerous studies developed methods for identifying and reducing IMU, with the focus of their intervention spanning from healthcare professionals and patients, to financial, organizational, and regulatory approaches [9,10]. Typically, these approaches rely on manual identification of IMU. Developing automated methods to reduce IMU is challenging. Inappropriate use of medications is still considered an understudied problem in general [11,12].

Manual identification of IMU requires extracting information about the patient, the medication, and other treatments, and comparing them with "medication appropriateness criteria", which are standards that define appropriate use of medications [13]. Consequently, developing automated solutions to reduce IMU entails two requirements: a framework to represent the medication appropriateness criteria formally, and methods to extract the information needed to compute these criteria. This article focuses on developing a framework for formal representation of medication appropriateness criteria.

Previous researchers have identified several medication appropriateness criteria and metrics through systematic review of the literature [12,14]. These criteria can be categorized into three groups: the first group enumerates the conditions in which the use of medication is appropriate (e.g. see Choudhrey *et al.*'s criteria for appropriate use of proton pump inhibitors (PPIs)[15]), the second group lists conditions in which the use of medication is deemed inappropriate (e.g. see the Beers' criteria[16]), and the third group provides a combination of both (e.g. see Oborne *et al.*'s criteria on appropriate use of neuroleptics[17]). Since older adults are frequently subject to polypharmacy and therefore more likely to experience the negative impacts of IMU (e.g. drug-drug interactions, adverse drug reactions and increased risk of hospitalization) [18–20] larger collections of medication appropriateness criteria exist for the geriatric population. Examples include the Beers' criteria[16] and the Screening Tool of Older Persons' potentially inappropriate Prescriptions (STOPP)[21] which aim to reduce inappropriate use of medications (overuse), and the Screening Tool to Alert doctors to Right, i.e. appropriate indicated Treatment (START)[22] which promotes appropriate use of medications that are omitted (underuse).

Medication appropriateness criteria can be described as a special form of clinical guidelines, although they have distinct features that separate them from the majority of clinical guidelines. Clinical guidelines provide best

practices for diagnosis and therapy of diseases, but medication appropriateness criteria are focused on proper utilization of a resource (namely, medications). Clinical guidelines are primarily developed by major medical associations, are organized in a common format and are hosted on repositories such as the National Guideline Clearinghouse [23]; in contrast, medication appropriateness criteria are mostly developed by independent groups of researchers and distributed without using a common format or central repository.

Medication appropriateness criteria are currently only available in narrative form, and transforming them into a computable format is challenging because a formal representation for the components of medication appropriateness criteria does not exist. Different criteria have varying levels of granularity and specificity in defining the medications, diagnoses, and symptoms; in addition, some but not all of the criteria are accompanied by information regarding the level of evidence, target population, or extent of clinical relevance. A framework in which these criteria can be explicitly and comprehensively represented is needed. We developed such a representation framework, which we call the Objective Medication Appropriateness Criteria (OMAC).

Methods

In order to study existing medication appropriateness criteria, we started by identifying these criteria by searching PubMed using the following keywords and their variations to identify published medication appropriateness criteria: inappropriate prescribing, overuse, overtreatment, overutilization, and utilization review. We grouped the relevant studies based on the actual criteria they used to identify IMU. We then curated a collection of published medication appropriateness criteria and used a random subset of those to develop OMAC (for examples, see Table 1). To ensure that we didn't have any biases in our component selection and semantic aggregation of the concepts, we used another independent set of criteria for evaluation of OMAC.

Developing OMAC

We manually analyzed a randomly selected subset of medication appropriateness criteria to identify their components. Each criterion can be described as one or more rules, and the purpose of OMAC was to provide a formal representation for these rules as well as any other aspects of the criteria. We semantically grouped the components we found in the sample criteria to define concepts that comprise the criteria, including high-level elements (such as the general sections of a criterion) and low-level elements (such as modifiers, identifiers, names, etc.) and we also identified the relationships between these concepts and represented them in OMAC.

Different medical concepts are frequently mentioned in the medication appropriateness criteria, such as medications and diseases. Since the purpose of OMAC was to provide a representation for the criteria, and not to enumerate each individual medication or disease, we ensured that OMAC takes advantage of previously developed ontologies and terminologies, by linking to external ontologies and terminologies to the extent possible. We saved OMAC using frames and properties in Protégé version 3.5.

Evaluating OMAC

After the initial design of OMAC was completed, we presented a separate set of 10 medication appropriateness criteria to a group of domain experts (physicians and pharmacists) in form of a questionnaire, asking them to identify and categorize the components of these criteria independently. Each item in the questionnaire consisted of one medication appropriateness criterion statement in its original narrative form, and requested that the participant breaks the statement into basic elements (such as medication names, medication class names, disease names, logical statements, or temporal modifiers). Disagreements in the experts' responses were identified through qualitative analysis of the responses. Three types of disagreements were considered: differences in the classification of the same word or phrase (e.g. classifying "hypertension" as a disease versus a problem), differences in specification of the elements in the statements (e.g. considering "severe hypertension" as two separate concepts versus one), and classification of terms into concepts that are not explicit (e.g. classifying "long-term use of drug X" as one concept of type "overuse"). In a subsequent questionnaire, we presented the experts with the same narrative criteria but clearly marked these areas of disagreement and asked the experts to translate those terms and phrases into more detailed, explicitly defined concepts. Note that the purpose of this process was not to reach perfect agreement, but rather to identify what "elements" constitute the criteria and also to describe the elements so that they are well-defined, so that we can evaluate OMAC's coverage for those elements.

	Source	Narrative criterion
1	2002 Beers' criteria	Disease: Seizures or epilepsy Drug: Clozapine, chlorpromazine, thioridazine, and thiothixene Concern: May lower seizure thresholds Severity Rating: High
2	STOPP, section A, item 2	Loop diuretic for dependent ankle edema only i.e. no clinical signs of heart failure
2	STOPP, section B, item 3	TCA's with cardiac conductive abnormalities
3	STOPP, section A, item 6	Beta-blocker in combination with verapamil
4	STOPP, section A, item 7	Use of diltiazem or verapamil with NYHA Class III or IV heart failure
5	STOPP, section B, item 9	Use of aspirin and warfarin in combination without histamine H2 receptor antagonist (except cimetidine because of interaction with warfarin) or proton pump inhibitor

Table 1 – Examples of medication appropriateness criteria previously published in the literature. These examples are all adopted from Beers' criteria[16] and STOPP[24] and each criteria expresses what medication should be *avoided* in the provided context. Other examples from other sources were also used in the development and evaluation of OMAC (not shown in the table). The narrative criteria are shown as they appear in the original source. *TCA: tricyclic antidepressant; NYHA: New York Health Association; H2 receptor: histamine 2 receptor.*

Subsequently, we evaluated whether OMAC could represent all of the explicitly defined concepts provided by the experts. We froze the development of OMAC before we started sending out the questionnaires, to ensure that our knowledge of the results of the previous step would not affect our evaluation of OMAC's completeness. We planned to correct OMAC for any areas of deficiency that would be found throughout this evaluation, only after the evaluation was completed.

Results

We identified 110 medication appropriateness criteria through literature review, and used a random subset of 40 to develop OMAC. We designed OMAC such that each criterion in this subset could be represented using four types of information: '*trigger'*, '*rules'*, '*action'*, and '*meta-data'*. The *trigger* may consist of one or more medications that are the primary focus of the criterion (when prescribing these medications the criterion would be triggered) or one or more clinical conditions in which the use of a certain medication is desirable (in this case the criterion would focus on underuse). *Rules* specify the conditions that a patient must meet to be eligible for the criterion (such as age limit, past medical history, medications prescribed, symptoms, or paraclinical findings). *Action* specifies the recommendation that the criterion makes once the patient meets all the rules; generally, actions are in two forms, either to *avoid* prescribing a medication or to *consider* prescribing a medication. *Meta-data* includes all the additional information that is used to describe the criterion (examples include a name or unique identifier, references to citations, or a justification or concern). As an example, Beers' criteria not only lists medications or combinations of drugs that should be avoided in the elderly, but also specifies what "concern" exists around using these medications, and also provides a "severity rating" for this concern (low vs. high) to help the clinicians determine the importance of each item in this criteria (Table 1) [16]. We represented the trigger, action and meta-data components using properties for the "criterion" class (Figure 1, right). We used a more complex classification as described below to represent the rules.

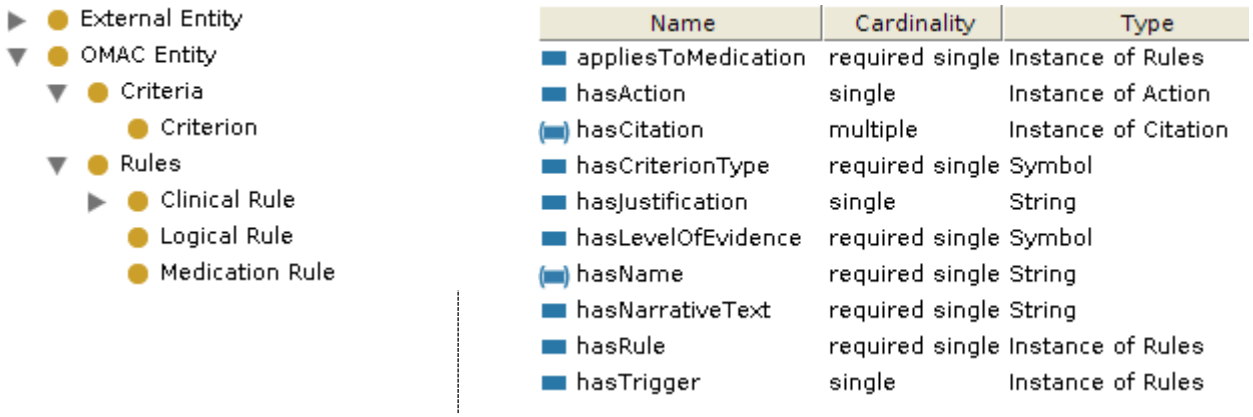

Figure 1 – Main concepts in the OMAC (left) and the properties of the *criterion* class (right).

Each criterion can contain one or more rules, and there are various types of rules in different criteria. These include *'medication rules'* which specify the medication that is the subject of the criterion as well as co-prescribed medications that need to be considered, and '*clinical rules'* which specify the diseases, symptoms, laboratory tests results, and demographics that have to be present or that should be absent for the patient to meet the criterion. This can be clarified using the third example shown in Table 1: "TCA's with cardiac conductive abnormalities"; this item from STOPP criteria states that in elderly patients who have cardiac conductive abnormalities, tricyclic antidepressants (TCAs) should be avoided because of their pro-arrhythmic effects [24]. To apply this criterion to a patient, three rules must be satisfied: (i) the patient must belong to the 'elderly' demographic group (formally defined as age ≥ 65 years), (ii) the patient must have been diagnosed with a cardiac conductive disorder (including, but not limited to Type I heart block, Type II heart block, or right bundle branch block), and (iii) the patient must have been prescribed a medication that belongs to the TCA class. The first two rules in this example are clinical rules, and the latter is a medication rule.

Concept Type	**External ontology or terminology**

Symptom	SNOMED CT, Symptom Ontology
Procedure	CPT, ICD, SNOMED CT

Table 2 – Examples of external ontologies and terminologies that can be used to define concepts that are contained in a clinical or medication statement, as part of a medication appropriateness criterion. *ATC: Anatomical Therapeutic Classification; NDC: National Drug Code; ICD: International Classification of Diseases; SNOMED CT: Systematized Nomenclature of Medicine, Clinical Terms; CPT: Current Procedural Terminology.*

Clinical and medication rules have different properties: clinical rules may focus on the existence, temporality and duration of a clinical finding or condition, or the value of a measurement, but medication rules may specify the dose, route, frequency and form of a medication. Both clinical and medication rules may include concepts that are externally defined in other ontologies or terminologies (Table 2). In the example provided above, "cardiac conductive abnormalities" can be represented as a clinical rule, which can refer to a pertinent concept in International Classification of Diseases, version 10 (ICD-10) or Systematized Nomenclature of Medicine, Clinical Terms (SNOMED CT), and thus, it is possible to link the concept to a standardized external knowledge source. A link to an external concept consists of four parts: the local name of the concept (e.g. 'cardiac conductive

abnormalities'), the name of the external ontology or terminology, including version number (e.g. ICD-10), URL of the external ontology or terminology (e.g., http://purl.bioontology.org/ontology/ICD10) and the unique identifier of the corresponding concept in that external ontology or terminology (in this case 'I44').

Clinical and medication rules can be combined with each other using *'logical rules'*. Each logical rule has a mandatory field which specifies the Boolean operator it is representing ('AND', 'OR', or 'NOT'). In the example above, the clinical and medication rules are combined using a logical rule with 'AND' logic (i.e. the patient must be among the elderly AND have a cardiac conductive disorder to be eligible for this criterion).

We grouped all the three aforementioned types of rules under a parent class called *'rules'* (Figure 1, left). To represent complex statements, these rules can be nested to create 'rule trees'. Clinical and medication rules can only appear as the leaves of the rule tree. Logical rules appear as branches of the tree, and each logical rule references one or more rules of any type. The latter enables nested rules which allow representation of complex logical statements. The last example in Figure 1 (STOPP, item B9) demonstrates a criterion with a complex logic. This complex statement can be encoded through nesting different types of rules, as shown in Figure 2.

Evaluating OMAC

Eight domain experts collaborated in the first questionnaire. There was no disagreement among experts in their responses for simple and well-defined criteria; for instance, all collaborators described STOPP criteria item A6 (shown in Table 1) using similar components. We observed disagreements in the way more complex criteria were broken down; for example, there was lower agreement on how the terms 'dependent ankle edema' and 'no clinical sign of heart failure' were categorized by different experts. When experts clarified the areas of vagueness using detailed explicit concepts, we noticed that although they clarified these vague terms using different sets of explicit concepts, they used similar 'types' of concepts to describe them. For example, each expert used a different set of 'signs', 'symptoms' and 'paraclinical findings' to describe the phrase 'clinical signs of heart failure', but all experts used exactly those three types of information.

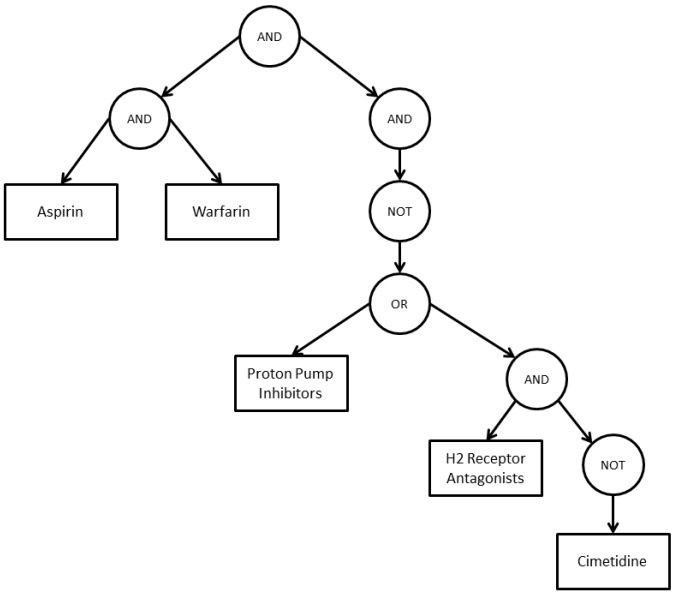

Figure 2 – A schematic diagram showing nesting of logical statements representing a complex criterion. For simplicity, logical statements are shown as circles that are labeled based on the Boolean operator associated with them, and medication statements are shown as boxes corresponding to the pertinent medication or medication class. Each of the medication statements may refer to an external ontology or terminology which formally defines the specific medication or drug class; those links are not shown in this figure. The narrative form of this criterion is available in Table 1.

All of the types of information that experts used to transform the vague phrases into explicit forms corroborated with the types of information that we had already incorporated into OMAC's clinical or medication rules. In other words, OMAC had completed coverage for all of the criteria that were coded by the experts, and as a result we did not modify OMAC after this evaluation.

Discussion

Developing a representation format for medication appropriateness criteria is the first step towards developing computable, interchangeable and reusable solutions to prevent inappropriate medications use. OMAC formally defines the structure of explicitly defined medication appropriateness criteria, and allows referencing to external ontologies and terminologies when applicable.

The results of our questionnaire study indicate that at least some of the medication appropriateness criteria are defined using vague terms that were interpreted differently by the experts. These criteria only provide guidelines for appropriate use of medications, and variability in the application of guidelines is a well-established phenomenon in health care practice; however, ideally the guideline itself should be interpreted identically by all of its users so that the variability should be only due to the specific characteristics of the patient or the settings in which the guideline is used, and not due to different interpretations of the appropriate care[25,26]. Although our questionnaire study has a small sample size, it signifies the need for well-defined medication appropriateness criteria. OMAC can facilitate this process, as encoding the criteria into OMAC requires translating all terms into explicitly defined medication, clinical or logical rules.

OMAC is designed to be flexible, and allow for multiple ways of defining concepts and their relationships. Through the use of logical rules, it is possible to model the steps that are used to implement medication appropriateness criteria in clinical practice and encode these steps in a computable way. When a clinical or medication concept is in fact referring to a class of diseases or medications, logical steps can be used to internally define these sets instead of referencing external knowledge sources, which is important when defining a concept that does not exist in any external knowledge source. Therefore, the user has the choice of either specifying a medication class by referencing an external entity, or by defining external references to each member of that class and then combining them using an 'OR' logic (Figure 3). Each approach has its own advantages: using an external reference for each of the elements in that class makes the local definition of the criteria more explicit, while using an external reference for the class itself reduces the amount of effort needed to encode the criteria in OMAC.

Using an external ontology or terminology to define the concepts in OMAC also has the advantage of reusing knowledge that has been vetted by a group of experts, but a suitable external knowledge source may not be available in all cases, or it may not be as accurate or complete. In addition, not all of the concepts that are found in medication appropriateness criteria can be identically found in external knowledge sources. For instance, one medication appropriateness criteria may specify the severity levels for heart failure using the classification provided by the New York Health Association (Table 1), but this classification may not be already defined in any existing disease ontologies and terminologies. OMAC flexibly supports defining these complex concepts either by external links (when possible) or locally, and the users can choose their preferred method based on the task at hand.

OMAC is different from a guideline representation language. While medication appropriateness criteria can be described as a special form of guidelines, guideline representation languages (e.g. GEM[27], GLIF[28], EON[29], PRO*forma*[30], and SAGE[31]) do not enforce the mandate level of detail in their formalism that is needed for representing medication appropriateness criteria. Guideline representation languages provide a structured way to encode the "flow" of decisions in a guideline. However, to ensure that they can support different types of decision and various forms of guidelines, they provide a significant amount of flexibility as to how each decision step is defined. Previous research has shown that these guideline representation models have limitations when applied to medication related guidelines used for chemotherapy, and that representing medication related guidelines as rules can address this limitation.[32] OMAC combines this rule-based approach with specific features of guideline representation language (such as the inclusion of meta-data about provenance of the guidelines), to provide a more strict structure to represent the medication appropriateness criteria than guideline representation models, thereby providing a common framework for encoding all such criteria in a similar, interchangeable way. In that sense, OMAC complements the guideline representation languages by providing the formalism that is necessary for a certain type of decisions, namely the decision about appropriateness of medications.

One potential challenge in interchanging OMAC-encoded criteria is that a criterion may be encoded using an external ontology or terminology which may be different from what is desirable for a second user of the criterion. This challenge can be addressed by creating cross-walks between these external knowledge sources; in many cases, this can be easily possible using the Unified Medical Language System (UMLS). Finally, our study is also limited in that we did not conduct a large scale evaluation of the completeness of OMAC. We intend to address this limitation in future research. We also intend to use OMAC to develop structured representations of well-established medication appropriateness criteria and then export them into a format supported by HL7 Clinical Decision Support (CDS) standards. Namely, we intend to use the virtual medical record (vMR) format[33] to represent the patient data, and use the OpenCDS platform[34] to integrate the computable medication appropriateness criteria with the medical records and evaluate the accuracy and impact of using this approach to provide decision support regarding appropriateness of medications**.**

Conclusions

OMAC provides the necessary flexibility for defining concepts using external ontologies or terminologies whenever applicable, and through the use of rules, it enforces the necessary formalism to ensure that all essential concepts of the medication appropriateness criteria are represented using a common structure. OMAC is the first framework that specifies encoding the medication appropriateness criteria into a formal, structured form, which is necessary to incorporate a decision support component aimed at reducing IMU.

Design Considerations for Post-Acute Care mHealth: Patient Perspectives

Patrick Sanger, BA, Andrea Hartzler, PhD, William B. Lober, MD MS,
Heather L. Evans, MD MS, Wanda Pratt, PhD
University of Washington, Seattle, WA

Abstract

Many current mobile health applications ("apps") and most previous research have been directed at management of chronic illnesses. However, little is known about patient preferences and design considerations for apps intended to help in a post-acute setting. Our team is developing an mHealth platform to engage patients in wound tracking to identify and manage surgical site infections (SSI) after hospital discharge. Post-discharge SSIs are a major source of morbidity and expense, and occur at a critical care transition when patients are physically and emotionally stressed. Through interviews with surgical patients who experienced SSI, we derived design considerations for such a post-acute care app. Key design qualities include: meeting basic accessibility, usability and security needs; encouraging patient-centeredness; facilitating better, more predictable communication; and supporting personalized management by providers. We illustrate our application of these guiding design considerations and propose a new framework for mHealth design based on illness duration and intensity.

Introduction

Although much mHealth research supports managing chronic illness, relatively little is known about how mHealth could apply to acute conditions. New incentives (e.g., Accountable Care Organizations, bundled payments) will lead hospitals and providers to optimize care across the whole care spectrum, including areas such as post-acute care (i.e., happening after acute hospitalization). Post-acute care mHealth could facilitate care coordination by filling in gaps that occur during this significant transition of care. This coordination could prevent costly readmissions as well as improve patients' experiences during this often stressful time.[1]

Improving care coordination among surgical patients after discharge is of critical importance. These patients are at high risk for surgical site infections (SSI), most of which occur after discharge.[2,3] SSIs are the leading cause of readmission among surgical patients, which occurs in up to half of patients who experience SSI.[2] In our previous work we found that patients were ill equipped to recognize and manage wound complications, and faced many barriers to communicating with their providers after developing a concern. Patients found the concept of an mHealth wound tracking and communication tool highly acceptable and believed it could help address many gaps in the current system.[4]

In this paper, we extend our previous work by describing design considerations for post-acute care mHealth apps, derived from interviews with surgical patients who experienced wound complications while at home. Many of these patients had extreme experiences, both in terms of their physical and emotional state (e.g., anxiety, disorientation) and their interactions with the health care system (e.g., late night calls to triage nurses, emergency department visits, readmissions). These experiences allowed us to explore a breadth of the post-acute mHealth design space, although not all issues we identified will likely apply to every post-acute care mHealth app. In our discussion, we describe several core themes that emerged related to communication and management that could be applicable to a wider range of acute care apps. We then illustrate how we applied these design considerations to an mHealth app we are developing to engage surgical patients in post-discharge wound tracking. Finally, we introduce a new framework for mHealth design based on illness duration and intensity.

Background

The design space around mHealth for management of chronic conditions is relatively mature, especially for conditions such as cancer[5,6] or diabetes[7,8]. It is unclear whether design considerations for chronic mHealth apps apply as well in a post-acute setting. Apps for management of chronic conditions are characterized by achieving symptom control and long-term behavioral change. In contrast, the purpose of a post-acute care app might be to help avoid escalation around a single, limited duration episode of treatment while a patient is returning to a usual health state.

Some design considerations likely apply across a wide range of mHealth settings. For example, Klasnja et al[9] found that the ability for cancer patients to capture and access a variety of care-related information while on the go, in a

single application, helped them manage their care and feel more in control of their information and health. Since managing information is a key task for patients in any setting, enabling the organized storage of health information is likely to be a universal mHealth theme. Arsand et al[10] found that diabetes patients preferred to have some reward (e.g. education or feedback) at the time of data entry to provide a built-in motivation for use. This finding relates to a broader theme that, in order to continue using apps, patients must find them to have utility—not just in a theoretical sense, but also in an immediate, concrete sense. Liu et al[11] found that parents wanted to communicate with providers in different ways to suit their needs, both synchronously (e.g. telephone) or asynchronously (e.g. email). Communication with providers can be critical across a range of chronic and acute conditions, and supportive mHealth applications should facilitate communication using means that are both efficient and acceptable to patients. Kientz et al[12] suggest that the act of tracking health measures (e.g. infant development) has the potential to increase anxiety over trends that appear abnormal. Apps that capture patient data will have to carefully consider how to reflect that data back to patients, including whether and how to provide interpretation of that data.

Other design considerations for chronic mHealth apps might be less applicable or introduce new challenges in an acute context, ranging from privacy and self-reflection to automated feedback and engaging social networks. For example, Patel et al[5] identified giving breast cancer patients ownership over data (e.g. controlling what data is shared, capturing custom fields) as important to promote engagement in care and capture of sensitive data. Although patients should always have control over what information is shared with others, acute care providers may be concerned about patients sharing *too much* data that cannot be efficiently reviewed. Mamykina et al[7] identified promoting self-reflection as a primary design goal to aid in self-management for people with diabetes. Self-reflection is a critical element in the management of many chronic illnesses that rely on patients to make lasting behavioral changes. However, the importance of self-reflection is unclear given the short time horizons, cognitive impairments (e.g., due to pain medication), and limited control that patients often have over their care outcomes that might be common in the post-acute setting. In addition to self-reflection, Harris et al[8] identified automated, programmed responses as a key design requirement for diabetes self-management. Automated responses may support self-reflection and have the benefit of giving immediate feedback and gratification to patients without burdening a clinician, however more urgent or complex assessments associated with acute concerns might not be reliably made without human involvement. Finally, much work has been done using mHealth to help patients engage social networks and online communities for support in their care (e.g., Liu et al[11] in the parenting of high-risk infants). However, the utility of online communities is unclear over short durations and highly individualized recovery periods following hospital discharge. In addition, unlike with chronic conditions, acute conditions tend not to have dedicated online communities.

Though the examples above are not exhaustive, and many design considerations for chronic mHealth apps likely apply to acute apps as well, we suggest that the requirements and user experience in acute and chronic settings are sufficiently different to warrant further research. In this paper, we report on our work to explore a design space for apps which improve communication and decision support in the post-acute care setting.

Methods

We conducted semi-structured interviews with patients who experienced surgical wound complications after hospital discharge. The study was approved by the University of Washington Institutional Review Board.

Participants and setting

We interviewed patients who had post-discharge wound complications after undergoing abdominal surgery at one of two Seattle hospitals: an academic medical center or a county hospital/ regional trauma center. We identified English-speaking, adult patients using two different approaches: through clinic nurses at follow-up visits or through flyers placed in surgery clinics.

Data collection

We conducted one-on-one interviews lasting 60-90 minutes in a private setting near the clinics. We began by using the critical incident technique to guide participants in recounting their complication experience.[13] Then, grounded in their experience, we used scenarios to provide context to allow participants to walk through paper wireframe mockups (Figure 1) of an mHealth wound tracking application (e.g. “Imagine you are very concerned about your wound.

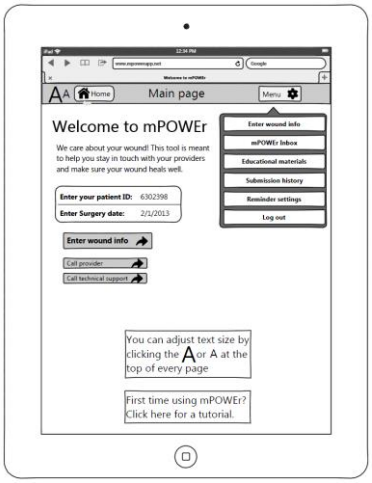

Figure 1: Paper mockups used during participant interviews to stimulate discussion.

You just clicked 'submit' to send your symptom data. What should happen now?"). We showed mockups of multiple versions of potential features such as symptom tracking, wound photography, secure communication, and informational content. Prior to showing mockups of each feature, the interviewer paused to ask the participant to describe how a particular feature might work; only then did the interviewer use the paper mockups to stimulate further discussion. Interviews were audio-recorded and transcribed. We collected data until thematic saturation was achieved.[14] We used written surveys to capture demographics and technology experience.

Data analysis

We collectively developed a codebook with two team members coding all the interviews using Atlas.ti (Atlas.ti v7, ATLAS.ti GmbH) while other team members spot-coded interviews to inform the codebook and check reliability. The whole team met periodically to resolve coding discrepancies. Cohen's Kappa between the two primary coders during early and late coding was 0.51 and 0.71, respectively, reflecting moderate to substantial inter-coder reliability.

Results

We interviewed 13 patients ranging from age 21 to 71 (mean 45), of whom 9 were female and 9 were white. Five were college graduates, 6 had some college, 1 graduated from high school and 1 had less than high school education. They self-rated their experience with computers as "some" (n=3), "intermediate" (n=4), "very" (n=4), or "expert" (n=2). Twelve used the internet at least occasionally and 8 owned a smartphone. Patients underwent major abdominal surgery, generally colorectal or ventral hernia repair, and struggled with complications for weeks or months after discharge. Five had one or more emergency department visits or hospital readmissions related to SSI.

From patient interviews, we identified 11 themes that we organized into 4 categories that describe qualities of a post-acute care mHealth application (Figure 2):

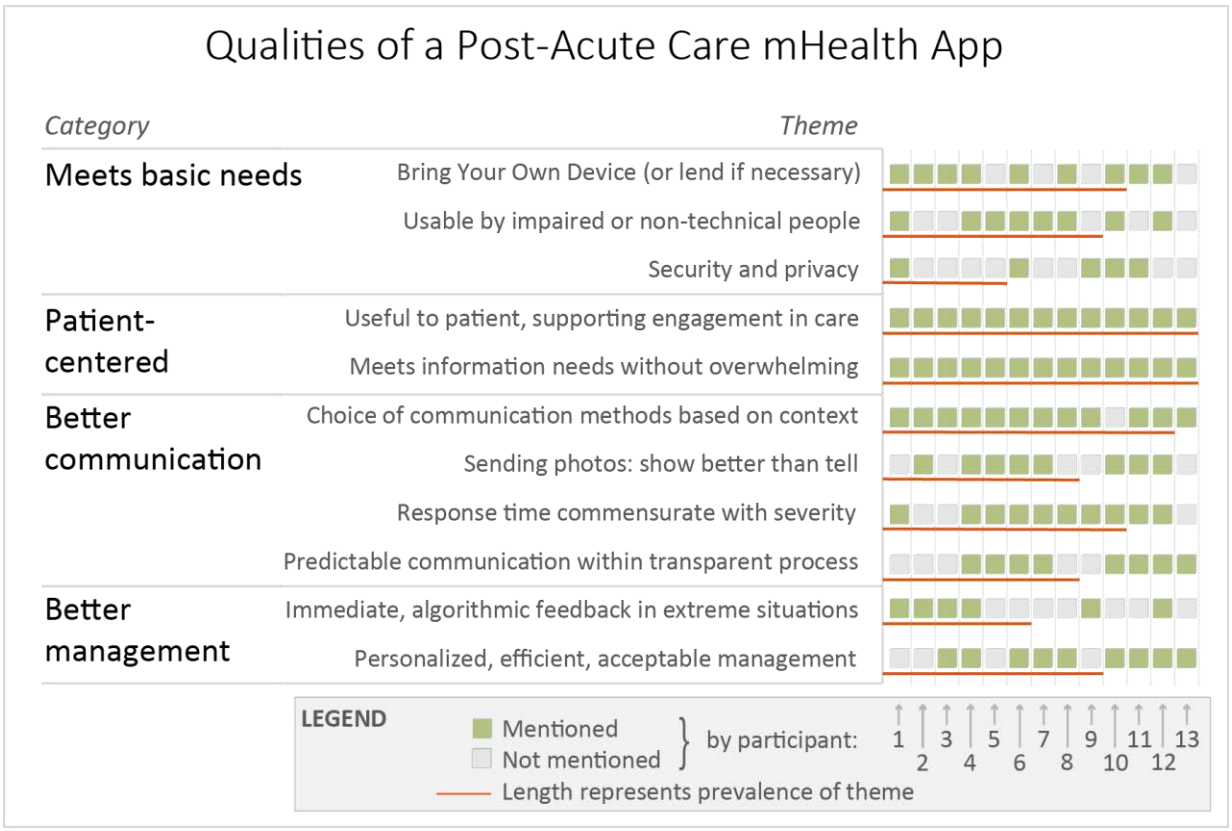

Figure 2. Each green square represents a participant who mentioned the theme during interviews. Length of red lines represents theme prevalence. Themes are organized into 4 major categories, visible on the left side of the figure.

Meets basic needs

One category of design qualities for a supportive mHealth tool expressed by participants revolved around meeting basic needs through accessibility of your own device, usability by impaired or non-technical people, and security to preserve privacy. P#'s following quotes are attributions to that particular participant.

Bring Your Own Device (or lend if necessary). Participants were concerned about an app being inaccessible on their preferred device or had concern for others who lacked access to a smartphone or computer. Several participants suggested that hospitals could loan patients devices.

> *What about people that don't have smart phones? Will you have this on a regular online website with it too? Because my phone is like ten years old.* ***P12***

> *I think it's a good idea if you have someone who's technology proficient in something like that. Some of the patients may not even have computer or computer access. But I think for me personally, I mean, because I'm used to computers, I think it's a great idea.* ***P4***

Usability by impaired or non-technical people. Participants had concern for technologically inexperienced users, and did not want to be overwhelmed with information or too many pages/functions. Participants mentioned the challenge of using an app while on pain medication, and wanted simple wording, obvious alerts and clear navigation.

> *But if you don't have [a smartphone] you might not know how to work it, so then you're going to have to get into who's smarter, the phone or you? You know, somebody's going to have to show you how to even operate the thing.* ***P10***

> *But it would make a complex website or doing something complex, it would require you to remember several steps. I think [navigating a complex website under influence of drugs] would make it very difficult for a lot of people.* ***P12***

Security and Privacy. While this was among the least prevalent themes, participants were most concerned about collection and transmission of particularly sensitive information such as photos of the groin area. Participants expressed concern that transmissions should be secure and go to the right recipients.

> *Some people might not want to [send pictures of private areas]. Your older generation.* ***P6***

> *As long as [the submissions] made it from point A to point B, it would be good. They didn't get lost in sending... to a bakery or something.* ***P11***

Patient-centered

A second major category of design qualities pointed to the importance of patient-centeredness: being genuinely useful to the patient to support engagement in their own care and meeting their individualized information needs without overwhelming them.

Useful to patient, supporting engagement in care. All participants voiced that the app should be genuinely useful to the patient—having an obvious benefit and not feeling like a burden on them. They felt that the app should allow patients to be engaged in and make decisions about their care, especially about how often and by what means they discuss their concerns with providers. Several expressed that the app should have a "personal feel" that gives the feeling that "we want to take care of you" (P1). Participants also felt that the app should connect them with a provider familiar with their history and with whom they already have a relationship/rapport.

> *The biggest thing is for me to feel like this is useful, because it's being sent to my doctor. This is a way of communication to my doctor, not just a survey I'm taking, you know what I mean?* ***P5***

> *[The ability to view past photos/history would be useful] because then you could see – oh, this is what this looked like 3 days ago and this is what it looks like now. This looks really different.* ***P7***

Meets information needs without overwhelming. Participants generally did not feel that their information needs were met well during their hospital discharge experience. Every participant saw an opportunity for the app to make up for this deficit by providing a personalized, succinct recap of their discharge instructions. They emphasized that they did not want to be overwhelmed, asking for just the highlights with links to more resources if needed. Most participants wanted to have information on procedures they themselves would be expected to perform after

discharge (e.g. how to clean and pack wound) and how to identify problems (e.g. infection). Participants preferred concrete examples through a variety of media over reams of pages (e.g. photos of infected vs normal wound, step-by-step instructions/video of wound care procedure). Several participants were also interested in receiving information about how to optimize their healing (e.g. dietary advice). Participants wanted the app itself to be well-documented with help/tutorials.

> *Like if you forget how to clean and pack your wound or whatever, or if your wound looks like this, then [it's infected] - or if your wound looks like this, then [it's not infected]. That might be helpful… Mainly just in terms of if this happens, don't freak out. If this happens, do freak out.* ***P7***

> *So if you're going to do a presentation for somebody coming out of the hospital, you should only have the highlights… [have a] mouseover if they [want] a big explanation.* ***P1***

Better communication

A third major category of design qualities pointed to the potential for enhanced communication, whether through more choice of communication methods appropriate to context (e.g., secure text for non-urgent matters), the ability to send photographs, rapid provider response when necessary, and patient control over and transparency about timing and method of provider contact.

Choice of communication methods based on context. Participants wanted to be able to choose the means of communication with their provider. Context was important—if they were very concerned about an issue, participants preferred a telephone call. When participants were not very concerned (e.g. routine check-ins, non-time sensitive care questions), many preferred text or email as it was more convenient for them and less interruptive to their providers than phone calls. Two participants suggested that real-time video conferencing should be incorporated into the app.

> *[The app should have] an option of how would you best like to be communicated with… Would you like it email, text message, phone call and they can select that, and it can go right in with the message. ... Because [grandmother] would pick a phone call, [mother] and I would pick a text message.* ***P6***

> *It depends on the situation, but I don't know, for me personally, I like to do stuff through email ... Unless it's like super urgent, so obviously phone call is the best way to get [urgent] communication. But I think for this type of stuff, I wouldn't mind email, as long as I knew that the doctor's looking at it throughout the day.* ***P4***

Sending photos: show is better than tell. Participants were very interested in sending photos to providers. They wanted their provider to really see that status of their wound rather than try to explain solely over the phone. They thought that this additional visual information would facilitate triage and management, be less subjective than patient-assessed symptoms (e.g. amount of redness), and help show trends across time through serial photography. Participants recognized that photos were necessary but not sufficient–some patient-assessed symptoms would be valuable to report (e.g. heat, pain).

> *I have a smart phone so I used that to take the picture. I thought that was very good to be able to send them an actual picture of what was happening so that way, you know, a little more hands on than "okay - this is… " - trying to describe it over the phone... The nurse commented about how good that was too to have a picture to look at.* ***P6***

> *So if you had it where you could take a picture of it… [the provider] might have said "oh boy, you need to go into the hospital" [or] they could say "hey – no, it's doing what it's supposed to do, just let it be."* ***P10***

Response time commensurate with severity. Participants wanted faster response times based on their level of concern and/or the apparent severity of their wound problem—in other words, the app should facilitate triage to enable provider feedback faster based on urgency. Many participants made comparisons to the main alternative to using the app—a phone call—saying that response times should be comparable (e.g. call back within 30 minutes). Participants voiced worries that waiting for even an hour might be too long for an acute concern and that if responses are too delayed, their condition could deteriorate. Of those who specified how quickly they would expect a response, 2 said under 30 minutes, 1 said within an hour, 2 said within 4 hours, and 4 said within 24 hours. Participants were willing to wait longer for a response if they had confidence in the system–that their responses were being monitored regularly and not falling into a "black hole" (P4).

I think that if it would have been really hurting, I would want a quicker response time for it. So I think based on the level of pain that somebody was having as to what the response - or felt they were having, the response time back would be quicker. ***P6***

When you pick up the phone you're getting a response. If you're using a tool and you're not getting anything back, then there's no reason to use it because the whole reason is to get communications. ***P1***

Predictable communication within a transparent process. Participants wanted a definite timeframe for a provider response, i.e. a shared expectation between patients and providers. Generally they expected the provider to set this parameter but several wanted to select a time and/or be able to "escalate" to request a faster response. Participants wanted the process to be transparent – to know when their data was received, viewed, and acted upon. They also wanted to be able to set the contact method so they would know what to expect (e.g. wouldn't have to wait around at their computer in case of email response).

Some type of timeframe. So it's not just kind of like sitting out there and you just submit it to a black hole, you know, when someone's going to get back to you. ***P4***

[After clicking submit, the app should say] 'please watch your email during the next three hours or something for a response'. Or whatever you guys decide the response time should be. And/or choose a phone call back. In other words, to know on here before I log off what I can expect next... ***P12***

Better management

A final major category of design qualities pointed to the potential for better, faster, more personalized and more acceptable (to the patient) management. Participants saw many potential benefits including earlier identification and treatment of problems, and the possibility of more efficient care through reduction in unnecessary visits.

Immediate, algorithmic feedback in extreme situations. Participants found the idea of algorithmic (i.e. immediate, app-generated) feedback most acceptable at the extremes—i.e. their situation appears very good or very bad. In less clear-cut cases, most favored the judgment of their health care provider. Participants thought algorithmic feedback was good if it was based on existing practices (e.g. algorithms used by triage nurses). Participants noted that algorithms could benefit both the patient (e.g. advise to go to emergency department immediately if reporting chest pain) and the provider (e.g. flag most concerning patients to review quickly). In general, most participants did not fully trust the computer to make unsupervised management decisions, noting that the quality of the patient input is critical; misjudgments about symptoms could lead patients to unnecessary emergency room visits.

I think yeah, that's all right for the extremes. But I still would feel more comfortable with the doctor responding. ***P4***

It's the same judgment that you would get if you called a nurse, well, it's probably the same thing you were told outright – if you see this, call the nurse or come into the emergency room. So if the app is just reinforcing that, it seems perfectly natural. ***P3***

Personalized, efficient, acceptable (to the patient) management. Almost universally, patients saw the potential for an app to facilitate better triage. For example, the app could help the patient answer the anxiety-ridden question, "What do I do? Come in or stay home?" (P8). Through better triaging, patients expected a variety of potential benefits. If they were healing normally, for example, the app could save time and unnecessary clinic/emergency room visits, which is especially important for distant patients, as well as alleviate stress and provide reassurance. If their wound was not healing normally, the app could facilitate earlier problem identification and quicker/easier re-admission than the current management process patients experienced. Patients liked the idea of giving their provider more data (especially photos) to track their progress, and would be more willing to accept providers' management decisions based on that more complete, standardized, and personalized data. For example, they would be more willing to go to ER if advised to do so.

That's pretty much what the triage nurse tells you anyway. You have to come in [to the emergency room]. *But if you have a picture of it, and it's nothing, then that would make it so that you wouldn't have to go in necessarily… It would be more advantageous and you wouldn't have to sit there for five hours (laughs) in the ER.* ***P10***

But it would have been really helpful, especially the first time that it started getting infected, I could have sent them a picture or whatever and then if a day later - because it did, it got a lot worse. It was itching, it

was bleeding and stuff - then I could have sent another picture and said it's a lot worse and they could have seen right then you need to come in now. Instead of waiting until it got really bad. ***P7***

Discussion

Our findings illustrate the large potential benefits that patients see in post-acute care mHealth apps. Indeed, such apps are probably inevitable, but the key question is: will they be embraced by patients? Due to the hectic and stressful time during care transitions after acute illness, it is critical that apps be immediately usable and obviously useful to patients or they will not be used. Both patients and clinicians will lose out if patients reject this powerful method to facilitate data gathering and communication in favor of the highly usable yet limiting alternative—the telephone. However, it is challenging to design for short-term post-acute episodes for a number of reasons. First, there are a large number of possible use cases, and acute problems do not necessarily follow a predictable disease course. Second, related to user-centered design, it is challenging to engage patients in the moment, while they are actually sick, and due to the short-term nature of acute conditions, patients may lack the expertise about managing their condition that patients with chronic illness may have. Finally, it is unclear whether prior work on mHealth for chronic illness management is applicable in a post-acute context.

Although many themes voiced by our participants were common across mHealth, several appeared novel, reflecting the specific needs of patients in a particular post-acute setting (Table 1).

Support for known themes across mHealth	New themes specific to post-acute setting
• Bring your own device/loans • Security and privacy • Useful to the patient, supporting engagement • Algorithmic feedback when appropriate • Choice of communication methods based on context • Photos (or other sensor-based data): show is better than tell • Meeting information needs without overwhelming	• Response time commensurate with severity • Predictable patient-provider communication within a transparent process • Personalized, more efficient, more acceptable treatment plan based on patient-reported data • Usability while in a cognitively or physically impaired state

Table 1: Common themes across mHealth vs new themes for post-acute care mHealth. Key themes identified from patient interviews have been categorized based on whether they are already known in the mHealth literature or appear novel to a post-acute setting.

The most important insights about patient expectations for acute care mHealth apps relate to patient-provider communication and resulting management of care concerns. This prioritization likely reflects the challenges and frustrations participants faced when managing their post-discharge complications. For example, after developing a wound concern, participants described a lack of control over their situation. Related to communication, they could not easily or quickly reach a familiar provider. Related to management, they often felt unnecessarily directed to the emergency department as the default option. Through an mHealth application, patients wanted to be empowered to choose how and when they would be contacted, and wanted to be satisfied that the provider managing their care made a personalized recommendation based on all available information (e.g. through review of serial symptom logs and wound photos). Because issues of patient-provider communication and management are essential to addressing many acute concern, future work could explore the generalizability of these themes across a variety of acute and post-acute conditions.

Although our findings are limited to *patient* views, one of the key differentiating elements of acute mHealth is the relative importance of other stakeholders, most notably *providers*. Acute mHealth apps must be designed to satisfy two very different user groups who almost certainly have competing priorities. In our previous work, a needs assessment of providers for a post-discharge wound tracking app[15], providers expressed concern over additional time requirements, workflow disruption, issues surrounding receipt of photos (e.g. liability, poor quality), and EMR integration. Patient and provider expectations differed on such things as frequency of and trigger for wound tracking: patients expected to track their wound routinely even in the absence of an obvious problem, while providers envisioned less frequent use, generally only if a problem was suspected. Similarly, many of the key patient expectations identified in this paper are subject to provider buy-in and will have to be negotiated between patients

and providers. Acute care mHealth apps might ultimately be disruptive, catalyzing a shift from provider-driven to patient-centered care processes.

Figure 3 depicts one such mHealth app we are developing to facilitate wound-tracking and patient-provider communication by surgical patients after hospital discharge. We demonstrate how the 11 guiding design considerations have informed the most recent prototype. This prototype is an interactive mockup currently undergoing heuristic evaluation and user testing; concurrently, we are using agile techniques for development of the patient-facing app and provider-facing dashboard.

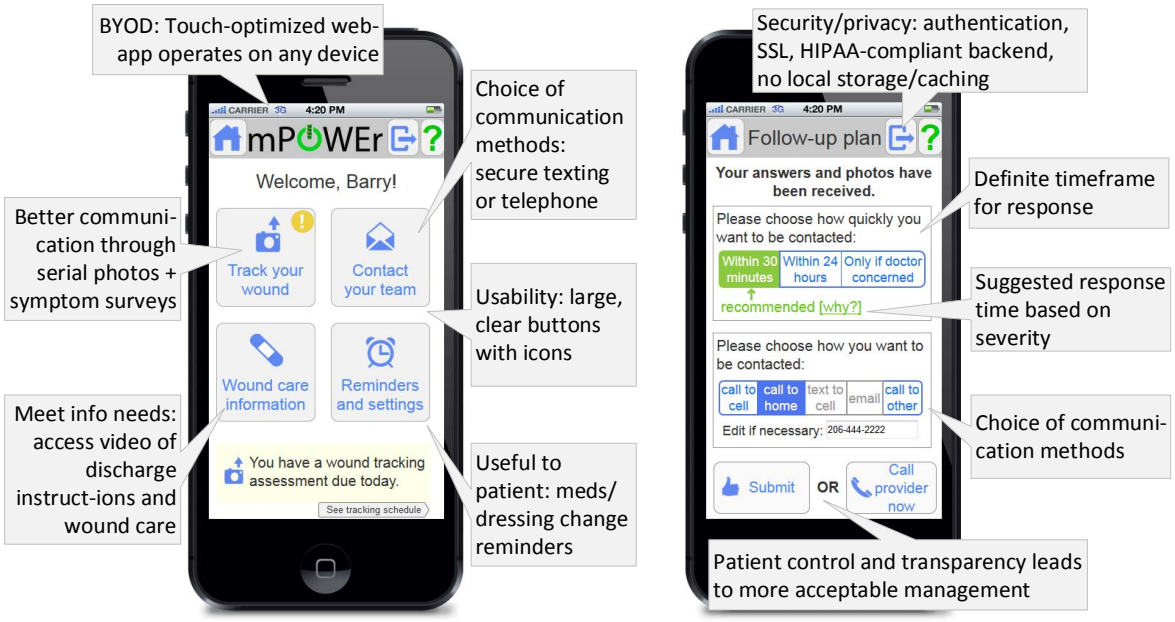

Figure 3: Application of design considerations to a wound tracking app. Each callout represents one of the 11 guiding themes that emerged from interviews with patients who experienced post-discharge complications.

Though the chronic vs. acute distinction is widely used, it may be more useful in generalizing mHealth design considerations to distinguish health conditions along two axes: short-term vs long-term and high-intensity vs low-intensity usage (Figure 4). Typical chronic illnesses tend to be long-term and low intensity while acute concerns tend to be short-term and high intensity, but other conditions (occupying the adjacent quadrants) can have elements of both chronic and acute conditions. Some conditions may even shift around, e.g. short-term, high-intensity surgical wound monitoring may shift to long-term, low-intensity chronic wound monitoring, or stable diabetes may become uncontrolled, shifting toward higher intensity. In designing apps for individual conditions or groups of conditions, it makes sense to consider both intensity and duration, and how these change over time. For example, short-term use may require simplicity and easy learnability, whereas long-term use may allow the possibility of more complexity and customization; high intensity use will require consideration of how to facilitate timely patient-provider communication, whereas low intensity use may not require provider involvement, using algorithmic feedback to patients instead.

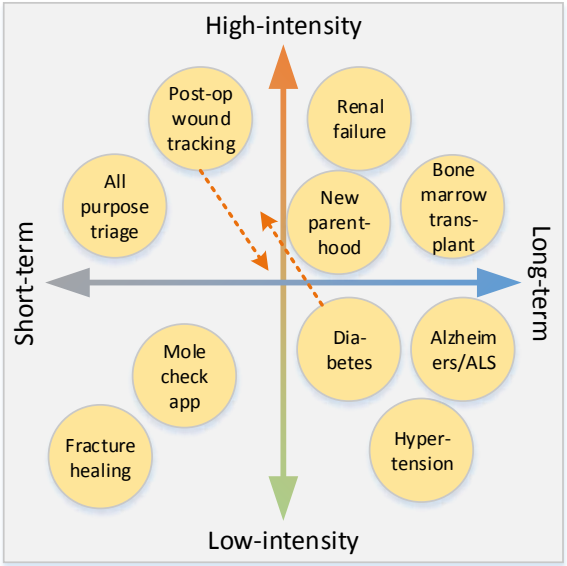

Figure 4: Example mHealth apps by duration and intensity. Dotted orange lines indicate possible shifts based on disease course or progression.

Our research has a number of strengths, including identification of new themes relevant to post-acute mHealth and affirmation of other themes that have been previously reported in the context of chronic illness mHealth. Our findings provide a sound basis for a patient-centered approach to software development, uncommon in the health domain, yet key to developing applications that patients will actually use.

Despite these strengths, this study has several limitations. First, we only interviewed surgical patients. Patients affected by other conditions may have different needs and preferences. We believe ours is a good initial test population due to the challenging and often eventful post-discharge experience following major surgery. Second, we only interviewed patients who experienced post-discharge complications. We believe that patients who experienced problems are the most likely users of the app and have the most insight into current system failings. Lastly, we interviewed a relatively small number of patients from two very different, but related, hospital settings. As is customary in qualitative research, the sample size was based on reaching saturation. In the future we will address some of these issues through user-centered development of our wound-tracking mHealth platform and examine its impact on patient satisfaction, quality of life, clinical outcomes, and healthcare utilization.

Conclusion

Through interviews with patients who experienced post-discharge complications, we explored the design space of a post-acute care mHealth app. Patients described lack of information at discharge, lack of control over communication and mistrust about management decisions made by providers about their care. In response, they envisioned design qualities of an mHealth app that could empower patients through meeting information needs and facilitating predictable communication, and empower their providers with information to make the best decisions about their care. We present a set of design considerations for post-acute care apps and propose a new model for differentiating mHealth apps by the intensity and duration of illness. These contributions incorporate key patient preferences to expand the mHealth landscape with apps that patients will embrace.

Acknowledgments

We thank our participants, the iMed research group, Sarah Han, Cheryl Armstrong, and Mary Ko for their significant contributions. Motivating the Additional Use of External Validity: Examining Transportability in a Model of Glioblastoma Multiforme

Abstract

Despite the growing ubiquity of data in the medical domain, it remains difficult to apply results from experimental and observational studies to additional populations suffering from the same disease. Many methods are employed for testing internal validity; yet limited effort is made in testing generalizability, or external validity. The development of disease models often suffers from this lack of validity testing and trained models frequently have worse performance on different populations, rendering them ineffective. In this work, we discuss the use of transportability theory, a causal graphical model examination, as a mechanism for determining what elements of a data resource can be shared or moved between a source and target population. A simplified Bayesian model of *glioblastoma multiforme* serves as the example for discussion and preliminary analysis. Examination over data collection hospitals from the TCGA dataset demonstrated improvement of prediction in a transported model over a baseline model.

Introduction

Substantial amounts of time, money, and effort are exerted to run scientifically sound experiments in the form of randomized controlled trials (RCTs) to determine the efficacy of medical therapies. In addition, systematic reviews and meta-analysis of the findings in RCTs and other research has been made paramount to demonstrating the validity of findings across the large body of medical research. The major focus to date has been in support of calculating the statistics of these experimental endeavors. Utilizing the combined findings from experimental studies and collected observational data, researchers attempt to develop prognostic disease models to aid in clinical decision-making. However, these models often show decreased performance when used to predict results for new data that were not a part of the original modeling dataset.

RCTs, systematic reviews, and meta-analyses investigate the internal validity of data obtained from one or more trials. Despite the rigors employed to ensure statistical accuracy and understanding, the derived knowledge still only represents a level of certainty in regards to the population examined during experimentation. Previous work has demonstrated that the internal validation of results is not suggestive of applicability to future patients[1]. The ability to apply obtained knowledge to new cases is still somewhat nebulous and rarely applies despite expectations[2]. This issue is related to the complexity of disease and treatment, the issues involved in working with populations without incorporating bias, and the difficulty in completely observing any population. The ability to apply data between populations by determining the external validity of findings is a growing area of study. The primary function of validated data is the ability to apply, or *transport*, experimental or observational results to future domains. Transportability theory is a recently developed method suggested for evaluating when the findings for a population meet the proper constraints to be considered externally valid and therefore are applicable to another population[3].

In this work we: 1) develop a limited Bayesian belief network (BBN) disease model for prediction of glioblastoma multiforme (GBM) survival; 2) examine the ability of transportability theory to provide information concerning the external validity of data collected for the model; and 3) test the transport of data between different contributing hospitals in our dataset. Publicly available data from The Cancer Genome Atlas (TCGA)[4] initiative of the National Cancer Institute (NCI) were obtained to form our training and test set populations. This work is meant to demonstrate the use of transportability and some of the complexities involved in moving data (and the resultant models) between populations for predictive purposes. The model used in this paper is simplified to provide an opportunity to examine the characteristics of a disease model and transportability without the complications a large set of predictive variables may add.

Background

Internal and external validity

Prognostic modeling research is largely driven by evidence-based medicine (EBM) tasks: RCTs, subsequent systematic reviews of RCTs, and meta-analysis derived from completed systematic reviews play a critical role in establishing accepted

clinical practice. Physicians update their understanding of disease, as well as new treatments or changes to existing treatment options, by reviewing these studies. These efforts establish important variables and design parameters for collecting data from a controlled population of patients and healthy controls. Despite attempts to use a standard design, it is often difficult to compare across RCTs, even when both studies examine the same drug's effect on a given condition; (confounding) differences can exist in the sampling size, collection constraints, patients lost to follow-up, etc. Moreover, randomized trials are designed to maximize internal validity (i.e. consistency within a cohort by controlling for potentially confounding variables). These studies validate the efficacy of an intervention under ideal conditions but do not necessarily address its clinical effectiveness across a real-world population (i.e., the external validity/generalizability of the intervention to routine practice)[5]. Though more "practical" or "pragmatic" clinical trials are now promoted to relax subject eligibility requirements (thereby broadening the test population), a given investigation may still encompass assumptions about the underlying study group and environment that are difficult to overcome.

The concept of internal validity allows claims about the treatment methods tested. With robust clinical trial design one can determine if true statistical differences exist between intervention and control groups. However, these statistical claims are only valid for the population observed in the RCT. Systematic reviews gather related RCTs, standardizing the differences between trials and providing documentation of the trends of findings for a particular disease or target therapy. Efforts such as the Cochrane Collaboration recognized the need for maintaining unbiased systematic review and meta-analysis for all of medical research. Contributions by members of the community to collaborations ensure that more medical treatments are reviewed than in the past.

Meta-analyses generate a further statistical evaluation of the internal validity of a set of RCTs linked through the systematic review process. In essence, meta-analysis aggregates the statistical findings of a group of RCTs into the semblance of a single, larger study. This analysis is not a combination of all the raw data from the individual populations of each trial, but an examination of the outcome statistics calculated in the results of each trial by performing a weighted average. This revised statistical evaluation of the individual findings is used to make claims about the consensus of medical research on the given topic examined. The conflicting information from RCTs can lead to inconclusive findings concerning a treatment with the suggestion of further research. Significant findings from a meta-analysis are suggestive of strong associations of the experimental findings; however, these conclusions are still decidedly internal as the analysis steps examine the consensus of medical research and do not directly evaluate the external applicability by applying findings from the RCTs to different populations. Thus, it remains difficult to apply the knowledge to future cases where not all circumstances of the RCT-defined environment will hold.

For this reason, a new set of research efforts are examining the concept of *external validity*, and the direct application of past studies' results to future analysis and prediction. Unlike the significant body of work for evaluating internal validity, few techniques have been developed to test external validity; and internal validity methods are not directly applicable to understanding how findings generalize. External validity is a growing concern in epidemiological research[1,6,7], and is encouraging a move towards testing all data findings with methods relevant to both internal and external validity so that evidence and study conclusions are fully contextualized and applied appropriately[8].

Causal models and transportability

Graphical notation is an increasingly prevalent technique for modeling probabilistic and causal relationships across observation and outcome variables of a disease in order to represent disease's etiology, presentation, interventions, and ultimate course. Graphical notation provides a visual interpretation using well-defined sets of vertices and edges: vertices are representative of the variables chosen for a domain of interest, and edges describe relationships that exist between a pair of variables. The relationships are descriptive of the inferences derived from experiments, the belief the model developer has about the variables from past experience or observations, and other sources of knowledge such as domain experts. For example, disease model graphs can make use of RCT and meta-analytical findings, as they provide a set of presumed belief in the relationships between disease variables.

When graphs contain only directional edges and do not provide any cyclical pathway between vertices they are termed directed acyclic graphs (DAGs). The special constraints of a DAG, in addition to only representing causal relationships between variables, form the basis for a *causal model* or *causal network*. Representation using DAGs has proven effective for working within a Bayesian framework as graph notation is able to provide an efficient means for describing the environment of variables and the associated probabilities of their states in the environment. Figure 1 contains an example of a graphical causal model for treatment effect on lung tumor progression.

Pearl and Barenboim introduced transportability theory as a basis for using relations expressed through a causal model to describe which variables' probability distributions "transport", or move, between populations[9]. For example, a physician in a

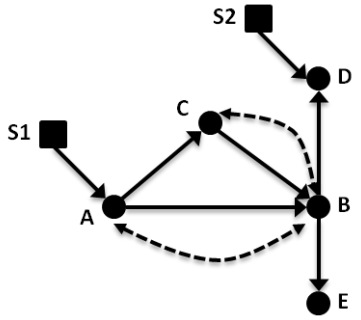

Figure 1. Example causal diagram for lung cancer treatment. Variables: (A) treatment; (B) tumor progression; (C) tumor biopsy gene expression; (D) clinical history; and (E) CT imaging findings. In this causal diagram, solid circles represent standard variables (such as in a Bayesian belief network), and solid arrows between these nodes represent causal relationships. Dashed arrows/arcs indicate confounding influences between two variables that may exist when considering other populations. Selection nodes, shown as squares, provide a means to sub-select or filter a given variable so that the evidence is comparable between two groups.

rural setting might wish to apply the results of an RCT conducted at a large research hospital to decision making for patients locally under his/her care. The RCT findings can be understood in the context of a causal graph, per Figure 1, as a treatment (A) with effect on a patient outcome (B), with additional measured factors such as clinical history, imaging, or genetics (C, D, E). Transportability allows a researcher to identify potential confounding evidence between variables (represented by dotted lines) and population differences (indicated by square nodes, S1 and S2) that are known or believed to exist between two cohorts. The influence of these constraints can be used to determine what data from the RCT can be applied to the rural patients in a principled way. For instance, the physician may not have enough genetic information for his population to build a model; applying transportability can help ascertain whether the genetic information collected in the RCT can be reused (i.e., transported) to the local group (and if not, under what different graphical circumstances such data transport would be valid). Similarly, differences between the hospital and local populations (e.g., demographics) can be accommodated via transportability. In general, if all existing differences can be accounted for, then the external validity of the findings makes the model variables transportable to the new population.

A distinction should be made concerning the differences between causal and probabilistic models (e.g., BBNs). Application of transportability theory is performed on a causal model where an arrow from node X to node Y denotes that X is used in the function that determines Y. Connections are representative of the process "X causes Y" seen in nature, conveying an inherent ordering of events and representing direct functional relationships. Within the probabilistic (Bayesian) context, edges between nodes are often interpreted in a similar fashion as causal connections, but relationships between variables are encoded only by conditional probability tables and statistical relationships. However, arrows in a causal model are meant not only to represent probabilistic dependence but also direct causation. Therefore a causal graphical model is a robust description of the assumptions made by the modeler.

To properly describe the full set of causal connections in the graph, additional information not commonly captured in a Bayesian belief network must be explicitly represented. First, unmeasured confounding information expected to exist between any two nodes needs to be marked accordingly. These confounders are represented by bi-directional dashed edges and cover the counterfactual circumstances of variables that may be impossible to observe or measure. An example of this situation could be the potential interaction of a non-prescription pain-killer and treatments prescribed by the physician (Figure 1, the dashed arc between A and B). Patients may not report their non-prescription drug use or there may be unmeasurable interactions even if the physician knows both drugs are being taken. Second, when population differences are suspected or known to exist for a particular variable, a selection node is added that embeds a method to control for this variation. A selection node serves this purpose by explicitly identifying population differences in the mechanism (e.g., disparities in demographics, socioeconomic status) that are responsible for assigning a value to that variable. By way of illustration, if age differences were significant between two populations, a selection node could be used to indicate the need to select patients who are age-matched. We discuss these points further in our methods and describe them in the context of the simplistic Bayesian model of GBM shown in Figure 2.

Motivating disease and data resources

Nearly half of the 45,000 newly diagnosed cases of adult brain tumor seen annually in the United States are cases of glioblastoma multiforme, an aggressive malignant primary brain tumor. When receiving targeted care at large research hospitals, GBM patients have an average survival time of 12-24 months. In addition, NCI SEER (Surveillance, Epidemiology, and End

Results) data over the last 20 years show little effective change in the survival of GBM patients[10]. A combination of surgical resection, radiation treatment, and chemotherapy are the current standard of care in modern brain cancer treatment. The attempt to improve patient survival time increases the need to study new chemotherapeutic agents and other potential interventions. A growing body of genetic research on the many types of cancer demonstrates the intricate variations that exist between cancer cells, both across tissue types and within individual cancer groups[11,12]. To aid future decision making tasks, statistical examination of cancer findings strive to provide predictive models of treatment and outcomes. However, statistical analysis of cancer studies have been unable to reach a consensus on the most effective predictive variables for GBM patients[13–16]. As our present understanding of cancer and effective treatments are limited, the field continues to work towards integrative models of disease to better employ the influx of experimental data towards improving clinical decision making tasks.

A number of multi-institutional efforts now exist to establish observational databases, supplementing experimental datasets. Two efforts focused on building databases for GBM research are The Cancer Genome Atlas (TCGA) and the Repository for Molecular Brain Neoplasia Data (REMBRANDT). TCGA is a public database of clinical and genetic information for 20 different types of cancer. Containing primarily clinical and genomic (copy number, DNA methylation, gene expression, single nucleotide polymorphisms) data, the TCGA dataset has ongoing efforts to also make radiological and pathological images available. The REMBRANDT database is focused specifically on data obtained for all types of brain glioma (astrocytoma, GBM, mixed, oligodendroglioma) with a limited number of unmatched non-tumor controls.

Methods

Many potential modeling variables from the clinical, treatment, imaging, and genetic domains have been explored in GBM research. A brief list of example variables from existing public GBM datasets are shown in Table 1. A subset of the available data related to a chosen clinical question is selected to facilitate discussion of transportability in the network. In this work, the number of variables considered is substantially limited in order to build a simple BBN. In this way, focus is given to introducing core concepts involved with the theory without discussing advanced causal situations prematurely.

Table 1: Partial list of potential predictive variables from among two multi-institutional data sources, TCGA and REMBRANDT.

Variable	
Demographics	Total radiation dosage
Presenting age	Other drug name
Family & social history	Other drug Frequency
Environmental exposure	Other drug Dosage
Tumor location	Steroid drug name
Tumor size	Steroid frequency
Tumor grade	Steroid dosage
VEGF	Karnofsky score
EGFR VIII	Other performance score
PTEN	Tumor volume (on imaging)
TP53	Necrosis imaging finding
MGMT	Contrast enhancement imaging finding
DNA methylation	Non-contrast enhancing region
Chemotherapy drug name	Tumor multi-focality
Chemotherapy frequency/dosage	Edema volume (on imaging)
Number of chemotherapy cycles	Mass effect
Type of surgical resection procedure	Satellites
Extent of resection	ADC map (imaging)
Type of radiation therapy	Time to progression (TTP)
Radiation therapy fractionation	Time to survival (TTS; death)

Predictive Model

Our example model (Figure 2) contains four variables; 1) a demographic variable, *age* 2) a cognitive assessment variable, *Karnofsky performance score* (KPS) 3) a genetic variable, a *9-gene metagene score* derived from Colman, et al.[17], and 4) an outcome variable, *overall survival* (survival past median of 12 months). Age and KPS were chosen due to their predictive significance in previous GBM models[18–20]. Overall survival is the most common outcome variable used for prediction in previous GBM models and is most commonly predicted using median survival time cutoff[18–20].

The incorporation of a genetic variable relates to the growing interest in genetic prediction variables for cancer. For example, a number of papers in GBM treatment discuss O6-methylguanine-DNA-methyltransferase (MGMT) methylation and tumor protein 53 (TP53) gene expression as potential predictive markers for GBM patient survival. Previous work has found a significant up-regulation of MGMT expression in the tumor tissue when treated with O6-alkylating agents such as temozolomide (Temodar), indicating a potential benefit for patient's survival[21–26]. Similarly, up/down regulation of TP53 factors into cell apoptosis; reduced rates of apoptosis are characteristic of many types of cancer and can contribute to large growth rates of cancerous cells[27].

Table 2. Selected model variables.

Variable	Range/Categorical values
Age	0 (<40); 1 (40<65) ; 2 (65<80) ;3 (>80)
Karnofsky Performance Score	20,40,60,70,80,90,100 - 7 Category Assignment
Metagene Score	0 (Low, Score <= 0), 1 (High, Score > 0)
Survival past median	0 (No); 1 (Yes)

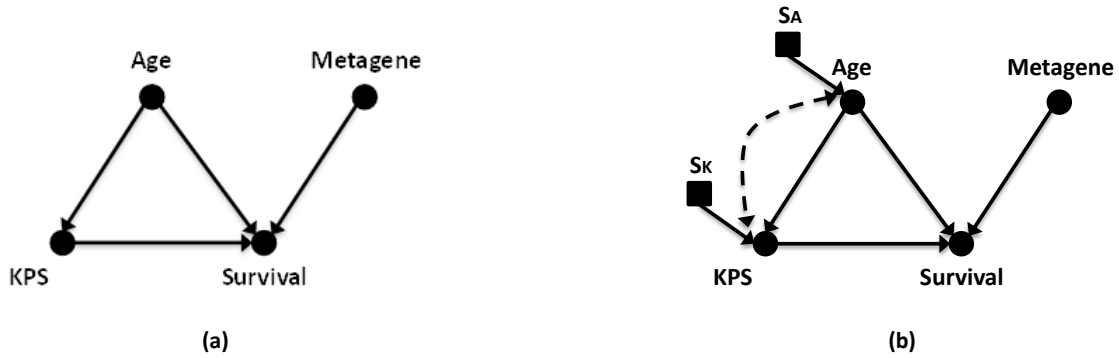

Figure 2: Example causal diagram for (a) GBM survival prediction and (b) the same causal diagram of GBM with links and nodes representing expected confounding information and population differences for variables. In the diagram, solid circular nodes represent observed variables; while square nodes indicate selection nodes controlling for population differences. Causal links are represented with solid lines with directional arrows. Bi-directional dashed lines indicate a variables linked by confounders. The selected observational variables are Patient Age (Age); Karnofsky Performance Score (KPS); 9-gene metagene score (Metagene); and Patient Survival at Population Median (Survival). Unique selection nodes for Age and KPS are shown as S_A and S_K.

Genetic testing is not available to most clinical locations and smaller locations will not have a large enough sample of cases to estimate the rates of expression for their population. Therefore, a genetic variable is a suitable example of an item from a model that would benefit from transportation from a source to target location.

As previously mentioned, our genetic variable is a metagene score derived from nine gene expression values measured in the TCGA dataset. The selection of these significant genes and the metagene scoring technique were derived from Colman, et al.[17]. Briefly, the metagene score is calculated by summation of the weighted expression levels of the genes for each patient and then discretized into high and low score classes. Discretized ranges for all variables in the model are shown in Table 2.

Data selection

Data was obtained from the TCGA public data repository. In total, 579 cases exist in the TCGA database with clinical information. Variable selection and preprocessing steps were performed on the full set of available TCGA cases with available clinical and genomic data. Cases were first selected for no evidence of prior glioma to match our analysis with the methods of Colman et al. and provide similar metagene analysis, reducing the number of available cases to 544. Because of the small number of variables in our Bayesian network we further sought to avoid missing data and the need for any imputation. A portion of the desired KPS variables were blank or unavailable for 143 cases. Finally, only cases observed until death or past the median survival cutoff are appropriate for the analysis in a Bayesian framework, so censored patients were removed. This reduced the final count of available cases for analysis to 346.

The final selected population for TCGA was then discretized based on the categories in Table 2. The dataset was divided into three source and target subsets based on contributing hospital location. Source cohorts serve as our "previous location" used for the majority of model construction and the Target cohorts are "new patients" for prediction at another location. Three target splits were made into a large, medium, and small set of cases to examine the effects of prediction when varying amounts of target data is available. The final TCGA hospitals chosen to serve as targets for analysis were Hospitals 2, 6, and 19 with contributed subjects of 84, 65, and 18 respectively. All remaining hospital locations supplied data to the complementary source cohort (262, 281, and 328 cases respectively).

Applying transportability

In the example GBM model in Figure 2a, we have a set of four variables and their causal connections. The example network comprises no connective links other than the direct causal connections derived from literature. Causal assumptions have been made in constructing this graph, and we must consider the differences that may exist between source nodes and nodes of a target population. Confounders and selection nodes are likely involved in most graphical networks and must be considered and dealt with when problematic. An example graph with a number of these issues, such as in Figure 2b, is a case where data may not be transportable unless certain constraints can be met either by transportability rules (do-calculus/d-separation mentioned below) or a valid belief that removal of the connections can be made without affecting the outcomes. The goal is to map between the messy real-world graph in Figure 2b and the ideal causal graph in Figure 2a to enable the transport of information. We review two issues below:

1) *Unobserved and confounding variables*. Let us consider the dotted connections in the example GBM network. Bidirectional dotted lines represent latent confounding variables in the causal graph. For this discussion, let us say that a connection represents interactions between age and Karnofsky performance score mediated by unmeasured variables (i.e., data that could not be observed). The addition of this link denotes that there is belief that complex biology explains the interaction between KPS and age and could mask our causal assumption. For example, KPS is derived from an examination of a patient's current mental and physical status. This status derives from a combination of the current symptomatic state of disease in the patient and some mix of other past disease. The patient's symptoms might be tied to a damaged hip from osteoporosis, causing a decreased score due to lost mobility, or be tied to a past stroke, causing a decreased score due to aphasia. These kinds of effects would mask our attempt to measure age's effect on KPS values caused exclusively by GBM. If proof exists in the literature that such an interaction is common, it might be required that additional variables be added to the model to correct the confounding before a proper transportability assessment can be made. This particular confounding example seems farfetched and we would remove the confounding link as we have a reasonable belief that clinicians are considering past injury when quantifying the KPS value.
2) *Population differences*. In addition to confounders, consideration must be given to the population differences that exist in the collected data. For example, the number of patients treated with given chemotherapies may vary between two locations depending on physician treatment preferences/experience, hospital practices, and availability of the potential drugs. Selection nodes in Figure 2b represent potential cohort differences in age and KPS scoring. Age often varies depending on the type and location of hospital where data is collected. KPS scoring can vary depending on factors such as amount of clinician training in performance scoring, the overall experience with patients in the domain, and the standard variability seen between different examiners. Adding new selection nodes changes how we consider these variables as we evaluate the ability to transport the network findings. Unless a belief or measurement can be made about invariance between the populations, selection nodes may indicate that stratification or re-estimation of variables may be warranted.

Having described the links assigned to the graph, the application of Pearl's work with transportability is possible for a given graph[28]. A set of algebraic rules called do-calculus[9,28] enables a formal mathematical statement to be derived that determines what elements of information are transportable with the given variables, relationships, confounders, and selection nodes. The do-calculus allows for links in the graph to be broken based upon forced experimental constraints. Further graphical analysis via d-separation, and front- and back-door criteria, can help determine which variables of the model are identifiable. Identification entails the evaluation of the graph edges that remain when observational data is used to set a variable to a specific state and then determining when the network is not directly affecting the transportation of findings. Thus, when a causal graph is not identifiable, its findings are not transportable. For example, KPS, a scoring of the neurological performance of a patient based on symptoms, can serve as a surrogate measure for imaging findings of brain tumor growth, which is influenced by population differences. When KPS can be determined as conditionally independent of population differences, it can serve as a replacement for the imaging information using the front door criterion of d-separation and unblock a situation where imaging findings may not be available. A full description of the do-calculus and d-separation can be found in Pearl's work[9,28]. Further individual examples can be drawn for situations involving back door paths and bidirectional counterfactual edges; many are reviewed in more detail in the available work from Pearl and Barenboim[9,29].

Network evaluation

Our Bayesian belief network predictive model for GBM was tested using custom code in MATLAB (version 7.10.0, MathWorks, Inc, Natick, MA). Source and target cohorts were built by splitting the TCGA dataset by contributing location; one TCGA participating location was held out as the Target set while all remaining data formed the Source set. For example, Hospital 2 contributed 84 cases to the 346 total TCGA dataset. A target dataset for the Hospital 2 split contains these 84 cases. Then, a source dataset was made from all remaining TCGA sites (6, 8, 12, 14, 15, 19, etc) containing 262 cases. In this way, the Source cohort acts as a previous location used for model construction and the Target cohort is a location with new patients in need of prediction. For this analysis, three splits were performed targeting locations with a large (Hospital 2, n=84), medium (Hospital 6, n=65), and small (Hospital 19, n=18) number of cases in the TCGA set. Four model considerations were used while varying the training and test cohorts from the three source-target splits. The four model considerations are: Source versus Source (SS), Target versus Target (TT), Source versus Target (ST), and Transported Source versus Target (TrST). Each consideration

Model	Training Data	Test Data
SS	All Source	Source
TT	All Target	Target
ST	All Source	Target
TrST	Age: Source, KPS: Target, Metagene: Source, Survival: Source	Target

Table 3: Description of training and test data used in the model considerations. Test data is cross validated using the leave-one-out cross validation method.

	Model							
	SS		TT		ST		TrST	
Hospital 2 (262,84)	0.69	(2.7E-08)	0.76	(1.5E-05)	0.74	(1.1E-04)	0.76	(1.7E-05)
Hospital 6 (281,65)	0.72	(1.6E-11)	0.68	(0.007)	0.63	(0.056)	0.63	(0.059)
Hospital 19 (328,18)	0.71	(4.7E-12)	0.94	(0.004)	0.68	(0.248)	0.94	(0.004)

Table 4: Leave-one-out validation results of transportability analysis. Values represented are Area under the curve (AUC) and Mann-Whitney U p-value for significant difference between survival prediction classes. Three hospitals in the TCGA dataset are compared to demonstrate the effects of target cohort size. Karnofsky performance score (KPS) was held out as missing/unmeasured data in this model.

describes the Training-Test setup used for modeling. Leave-one-out validation was performed on test cases to determine the prediction rate of the models. Mann Whitney U-tests were used to test for significant difference between prediction classes of the model.

The SS and TT examinations represent the gold standard evaluation of a model built using data from source and target locations respectively. This emulates the current state of practice where each research location builds a model rather than pooling data or using a past model. The ST examination tests the external validity of the Source model at predicting new cases from the Target cohort. The ST examination represents the special case where all variables are assumed to be trivially transportable (i.e., there are no differences affecting the Source variables, a very rare circumstance). All model probabilities are obtained from the original Source cohort with no training input from Target patients. Finally, the TrST split examines a more realistic transport where the KPS variable is trained by the Target data under the assumption that the Source KPS data is too different from the Target patients. In this model, all other variables are trained using transported values from the Source cohort. The expectation is that the joint use of information from the Target and Source datasets will outperform the ST method where differences of target information are not taken into account. Table 3 provides a full breakdown of the training and test data used in each of the four model considerations.

Results

After variable selection and application of selection criteria, 346 TCGA cases were available for analysis and were split into three source-target cohorts of Hospital 2 (262 source, 84 target), Hospital 6 (281 source, 65 target) Hospital 19 (328 source, 18 target). Each source-target cohort was then used for model training, followed by testing using leave-one-out cross validation (LOOCV) across the four described training variations (SS, TT, ST, TrST). LOOCV was chosen in order to maximize the number of cases available for the training steps, as the available hospital sample sizes are small. Complete results of the Bayesian analysis are shown in Table 4 and are discussed in more detail below.

Prediction using source training data (SS and TT)

Results from the analysis of standard methods of source and target modeling demonstrate moderate rates for LOOCV. Area under the curve (AUC) values ranged from 0.69-0.72 (LOOCV) for SS models. TT models ranged from 0.68-0.94 (LOOCV). TT models outperformed SS models in most considerations. However, the sample sizes of each TT model are smaller, reducing confidence in AUC values holding steady under all circumstances as seen by the weaker p-values in Mann-Whitney testing. We refer to the TT model AUC values as the standard accuracy target for the subsequent model applications, ST and TrST.

Prediction using outside training data (ST)

When the source model is applied as training data for a target location in the ST model, a decrease in performance is seen for all hospital combinations when compared to the TT score. In LOOCV, AUC values drop by 2.7%, 5.3%, and 26% respectively for the three hospital splits. These lower AUC values indicate that the training data from the source model is not able to predict cases in the target set as accurately as a target trained model. Results are most externally valid when populations are the same and variations between variables are minimal. Only in the large target cohort split, Hospital 2, do we see a significant differentiation ($p = 1.1E-04$) between prediction classes and therefore see potential external validity. For the other splits, external validity does not hold for the source model on outside data as p-values do not reach significance (0.056 and 0.248).

Prediction using transported probabilities (TrST)

By transporting appropriate information from the source location and using information for appropriate variables from the target location, the intention is to improve the model by making it more accurate against the differing variables and distributions at the target location. In our TrST model, the KPS value is assumed to vary between Source and Target populations. Therefore, KPS probabilities are trained using Target patient data while other variables use transported data from the Source.

In two applications of the TrST model, we see an improvement of AUC over the application of the source trained model, ST. Performance for Hospital 2 and Hospital 19 improved to match the original prediction accuracy seen in the TT model for this validation. In the case of Hospital 19,the smallest target cohort, the Mann-Whitney U test statistic also changed from being insignificant (ST p=0.248) to significant (TrST p=0.004). These improvements suggest that data from the KPS variable in the Target was able to better model local cases. Hospital 6, however, showed no improvement in accuracy between ST and TrST attempts, suggesting no significant difference between the Source and Target KPS data for this split. When these values are similar, little new information is added to improve predictions and the external validity of a source must be high to match prediction accuracies reached using target data. Detecting these cases is important to using transportability for improving model accuracies.

Discussion

The transport of probabilities for prediction from a source model to a target cohort imparted an increase in the predictive power of the model over an original source model for two of the three sites in our evaluation. These results demonstrate at a basic level the potential power of transportability theory to assess a model and determine appropriate variables for transport. Consideration of confounding and population difference that are possible in new cases is important when determining whether external validity applies to a model.

Transport of data for Hospital 2 and Hospital 19 demonstrated improvements over source models. This result indicates that the recovered target information works in concert with the transported source information to bring model predictions back to a rate similar to training a full model from scratch. Transporting data in this way can lead to more accurate models when data is unmeasurable or unavailable. In addition, it can be beneficial to future studies by reducing the number of variables that must be measured at the new location, saving time and money. Recall, in our simplified model for this work (Figure 2) we transported age, metagene, and survival information from the source. In doing so, the target was not required to provide information to estimate probabilities for these variables: only KPS data was collected from the target.

Overall, the predictive power of the models in this work is moderate, a common issue for current GBM models. While the highest AUC for a gold standard model in our analysis is 0.94, this score is for a very small dataset. Nevertheless, our results demonstrate the effect transportability can have in making an outside model useful to a target location. In two of the three splits of TCGA data, performance was improved over directly applying the source model.

One limitation within this work is the overall simplification of the problem. A probabilistic model of GBM should include a number of variables covering clinical, treatment, imaging, and genetic factors. The presented model only examines two such facets (clinical and genetic) and minimized the feature set to four specific nodes for the prediction task. This simplification was necessary for an introductory discussion of transportability, but is unrealistic as we consider the proper model options for testing external validity in the future. More realistic models with 10-20 features will complicate the ability to analyze the transportability of findings. Future analysis must examine the computational sophistication of larger disease models in order to find tractable solutions to transportability questions.

Also, low prediction rates for the current model are likely tied to the simplistic model representation chosen in order to facilitate discussion. Other statistical models have reported higher levels of time to survival prediction in GBM (AUC 0.81)[20]. In addition, we only explore a limited number of contributions from confounding information and population differences related to this model. Additional examination of location differences in the TCGA dataset might elicit the variable(s) that cause poor improvement in a situation such as Hospital 6 and indicate problems assumed away incorrectly. Providing a robust examination of factors that can disturb the external validity of data is necessary to support the claims made when completing evaluations with transportability rules. Such factors may lead to inaccurate decisions that findings are applicable externally. Overlooked or ignored confounders may destroy this capability in practice.

Another limitation of the current model is the use of a 9-gene metagene score that summarizes a set of gene expression values. The 9-gene metagene was used in this work based upon a previous assessment against TCGA data by Colman et al.[17]. An examination that treats each gene as a variable of the model rather than a summary statistic might yield improved results. In addition, many other gene expression rates are measured for these populations and more statistical examination of the predictive involvement of these genes is warranted.

Application of transportability theory to increasingly complex model designs will be important to expand the utility of this approach. For instance, adding a new variable to the model can cause a number of complications in the causal network not fully discussed here. A few considerations that might be made when adding items to the network include: how the variable was measured, what other variables it is causally connected to, how the addition affects the previous assumptions of the links in the model (changes to independence), and if measurement of the variable introduces difference into the population. As model complexity rises, it appears that the number of considerations may become difficult to appreciate.

While this work has a simplified model and assumptions, the potential utility of transportability theory is clearly demonstrated. In our working example, the step of adding confounding arcs and selection nodes in the simplified GBM model imparts that there are additional factors to consider. Honestly evaluating where these links and nodes can exist enables a discussion that faithfully considers the causal nature of the relationships described in a graph. In this way, a researcher can use transportability theory to demonstrate that issues have been considered and the assumptions made when attempting to claim findings are externally valid. With the proper examination, a mathematical description of this fact is derivable via the do-calculus.

Another potential area for future investigation is the addition of better descriptions for model design, parameters, and causal graph assumptions. One mechanism for providing this information is through the Predictive Model Markup Language (PMML), an XML-based language for describing models to improve interoperability[30]. However, PMML currently lacks descriptions for Bayesian networks, so extensions will be necessary for application. By including model information and graphs designs to experiments and RCTs, investigators can explicate the study's experimental target and the specific assumptions and decisions involved with the chosen design. The provided graph might then act as a template for outside researchers to test the model transportability against their own datasets. With the time and cost investment involved with running RCTs and cleaning observational data, these explicit descriptions could aid in the discovery process and also influence future investigations if transportable findings from a previous study mean that time and resources can be spent targeting previously unexamined variables in the domain.

Despite the strengths of transportability, there is difficulty in describing the method using more than basic examples with a minimized set of considerations such as those used above. Pearl and Bareinboim have incorporated more complex graph models in their work[9,28,29], but those models are not always contextualized in a way that is clear to the layman. In this work we have attempted to begin bridging this gap and make an attempt at introducing the core concepts of transportability. However, future work must address the best means to introduce the complex methods involved in determining external validity in this fashion. Further efforts must be made to provide descriptions of the theory that are accessible to a broader audience with an interest in testing external validity. This will require communication between computer scientists, statisticians, and informaticians to balance the descriptive language used and ensure that papers related to transportability and external validity can be published more widely.

Conclusions

Testing the external validity of scientific findings is important for the application of knowledge across populations. Transportability theory provides a robust method for describing the causal relationships of experimental variables and the circumstances that allow findings to be transported to additional populations. We have described core concepts of transportability in the context of a GBM model that describes transportability of a metagene biomarker for gene expression between two cohorts. The increase in AUC in testing for two of the three examined test cases is indicative of the utility of transporting information. The need to perform robust analysis of the potential confounders and population differences using a technique like transportability is important and future work will focus more heavily on these restrictions. The simplified model provides an understandable introduction to transportability and the examination of how poor assumptions and population differences may encourage use of models prematurely. Additional work in the area of transportability can provide a useful tool set for examining the causal relationships of experimental work and calculating the circumstances where the findings are externally valid with another population.

Abstract

Acute coronary syndrome (ACS) accounts for 1.36 million hospitalizations and billions of dollars in costs in the United States alone. A major challenge to diagnosing and treating patients with suspected ACS is the significant symptom overlap between patients with and without ACS. There is a high cost to over- and under-treatment. Guidelines recommend early risk stratification of patients, but many tools lack sufficient accuracy for use in clinical practice. Prognostic indices often misrepresent clinical populations and rely on curated data. We used random forest and elastic net on 20,078 deidentified records with significant missing and noisy values to develop models that outperform existing ACS risk prediction tools. We found that the random forest (AUC = 0.848) significantly outperformed elastic net (AUC=0.818), ridge regression (AUC = 0.810), and the TIMI (AUC = 0.745) and GRACE (AUC = 0.623) scores. Our findings show that random forest applied to noisy and sparse data can perform on par with previously developed scoring metrics.

Introduction

Coronary heart disease is the leading cause of death worldwide, accounting for 7.0 million (11.2%) of all deaths annually. It is also the most common cause of death in the United States[1]. There are many negative sequelae of coronary heart disease, including acute coronary syndrome (ACS), which is an umbrella term for unstable angina and myocardial infarction[2]. Many patients with ACS seek treatment in the emergency departments of hospitals, where chest pain is the second most common presenting complaint[3].

There is significant variation in presentation for patients experiencing ACS. The variability includes often atypical presentations, and there is a large overlap between symptoms of a patient with ACS and those of a patient with diseases of non-cardiac etiology[4]. To appropriately rule in or out ACS, physicians rely on many different testing modalities, such as cardiac markers, electrocardiographic readings, stress tests and coronary angiography.

Despite the advancements made in diagnostic technology, between 2 and 5% of true ACS cases are reported to have findings indicative of non-cardiac disease and mistakenly discharged from the emergency room[5]. This error confers nearly twice the risk of 30-day mortality[6]. Furthermore, a missed diagnosis of ACS can be costly for a physician or hospital. Data from the Physician Insurers Association of America show that 26% of all malpractice claims against emergency departments from 1985 to 2003 were for patients evaluated for chest pain[6]. It also is estimated that greater than 25% of all medical malpractice dollars paid out to plaintiffs result from missed cases of ACS[7].

In response to the very real threat of life-endangering medical errors and malpractice litigation, emergency room doctors often perform a full gamut of tests on every patient who presents with chest pain. Of patients worked up and admitted to the hospital for ACS, only 30% are ultimately determined to have a cardiac origin for their symptoms[9]. The costly workup for suspected ACS is the main driver of the 10 to 15 billion dollars spent to accurately diagnose patients with unclear chest pain symptoms[10].

Risk stratification, or formal prediction of a patient's ACS risk at the time of presentation, is recommended by American College of Cardiology and American Heart Association guidelines[11]. Many risk stratification tools have been developed over the past 50 years to provide structure to the often unstructured process of prognostication, and these tools rely largely on the same individual tests employed in diagnosing ACS. Some of these tools, such as TIMI[12], were derived from clinical trials data. Others, such as GRACE[13], came from global registries. Still others, like HEART[14], were created by expert consensus without a defined study population. These types of models have performed with varying degrees of success (Table 1). A catalog of the tools used to risk stratify patients with potential ACS, and the performances of these various approaches, is beyond the scope of this paper. Than, Flaws, Cullen and Deely provide a useful, though not comprehensive, reference[12]. Even with these predictive tools, the rates of over- and under-treatment have remained largely unchanged.

Table 1. Selected Examples of ACS Risk Stratification Tools, Included Features, and First Performance

Tool	Source	Included Features	Performance
TIMI[13]	Clinical Trial	age, risk factors for CAD, prior coronary stenosis, ST deviation on ECG, severe anginal symptoms, aspirin use in past week, elevated serum cardiac markers	AUC = 0.74
GRACE[14]	Registry	Killip heart failure class, systolic blood pressure, heart rate, age, creatinine, presence of cardiac arrest, ST-segment deviation, elevated cardiac enzymes	AUC = 0.84
HEART[15]	Expert Opinion	history, ECG, age, risk factors, troponin	AUC = 0.89

Several limitations related to current risk models may explain this unimproved clinical performance. For instance, use of these risk scores is likely affected by their ease of application. Some, like GRACE, require the use of a computer for the complicated risk score calculation. Others, like TIMI or HEART, use as input clinical findings that are subjective in nature, which may require additional time on the part of the physician. Either of these issues might limit the use of such risk stratification tools in a busy emergency department.

Generalizability to clinical practice is another shortcoming of these models, as clinical trials or registries may not represent the typical emergency department patient population[16]. For clinical trials, strict inclusion and exclusion criteria cause older and multi-morbid patients to be underrepresented. Inclusion in many registries is dependent on final diagnosis, which can lead to problems in model development due to a lack of negative examples. In both clinical trials and registries, standardized data procedures lead to largely complete and error-free data from these sources, which is also not representative of clinical practice.

From a model development perspective, simpler model building approaches have also led to a lack of generalizability. Feature selection via stepwise selection or recursive partitioning, which have been used in several previous models, are not robust to idiosyncrasies in training data, which leads to poor performance in real emergency departments[17].

Based on these limitations, there is a need for ACS risk stratification models that can utilize data as it exists in the electronic medical record (EMR), imperfections and all. Such models would be derived from data reflective of

medical practice, and thus generalize to a broader population. They would not rely on a priori knowledge or simple methods of feature selection, but effortlessly handle large numbers of variables to make the best predictions. Ideally, these models would also not require direct human calculation or input of subjective features, but could be run in the background of an EMR system, automatically updating their predictions as new information is entered into the system, and support the clinician at the time of decision making.

While there are many machine learning approaches available for building such models, elastic net and random forest are excellent choices because they easily include many variables, resist overfitting, and provide generalizable performance. The elastic net algorithm, which combines the lasso and ridge penalties on top of regularized logistic regression, avoids overfitting and induces sparsity[18]. Random forest creates an ensemble of decision trees built using different random subsets of the features available for training, and votes for the most likely outcome between the trees to achieve generalizability of the model to future predictions[19]. In this work, we explore the performance of both of these methods.

Materials and Methods

We obtained the data for this study from Vanderbilt University Medical Center's Synthetic Derivative (SD), which is a deidentified copy of the main hospital record databases created for research purposes. The SD contains over 1.5 million deidentified electronic records with up to 15 years of data per patient with no defined exclusions. The deidentificaton of SD records is achieved through the application of a commercial program which removes HIPAA identifiers and shifts dates by a random amount of time up to one year that is unique for each individual's record. This study was approved by the Vanderbilt University Medical Center Institutional Review Board.

From this large dataset, we selected records from patients who had presented to the emergency department between the shifted dates of January 1, 2007 and May 31, 2012. Criteria for inclusion were that the patient be at least 18 years of age at the time of presentation and that they have a troponin measurement and ECG recorded during their visit to the emergency department. This selection schema is similar to an approach adopted by Vaidya, Shapiro, Lovett and Kuperman, who demonstrated their approach in identifying an ACS cohort[20]. Our method yielded similar results on our data set as theirs, and as a result we believe that we captured the vast majority of suspected ACS cases to present to the emergency department during this time period. In total, 20,078 patients were included in this data analysis, and no records were excluded for missing data.

We defined our reference standard label identifying the presence or absence of ACS using billing and procedure codes found in the patient record. We used the collection of codes proposed by one of the value-based care teams for Vanderbilt University, in which they define a patient with ACS as one who visited the emergency department for chest pain and who received any ICD-9 code listed as an ACS diagnostic code, or any ICD-9 or CPT procedure code for percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) over the thirty days following the admission date (Table 2). If a patient was admitted twice within a short amount of time, and within thirty days of both visits received a code consistent with ACS, both admission instances were considered positive for an ACS event. Of the 20,078 encounters, we determined 8,408 to be positive for ACS by this rule (41.9%).

Table 2. Codes Use for Identification of ACS Events

Parent Code	Individual Codes
410: Acute Myocardial Infarction	410, 410.0, 410.00, 410.01, 410.02, 410.1, 410.10, 410.11, 410.12, 410.2, 410.20, 410.21, 410.22, 410.3, 410.30, 410.31, 410.32, 410.4, 410.40, 410.41, 410.42, 410.5, 410.50, 410.51, 410.52, 410.6, 410.61, 410.62, 410.7, 410.70, 410.71, 410.72, 410.8, 410.80, 410.81, 410.82, 410.9, 410.90, 410.91, 410.92
411: Other Acute/Subacute Ischemic Heart Disease	411, 411.1, 411.8, 411.81, 411.89
413: Angina Pectoris	413, 413.0, 413.1, 413.9
414: Other forms of Chronic Ischemic Heart Disease	414, 414.0, 414.00, 414.01, 414.02, 414.03, 414.04, 414.05, 414.2, 414.3, 414.8, 414.9
ICD Procedure Codes: PCI or CABG	0.66, 36.03, 36.04, 36.06, 36.07, 36.09, 36.10, 36.11, 36.12, 36.13, 36.14, 36.15, 36.16, 36.20, 36.31, 36.32, 36.3, 36.34
CPT Codes: PCI or CABG	33510, 33511, 33512, 33513, 33514, 33516, 33517, 33518, 33519, 33521, 33522, 33523, 33533, 33534, 33535, 33536, 92973, 93980, 92981, 92982, 92984, 92995, 92996

Features used in the model were included based on the structure of the data, the frequency with which they occurred, or whether they had been proven as predictors in previous models. Features were included only if they were unambiguous in their interpretation and recorded in a structured (numeric or positive/negative) form. As such, many features that we expected to be predictive were excluded, such as quality of pain, length of pain symptoms, or qualitative interpretation of ECG readings. From the subset of structured findings, we collected many known risk factors for ACS, including vital signs, laboratory values that were recorded for at least 10% of our study population, and select past medical history. For all laboratory findings we included only the first instance of that finding within their medical encounter, except for troponin and ECG measurements, where we included the first two measurements if possible. We collected 88 variables for use in our models (Table 3). No data were assessed or modified for quality assurance, regardless of the potential severity of misrepresentation or nonsense. We separated out and set aside a validation cohort (4015 records, 20%) for final testing of the single best performing model. On the remaining data, or modeling data, repeated the following procedure 100 times. We sampled with replacement to create a training set of the same size as the modeling data (16063 records), keeping the instances that were not included in this training set as a test set. Missing values in the data were then replaced by the median value for that feature in the test and training sets separately to avoid information leak.

Table 3. Features, Distributions and Missingness of Included Features, by Label

Feature	Label Negative (n=11670; 59.1%) Median (IQR)	Missing (%)*	Label Positive (n=8,408; 41.9%) Median (IQR)	Missing (%)*

* Features without missing percentage were either present or absent in medical record.

We compared the elastic net and random forest algorithms against logistic regression with only the ridge penalty, a common method of benchmarking. We performed parameter tuning by an additional step of ten-fold cross-validation. For ridge regression, we selected the lambda penalization parameter in this way. For elastic net, we selected the lambda penalization parameter, as well as the alpha mixing parameter, by grid search from a possible range of 0 to 1 by intervals of 0.1. For random forests, we selected the values for the number of trees (500) and the percentage of features (square root of total predictors) explored at each random split by grid search and human guided search.

We compared our models to the TIMI and GRACE scores. For both TIMI and GRACE scores, available features were included and appropriately transformed to the scale of these scores. Our data did not include all variables needed to populate these models, but a prior study demonstrated a method for imputing missing features for these scores, though their study population experienced significantly fewer missing values[21]. In accordance with the methods of this study, data that were missing were either replaced by a reasonable surrogate, such as any history of past aspirin use replacing aspirin use within the past seven days for the TIMI score, or they were replaced with the most common clinical finding, such as all records being considered negative for cardiac arrest on admission. As a result, our calculated TIMI and GRACE scores had possible point totals of 5 and 246, compared to fully populated maximums of 7 and 372.

All five models were evaluated by visual comparison of receiver operating characteristic (ROC) curve plots and by calculation of the area under the curve (AUC) for their performance on the test data sets. We calculated the median performance and 95% confidence intervals for AUC over the 100 replicates for each algorithm. After identifying a clearly best-performing algorithm, we built a model using all of the modeling data, and tested that model on the validation set to obtain a generalizable estimate of performance. Analysis was carried out using R version 3.0.1 and the packages randomForest, glmnet, ROCR, Epi and rms downloaded from the CRAN website[22–27].

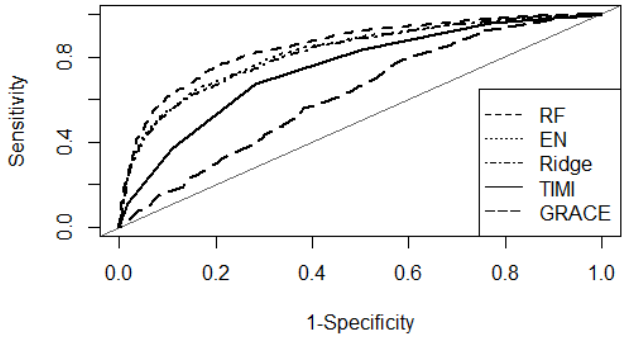
Results

Over all 100 replicates, the random forest outperformed all other methods examined (Figure 1, Table 4). Figure 1 represents a typical run of these five algorithms in our experiment.

Table 4. Performance of Compared Model in this Study

Model	Median [95% CI] AUC over 100 Replicates
Random Forest	0.848 [0.841, 0.857]
Elastic Net	0.818 [0.808, 0.828]
Ridge Regression	0.810 [0.801, 0.820]
Modified TIMI	0.745 [0.737, 0.755]
Modified GRACE	0.623 [0.615, 0.634]

Figure 1: ROC for Prediction of ACS on Test Set



The elastic net, while not performing as well as the random forest, also did not significantly reduce the complexity of the model, retaining on average 75% of the coefficients in the full regression model. There was no significant difference between the elastic net and the ridge penalized logistic regression. Random forest, elastic net and ridge regression all outperformed the modified TIMI and GRACE scores.

The generalization performance of the random forest on the validation set was good, with AUC = 0.849.

Discussion

We developed models using the random forest and elastic net algorithms utilizing a novel clinical database that improved upon existing ACS risk prediction tools and which used only structured inputs from an EMR. This work represents the first attempt that we know of to use data from the uncontrolled environment of a non-trial, non-registry emergency department for the development of such a model. These data more fairly represent the heterogeneous patient population that comprises the cohort of suspected ACS cases nationwide. We have also demonstrated that computationally advanced models can potentially outperform simpler statistical methods. While our random forest and elastic net models outperformed the TIMI and GRACE models, we found random forest to significantly outperform all other models.

Random forests have many advantages that make them useful for classification. They are able to use all of the available data without overfitting, and can also utilize data that is largely missing or that contains multiple recording errors. In the case of these experiments, we worked with an available large dataset which contained many outliers and no apparent quality control. As an example, height and weight were recorded with a mixture of metric and standard units. For some features, as much as 90% of the data were missing. Even with un-curated and sparse data, we were able to produce a classifier that outperformed previously developed methods in a head to head comparison.

While the random forest automatically explores complex interactions between variables, these interactions must be manually specified in regression-type approaches. As it was not clear a priori which interactions were important, and it would be intractable to include all possible interactions, we elected not to include interaction terms in our elastic net and ridge regression models. This may account for a portion of the apparent outperformance of the regression methods by random forest, while also demonstrating the capability of random forests to automatically select complex interactions which would not be available to other methods without user specification. We further explored this capability of random forest using only the features used to calculate the TIMI score. Unbinning the discretized variables from TIMI improved predictive ability, but random forest remained superior to logistic regression. We also found that creating flags for missing features did not significantly affect our results (data not shown).

One key limitation of this study is the availability of data in the system with which we worked. Many of the timestamp entries, in addition to being shifted through the de-identification process used in creating the SD, were truncated to one-day resolution. While temporal specificity down to the minute is not important in some studies, such as genome-wide or phenome-wide association studies, knowing the correct relationship between event times in the complex and sometimes brief encounter with a patient suspected of ACS is critical. Despite the lack of temporal clarity, our model still performed on par with existing methods. Additionally, we were unable to determine which patients discharged from Vanderbilt presented again within 30 days to an outside hospital, resulting in a possible underestimation of the total number of positive events. Use of identified data in the future would allow us to consider patients whose ACS event might be unobservable in the current research paradigm. In the current version of the SD, we were unable to capture the outcome of death, which may have also led to undercounting.

Another limitation of this study is in the definition of positive events in our cohort. We believe there may be label bias due to use of ICD-9 and CPT codes to define an ACS event, but were unable to identify other approaches that would solve this issue. Increasing the number of ICD-9 codes required for a positive label, which has improved phenotype identification from electronic medical records in previous studies, did not significantly improve our performance here (data not shown). Our definition of an ACS event relies heavily on work done by the value-based care group at Vanderbilt University Medical Center. There are several other definitions, including the World Health Organization-accepted universal definition of myocardial infarction. However, alternative methods of identifying ACS-positive records would have required significant manual chart review.

The purpose of our model is to help physicians stratify patients by risk of ACS, in order to more appropriately deliver care. In this context, missing an ACS case would be extremely undesirable. We believe that the majority of suspected ACS patients were included in our analysis, due to the low threshold for inclusion in our study. It is possible, however, that some atypical patients were not included.

Our model has good discriminative ability. However, in order to be clinically useful, such a model must also perform well on the lowest risk individuals, which can be assessed via a calibration curve. Our model had good calibration, but improvement is needed before we physicians could confidently use this model as a decision support tool.

With the continued growth of electronic medical records, automated approaches such as this one will gain traction as providers seek to leverage the expanse of data. If confirmed, this tool could ultimately improve the quality of care by reducing unnecessary admissions and discharges of patients with acute chest pain, and help shift the cost curve for healthcare that has so heavily weighed on the medical system by addressing one extreme case of resource overutilization.

Abstract

The patient problem list, like administrative claims data, has become an important source of data for decision support, patient cohort identification, and alerting systems. A two-fold intervention to increase capture of problems on the problem list automatically – with minimal disruption to admitting and provider billing workflows – is described. For new patients with no prior data in the electronic health record, the intervention resulted in a statistically significant increase in the number of problems recorded to the problem list (3.8 vs 2.9 problems post- and pre-intervention respectively, p value $2x10^{-16}$). The majority of problems were recorded in the first 24 hours of admission. The proportion of patients with at least one problem coded to the problem list within the first 24 hours increased from 94% to 98% before and after intervention (chi square 344, p value $2x10^{-16}$). ICD9 "V codes" connoting circumstances beyond disease were captured at a higher rate post intervention than before. Deyo/Charlson comorbidities derived from problem list data were more similar to those derived from claims data after the intervention than before (Jaccard similarity 0.3 post- vs 0.21 pre-intervention, p value $2x10^{-16}$). A workflow-sensitive, non-interruptive means of capturing provider-entered codes early in admission can improve both the quantity and content of problems on the patient problem list.

Introduction

Administrative claims remain the bulwark of medical billing, and they are also frequent elements of decision support systems including clinical alerts, comorbidity capture, and predictive models. At the same time, the patient problem list has evolved from the "Problem-Oriented Medical Record" defined by Dr. Lawrence Weed in 1968 to an area of research and application of clinical informatics.(1, 2) Both administrative claims abstracted by billers and patient problems derived from provider documentation or provider-entered codes may fall into similar classification schema like the International Classification of Diseases (ICD).(3) But while the literature on claims and on the problem list has expanded markedly since the 1990s, studies evaluating the intersection between these codes are less common.

Because of their ubiquity and classification standards primarily through ICD9/10, administrative claims and their secondary use touch on domains across quality, patient safety, decision support, prediction, personalized medicine, and more. A review of all of these applications would be exhaustive. A cogent example exists in the interplay of diagnostic and pharmacy claims data on medication management.(4-6) A Dutch study in 2013 demonstrated up to 38% of drug therapy alerts failed to appear because of missing information in the electronic patient record; of the 442 records considered, disease information was missing in 83%.(7) A systematic review outlined statistically significant reductions in medication errors in patients with renal insufficiency and in pregnant patients in studies of alerting systems in the electronic medical record.(8)

Biller-assigned administrative claims do come with their own limitations and biases. From predicting mortality to identifying complications particularly in work led by Iezzoni, administrative claims alone may be insufficient data sources for particular tasks.(9-11) Code "creep" – overbilling for more codes than are supportable by documentation – is well-described.(12-14) However, there remains another critical limitation of systems relying on administrative claims; these claims are not coded until after a patient has been discharged and therefore are not available to any of the panoply of systems waiting to use them until days post discharge.

The patient problem list offers some of the advantages of administrative claims – structured data, easily integrated into decision support or quality reporting. Indeed, a coded problem list is a core objective of Meaningful Use, Stage I.(15, 16) A small amount of research has linked problem lists to higher quality care such as increased rates of appropriate prescription of ACE inhibitors or Angiotensin Receptor Blockers for patients with more accurate problem lists; similarly, adding chronic health concerns like obesity to the problem list increase rates of providers

addressing these problems with patients.(17, 18) A number of studies since the 1990s have outlined approaches to maximize the accuracy, completeness, and ease of populating problem lists through methods as varied as direct provider documentation of problems, natural language processing, inference rules, and wikis.(19-29) Some of these approaches are computationally intensive, and others may alter workflows.

Study Aims

The aim of this study is to evaluate a two-fold intervention built into existing provider workflows to increase documentation of problems on patient problem lists. One intervention is the conversion of the "Admitting Diagnosis" Field in the Admit Patient Order Set from a free text field to a structured data entry field using a diagnostic synonym lookup table. The second intervention is the alignment of a daily provider workflow – Evaluation/Management Billing (E/M) by providers on their own documentation – with the population of the patient problem list using a tool locally known as iCharge.

Methods

Admitting Diagnosis Problem List Intervention

The initial order set for every patient admitted to the medical center starts with the Admit Patient Order in the inpatient electronic medical record, Allscripts Sunrise Clinical Manager. The admitting diagnosis must be completed, and until fall 2013, this field was a free text entry field that was pre-filled with free text data obtained through the Admit/Discharge/Transfer Registration System. In November 2013, the field was converted into a structured order entry field that asked providers to continue inputting an admitting diagnosis but provided a means to enter a diagnosis that correlated with an ICD9 code on the patient problem list.(Figure 1) A synonym lookup table provided by Intelligent Medical Objects (IMO), a third party interface terminology,(32) permitted the entry of common abbreviations and natural language to obtain a structured diagnosis for the reason for admission. The order set was not changed in any other way and minimal education around this intervention was required.

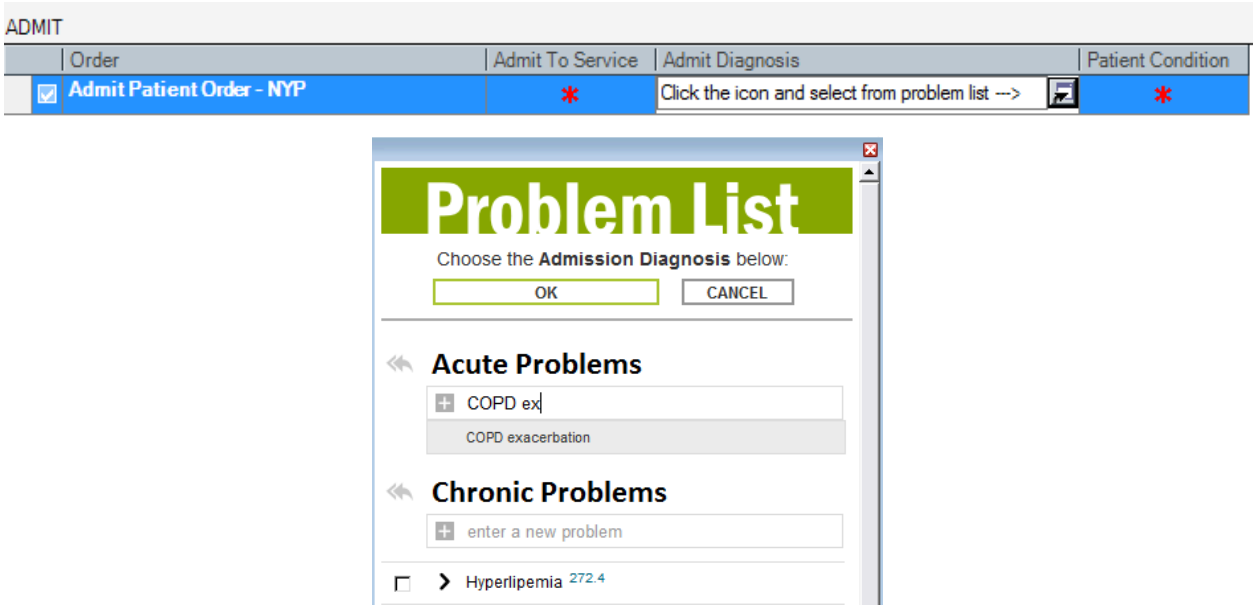

Figure 1. Activation of the custom Problem List Tool (bottom) via the Admit Order Admit Diagnosis Field (top)

In activating the problem list tool, providers were also able to enter secondary diagnoses at the same time. These diagnoses were categorized as acute, chronic, and prior, to reflect common clinical categorizations of a patient's past medical history. The problem list tool was also available at the time of inpatient documentation entry and permitted pasting already coded diagnoses into notes directly under "Past Medical History" (Figure 2).

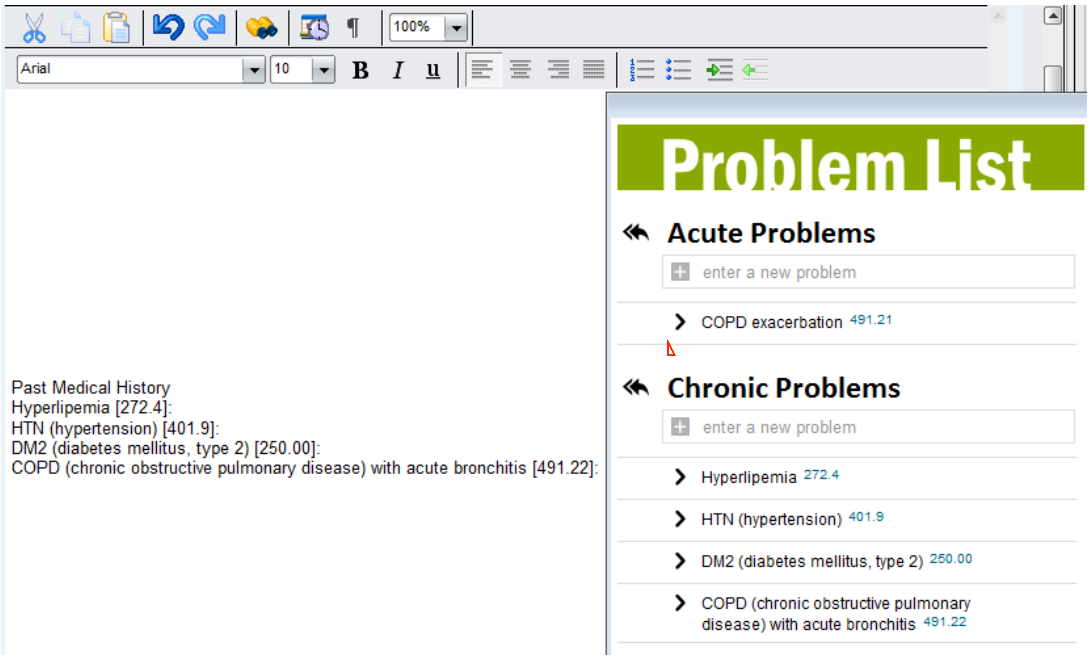

Figure 2. Problem List Integration into Inpatient Notes. Clicking the arrow (circled in red) pastes the diagnoses into the free text note shown on the left

iCharge – Provider E/M Billing Tool with Transparent Connection to the Patient Problem List

In January 2011, the iCharge tool was implemented into provider billing workflows. The prior billing process incorporated paper billing slips submitted by providers after they'd completed requisite inpatient documentation. iCharge converted this process into an electronic "widget" that was readily accessible in the electronic health record. The iCharge workflow started with the provider selecting the inpatient note for which a bill was to be generated. A link in the iCharge tool opened the note itself for providers to review details and to verify the correct note would generate the bill. iCharge was applicable to initial and follow-up provider documentation throughout a patient's admission.

Once a bill and an encounter had been selected, iCharge directed providers to link at least one coded diagnosis to the encounter. From 2011 through November 2013, iCharge permitted but did not require the storage of coded diagnoses to patient problem lists. An option was provided to save coded diagnoses for an encounter back to the problem list, known as "Health Issues".

On November 7, 2013, iCharge was upgraded with a core functionality change – the automatic addition of coded diagnoses to the patient's longitudinal problem list – this will be referred to as "auto-save" for purposes of this work. The option for providers to manually save coded diagnoses back to the problem list was removed but the remainder of iCharge functionality, while enhanced incrementally, was intact.

Throughout the intervention time period, traditional administrative medical billing was conducted by the billing department of New York Presbyterian Hospital. The billing codes assigned to each inpatient admission post discharged were stored in the clinical data warehouse for the hospital.

Data Collection

All health issues/problem list data were extracted from problem list tables in the clinical data warehouse. Administrative claims data assigned to inpatient admissions from January 1, 2011, to March 1, 2014, were also extracted for comparison to the problem list. The admissions occurred at Columbia University Medical Center in New York, NY. Admissions to affiliate hospitals or to other hospitals in New York were not included.

In addition to the Problem List Tool and iCharge, it is possible for providers to enter problem list codes into the problem list via "Health Issues". This step is an additional and rare action in the provider clinical workflow, although precise frequency data for this means of problem entry was not separable from the main data sources in this study.

Evaluation Methods: Change in Problem List Codes Before and After Intervention

The evaluation of the problem list interventions - 1) Admitting Problem List Tool; 2) iCharge and Problem List Integration via auto-save – is based in a comparison of the quality and quantity of problem list codes before and after these interventions. Problem List auto-save was activated on November 7, 2013. The four months prior to auto-save activation was compared to the period following its activation. Attributes of problem list entry were collected including provider type, the time of data entry, and the coded problems themselves.

An important subgroup of this analysis remains patients who have never been encountered in the medical center before. While these patients will not have administrative claims assigned until after they are discharged home, they will have problems assigned to the problem list via the Admitting Diagnosis, iCharge, and the custom Problem List tool.

One subset of ICD9 coding, "V Codes" (V00-V91), correspond to diagnostic circumstances beyond disease definitions. These codes range from "Normal Pregnancy, V22", to "Artificial Opening Status, V44" (gastrotomy tubes, etc) to "Housing, household, and economic circumstances, V60". Factors of mental illness such as suicidal or homocidal ideation are similarly captured by these codes. While not a complete surrogate to psychosocial determinants of health, V codes do capture aspects of a patients' clinical history that are not well-defined in other areas of the ICD9 schema. The number and type of V Codes entered via the problem list interventions were recorded and compared.

Evaluation Methods: Comparison of Problem List to Administrative Claims

Problem list data entered by providers was compared to administrative claims data entered by medical billers using the Charlson/Deyo Comorbidity Index.(30, 31) The Charlson/Deyo comorbidity index aggregates ICD9 coding into clinical categories.(31) ICD9 codes 250-250.3 and 250.7, for example, are aggregated into "Diabetes" while ICD9 codes 250.4-250.6 are aggregated into "Diabetes with Chronic Complications." Both ICD9s derived from the problem list over the course of an admission and those derived from administrative claims data after discharge were aggregated according to Deyo/Charlson comorbiditiy indices. While there is no gold standard indicating how similar problems on the problem list should actually be, it is possible to compare the similarity of the vectors of Deyo/Charlson comorbidity indices between the problem list and administrative claims.

To compare these categorical binary vectors (the presence or absence of ICD9 codes corresponding to the Deyo/Charlson comorbidities without weighting), the metric of Jaccard similarity was used.(36) In the Jaccard index of similarity, a typical approach for two vectors, A and B, is:

$$J = \frac{M_{11}}{M_{01} + M_{10} + M_{11}}$$

where M_{11} is the number of attributes present in both A and B, M_{10} is the number of attributes present only in A, and M_{01} is the number of attributes present only in B. A higher value of J corresponds to greater similarity between A and B.

Data was processed and analyzed in the R statistical environment using packages, "plyr" and "data.table".(33-35)

This study was approved by the Institutional Review Board.

Results

From January 1, 2010, through March 1, 2014, there were 271,615 inpatient admissions corresponding to 140,538 unique medical record numbers. There was an average of 5,400 inpatient admissions per month. In any given month, an average of 2,800 new medical record numbers were assigned corresponding to patients who have not had prior encounters in the medical center and to a very small number that are inadvertently given a second medical record number at registration on a subsequent admission.

Administrative Claims Data

There were 2,785,658 ICD9 codes assigned to the entire study cohort since 2010. There were an average of ten ICD9 codes assigned to each admission. The number of ICD9 codes assigned ranges from a minimum of 1 code to a maximum of 51.

Problem List auto-save was activated on November 7, 2013. The four months prior to auto-save activation was compared to the period following its activation. With respect to medical billing assigned codes irrespective of the problem list, there was a decrease in the average number of ICD9 coded by medical billers in period after auto-save compared to the period before (10.8 ICD9 codes assigned prior to auto-save compared to 9 codes on average after, p value $2x10^{-16}$).

Administrative claims are linked to inpatient admissions in the clinical data warehouse, but they are not assigned until patients have been discharged from the hospital.

Problem List Data

Over the entire study period, there were 319,420 problems entered onto patient problem lists. All providers either completing billing through iCharge (physicians) or entering admission orders through the electronic health record could impact the problem list. There was also an option to bring up the problem list independently in the electronic health record and any member of the care team could do so. Table 1 outlines the usage of the problem list by provider type over the study time period.

Provider Type	Number of Health Issues Entered	Percentage
Physicians – attendings, fellows	270,958	84.8%
Physicians – residents	19,797	6.2%
Physician Assistants	15,012	4.7%
Nurse Practitioners	5,719	1.8%
Medical Students	496	0.2%
Physical or Occupational Therapists	1,308	0.4%
Nurses	159	0.04%
Other or Not Recorded	5,971	1.8%

Table 1. Problem List Entry Count by Provider Type

The timing of entry of health issues was considered in aggregate and specifically for the period before and after the implementation of Problem List auto-save. The vast majority of problems were coded to the problem list at the time immediately before or after the admission event.

A histogram illustrating the timing of problem list diagnosis entry in the first 24 hours of admission is shown with a comparison between the four months preceding and the four months following the activation of Problem List auto-save (Figure 4).

The highest frequency of problem list entry events occurred in the time *before* patients were officially registered as admitted; that registration time correlates with the arrival of patients on the medical ward. In the time before this registration, providers are preparing for patients' arrival on the wards by entering pending admission orders, writing admission notes, and billing on admission documentation. The increase in coded problems after the activation of auto-save is apparent in the plot.

The proportion of patients with at least one problem in the problem list within 24 hours of admission increased from 94% before auto-save to 98% after auto-save activation (chi square 344, p value $2x10^{-16}$).

To assess whether the increased frequency of problem list entry events was sustained throughout admission, all problem list entry timestamps were normalized to length of stay for their respective admissions. The following histogram illustrates that the impact of health issue auto-save is maintained throughout the admission via subsequent billing and documentation events and not solely on the day of admission itself (Figure 5).

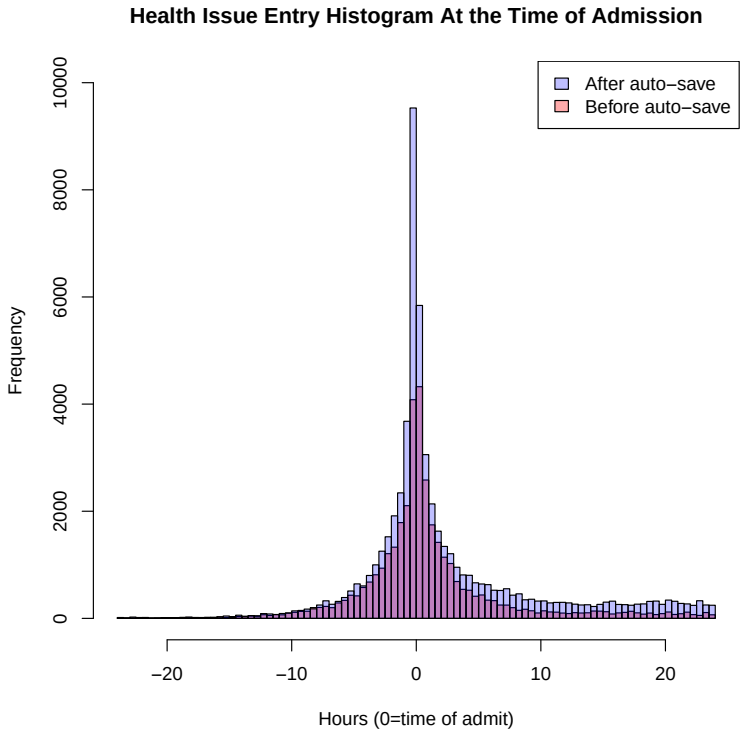

Figure 4. Histogram comparing problem list entry in the first twenty-four hours of admission, comparison between the four months preceding and following the activation of Problem List auto-save

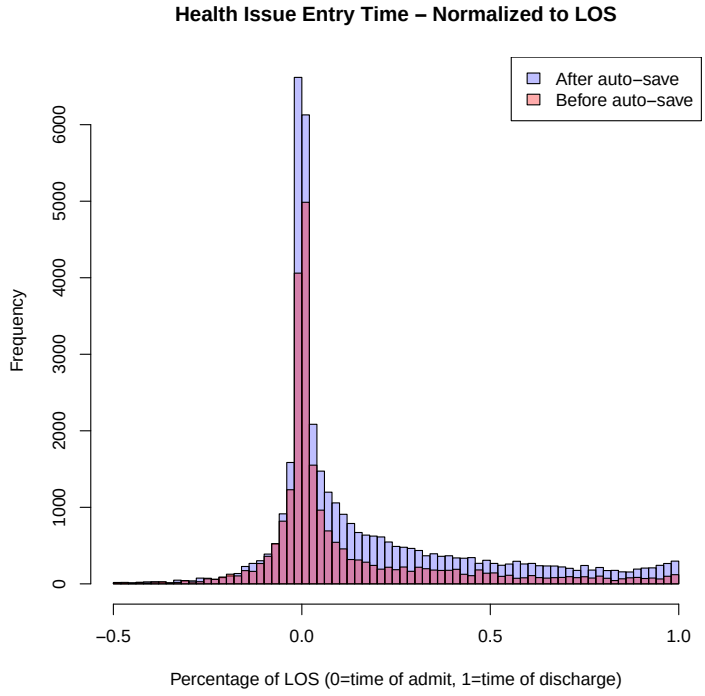

Figure 5. Histogram showing time of problem list diagnosis entry normalized to percentage of length of stay (LOS) - time of admission is 0% and time of discharge is 100% or 1.

Change in problem list entry for patients never before admitted to the medical center

The number of problems on the problem list for new patients increased to 3.8 problems from 2.9 problems on the problem list in the period after activation of auto-save compared to before; this result was statistically significant, p value $2x10^{-16}$. A similar result was seen for all patients in the study period, but particular emphasis is placed on those patients who would not have had problems in the problem list or prior administrative claims.

Content of problem list codes

In the period following the activation of Problem List auto-save, there was a marked increase in the number of V codes being captured (Figure 6). Some of the largest differences are seen in V45 and V42 (corresponding to organ transplantation), V30 (single liveborn), V27 (outcome of delivery), V22 (normal pregnancy). The quantity of V code counts before and after auto-save activation were different (chi square 920, p value 0.002).

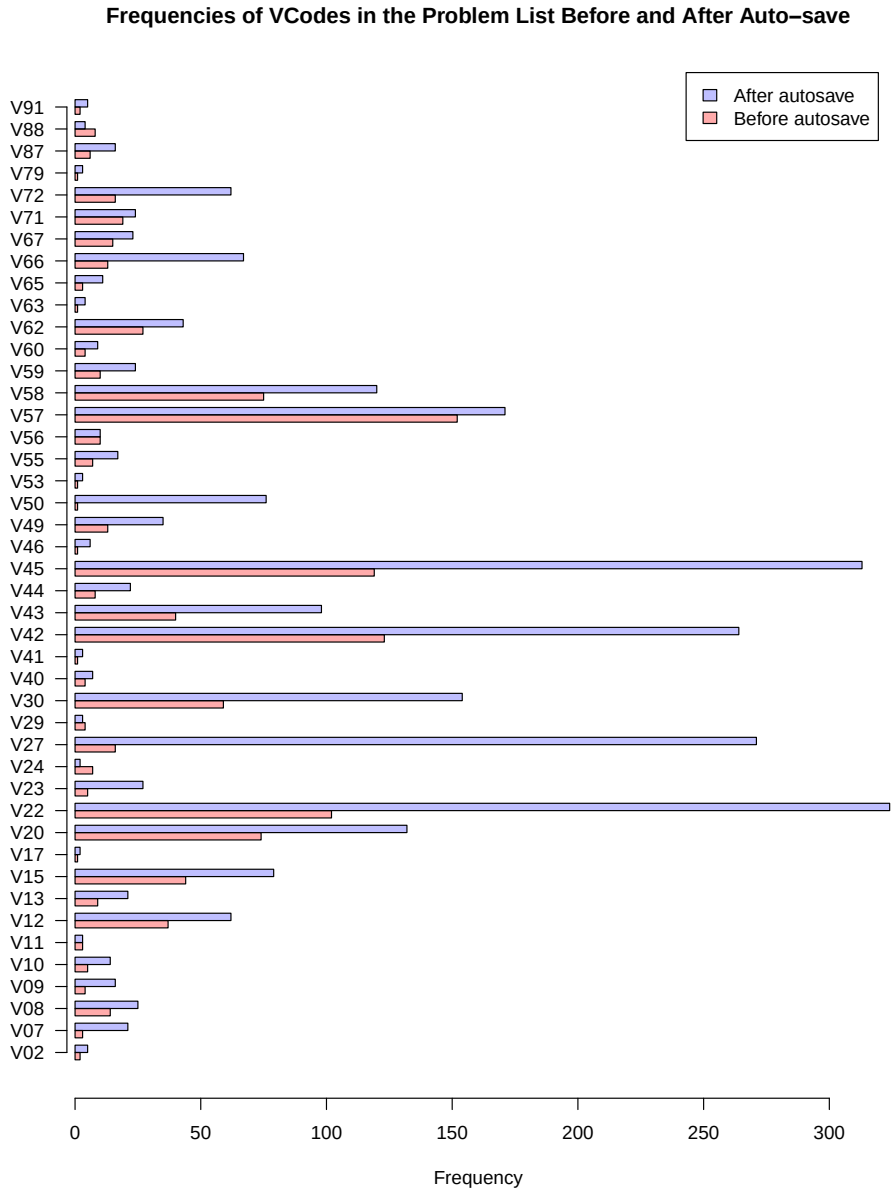

Figure 6. Barplot showing frequency of ICD9 “V code” entry before and after auto-save

Comparison of Administrative Claims Data Compared to Problem List

Jaccard similarity was calculated for Deyo/Charlson comorbidities derived from claims compared to those derived from the problem list before and after auto-save. The similarity of Deyo/Charlson comorbidities was higher for problems entered after auto-save activation compared to the period before, Jaccard similarity of 0.3 compared to 0.21, respectively, p value $2x10^{-16}$.

Discussion

The primary findings of this work demonstrate that interventions to automatically populate problem lists through extant admitting and billing workflows can increase the number of problems codified to those lists. This effect was achieved without altering or interrupting provider workflows. The majority of problems coded through this method are obtained at the time of admission, not the time of discharge, making them available for use while the patient is still admitted to the hospital. A number of decision support tools, such as drug-condition alerts, are enabled by this finding. Another important finding relates to the content of automatically populated problems on the problem list. V codes, a class of ICD9 codes connoting social, mental health, and even economic factors in a patient's clinical history, were captured at a higher rate through Problem List auto-save. Finally, a comorbidity index was applied to both administrative claims and to problem list ICD9 codes. While similarity was low overall, it increased between claims and problem list codes with the introduction of auto-save.

This study extends the work of others by demonstrating the impact of problem list interventions that are integrated mid-stream with existing provider workflows and without development of or validation of methods in natural language processing or machine learning. Collecting problem list entries through admit orders and through billing workflows also permitted other members of the care team to contribute to the problem list itself. While physicians contributed the vast majority of problems, the potential remains for a multi-disciplinary problem list incorporating biopsychosocial determinants of health. The effect on V codes of this intervention is one small step in this direction.

Limitations of this study include the length of time that auto-save was active compared to the overall study period. Generalizability is limited by differences in clinical and billing workflows across different sites. Deyo/Charlson comorbidity indices were not validated on problem list data, so the results of similarity measurements should be considered in this light. The effect of concomitant educational interventions within departments or specific units were not recorded and may confound these results; the relatively short length of time comparing the periods before and after auto-save have the secondary benefit of minimizing such effects. Frequency of problem entry via Health Issues, outside of the iCharge and admitting order workflows, could not be measured precisely in this study although the overall contribution was felt to be small. It is also worth noting that the ability to enter problems via Health Issues was not modified during the study time period so any baseline rate of use for some providers would be reflected in the data for the pre- and post-intervention periods.

Future research should compare the integration of problem list data along with and in place of administrative claims data. Predictive models built on problem list data, for example, would need to be validated separately and not simply used in place of claims data. The underlying workflows behind administrative claims and problems lists are not the same. The effect of Problem List auto-save should be evaluated to determine if it is sustained over time. Also, the impact of problem list evolution over the course of an admission and over the course of a patient's longitudinal care can be examined in subsequent work. Finally, as problem list capture improves, issues seen in administrative claims could also arise. "Problem creep" or "problem clutter" may be unintended consequences of these efforts.

Conclusion

A workflow-sensitive, two-fold intervention to increase capture of the patient problem list resulted in a statistically significant increase in recorded problems. These problems were recorded even before patients have left the emergency room to arrive on the hospital ward. Decision support integrating coded diagnostic data is enabled early in admission for all patients, not only those who have been admitted before. Problems recorded in this way improved in both quantity and content.

A Mobile/Web App for Long Distance Caregivers of Older Adults: Functional Requirements and Design Implications from a User Centered Design Process

Steven S. Williamson, BS[1], Paul N. Gorman, MD[1], Holly B. Jimison, PhD[2]
[1]Oregon Health & Science University, Portland, OR; [2]Northeastern University, Boston, MA

Abstract

Recent trends of population aging and globalization have required an increasing number of individuals to act as long distance caregivers (LDCs) to aging family members. Information technology solutions may ease the burden placed on LDCs by providing remote monitoring, easier access to information and enhanced communication. While some technology tools have been introduced, the information and technology needs of LDCs in particular are not well understood. Consequently, a needs assessment was performed by using video conferencing software to conduct semi-structured interviews with 10 LDCs. Interviews were enriched through the use of stimulus materials that included the demonstration of a prototype LDC health management web/mobile app. Responses were recorded, transcribed and then analyzed. Subjects indicated that information regarding medication regimens and adherence, calendaring, and cognitive health were most needed. Participants also described needs for video calling, activity data regarding sleep and physical exercise, asynchronous communication, photo sharing, journaling, access to online health resources, real-time monitoring, an overall summary of health, and feedback/suggestions to help them improve as caregivers. In addition, all respondents estimated their usage of a LDC health management website would be at least once per week, with half indicating a desire to access the website from a smartphone. These findings are being used to inform the design of a LDC health management website to promote the meaningful involvement of distant family members in the care of older adults.

Introduction

2011 marked a critical milestone for Americans; the first set of baby boomers reached the age of retirement. For the first time in the United States' history, the number of adults age 65 and older exceeded the number of children under the age of 5. By 2014, the percentage of the population age 65 and older will reach an all-time high of 14%; double the proportion that was seen in the 1940's [1]. As this process of population aging unfolds, the problems associated with caring for unprecedented numbers of older adults become increasingly apparent. Unparalleled demand will be placed not only upon the US healthcare system, but also, upon the millions of family members, friends, and neighbors that provide unpaid care to elderly loved ones. These individuals, often referred to as informal caregivers[2], form "the backbone for much of the care that is received by older adults in the United States"[3]. In an increasingly global society, geographic separation presents a significant challenge to many as they strive to provide care from afar. Challenges such as inadequate methods of communication, living in different time zones, and lack of familiarity with a loved one's surroundings may all combine to prevent a long distance loved one from providing care[4]. Such separation often increases the burdens of time, cost, and emotional strain upon the caregiver[5]. In the last few years, it has been suggested [6,7]that internet technologies have matured insomuch that they may prove to be viable options for providing support to long distance caregivers (LDCs). Such an approach however, remains understudied.

Some early research has focused on identifying information needs of caregivers for individuals with dementia [8,9], while others have focused on providing appropriate information regarding how to care for other specific illnesses/conditions[10,11]. One promising study, conducted by the National Alliance of Caregiving and United Healthcare [12], investigated caregivers ranking of various health IT tools to support them in their care. This study, measured perceived benefits and barriers of 12 technologies for both in-home and out-of-home caregivers. Systems that allowed for personal health record tracking, caregiving coordination and medication support had high levels of perceived benefits and lower levels of perceived barriers. We suggest that these and other caregiving tools may be especially useful in the context of a smart home in which older adults are monitored using unobtrusive sensors to track various health metrics.

Recently, work[13], has been undertaken to provide a better understanding of the prevalence of technology use by out-of-home caregivers in the United States. Current estimates indicate that about one third of out-of-home caregivers use health IT in their caregiving activities. An interesting contrast is found however, in that even among "technology nonusers", over 70% of LDCs expressed an interest in using technology in their caregiving

responsibilities. The incongruence between interest to use health IT tools and actual usage may be explained by barriers such as perceived cost, potential resistance by the care recipient[12], and a lack of user-centered focus in the design and implementation of current LDC systems[13].

In the interest of promoting higher levels of usage and utility, we resolved to use a user-centered-design approach to assess information needs and discern important usability principles in the design and development of health IT tools for LDCs. The research outlined below is innovative, due to the fact that no studies have specifically looked at the information needs and technology preferences of LDCs by providing caregivers an opportunity to openly discuss their needs and preferences. Furthermore, our study is unique in that we are investigating information needs in the context of a smart home, containing multiple sensors that provide important data streams about activity, cognition, and physiologic parameters. Investigating LDC needs from this perspective provides us with additional information that will enable us to better understand the emerging needs of caregivers living in an increasingly "electronic" world.

Methods

Due to the exploratory nature of this research, qualitative methods were chosen. Since our subject recruitment pool contained individuals throughout the United States, we chose to conduct semi-structured interviews via Skype as the primary method of data collection. We chose Skype over a traditional telephone as we felt that the face-to-face interaction would help subjects to feel more at ease when talking to an unfamiliar person. The use of Skype also helped us to detect any visual cues that may not have been as apparent via a phone call and allowed us to visually present questions and stimulus materials to subjects as we spoke with them. Skype also served as an ideal platform for data collection due to the fact that all communications are encrypted using robust encryption algorithms.

Prototype Development

In keeping with other qualitative research, [14,15] we elected to develop basic prototypes of a caregiver web (shown in Figures 1 & 2) and mobile app as stimulus materials to facilitate and further enrich our discussions. This approach was chosen due to the limited availability of remote caregiving systems and the anticipated lack of familiarity with the types of data that may be collected in a smart home environment. In an attempt to intelligently develop an initial prototype that delivered an optimal user experience, we drew upon the following four data sources for guidance:

1. Well established usability principles from the human computer interaction literature
2. Scientific articles that specifically described caregiving systems/prototypes
3. Existing commercial systems designed to be used by caregivers
4. Usability experts within our institution

Based upon our review of the literature and existing systems, we begun development of an initial mockup using

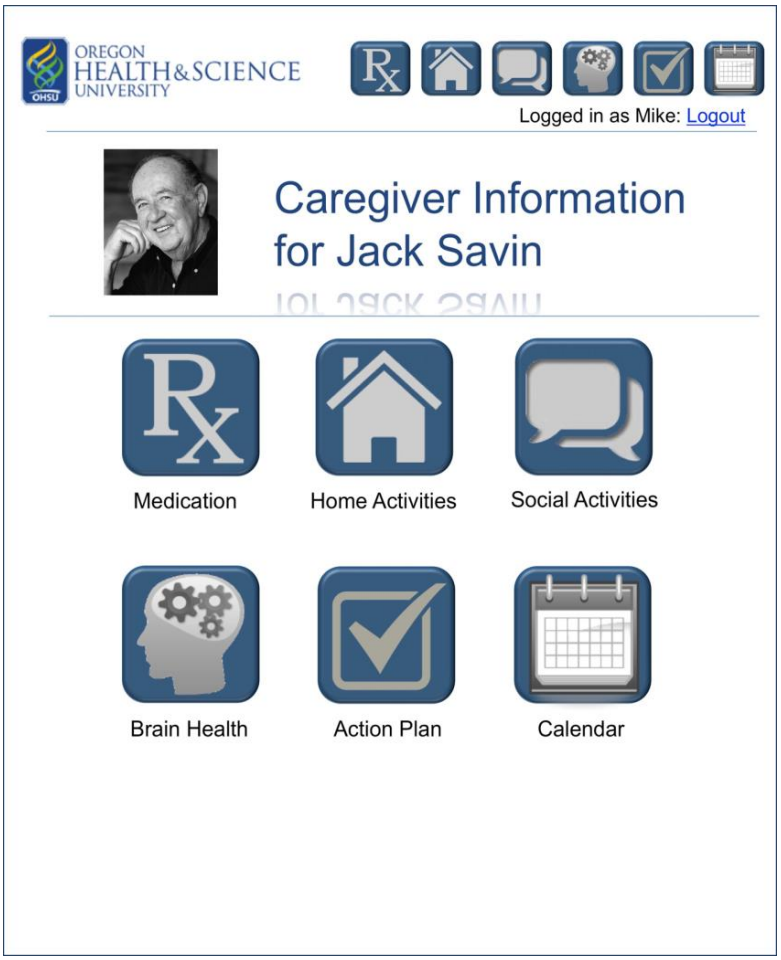

Figure 1: Screen shot showing splash page from prototype caregiver web app

Microsoft PowerPoint. During this process, usability experts within our institution were also consulted. To provide caregivers with a better understanding of system functions, we opted to make parts of the mockup interactive. This was accomplished using transitions and animations within the PowerPoint slideshow and allowed us to demonstrate behaviors and actions when we clicked on various elements within the user interface.

Interview Guide Development

Careful thought and attention was given to development of an interview guide[16]. Our guide was developed with the primary goal of facilitating open conversation with the caregivers in our study. As such, we elected to start by asking very broad, open-ended questions which were then followed up with more focused questions and probes when greater clarification was needed. Great care was taken to ensure that questions would be easily understood and would not lead study participants towards a specific idea or thought, but rather to allow them to express their own thoughts freely. Due to the fact that interviews were conducted via Skype, we also elected to display each question on the participants' screens as they were asked. This allowed each subject to both hear each question audibly as well as see the questions visually. It was our hope that doing so would help to ensure that each question was better understood and would allow respondents to re-read the question as they formulated their response.

After an initial draft of the interview guide was completed, two scholars were asked to review each question for simplicity, readability and neutrality and to suggest changes when necessary. As a final step in development, the interview guide was then used to conduct two mock interviews. This process not only allowed for minor changes to the guide but also helped the research team to practice interviewing techniques before the start of formal data collection.

Study Setting

A network of older adults living in smart homes throughout the Portland, Oregon region has been established as part of our existing cognitive health coaching platform[17]. Older adults that participate in this health coaching platform are continuously monitored using various health tracking sensors. Areas of study include:

- Medication adherence and reminding - measured by a camera embedded pillbox
- Socialization - measured by phone, Skype and email monitors
- Sleep quality - measured using mattress pressure sensors
- Cognitive health - measured by cognitive computer games

Because the socialization module encourages the use of the telephone, email and Skype video calling, each older adult in the socialization intervention had previously chosen a remote partner with whom they would regularly communicate. These individuals in turn agreed to provide remote support to the older adults in our project. All remote partners lived in a location different than the older adult and were generally a close friend or family member. A group of 11 subjects was recruited from within this pool of remote partners as participants in our needs assessment.

Data Collection

Each participant was contacted initially via telephone and then later interviewed for approximately 45 minutes. Due to geographic separation between the subjects and the researchers and as all enrolled LDCs were familiar users of the Skype video conferencing software, interviews were conducted remotely through the use of this system. Initially, a short introduction was given in which the purpose of the study and each subject's role was clearly explained. An emphasis was placed on the fact that subjects could ask questions or make suggestions at any time. Next, subjects were asked to introduce themselves and to describe some of the challenges that they had encountered as they strived to provide care from a distance. Respondents were then asked which types of information are most important to them as caregivers. Next, subjects were asked to identify ways in which technology might serve to ease some of the burdens encountered by LDCs.

After respondents answered these questions, stimulus materials including sample screen-shots for web and smartphone based health management were displayed using Skype's screen sharing feature. These materials enriched discussion and provided subjects with a real world example of ways in which technology could help them to provide care. In particular, subjects were shown a prototype website in which sensor data regarding medication adherence, socialization, calendaring, sleep quality, and cognitive health was presented using easily understood language and graphics. Tips and suggestions for how to help the older adult were also displayed. After presenting the prototype, discussion was facilitated by the presentation of thoughtful questions designed to promote feedback about key areas of interest (*e.g.* estimates regarding level of usage, importance of mobile devices, design recommendations). Finally, each subject was asked for any additional comments or suggestions regarding site design and types of information available. Each interview was recorded, transcribed, and subsequently analyzed by grouping similar thoughts and concepts into appropriate themes and ideas. The findings of our needs assessment will then be used to inform the development of version 2.0 of our prototype. This new and improved prototype will then be used in a usability study investigating the way that real world users interact with the proposed application.

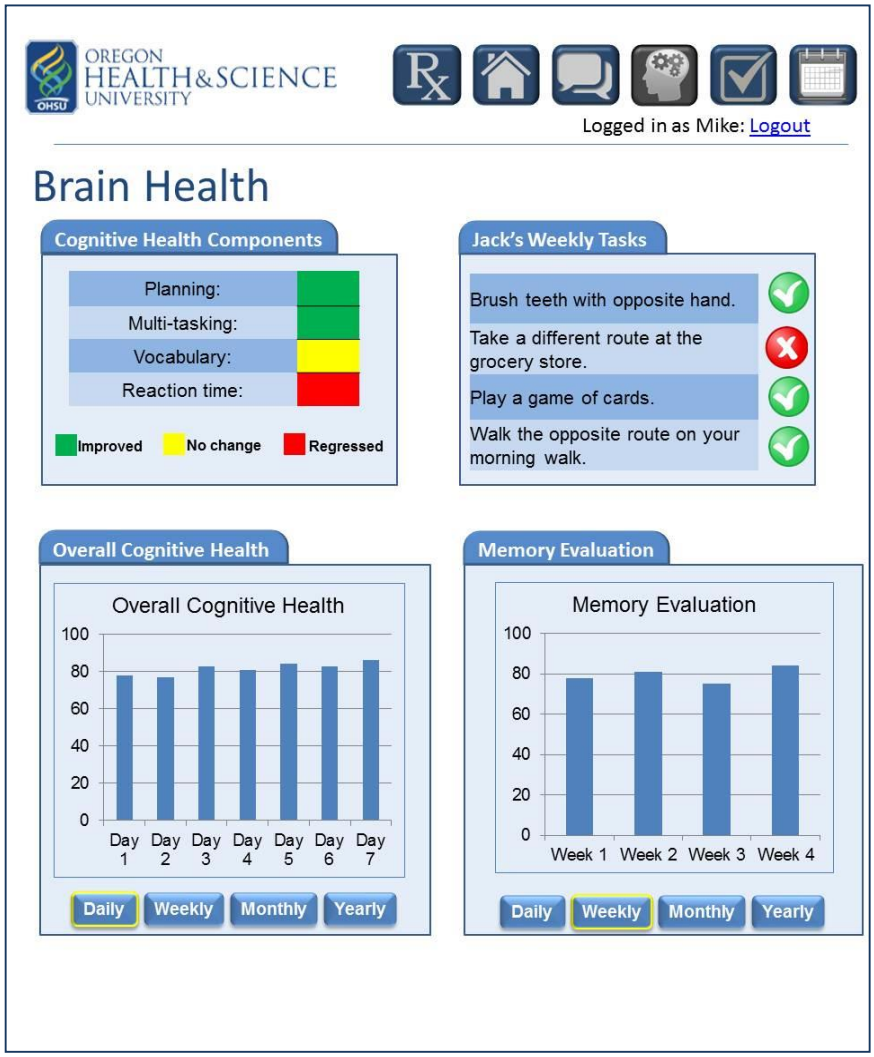

Figure 2: Screen shot showing the brain health page from prototype caregiver web app

Results

Of the 11 subjects that were initially recruited, 10 individuals were successfully contacted and interviewed, with one participant unable to proceed due to lack of a sufficiently reliable internet connection. Of these 10 individuals, 6 were female and 4 were male.

Desired Functionality

Subjects in our study reported that LDCs desire 14 different basic functions: video calling, calendaring, medication tracking, cognitive health tracking, sleep tracking, physical exercise tracking, access to medical records, asynchronous communication, photo sharing, journaling, online health resources, real-time monitoring, an overall summary of wellness, and guidance/feedback regarding the care they provide. These 14 functions are described in Table 1.

Table 1: Fourteen Basic Functions for Long Distance Caregiving	
Video Calling	Nearly all of the individuals interviewed spoke about the benefits of using videoconferencing software such as Skype to communicate with the older adult under their care. Four individuals spoke of the value of nonverbal communication that is not available over a regular telephone call. The participants' thoughts regarding this matter are well summarized by the comment "Now, instead of hearing how she's doing, I can see how she's doing. It's one thing to tell someone how you're doing but it's a little harder to look at someone and tell them that you're feeling good when you're not." In addition, one interviewee talked about the benefits of being able to show objects over video rather than simply describing them. Some frustration was expressed that this was only a valuable form of communication when there were not technological barriers such as unreliable internet connections, audio dropouts or pixelated video.
Calendaring	Six individuals indicated that a shared calendar would be useful to them in their caregiving responsibilities. Respondents were especially interested in being able to view upcoming doctors' appointments and any planned trips or outings. One person commented that "to [her] the calendar would not be at all useful because digital calendars are cumbersome". Another commented that "it might take a bit of switching going from a paper calendar to an electronic one but I think I can convince my mom to switch". The comment was also made that it would be useful for older adults to see a very high level version of the caregiver's calendar so that the older adults could be reminded of times that the LDC would not be available and the care recipient would know to contact somebody else if a concern arose. The idea that the calendar could be used to coordinate care by multiple LDCs was also mentioned. This would allow multiple individuals to share the responsibilities of caregiving rather than a single individual being expected to carry the burden for the majority of care.
Medication Tracking	Four individuals indicated that information regarding medication adherence was very important to them. In addition, the importance of knowing the older adult's medication list and regimen was also mentioned. Respondents made comments such as "medications are a big concern" and "if you're not taking your medication, everything else would fall apart". One individual, however, said that medication information was the least important of all the types of information presented. He commented that this was due to the fact that using images obtained from a camera embedded inside a pill box did not really indicate if the medication had actually been taken. In his words "they could take it out of the box but then not really take it".
Cognitive Health Tracking	Four interviewees suggested that data regarding cognitive health was very important to them. Two of these individuals indicated that this information would be especially interesting to them if it could be presented over a long period of time allowing the caregiver to track any problems. In the words of one subject, "as he gets older, I especially worry about his brain and memory".
Sleep Tracking	Three respondents spoke of the importance of knowing if and when an older adult was experiencing difficulty sleeping. Each of them expressed concern that inadequate sleep can then lead a large number to other problems/concerns. One interviewee described the utility of a system that would automatically alert her after her loved one had experienced multiple consecutive nights of poor sleep so that she could call and check on the older adult and then intervene if necessary.
Physical Exercise Tracking	The importance of knowing whether or not an older adult is regularly exercising was also mentioned. Caregivers wanted to know that the older adult in their care was able to regularly exercise. Along with this information need one caregiver also mentioned the importance of knowing certain metrics of physical ability such as strength and balance.
Medical Records Access	Two LDCs asked about the possibility of being able to access the older adult's medical information and test results. They expressed a desire to be more informed and involved in the older adult's medical care because "sometimes if we don't go with him/her, then his/her story doesn't make sense".
Asynchronous Communication	Many of the LDC's interviewed spoke about the need and value that comes from asynchronous communication. Whether this communication was via e-mail, text message, instant message *etc.* seemed to be less important than the ability to communicate asynchronously. This was important to

Asynchronous Communication (continued)	them because it allowed them to communicate with the older adults without having to worry about the time of day (*e.g.* too early, too late, while the older adult was busy). One respondent also said that this form of communication allowed the care recipient to communicate with him without worrying about disrupting him at work.
Photo Sharing	The ability to share photographs was mentioned in a few different interviews as an important form of communication. Two LDCs spoke about the value of being able to send pictures back and forth. These individuals mentioned that seeing pictures helped to bridge the gap between caregiver and care recipient and made them feel more involved in each other's lives.
Journaling	Two caregivers spoke about some sort of electronic caregiving journal that would allow for note taking and could be used to keep track of items that may not be included within the caregiving application. One suggested that the journal could be tied to a calendar so that reminders could also be integrated within the journaling feature.
Online Health Resources	Multiple caregivers talked about the importance of being able to access reliable health information electronically. Caregivers described medical websites as an important resource that they could use to research a specific condition or illness and then share the pertinent information with the older adult.
Real-time Monitor	The need for a real-time indication of an older adults status was described throughout our conversations with LDCs. Caregivers were especially interested to know if an older adult had fallen or was in immediate need of help. Conversely, caregivers also wanted to know when the older adult was doing well and no intervention was needed on their part. One caregiver talked about a system that could not only communicate when their help was needed but also "how badly [the care recipient] needed help".
Summary Metric of Overall Wellness	While many caregivers saw the value in providing data regarding individual items (*e.g.* medication, sleep, *etc.*) they also expressed a need for a summary metric that could be an overall indicator of wellness. This would allow caregivers the ability to look at a single graph and see a general trend of wellness over time.
Feedback /Guidance	Over half of the respondents talked about the importance of providing guidance and feedback. Not only is it important to provide monitoring data to caregivers, but it is essential to also provide suggestions of what they as the caregiver can do to provide better care and encourage healthy behaviors by the older adult. One caregiver also spoke about the importance of providing encouragement to caregivers when they logged into the system and tried to play a more active role.
Other Suggestions	Some respondents also suggested other types of information that would be useful to them as long distance caregivers. One caregiver suggested the inclusion of "information about hobbies and interests". He went on to suggest a page in which the older adult could share pictures and information regarding hobbies with the caregiver. Another caregiver was interested in the possibility of including information regarding diet through the use of a "smart refrigerator to track if she needs milk and that sort of thing". One final suggestion was the ability to send an alert to the older adult. He commented that "Dad hasn't been drinking enough water lately. It would be really nice if there was some way to remind him with a beep or something."

Design Implications

In addition to describing desired functions of an LDC web/mobile app, study participants also shared insights that have important design implications for those seeking to develop such a system. These design implications concern usage patterns, device preferences, data sharing preferences, and the presentation of longitudinal tracking data, described further in Table 2.

Table 2. Design Implications for a Mobile/Web App for Long Distance Caregivers.	
Usage Patterns	Every individual interviewed expressed optimism about their usage of the proposed system and felt that they would use it on a fairly regular basis. All participants indicated that they would likely use the system at least once per week with three participants indicating that they thought they would use the system "a couple times per week" and two respondents suggesting that they would use the system on a daily basis. Two individuals indicated that they would be much more willing to use the system regularly if "the system had the ability to alert me when there was something that needed my immediate attention". Some LDCs estimated that their usage would be heavily tied to the health of the older adult under their care. They suggest that when the older adult was healthy they would be less likely to have any concerns and would not use the system as regularly. In contrast, they felt they would use the system much more frequently when the older adult's help was concerning to them. While not as valuable as actual usage data, these expected usage patterns provide valuable information regarding the overall flow and design of a caregiver website. Such high frequency of usage would suggest the need to design a dashboard that would allow the caregiver to quickly check an older adults condition without the need to click on each individual category. Also, as noted by two of our participants, an intelligent alerting system that drew the caregiver's attention to potentially worrisome data would be ideal. If alerts are to be used however, the authors urge that a great deal of care be taken so as to not inundate caregivers with false alarms as this is likely to lead to alert fatigue.
Device Preferences	Of our sample, half of the respondents indicated that they would be likely to access the LDC website from a smartphone. This closely mirrors smartphone adoption data for the US population during the time that the interviews were performed. As such, we expect an increasing proportion of caregivers to request smartphone compatibility for a caregiver website. Of those that desired smartphone compatibility, many talked of the convenience and importance of having access to the system while traveling either to/from work or while on vacation. These participants described use cases in which a smartphone would be used while on the go but a traditional PC would still be the preferred choice if available (i.e. when at home). Such usage in which both a smartphone and a traditional PC are used interchangeably requires a consistent look and feel, as well as similar functionalities and feature sets regardless of which device is used to access the site. In addition, due to respondents reporting high levels of expected usage, a mobile app is recommended in lieu of a smartphone compatible website. Such an approach allows caregivers to view historical data even when no data connection is available and allows for more sophisticated alerts to be displayed when necessary. Identified barriers to using a smartphone to access the LDC website were a small screen and relatively high costs of ownership and usage. However, we expect these concerns to fade somewhat as smartphone manufacturers/providers continue to shift towards larger screen sizes and lower cost devices/services.
Data Sharing Preferences	A few caregivers expressed concern that due to the sensitive nature of health data, their older adult may not be willing to share all of the different types of information with them. Though this was not confirmed by discussing data sharing preferences with older adults in our study, we suggest that any such system provides a way in which older adults are able to control the visibility of the data collected. It was also suggested that older adults may be more willing to share monitoring data if the system is implemented before they are facing serious health challenges. In the words of one subject "It might be better to start them when they don't need it because if you start too late then they may not want to do it. I guess it's one of those things that if they sense that they aren't doing well then they will resist that." As such, we recommend the early implementation of health monitoring systems as a possible way to mitigate this challenge. Such an approach also has the added benefit of collecting longitudinal data while an individual is still healthy so that there is a greater likelihood of early detection when problems arise.
Longitudinal Tracking	Caregivers reacted favorably to the idea that longitudinal data could be presented in a meaningful way. They recognized the value of being able to look at data over different periods of time to identify potential areas of concern. As one subject put it "looking by week or month that data is very useful. What I keep trying to get in my head is the progression …seems like this is a great tool to know their decline". While we agree that there is likely value in providing longitudinal data to caregivers, we also expressed concern about the possibility of either misinterpretation or over interpretation of these data. Contributing to this is the fact that many data streams from current smart home environments are fairly noisy. These concerns may be mitigated somewhat through the use of data smoothing algorithms and clear indications to the caregiver when specific scores are vastly different from an individual's baseline.
Caregiving Terminology	Very few individuals that we interviewed identified themselves as either a long distance caregiver or a caregiver in general. Many individuals expressed that they thought of a caregiver playing a more hands-on role that was not possible from a distance and instead viewed themselves as a helper, friend or family member. While we feel that it would be healthy to help redefine the lay definition of what constitutes a caregiver, we also recognize a need to properly frame any communication with LDCs in language that they understand and can relate to.

Overall Impressions

The overall reaction from caregivers was very positive with many making comments such as "I think this is a great idea" and "This is going to be really helpful for people like me". Though individuals suggested the improvements detailed above, none of the participants thought that building a web site/app for LDCs was a generally bad idea. In addition to the expected benefits of being able to ease the burden of providing care and improve involvement of LDCs, a few other benefits were suggested. One caregiver remarked that the system would "help [her] not feel so guilty for living so far away". It was also suggested that such a system would help older adults because "having us involved helps her to feel loved and valued". Even when an older adult already lives near family members, one individual suggested that "I can help my mom and uncle by alleviating some of their stress. If there's something going on I can let them know and have them go visit her". At the conclusion of one of the interviews, one caregiver became emotional as he spoke of the privilege of being able to care for his aging parents as they "experience this amazing process of the end of life" and suggested that a LDC website would allow him to do that more effectively.

Discussion

After conducting qualitative semi-structured interviews with 10 subjects, we identified 14 different functions that LDCs desire (video calling, calendaring, medication tracking, cognitive health tracking, sleep tracking, physical exercise tracking, access to medical records, asynchronous communication, photo sharing, journaling, online health resources, real-time monitoring, an overall summary of wellness, and guidance/feedback regarding the care they provide). We also identified 4 important design implications concerning LDC usage patterns, device preferences, data sharing preferences, and the presentation of longitudinal tracking data. Overall, we found that participants reacted very positively to the proposed system.

These results are concordant with previous studies that have investigated the role of technological solutions for caregivers. Our findings are similar to those of The National Alliance for Caregiving (NAC)[12] who also identified health record tracking, medication support tools, caregiving coordination tools, interactive systems for physical, mental and leisure activities, a symptom monitor and transmitter, a video phone system and a caregiving decision support tool as some of the most important tools for caregivers. Though described by our respondents using different terminology, many of the desired features identified in our study are functionally very similar. One feature listed in the NAC that was not reported by our study is the need for caregiver training simulations. While it is possible that this feature is also desired by LDCs, we note that the NAC study involved both long distance and in-home caregivers and this feature in particular may be more important to individuals serving as traditional “hands-on” caregivers. We also identified some desired features that have not been suggested previously and identified design implications that we believe are important for those looking to develop successful LDC systems.

During the planning of this study, there was some concern that presenting the prototype to interview participants may bias our findings. We expected that we might lead interviewees to talk about the information needs that we anticipated them to have rather than actual information needs. We were surprised to find that while some participants did not speak of some types of information until prompted, at least one participant spoke of each type of information need before the prototype was presented to them. This leads us to believe that our approach was indeed appropriate and the prototype served as a probe to elicit deeper understanding rather than serving to bias our respondents. This is reaffirmed by the high level of agreement between our study and previous work.

The overwhelmingly positive reaction towards our prototype system also follows trends found by other researchers[13]. Our results however, indicate an even higher level of acceptance with 100% of subjects expressing enthusiasm for an LDC system. While somewhat explained by the limitations listed below, we also suggest that such high levels of enthusiasm are the result of high levels of caregiver burden, with many caregivers desperately looking for assistance as they struggle to provide for loved ones.

Limitations

While we feel that the findings of this study are indeed useful, our choice of methodology and sample population created some important limitations that should be considered. These include:

1) Small Sample/Lack of Diversity - Though not as important due to our use of qualitative methods, our sample size was still very small (N = 10) and had limited inclusion of ethnic minorities. Also, the LDCs in our study only provided care to older adults that had displayed little to no cognitive impairment

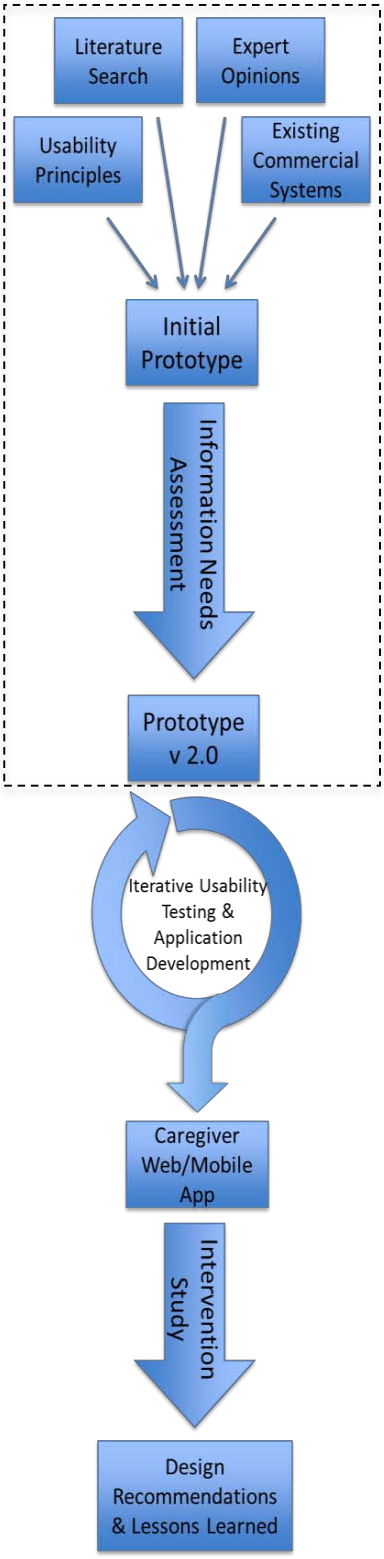

Figure 3: Long term research plan for development and evaluation LDC web/mobile app (dashed box designates work described in this paper)

2) Pro-technology - Study participants were drawn from a pool of technology using seniors and LDCs and are likely more receptive to new technologies than the general population.

3) Hesitant to criticize - Study participants may have been unwilling to provide a critical analysis of our prototype for fear of offending members of the research team.

4) Unable to Discern Needs - It is unclear if subjects are entirely aware of their own needs. As with many needs assessments, there is concern that individuals are unable to identify specific needs, choosing instead to be content with their currently available toolset. This may be especially true when discussing a new technology that subjects have not had the opportunity to use in the real world. During our interviews, this was evident when individuals responded that they were not sure whether or not they would need a particular type of information.

As such, we stress the importance of conducting future research to address these limitations by investigating what other information needs are required by other caregiving populations and by trying to answer our research questions with complementary methodologies.

Despite these limitations, many valuable themes emerged that we hope will prove useful as we strive to provide LDCs with new information technology tools. It was very encouraging to find that all 10 individuals interviewed suggested that building a LDC web/mobile app would be accepted positively. Equally encouraging were indications that the proposed application may be used on a regular basis. However, perceived usefulness and usage may not be accurate indicators of actual system usage and utility.

While this study has identified information types that are likely to be useful and valuable to individuals providing care from afar, the best methods for presenting these data to caregivers warrants further exploration. In addition, while the ability to access an older adult's medical information and test results has been suggested as a useful feature, limitations regarding privacy of medical data may prove to be substantial hurdles.

Future Research

The work described here is the initial step in a larger effort to better understand the role that heath IT can play in assisting caregivers. Our future research will use these findings to improve our existing prototype. As shown in Figure 3, these improvements, along with making the prototype fully interactive will allow us to enter an iterative usability testing and development phase during which users will be asked to use our prototype to perform various tasks. This iterative cycle of development will then allow us to create a final caregiver web/mobile app that is both useful and user-friendly. This out will then be evaluated by means of an intervention study. Both quantitative and qualitative methods will be used to determine the impact that our caregiver application makes in the real world. These data will then be synthesized into design recommendations and lessons learned for future researchers interested in the field of technology enhanced caregiving.

Conclusion

The information needs of long distance caregivers are extensive and may vary somewhat depending upon the health problems of the care recipient. LDCs described needs for video calling, calendaring, data regarding medication, sleep, physical exercise and cognitive health, asynchronous communication, photo sharing, journaling, access to online health resources, real-time monitoring, an overall summary of health, and feedback/suggestions to help them improve as caregivers. We feel confident that we have obtained sufficient preliminary data to justify the continued development of a long distance caregiver application with the final goal of conducting a field trial of such a system in the real world.

Does Sustained Participation in an Online Health Community Affect Sentiment?

Shaodian Zhang[1], Erin Bantum, PhD[2], Jason Owen, PhD, MPH[3], Noémie Elhadad, PhD[1]

Abstract

A large number of patients rely on online health communities to exchange information and psychosocial support with their peers. Examining participation in a community and its impact on members' behaviors and attitudes is one of the key open research questions in the field of study of online health communities. In this paper, we focus on a large public breast cancer community and conduct sentiment analysis on all its posts. We investigate the impact of different factors on post sentiment, such as time since joining the community, posting activity, age of members, and cancer stage of members. We find that there is a significant increase in sentiment of posts through time, with different patterns of sentiment trends for initial posts in threads and reply posts. Factors each play a role; for instance stage-IV members form a particular sub-community with patterns of sentiment and usage distinct from others members.

Introduction

Online health communities, such as forums, blogs, and health-related Facebook or Yahoo groups, have become popular places for patients to exchange information with and seek psychosocial support from their peers[1–3]. Content analysis of online health communities has shown that there are primarily two types of support members provide to each other: informational and emotional support[4–7]. For patients with chronic or life-threatening diseases, there is evidence that psychological distress and anxiety related to medical decision making process as well as daily coping with the disease can be alleviated through the emotional support obtained in a community[8]. Like for other conditions, patients with breast cancer as well as caregivers of patients, rely on cancer-specific online health communities for both informational and emotional support[4,9–11]. Observational studies of breast cancer communities based on analysis of questionnaires and surveys of their members have indicated a positive association between a member's community participation and emotions such as empathy and satisfaction[10,12–15]. Meanwhile, content analysis of online patient-authored text has provided new perspectives on the health impact of online social networking[16,17], but such analysis usually requires manual annotations which can be costly when the contents are in large scale. As such, automated solutions that can be leveraged to study outcomes of online participations are needed.

More recently, automatic sentiment classification methods have been exploited to investigate sentiments of forum posts published by patients. For instance, studies found that thread originators change their sentiment in a positive direction through reviewing others' replies and self-replying[18], and such changes are largely resulting from postings of influential users[19]. The studies also find that within threads, sentiment changes are correlated with several factors such as number of self-replies, number of replies by others, and length of replies. In the general natural language processing community, sentiment analysis has been carried out on various genres of texts such as product reviews[20], news and blogs[21], and tweets[22].

In this study, we focus on a large online breast cancer community and seek to understand the effect of changes in post sentiment overall through sustained participation in a community. We leverage automated sentiment analysis to conduct large-scale analysis over all the posts in the community. But instead of examining sentiment changes within threads, we examine changes of sentiment from a longitudinal standpoint. We seek to answer the following two research questions: (1) does member participation in the community over different periods of time have an impact on the member posts' sentiment? And (2) do the following factors contribute to changes in posts' sentiment: age of members, cancer stage of members, duration of membership, and amount of posting affect?

Methods

To explore changes in post sentiments in an online health community, we carried out the following steps. First, we collected all the posts in a large, public community. We trained and evaluated an automated sentiment analysis tool, specific to the community at hand. We applied the sentiment analysis to all posts and assessed the changes in

sentiment through various factors of interest both in a static and longitudinal fashion. The study was reviewed and approved by the Columbia University Medical Center IRB.

Dataset

We crawled, collected, and analyzed data from the publicly available discussion board of breastcancer.org, one of the most popular online breast cancer communities. The discussion board is organized in several forums, each with threads and posts. At the time of collection, dataset consisted of 291,528 posts in 31,034 threads, published by 12,819 community members between May 2004 and September 2010[23]. Metadata including user profiles was also extracted, consisting of self-reported demographics, diagnosis histories, and treatment histories.

Automated Sentiment Analysis – Annotation, Training, and Testing

Since this study relies on automated sentiment analysis on all posts, we built our own sentiment analysis classifier, specific to our dataset, to ensure accuracy and robustness on this particular community.

Sentiment Annotation. A random sample of 1,000 posts from the dataset was manually annotated by two annotators according to the sentiment they conveyed overall[24]. To ensure annotators chose a polarity, we restrained the annotation to positive or negative only (no neutral), and provided guidelines and examples to the annotators. Overall, a post was considered positive if its author conveyed typical positive emotions, like joy, happiness, gratitude, as well as curiosity, independently of the topic discussed. Conversely, a post was considered negative if it conveyed negative emotions, such as anger, anxiety, sadness, and hopelessness. Disagreements between the two annotators were adjudicated, resulting in a dataset of 1,000 posts annotated as either positive or negative sentiment.

Sentiment Classification. The annotated 1,000 posts were used to train and test binary sentiment classifiers. We experimented with three established robust classifiers: Maximum Entropy[25], Adaboost[26], and Support Vector Machine (SVM)[27]. Among them, Adaboost outperformed other models in a similar sentiment classification task[18], but over a dataset different from ours and with different features. Each classifier was evaluated through 5-fold cross validation according to accuracy, AUC of the ROC curve, and F measures of positive and negative classes.

Table 1. Features used for sentiment classification.

General linguistic features	
Words: number of words	*Emarks*: number of exclamation marks
PosWords: number of emotionally positive words	*NltkProb*: probability of being positive generated by the online NLTK based sentiment classifier
NegWords: number of emotionally negative words	*NltkProbNtr*: probability of being neutral generated by the online NLTK based sentiment classifier
AvgWdLen: average word length	
Sen: number of sentences	
Qmarks: number of question marks	
Domain-specific features	
Symp: number of domain-specific symptoms mentioned	*Meds*: number of domain-specific medication or treatment methods mentioned
Genre-specific features	
PosEmo: number of positive emoticons	*Person*: number of person names
NegEmo: number of negative emoticons	

We exploited several types of features to build the sentiment classifiers, from general linguistics to domain and genre specific features, as listed in Table 1. Features specific to the genre of online community and social media included emoticon lists for extracting *PosEmo* and *NegEmo* features (from http://en.wikipedia.org/wiki/Emoticon), as well as presence of people's names (personal names were tagged automatically using the Stanford Named Entity Recognizer [28] over the dataset as part of the pre-processing). General linguistic features included number of words in the post, and dictionary matching based features like number of emotionally positive/negative word stems. *PosWords* and *NegWords* were extracted by looking up two adjective lists: *glad, happy, relieved, grateful, excited, thrilled, thankful, great, lucky, pleased, blessed, fortunate, hopeful, inspiring, encouraging;* and *scared, sad, anxious, embarrassing, disappointing, confused, heartbreaking, frightened, frustrated, angry, upset, distress, stress, discouraging,* as well as their morphological variants (e.g. frustrated -> frustrating). Finally, to include other general linguistic features, we leveraged the output of a robust sentiment classifier which uses the NLTK package[29] and returns the probability of a post to be negative or otherwise, its probability of being positive.

For domain-specific features, we focused on mentions of medical terms in the posts, like treatments and side effects[30]. As such, recognizing these domain-dependent medical terms, which form a sublanguage of breast cancer communities, is a critical step in our analysis[31]. For example, in our dataset, since Tamoxifen is a widely used

medication for breast cancer patients, there are a large amount of abbreviations and misspellings such as "tamox", "tamo", and "tamoxifan" referring to this medicine. In order to capture these variations without relying on dataset-specific knowledge, we used an unsupervised, domain independent, distributional semantics based method[32] to generate two lexicons for symptoms and medications, respectively (features *Symp* and *Meds*).

Impact of Different Factors on Post Sentiment

The automated sentiment analysis output for each post a predicted probability of being positive, or sentiment score. The sentiment scores are useful, because they allow us to compare posts against each other. As such, the scores are not absolute representation of sentiment, but rather enable us to rank posts according to their sentiment polarity.

Armed with such sentiment score for each post in the dataset, we conducted the following analyses. The primary objective for our study was to assess if participation in the community has an impact on sentiment. We thus compared average sentiment scores of posts published in different periods of time with respect to user's registration date, and tracked changes of sentiment. As such, each data point is the average sentiment of all posts in a given time slice (e.g., all posts published by their authors after 3 weeks of their joining the community). To visualize the changes in sentiment through time, we plotted in addition to the individual data points a fitted curve.

For our second research question, we considered three factors (age of members, cancer stage of members, and amount of posting) in both static and longitudinal analyses to examine their impact on post sentiment. In the static analysis, members were stratified by age/stage/amount of posting, and average post sentiments were calculated for each group. Statistical tests (ANOVA and TukeyHSD[33]) were carried out to detect differences across groups. In the longitudinal analysis, sentiment scores were compared across stratified groups and duration of participation in the community to identify the patterns of sentiment change across members from different groups through time. All p-value were adjusted for multiple comparisons with the Bonferroni correction.

For both research questions, we distinguished in our analyses the initial posts (i.e., first posts that initiate threads) and all other posts. Previous research[19] found that community members expressed significantly different polarities of emotions in the initial post of a thread compared with other posts. This could be explained by the fact that the post originators were more likely to express concerns and seek support, while responses to such posts tended to be more positive by conveying encouragement and empathy.

Results

Data Annotation and Sentiment Classification

The manual sentiment annotation of the 1,000 yielded good inter-annotator agreement (Cohen's Kappa of 0.798)[34]. After adjudication and resolving disagreements, 728 out of 1,000 posts were annotated as positive, and 272 were annotated as negative. Examples of two positive and two negative posts are given in Table 2.

Table 2. Example posts of positive and negative sentiments.

Positive posts	*Negative posts*
The recovery from my lumpectomy was easy. Really. Nowhere near as difficult as I imagined. Very little pain at all. I never needed any pain meds after surgery. Good luck.	I had a mastectomy about three weeks ago and will be starting chemo at the end of the month (Dec. 27th). I wake up every morning anxious and scared. When does this go away?
I'm so happy you're feeling better!! Strange, but hey, that's our life these days. !	Just had a 6month followup with my onc. My second round of scans came out clean. However in 3 months I will be doing bloodwork for tumor markers. She didn't discuss it with me and I don't know what it is about. I understand my cancer is aggressive, but what am I not understanding here? :(

The classification performances of the three classifiers are given in Table 3. To demonstrate the effectiveness of machine learning models, performance of a baseline system is also given, which simply classified all posts as positive. The best performing system was Maximum Entropy (MaxEnt), followed by SVM and AdaBoost. Both MaxEnt and AdaBoost tended to classify posts as positive, caused by the uneven distribution of positive and negative samples in the training set. For MaxEnt, once the threshold of prediction was calibrated towards favoring negative (i.e., a post is classified as negative once the predicted probability was lower than 0.6 rather than 0.5), the F score of negative was dramatically improved. Fortunately, in our application to the entire dataset, we are more concerned with probabilities rather than discrete labels, since our modeling was based on the average likelihood of various groups of posts being positive or negative, rather than number of predicted positive and negative instances. In the remainder of the study, we relied on the MaxEnt classifier to output a sentiment score for each post.

Table 3. Performance of different sentiment classifiers according to Area under Curve of ROC, accuracy, and F scores for positive and negative sentiment polarity respectively. The baseline system classified all posts as positive.

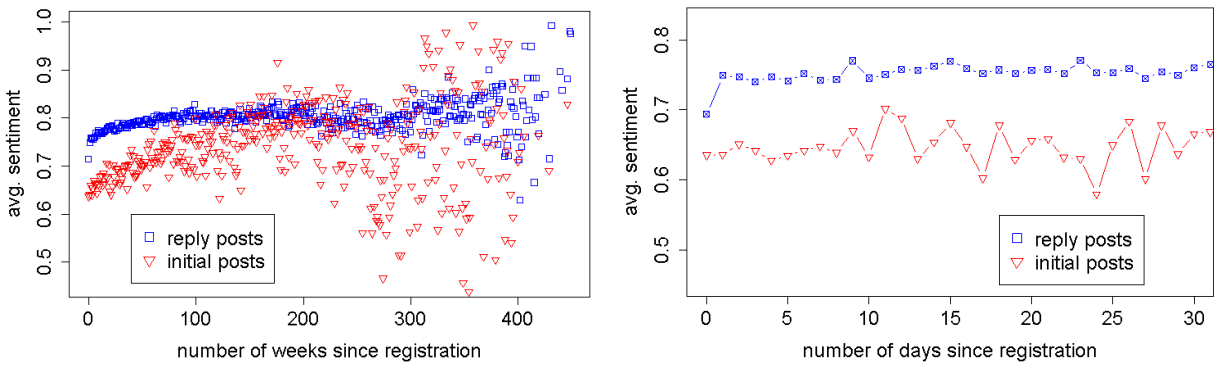
	AUC of ROC (95% CI)	Accuracy (95% CI)	F (positive) (95% CI)	F (negative) (95% CI)
MaxEnt	82.0% (2.7)	79.4% (1.8)	86.8% (1.9)	53.7% (2.8)
AdaBoost	76.0% (3.3)	76.3% (1.5)	84.6% (2.1)	48.5% (3.9)
SVM	78.1% (2.9)	73.4% (2.9)	68.4% (1.9)	58.4% (1.4)
Baseline	49.8% (0.8)	72.9% (0.7)	84.3% (1.0)	0% (0)

We analyzed the impact of individual features on the MaxEnt classifier, which assigns a weight to each feature after training, indicative of its discriminative power for the given task. Among all features, *NltkProb* (weight +2.7) had the strongest correlation with positive emotion, while *NegEmo* (weight -1.9) and *NegWords* (weight -1.2) were most correlated with negative emotion. On the contrary, *Words* (weight 0.003) and *Emarks* (weight 0.03) were borderline features, suggesting similar distributions of these features in positive and negative samples.

Participation and Posts Sentiment – Static and Longitudinal Analyses

The best performing classifier, the MaxEnt, was applied to the entire dataset based on the model trained with the 1,000 annotated samples. For each post in the dataset, a sentiment score (probability of post being positive) was calculated. The average sentiment score of the entire dataset was 0.785 (0.210 standard deviation). For the initial posts, the average sentiment score was 0.695 (0.263 standard deviation). In general, our research aligned with previous work on other online health communities that found initial posts to be less positive.

In order to examine the impact of participation through time in online discussion on sentiment overall, we plotted how sentiment scores changed through time, as computed since members' registration date. The registration dates of users were provided in the profile information of metadata. Figure 1 shows the average sentiment scores of posts that were published after membership creation at both weekly (a) and daily (b) intervals. For example, the left-most blue data point in Figure 1(a) represented the average sentiment score of all reply (i.e., non-initial) posts published by all users respectively within one week of their joining the community.



(a) (b)

Figure 1. Sentiment changes by length of membership at the time of posting, by number of weeks in (a) and number of days in (b). A colored point at (x, y) in the graph represents that the average sentiment score of all posts published by all users in the xth week (a) or day (b) after their registration is y.

Figure 1(a) indicates that, for both responding and initial posts, sentiment gets more and more positive through at least 100 weeks (2 years) of participation, with such changes most significant right after joining the community. Members, in their first days joining the community, publish posts, which are significantly more negative than later on. This is particularly true for initial posts, suggesting that newcomers to the community (likely newly diagnosed patients) express more anxiety and concerns than later in their questions to the community. Figure 1(b) provides a more granular view over the sentiment changes in the first 30 days of participation in the community, confirming that reply posts are significantly more positive than initial posts, and the increase of sentiment of initial posts does not happen until later on, at least 1 month into participation in the community. We do note a drastic increase in sentiment from posts published on the first day of joining the community to the later days, when looking at all posts (replies and initial posts combined).

In our dataset, the average length of membership of all users was 2 years 5 months (around 120 weeks); therefore, most of posts published after 200 weeks were written by a small portion of long-time users. We found that most of them were stage IV patients and showed a slight sentiment decline between 200 and 300 weeks. Topics of these posts were primarily about chemotherapy or metastasis/recurrence. While this set of posts is indeed homogeneous in sentiment and topic, it is difficult to assess the value of the analysis on such a small sample for the posts written by members who have been more than four years active in the community.

In order to obtain a more concrete understanding of how sentiment changed through sustained participation in the community, we grouped posts into nine groups, considering both short-term and long-term periods of participation. The nine groups were posts published within one day of registration, 1-3 days, 3 days to 1 week, 1 to 2 weeks, 2 weeks to 1 month, 1 to 3 months, 3 months to 1 year, 1 to 2 years, and more than 2 years since registration. An ANOVA test was carried out for the groups, for all posts and initial posts respectively, followed by a TukeyHSD test to illustrate the significances of differences between all possible group pairs. ANOVA test showed significant difference among groups in both cases (p values << 0.001). Post distribution, average sentiment scores, and p values compared with previous category given by TukeyHSD test are listed in Table 4. In this table as well as following tables, "all posts" represent initial posts and reply posts. Results showed same pattern as Figure 1, and demonstrated that the dramatic sentiment change after the first day was statistical significant in the case of all posts, while we could only see long term (3 months and then 1 year) significant changes for initial posts.

Table 4. Post distribution, average sentiment scores, and p values compared with previous category returned by TukeyHSD test, for all posts and initial posts respectively. The first p value for <1d is not available since there is no previous category to compare sentiment to. P values are adjusted for multiple comparisons with the Bonferroni correction.

		<1 d	1-3 d	3d – 1w	1-2w	2w-1m	1-3m	3m-1y	1-2 y	>2 y
All posts	Sentiment	.693	.748	.745	.753	.756	.766	.782	.800	.804
	# posts	8,369	4,203	4,361	6,235	9,906	32,302	89,304	60,944	75,781
	p value	N/A	<<0.001	1.000	1.000	1.000	0.025	<<0.001	<<0.001	0.577
Initial posts	initial	.636	.642	.637	.656	.644	.664	.685	.728	.760
	# posts	3,304	732	734	1,064	1,487	3,842	8,085	5,134	6,641
	p value	N/A	1.000	1.000	1.000	1.000	1.000	0.032	<<0.001	<<0.001

Impact of Members' Age on Sentiment

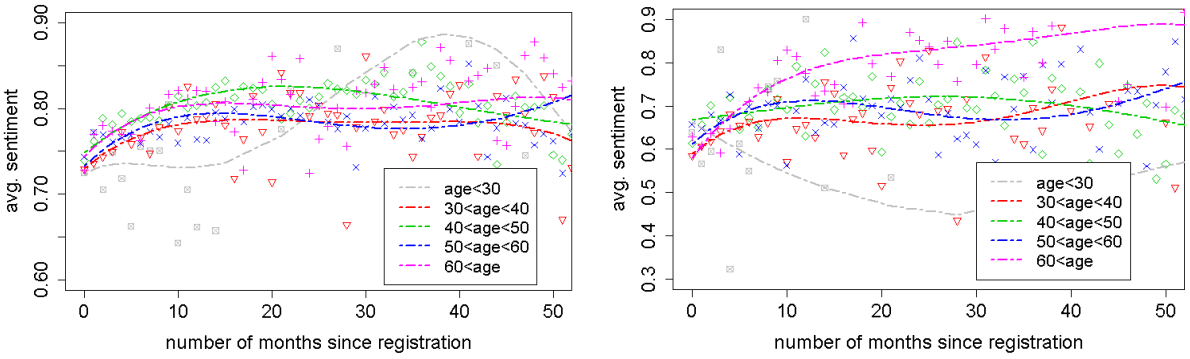
The posts in the dataset were published by 12,819 users, while a total of 14,919 user profiles were filled at least partially in the online breast cancer community and there were about 60,000 members overall. This meant that a very large majority of members were so called lurkers [35,36], who never published anything but were likely to browse some of the posts. Behavior of lurkers was beyond the scope of this study. Rather, we focused on members who had posted content. Among all non-lurkers, 1,211 provided date of birth in their profiles. Members born between 1960 and 1970 were the most dominant at the time of data collection, and the average age of all users were 47.5 (standard deviation 9.6 years), an older mean than in some other online health communities, such as weight loss forums[37].

Table 5. Average sentiment scores and number of posts published by different age groups, for all posts and initial posts respectively. This analysis is restricted to posters who provided date of birth in their profile only, 1,211 members overall.

Age group (# users)		<30 (38)	30-40 (198)	40-50 (485)	50-60 (358)	60+ (132)
All posts	Sentiment	0.742	0.768	0.793	0.778	0.791
	# posts	278	6,417	22,180	14,479	4,217
Initial posts	Sentiment	0.614	0.643	0.681	0.681	0.744
	# posts	54	841	1,873	1,323	339

To study whether age affected sentiment, we considered members who disclosed their date of birth, and grouped them into 5 groups: below 30 years old, between 30 and 40, between 40 and 50, between 50 and 60, and above 60 years old. There were 47,571 posts in the dataset published by members with date of birth information. We calculated averaged post sentiment scores, and carried out statistical tests for the groups. Table 5 shows numbers of posts published by each age group and average sentiment score of posts of each group. The ANOVA test showed significant differences among groups for both all posts and initial posts. For all posts, TukeyHSD test found that difference between all pairs of groups were significant, except between <30 and 30-40, <30 and 50-60, and between 40-50 and 60+. For initial posts, differences between <30 and all other groups were not significant. We suspect that this is caused by the very low number of members in the age group <30, as expected in a community for a disease that affects older women predominantly. Members older than 60 showed markedly more positive sentiment than

younger members, especially while publishing initial posts to start new threads. These facts might be explained by previous psychological finding of effects of older age on lower levels of psychological distress[38–40].



(a) all posts (b) initial posts

Figure 2. Sentiment changes by length of membership at the time of posting for different age groups, for (a) all posts and (b) initial posts. A colored point at (x, y) in the graph represents that the average sentiment score of all posts (a) or initial posts (b) published by users in corresponding age group in the xth month after their registration is y. Polynomial curves fitting each group were drawn for the sake of visualization.

To illustrate age's impact on longitudinal sentiment, sentiment changes over time after registration for different age groups were plotted, along with polynomial curves fitting each set of points to visualize the tendencies (Figure 2). Keeping in mind the very low sample size for members <30 years old, we do not attempt to interpret their longitudinal sentiment changes. For all other groups, however, the general trend observed earlier holds true independently of age: the longer the members participate in the community, the more positive their posts are on average. The observation that older members (>60 years old) post more positive posts, especially initial posts is visible as well on the plots.

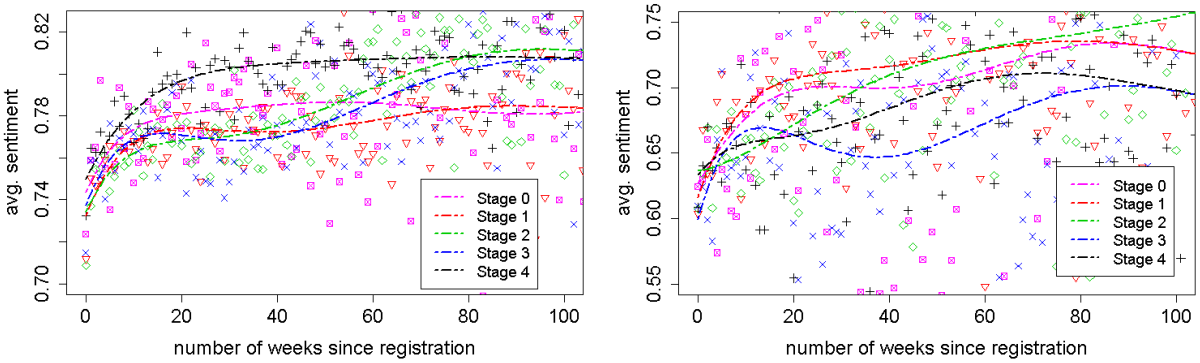
Impact of Member's Cancer Stage on Sentiment

In our dataset, 4,602 users (who published 172,566 posts) had self-reported cancer stage information. Among them, 442 members were stage 0 patients, 1,407 were stage I, 1,544 were stage II, 650 were stage III, and 559 members were stage IV. Table 6 provides numbers and average sentiment scores of posts published by members in different stages. Although there were significantly fewer stage IV patients than stage I and II patients, they published many more posts and formed the most active cancer stage group in breast cancer forum[23]. Moreover, stage IV patients were the most positives posters in term of the emotion expressed through the reply posts they wrote, but not initial posts. For all posts, comparisons between stage 0, stage I, and stage II, returns non-significant results according to adjusted p values.. For initial posts, only the differences between stage I and stage III and between stage II and stage III were significant.

Table 6. Average sentiment scores and number of posts published by patients in different stages, for all posts and initial posts respectively.

Cancer stage (# users)		Stage 0 (442)	Stage I (1,407)	Stage II (1,544)	Stage III (650)	Stage IV (559)
All posts	Sentiment	0.775	0.771	0.776	0.782	0.796
	# posts	9,229	36,422	39,398	27,806	59,711
Initial posts	Sentiment	0.675	0.690	0.687	0.661	0.675
	# posts	820	3,344	4,218	2,534	4,829

Figure 3 illustrates longitudinal sentiment of different cancer stage groups. Not only were the stage IV users the most positive, but they also showed the fastest change towards positive after registering in the breast cancer forum. However, these findings were specific to reply posts. These findings indicate that stage IV users seek support through starting threads with negative posts, but are very active in providing emotional support to their peers, through posting positive replies.



(a) all posts (b) initial posts

Figure 3. Sentiment changes by length of membership at the time of posting for different cancer stage groups, for (a) all posts and (b) initial posts. A colored point at (x, y) in the graph represents that the average sentiment score of all posts (a) or initial posts (b) published by users in corresponding cancer stage in the xth month after their registration is y. Polynomial curves fitting each group were drawn for the sake of visualization.

Impact of Member's Posting Activity on Sentiment

The last factor we considered was the amount of posting by each individual. Table 7 groups members into 5 groups by number of posts, listing the distributions and average sentiment of each group. There were 8247, 3527, 757, 255, and 24 profiles in the 5 groups respectively. Although members who published less than 50 times wrote only 20% of all posts, approximately half of the initial posts were authored by these members. This suggests that new members tend to seek information and support while long-time members provided information and support more than they requested it. All differences of sentiment scores between groups, including both all posts and initial posts, were significant, except between group of < 5 and 5-50 for initial posts.

Table 7. Average sentiment scores, number of posts published by patients, and number of posts published per user in different stages, for all posts and initial posts respectively.

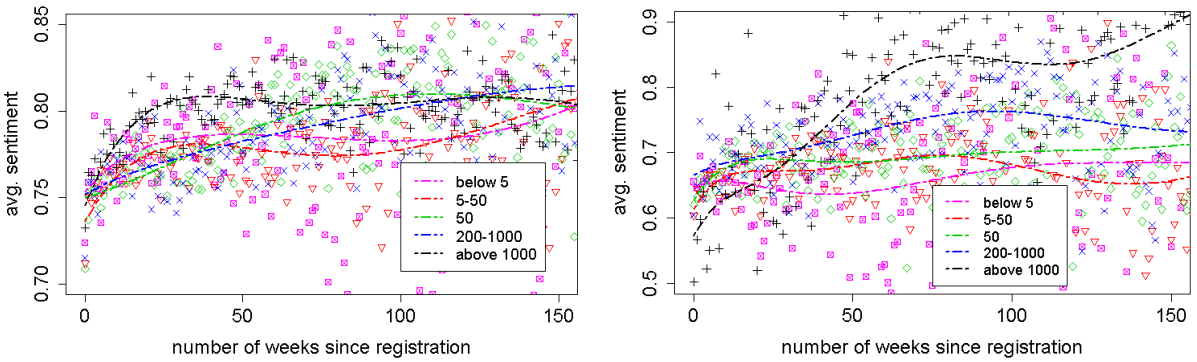
User post number (#users)		< 5 (8,247)	5-50 (3,527)	50-200 (757)	200-1000 (255)	1000+ (24)
All posts	Sentiment	0.727	0.754	0.779	0.806	0.817
	# posts	16,725	36,422	73,951	102,466	39,944
	avg # post	2.0	10.3	97.7	401.8	1664.3
Initial posts	Sentiment	0.657	0.658	0.683	0.730	0.828
	# posts	4,565	9,445	7,399	6,635	2,990
	avg # post	0.6	2.7	9.8	26.0	124.6

Figure 4 illustrates how sentiment changed over time for different groups of members with different posting activity count. In general, active members (i.e., with more posts authored) were likely to gain sentiment improvement faster and more significantly. It is particularly interesting to note that although members posting more than 1,000 times throughout their time in the community, and who were long-time users, had a significantly higher sentiment score in average, their sentiments were as negative as other members when they just joined the forum, especially for their initial posts. The pattern seen in Table 7 and Figure 4 seems to suggest that long-time users, who suffered from cancer but benefited from hearing from their peers online at early stages of participation, changed their roles in the forum later and acted as information and support providers more than requesters. Such role change should be another important outcome of online discussion participation.

Discussion

Principal Findings

Our study results suggest that members benefit from sustained participation in a breast cancer community with respect to the sentiment they convey through their posts. At the early stages of participation, sentiment of users usually increased significantly, and the rate of improvement dropped after several weeks, followed by a slower positive sentiment increase which could last for as long as several years. Our study also showed that compared with



(a) all posts (b) initial posts

Figure 4. Sentiment changes by length of membership at the time of posting for different groups of posting amount, for (a) all posts and (b) initial posts. A colored point at (x, y) in the graph represents that the average sentiment score of all posts (a) or initial posts (b) published by users grouped by their number of posts in the xth month after their registration is y. Polynomial curves fitting each group were drawn for the sake of visualization.

reply posts, initial posts of threads were more emotionally negative, especially at the beginning of participation. Sentiment increases of initial posts were more dramatic but long term. A qualitative analysis over the forum data showed that newcomers of the forum were more likely to be newly diagnosed or post-treatment patients. For most of them, going online was the choice when some of their needs, either informational or emotional, could not be met in other settings such as family and hospitals. As a result, we found a large amount of posts with strong negative sentiments, especially initial posts, published by newcomers asking various questions about cancer symptoms, medication use and side effects, and choices of therapeutic method, which were the issues usually brought up by individuals with little cancer or treatment experiences. In contrast, long-time members were more likely to be cancer survivors or patients who were recovering or being treated as a routine part of their lives. It is likely they were more experienced, empowered, and acted more as informational and emotional support providers rather than requesters, and were expressing more encouragement and empathy in the threads in which they participated. The different patterns of reply posts and initial posts also suggested that people immersed themselves quickly into the discussion by learning to encourage others and provide information through replying, but were still concerned about their own issues.

Our study examined three factors' impacts on sentiment and sentimental changes: age, cancer stage, and amount of posting. We showed that all three factors had an impact on the members' sentiment on average. Statistically significant differences were found for every stratified group. For age, we found that users older than 60 years old showed the most positive sentiment, especially while publishing initial posts. There were no significant differences between longitudinal aspects of different age groups. With respect to cancer stage, although there were significantly fewer stage IV patients than any other stage, they published many more posts and formed the most active cancer stage group in the breast cancer forum. They showed the fastest change towards positive sentiment after registering in the breast cancer forum. They also were the most positive in their replies, while the most negative in their initial posts. The last factor, amount of posting, also made a difference. Members who published less than 50 posts, mostly newcomers and lurkers, were responsible for only 20% of all posts, but around half of the initial posts were authored by these users, which indicated that new users and lurkers tended to seek information and support while long-time members provided information and support more than requested it. Long-time members, who suffered from cancer but benefited from hearing from their peers online at early stages, later changed their roles in the forum later and acted more as information and support providers.

Limitations

Our study was exploratory and has several limitations. First, the analyses rely on the output of an automatic sentiment classifier, which while providing state-of-the-art accuracy is not 100% accurate. Further feature engineering has the potential to improve the classification accuracy. Second, the classification was defined as a two-category problem: positive and negative, and documents with neutral sentiment were simply regarded as ones whose sentiment scores lie near the boundary of the binary classification. Since the sentiment scores are a mean to comparing posts in aggregate, it might be also useful to leverage a more granular classification, or at least one that

considers neutral as a category on its own[41]. Third, profile information, especially cancer stage, was extracted at the time of data collection, and such information might have been edited by members through time, as their disease evolved. Finally, this study was conducted on a single online health community. It will be interesting to see the impact of these factors in different communities specific to breast cancer as well as to or other chronic conditions.

Future Work

This study brings up several research questions we would like to explore in the future. While one interpretation of our findings is that sustained participation in an online health community overall increases the sentiment of members' posts, we must acknowledge that there is a strong uncertainty to this interpretation due to right censoring issues, common to longitudinal observational studies. As the number of members who stay in the community decrease with time since registration, one must think of potential reasons for the right censoring of data: is it that members with adverse health outcomes were too sick to continue participating in the community, or even that individuals who did not receive appropriate support from their peers stopped participation. In other words, it is possible that only the people for which the community is beneficial emotionally are the ones that stay in the community through time, while others simply stop posting. Under this assumption, there is no causal link between participation in the community and positive sentiment on average.

We did not examine the impact of lurking (and of its duration before posting for the first time) on participation and sentiment in particular. Because the community we studied does not keep track of members' reading activity, this is a difficult question to study quantitatively, but an important one to consider in the future.

Another area of research we plan to explore further is that the sentiment of the posts alone is a rough representation of the sentiment or emotions of community members. As we refine our understanding of the different topics conveyed in an online health community, it will be critical to understand the relationship between sentiment and different topics. For instance, a member's anger at an insurance company refusing to reimburse her treatment and a member's anxiety faced with a dire test result represent very different aspects of sentiment with respect to cancer in general. The longitudinal evolution of topics and their associated sentiments for community members is an area in much need for further analysis.

Conclusion

This paper carried out an exploratory study over a popular public online community for breast cancer and used automated sentiment analysis to investigate correlations between sentiment changes of users and different participation-relevant factors. Finding suggests that as participation is sustained, posts' sentiment increases towards positive. Further, members convey more positive posts when replying to their peers than when initiating a thread. In addition, we discovered that users in different ages, cancer stages, and stages of participation showed different sentiment patterns. Most significantly, members over 60 years old and stage IV members were expressing more positive sentiment than any other groups of people, while newcomers to the community tend to post more negative initial posts than long-time members. This study contributes to further the understanding of community participation on members' attitudes and opens up to a number of research questions to explore further.

On Learning and Visualizing Practice-based Clinical Pathways for Chronic Kidney Disease

Yiye Zhang, MS, Rema Padman, PhD, Larry Wasserman, PhD
Carnegie Mellon University, Pittsburgh, PA

Abstract
Chronic Kidney Disease (CKD) is a costly and complex disease affecting 20 million US adults. Recent studies suggest that care delivery changes may improve clinical outcomes and quality of patient experience while reducing costs. This study analyzes the treatment data of 8,553 CKD patients to learn practice-based clinical pathways. Patients' visit history is modeled as sequences of visits containing information on visit type, date, procedures and diagnoses. We use hierarchical clustering based on longest common subsequence (LCS) distance to discover six patient subgroups, with each subgroup differing in the distribution of demographics and health conditions. Transitions of visits with high probabilities are elicited from each patient subgroup to learn common clinical pathways and treatment durations. Insights from this study can potentially result in new evidence to support patient-centered treatment approaches, empower CKD patients to better manage their disease and its complications, and provide a review guide for clinicians.

1. Introduction

Chronic Kidney Disease (CKD) is a costly, complex and high mortality health condition affecting 20 million US adults[1]. Prevalence is estimated to be 8-16% worldwide[2]. Most patients are unaware of their disease, with more than 40% with end-stage renal disease (ESRD) requiring emergency hospitalization and dialysis for acute kidney failure[3]. CKD patients make up only 1.5% of US Medicare population, but incur almost 10% of Medicare costs annually[1]. These adverse outcomes are potentially preventable or can be mitigated through early identification and treatment of individuals at risk as they progress through the five stages of CKD. Typically, the treatment of CKD is focused on preventing the worsening of condition, such as maintaining patients in their current disease stage and delaying the progression from stage 5 to ESRD and dialysis. CKD treatment currently follows opinion-based, consensus guidelines developed by nephrologists. The two widely known guidelines are Kidney Disease Outcomes Quality Initiative (KDOQI) and Kidney Disease: Improving Global Outcomes (KDIGO), which is a collection of global clinical practice guidelines for different complications of kidney disease[4,5]. However, recent studies suggest that care delivery changes may improve clinical outcomes, enhance quality of patient experience, and reduce annual total per capita health spending[1,6]. Hence, there is a need to review the actual clinical events performed on patients and discover practices that may lead to improved outcomes. At the same time, patient education plays a vital role in effective CKD treatment. For example, pre-ESRD education may enhance patient satisfaction, delay dialysis, and increase cost-effectiveness[7]. Engagement and education using personalized clinical pathways and tools that support shared decision-making with their clinicians are likely to be a valuable approach in delaying disease progression. Leveraging the availability of a rich and unique clinical dataset extracted from the Electronic Health Record (EHR) of a community nephrology practice in Western Pennsylvania, we analyze the treatment of 8,533 CKD patients to learn practice-based clinical pathways that have the potential to meet these objectives.

2. Background

CKD is a condition where the kidney gradually loses its function[1]. Patients with high blood pressure and diabetes are especially at risk for CKD, but other health problems such as cardiovascular disease and high cholesterol are also known risk factors[1]. Due to the close monitoring requirements of the disease, a large proportion of Medicare budget every year is utilized in the treatment of CKD patients[1]. In fact, the per person per year average cost of CKD patients is $23,128, which is more than twice the average cost, at $11,103, of non-CKD Medicare patients, and the cost increases as the disease condition deteriorates[1]. The best estimate of kidney function is the glomerular filtration rate (GFR), or the amount of blood that passes through glomeruli per minute[8]. Patients are divided into 5 stages based on their GFR level: $\geq$ 90 mL/min as stage 1, 60-89 mL/min as stage 2, 30-59 mL/min as stage 3, 15-29 mL/min as stage 4, and finally <15 mL/min as stage 5[8]. Conditions worse than stage 5 include ESRD, which requires costly dialysis and poses significant negative impact on patients' life styles and health outcomes[9]. Studies have suggested that risks of CKD increase with age, with half of the CKD stage 3 cases developing after the age of 70 years[10,11]. The interactions between age, sex, race, especially between African-American and White, and the risk of CKD and

ESRD are also found in multiple studies[12-14], but there have been limited efforts in discovering pathways of care from actual treatment data.

In this study, we elicit practice-based clinical pathways of CKD treatments using 4 years of office visit data containing detailed information on 8,533 patients who were treated at a community nephrology practice in Western Pennsylvania. Practice-based clinical pathways reflect patients' disease progression over time in terms of the treatments provided during office visits. Specifically, we aim to identify the different patient types and the distinct paths along which their treatments may evolve. Office visit data is modeled as a sequence of visits, such that we can capture the chronological changes in visit type, visit date, procedures and diagnoses. Each patient is represented by one and only one sequence. We apply hierarchical clustering, a cluster analysis method frequently used in biomedical research to identify underlying structures[15,16], to patients' visit sequences in order to discover distinct patterns in the sequences that separate one subgroup of patients from another. To visualize the clinical pathway in each subgroup, we incorporate a stochastic model to connect pairs of visits that have high transition probabilities. This learned model can be instantiated for any patient, to allow the patient to visualize a projected clinical pathway and engage with the clinicians for shared decision making. It can also be used as a practice management tool for clinicians who wish to review their practices against current consensus guidelines for CKD.

Prior research has studied methods for identifying clinical pathways for a few health conditions[17-19]. Huang et al. developed a clinical pathway mining algorithm and applied it on hospital inpatient care for bronchial lung cancer, gastric cancer, cerebral hemorrhage, breast cancer, infarction, and colon cancer[17]. Lin et al. adopted Hidden Markov Model in mining clinical pathways and applied it to the normal spontaneous delivery process[18]. Also, Lin et al. applied Bayesian networks to study the causal relationships between medical treatments and transitions of patient's physiological states in the Hemodialysis process[19]. Yet, there is limited research specifically targeted for the five CKD stages prior to ESRD for many reasons. First, CKD treatments last for years as patients progress from stages 1 to 5, completing multiple office visits during this period. Second, CKD treatment is laboratory-test driven; before each visit to the clinic, patients are asked to complete specific laboratory tests and bring the results for physician review. Results from laboratory tests largely determine the next steps in treatments. Few procedures are performed as part of CKD treatment. Finally, CKD patients tend to suffer from a variety of comorbidities such as hypertension and diabetes[1]. Thus, patients need to be treated for those conditions as well. In fact, patients in the same CKD stage can evolve along distinctly different clinical pathways depending on their comorbidities and lifestyle choices. Therefore, clinical pathway mining algorithms designed for other conditions do not apply well to CKD due to the differences in the nature of disease and the many dimensions associated with its treatments. In Section 2, we describe our data set and illustrate the methods used to mine clinical pathways. In Section 3, the generated pathways and their components are presented using figures and tables. We discuss limitations and future steps in Section 4, and finally summarize our conclusions in Section 5.

2. Data and Methods

2.1 Data

De-identified data for this study was obtained from a large, forward-thinking nephrology practice in Western Pennsylvania that implemented an Electronic Health Record (EHR) system in 1994. The community practice provides care to patients at multiple clinics dispersed over a three-county geographic region. A four-year extract of the data, from March 2009 to May 2013, is drawn from the EHR. There are 8,553 patients in our study dataset, 4,195 female and 4,358 male patients (Table 1). Majority of the patients are White or African-American, with the ethnicity ratio remaining steady over the years. In this study, we mainly focus on patients' office visits, which are categorized as new patient visit, follow up, extended follow up, hospital follow up, pre-ESRD education, and kidney biopsy review. Excluding vascular access center visits and check up for dialysis patients, 8,500 patients had at least one office visit. To reduce noise in the data set, diagnoses captured in our pathways include only CKD stage 1 through stage 5 (ICD9 = 585.1-585.5) and its commonly known comorbidities: diabetes (ICD9 = 250.xx), hypertension (ICD9 = 401.xx or ICD9 = 405.xx) and acute kidney failure (AKF, ICD9 = 584.xx). We chose these 3 conditions because AKF is frequently associated with increases in CKD stages, and prevalence of CKD is high among patients with diabetes and hypertension[1,20,21]. Procedures are captured using Current Procedural Terminology (CPT) codes. We include 27 types of procedures, such as renal ultrasound and renal artery Doppler.

Table 2 lists the number of occurrences of diagnoses and procedures recorded during visits over the 4-year study period. From previous study[22], we suspect that a clinical pathway for CKD may contain 4 to 6 office visits, so we extracted data on patients who started from a specific point in CKD stages 1 to 5 and had at least 8 visits, to ensure

adequate number of visits are included in the learned pathways. A total of 2,511 patients fulfilled the criteria. Our data shows that procedures are not commonly performed for CKD patients during office visits. Out of 52,349 visits in the data, only 201 visits had some type of procedures performed, for a total of 262 times. Patients in CKD stage 4 received the largest number of associated procedures, majority of which were referral to pre-ESRD education (Table 2). In this analysis, we exclude patients who only had hospital visits, but do not exclude hospital visits of patients who are also office patients so that we can capture the complete history of each patient's treatments. In addition, since CKD is a chronic condition, patients may not start and complete treatments during the four-year study period. Therefore, the clinical history we see may start from a follow-up visit and end before patients complete treatment, move on to dialysis, or decease. Mortality information is not captured in the dataset.

Table 1. Patient demographics

		70 and above	Between 50 and 69	Under 50	Total
Female	White	2229	1080	337	3646
	African-American	101	93	31	225
	Other	8	11	12	31
	Unknown	157	97	39	293
Male	White	2328	1221	293	3842
	African-American	74	110	43	227
	Other	15	10	11	36
	Unknown	134	84	35	253
Total		5046	2706	801	8553

Table 2. Occurrence of diagnoses and procedures recorded during visits over the 4-year period

Condition	Number of occurrences	Number of Associated Procedures
CKD stage 1	407	3
CKD stage 2	2290	2
CKD stage 3	18698	22
CKD stage 4	9363	141
CKD stage 5	1493	8
Acute Kidney Failure	4298	13
Diabetes	10269	19
Hypertension	30926	54

2.2 Methods

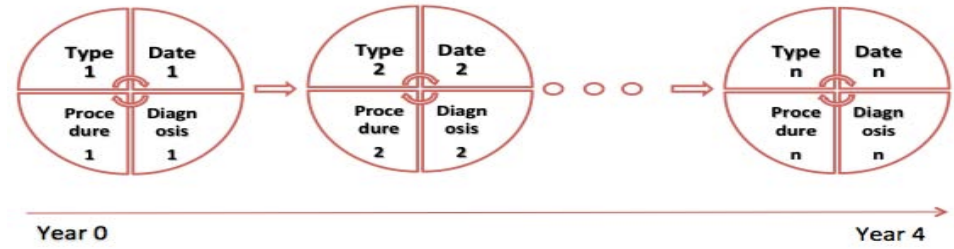

Figure 1. Illustration of a patient's sequence of visits

We represent each patient's clinical history as one and only one sequence of office visits ordered chronologically, with each visit in the sequence categorized by visit type, visit date, procedure(s) performed, and diagnoses noted (Figure 1). Length of sequence is the number of visits in the sequence. Unfortunately, data on medications was incomplete, so we do not include medications in the visit node in this analysis, but this extension is straightforward using the current representation. Each variable in the visit, such as diagnosis, is stored as an independent table in a secure relational database. Patients are characterized by a de-identified patient ID, age: under 50, above 50 and below 70, 70 and above; sex: female/male; and race: White, African-American, Other. Patients receive none, or multiple procedures and diagnoses during a visit. Given the data set, we first identify all combinations of unique procedures performed during a single visit, such as 'renal Doppler, renal ultrasound', and combination of unique diagnoses noted during a single visit, such as 'CKD stage 4' or 'CKD stage 3, hypertension.' Each combination of procedures is given a label 'PCx', where x is a number from 1 up to the total number of combinations. We apply the

same to the combination of diagnoses, labeling each as 'Dy', where y is a number from 1 up to the total number of combinations. Then, each visit can be represented as 'type', 'date', 'PCx', and 'Dy.' We scan all visits and identify unique combinations of 'type', 'PCx', and 'Dy,' so we can label each visit as 'Vz' where z is a number from 1 up to the total number of combinations. For each patient, we use 'date' to chronologically order each 'Vz' into a sequence. It is possible for a sequence to have multiple visits of the same sort, such as V1-V3-V3-V2-V1, if the visit is of the same type, procedures and diagnoses. The numbers in the labels are used to distinguish each label, not to show the order of time. Table 3 lists examples of how we label combinations of procedures and diagnoses, and visits.

Table 3. Examples of procedure, diagnosis and visit labels

Label	Description
D1	CKD stage 3, hypertension
D2	CKD stage4
PC1	renal ultrasound
V1	type: follow up, date: 2011/1/1, procedure: PC1, diagnosis: D2
V2	type: new patient visit, date: 2012/1/1, procedure: N/A, diagnosis: D1

After visit sequences are properly represented, we apply hierarchical clustering[23], based on a distance measure called longest common subsequence (LCS) distance[24], to cluster sequences by similarity. LCS has been widely applied in biomedical research as a similarity measure used in trajectory analysis and protein sequence analysis[25]. It is the longest subsequence that 2 sequences have in common, while preserving the order of occurrence, but possibly separated. For instance, if patient 1 has a sequence V1-V2-V1-V3-V1-V2, and patient 2 has a sequence V1-V2-V3-V1-V4, then their LCS is of length 4, being V1-V2-V3-V1.

$$\mathrm{LCS}(\mathrm{x},\mathrm{y}) = \max\{|\mathrm{u}|: \mathrm{u} \in \mathrm{S}(\mathrm{x},\mathrm{y})\}$$

is the length of LCS, where |u| is the length of the longest common subsequence for the pair of sequences (x, y), and S(x,y) is the nonempty set of subsequences of sequences x and y. LCS distance (dLCS) is defined as

$$dLCS(x,y) = |x| + |y| - 2LCS(x,y)$$

Each patient's visit sequence will be compared to the rest of the patients' sequences, and each such comparison generates an dLCS. Since our sample size is 2511, the size of the dLCS matrix is 2511 by 2511. To enhance the result of hierarchical clustering, we apply a data transformation and square each dLCS in the matrix. Hierarchical clustering is applied on this transformed matrix to cluster similar sequences into subgroups. The optimal number of clusters is detemined using Silhouette,[26] a measure commonly used in cluster analysis .

In order to create clinical pathways for each cluster, we elicit all transitions seen in the visit sequences of patients. The visit taking place first is called *source* and the successor is called *target*. For example, given a sequence V3-V2-V2-V5, there are 3 transitions: (V3, V2), (V2, V2), (V2, V5), where the source is V3 and target is V2 in the first transition. To build pathways, we connect transitions with a certain threshold such that they form an overall path. For example, given 3 transitions: (V1, V2), (V3, V4), (V2, V4), we can connect 1st and 3rd transitions to form a path V1-V2-V4, because the target in the first transition is the source in the 3rd transition. In order to ensure that transitions we use to build pathways occurr in the data beyond a certain probability, we define a measure called *weight:*

$$weight = \frac{\left|N_j = target \middle| N_i = source\right|}{|N_i = source|}$$

where $|N_i = source|$ is the number of times N_i appears as a source, and $|N_j$=target | N_i=source| is the number of times N_j appears as a target given N_i is the source. Weight is the conditional probability that N_i will transition to N_j. For example, in the sequence V3-V2-V2-V5, (V3, V2) has weight of 1, and (V2, V2) and (V2, V5) have weight of 1/2, respectively. In order to reduce noise, we include only transitions with weight above 0.3, a threshold that we think will give rise to a map of pathways that contains sufficient information and easily interpretable by clinicians. We also capture and categorize the difference in days between source and target as *gap*: 1) less than 1 week, 2) 1-2 weeks, 3) 2-3 weeks, 4) 3 weeks-1month, 5) 1-2 months, 6) at 2-3 months, 7) 3-4 months, 8) 4-6 months, 9) 6-12 months, and 10) at least 1 year. If the same transition of visits has more than one gap observed in multiple sequences, we take the average of all the gaps for a transition in term of days, then categorize it into the above categories. A pathway is not necessarily created from one patient's visit sequence. It can be built with multiple transitions by multiple patients, if the target of one transition of a patient is identical to the source of one transition of another patient. Length of a pathway is the number of visits included in the pathway.

In each cluster, we visualize clinical pathways of length more than 3 as graph of nodes using Gephi[27]. Each node in the graph represents a visit label 'Vz', and 2 nodes that have transitional relationships are connected by an edge. The thickness of the edge is determined by weight. The node colors in the pathway graph range from purple to white, and is determined by degree, the number of directed edges connected to a node, both inbound and outbound[28]. The more purple a node appears, the more connecting edges it has, and conversely the whiter a node appears, the fewer connecting edges it has. We also keep track of high out-degree nodes, which are the nodes with high number of outbound edges, because they are points where one pathway split into two or more pathways. In order to check how many of the actual transitions are captured by the learned clinical pathways, we define a measure called average maximum LCS. Given all the pathways learned in a cluster, we calculate the length of LCS between each pathway and each patient's sequence in the cluster. For example, given 3 pathways and 5 patients, we will have a 3 by 5 matrix of LCS between each of the 3 pathways and each of the 5 patients' sequences. We call the maximum length of LCS for each patient as maximum LCS (mLCS). Average maximum LCS is the average of the mLCS.

3. Results

There are 2,468 unique sequences among 2,511 sequences, whose lengths range from 8 to 41, with an average of 12. Of 2,511 patients in the sample, only 65 patients shared the same clinical history with one or more other patients. Thirty-nine patients with CKD stage 3 and hypertension had follow up visits only while maintaining the same diagnoses. Four patients started as new patients with CKD stage 3, diabetes, and hypertension, and continued with the same diagnoses for 7 more follow up visits. Another 4 patients with CKD stage 4 and hypertension had 10 follow up visits with the same diagnosis. Aside from these patients, our data shows that 98% of the patients have evolved in their unique ways regardless of their initial diagnoses, an indication of the unpredictability and diversity in the conditions of CKD patients, and variations in practice patterns. A total of 281 V's were found from the data, and the total number of visits is 30,780. Table 4 lists the 10 most frequent V's, and their occurrences in the data. Follow up visits with CKD stage 3 or CKD stage 4, and hypertension are the most common, and ESRD education sessions for CKD stage 4 patients also count as one of the most frequent.

Table 4. Frequent visit contents

Visit Type	Diagnoses	Procedures	Count	% of Total
FUP	Chronic Kidney Disease Stage 3, Hypertension	N/A	5050	16.4%
FUP	Chronic Kidney Disease Stage 4, Hypertension	N/A	3837	12.5%
FUP	Chronic Kidney Disease Stage 3, Diabetes, Hypertension	N/A	2849	9.3%
FUP	Chronic Kidney Disease Stage 4, Diabetes, Hypertension	N/A	1833	6.0%
FUP	Chronic Kidney Disease Stage 5, Hypertension	N/A	751	2.4%
FUP	Chronic Kidney Disease Stage 2, Hypertension	N/A	396	1.3%
FUP	Acute Kidney Failure, Chronic Kidney Disease Stage 3, Hypertension	N/A	381	1.2%
ESRD	Chronic Kidney Disease Stage 4	N/A	376	1.2%
FUP	Chronic Kidney Disease Stage 5, Diabetes, Hypertension	N/A	319	1.0%
FUP	Chronic Kidney Disease Stage 2, Diabetes, Hypertension	N/A	213	0.7%

We identified 6 clusters of patient sequences based on the data of 2,511 patients who had at least 8 visits (Figure 2). The length of pathways is between 4 and 6, and number of pathways ranges from 17 to 67. As Figure 2 shows, graphs of clusters 1 and 6 are relatively sparse compared to graphs of clusters 2 through 5. More than half of the pathways in cluster 1 ended with follow up visits with diagnoses of CKD stage 4, diabetes and hypertension. Majority of the cluster 2 pathways ended with follow up visits with diagnosis of CKD stage 3, diabetes and hypertension. All pathways in cluster 3 ended with follow up visits of CKD stage 3 and hypertension. Pathways in cluster 4 predominantly ended with CKD stage 4 and hypertension. All pathways in cluster 5 ended with hospital treatment, and diagnoses are not noted in the data because office and hospital visits have separate billing systems. Finally cluster 6 seems to contain many non-compliant patients. Patients in cluster 3 have cancelled or not shown up for more than 56% of the visits, causing the data to contain empty visits without noted diagnosis. Given that most of the pathways have length of 4, average maximum LCS in clusters 2 through 5 suggest that pathways in these clusters represent a fair amount of information about their patients. On the other hand, clusters 1 and 6 may contain patients whose conditions are more complex and difficult to generalize. In fact, as Table 5 shows, the most common

end point in cluster 1 has diagnoses of CKD stage 4, diabetes and hypertension, the most severe set of conditions out of the 6 clusters. All most common end points and high out-degree points had no procedures performed.

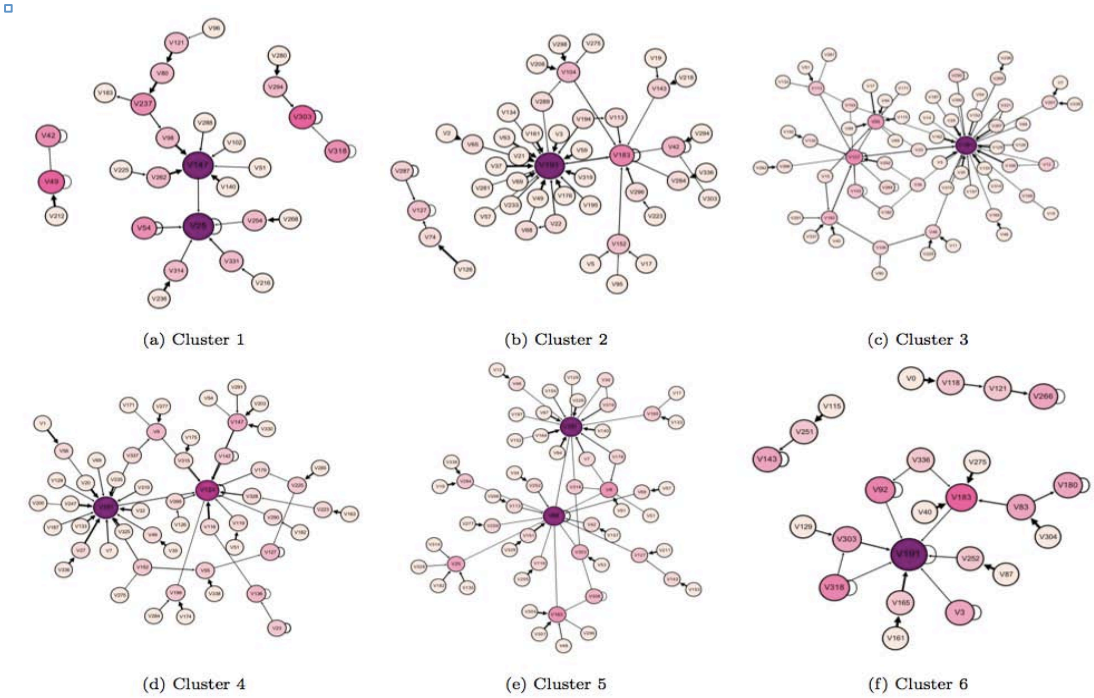

Figure 2. Pathway for identified clusters

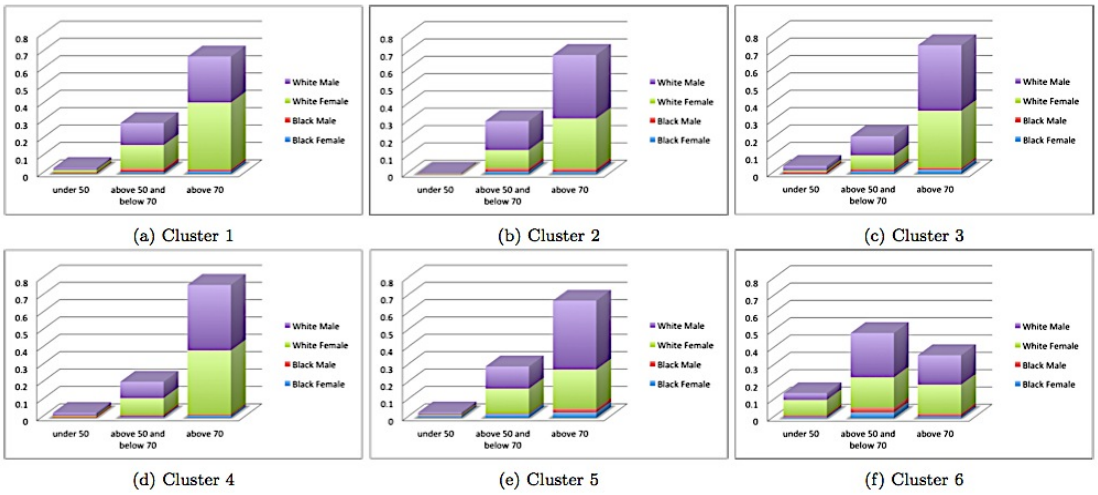
Table 5. Summary of Clusters

Cluster	Number of Patients	Number of pathways	Most Common End point			Average maximum LCS[3]	High out-degree point	
			Type	Diagnosis	% of all pathways		Type	Diagnosis
1	433	17	FUP[1]	CKD stage 4, diabetes, hypertension	65%	1.8	HOSP[2]	AKF[4], CKD stage 2
2	462	40	FUP[1]	CKD stage 3, diabetes, hypertension	95%	2.8	FUP[1]	AKF[4], CKD stage 4
3	582	67	FUP[1]	CKD stage 3, hypertension	100%	3.0	NEW[5]	CKD stage2, hypertension
4	433	45	FUP[1]	CKD stage 4, hypertension	93%	3.0	FUP[1]	AKF[4], CKD stage 3, diabetes, hypertension
5	233	50	HOSP[2]	N/A	100%	3.2	FUP[1]	CKD stage 5, diabetes
6	368	16	FUP[1]	N/A	75%	2.0	FUP[1]	CKD stage 5, diabetes

[1] Follow up, [2] Hospital follow up, [3] Longest common subsequence, [4] Acute Kidney Failure, [5] New patient visit

We examined whether there are differences in terms of age, race, and sex (Figure 3). Applying Chi square test with Monte Carlo methods against the frequencies in the entire sample of 2,511 patients, we found significant differences in the expected and observed frequencies in clusters 2 through 6 (p-value < 0.05 using chisq.test in R)[26]. For example, prior to clustering, 1.7% of the sample population are African-American males between 50 and 70 years of age, but the percentage increases to 2.8% in cluster 6, and decreases to 0.4% in cluster 5 after clustering. Similar trend can also be seen among White female under 50 years of age. Also, the percentage of White female above 70 years of age in cluster 5 nearly doubles compared to the original percentage in the overall sample. Similar pattern can be seen with African-American male above 70 years old and African-American female above 70 years old. These subgroups may have higher likelihood of receiving hospital treatment.



(a) Cluster 1 (b) Cluster 2 (c) Cluster 3

(d) Cluster 4 (e) Cluster 5 (f) Cluster 6

Figure 3. Distribution of patients by age, race and sex

We illustrate 3 example pathways below. Figure 4 shows a pathway belonging to cluster 1. It starts with a follow up visit where patient is diagnosed with CKD stage 4, diabetes and hypertension. Patient receives a chest X-ray during the visit. On average at least 1 month later, patient visits the office for a pre-ESRD education, which is held by a nurse to prepare and educate patients about potential onset of ESRD. Patient comes for a follow up visit at least a month later on average, without changes in diagnoses. Patient is able to maintain the condition for at least a year on average, and visits the office for another follow up. This pathway's duration is on average 1 year and 2 months. Figure 5 shows a pathway in cluster 2, which starts with a CKD stage 3 patient attending an ESRD education session. After an average of 2 weeks, the patient is seen for a hospital follow up, where patient is diagnosed with AKF in addition to CKD stage 3. Then, in an average of 1 year, patient comes for an office follow up visit to receive diagnoses of diabetes and hypertension, in addition to CKD stage 3. Same visit is repeated one year later. On average, it takes at least 2 years 1 month and 2 weeks to complete the pathway. In Figure 5, patient avoids worsening of CKD for more than 2 years, in addition to the pathway in Figure 4 where patients avoid worsening for a year, indicating the known role of pre-ESRD education in helping patients to maintain their current conditions[7]. In fact, cluster 1's high out-degree point (Table 5) divides one pathway into two, with one ending with the same CKD stage upon pre-ESRD education, and another progressing to CKD 3, diabetes and hypertension. One of the visits in cluster 2 with high out-degree is a follow-up visit where patient is diagnosed with AKF and CKD stage 4, which leads to a visit of same type and diagnoses, or in another case an improvement to CKD stage 3 (Table 5). In both cases, they eventually end with a follow up visit with CKD stage 3, diabetes and hypertension. One pathway from cluster 3 is shown in Figure 6. It starts with a follow up visit with a CKD stage 1 patient, who maintains the condition for at least 2 years on average. Patient then develops hypertension, but maintains the same for at least 2 years on average. At least 4 years later on average, patient progresses to CKD stage 3, while still suffering from hypertension. Same diagnoses are noted on a follow up visit at least 1 year later on average. In total, it takes at least 5 years to complete the learned pathway. This is an example where the duration of the learned pathway is longer than the real time range in data, since it is created using high-likelihood transitions of multiple patients. Pathways like this may serve as a projection for future patients who share the same earlier visits.

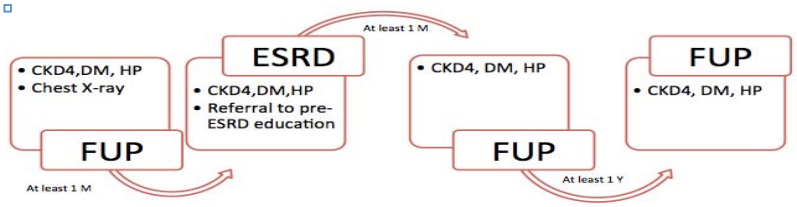


Figure 4. An example pathway in cluster 1

4. Discussion

Learning clinical pathways from EHR data allow us to discover improvement, deterioration or maintenance of the status quo in the course of disease evolution, so we may re-visit the historical data and clinicians' notes to identify interventions that may have played a role in the evolution. For instance, examining pathways with pre-ESRD education may allow us to compare the time it takes for patients to deteriorate with, or without, pre-ESRD education. Also, finding patterns in pathways where improvements were seen in patients' conditions may help clinicians to identify promising care models for a subgroup of the population. In addition, comparing the pathways of compliant and non-compliant patients may help clinicians to engage non-compliant patients in treatments using new approaches. Exploring clinical pathways also allow us to discover significant differences in the distribution of age, race and gender among clusters of patients. Learning about these differences may enable clinicians to design personalized treatment plans for patients according to demographics and health conditions, and develop hypotheses that can be tested in large populations.

In this paper, we chose to show all transitions of visits with weights above 0.3, but different thresholds of weight may produce pathways of different complexity. For example, the maximum length of pathways is 6, and the total number of pathways is 235 in this study. If we reduce the threshold of weight, we may be able to identify pathways of longer lengths, or larger total number of pathways. Developing a measure that takes into account the number of patients and their diversity may determine an optimal threshold of weight that allows most reasonable clinical interpretation of the pathways. Although clustering was applied to separate patients into subgroups, differences in clinical history still exist, even within one cluster, due to the diversity and complexity of patients' conditions and practice variations. Perhaps instead of using weight to elicit a sample population, a more individualistic approach, where we learn the clinical pathways based on patients' biochemical data, demographics and lifestyle choices, can help us to create personalized pathways and detect granular but important differences that separate one patient's sequence from another. Furthermore, in this study we studied only CKD stage 1 through 5, AKF, diabetes and hypertension as diagnoses to control for noise. The patient subgroups may be further divided into smaller subgroups if we included more conditions such as anemia and proteinuria, also commonly seen among CKD patients[1].

In this study we investigated 6 visit types, 8 conditions, and 27 procedures. Theoretically, there can be up to 1,296 combinations of visit types, conditions and procedures reflected in the visits. We observed 281 combinations from the data, as some combinations did not occur in actual visits. However, as the number of component we include increases, the number of possible combinations may explode computationally. For example, if we include 10 medications in the study, the number of possible combination increases by 10-fold. Alternatively, if we increase the conditions by 2, we double the number of possible combinations. As Table 4 shows, only a few of the 'Vz's are observed with high frequencies, making the distribution of 'Vz's right skewed with a long tail. In future studies where more components in the pathway need to be explored, we may focus only on the most frequent combinations, to avoid including too much noise in the pathway creation.

A big challenge in the study is the incomplete documentation in EHR. For example, clinicians may mention an existing condition only in their notes, and patients' medication lists may not be up-to-date. In order to gain the most value from EHR data, it is vital that treatments are accurately recorded with the help from healthcare providers. Once curated data is available, we should investigate complete treatment data including medications, and also patient demographics and life style choices if possible, since these are crucial factors in altering the disease evolution as well. Similarly, we recognize that the types of laboratory tests ordered characterize patients' current conditions and future treatment plans. Hence, results from important laboratory examinations such as GFR, serum Creatinine level, and serum Albumin level should also be included in the study data to provide a more accurate view of the patients' clinical history. This way, we can use laboratory results to ensure that there is no discrepancy between the diagnostic codes and actual conditions, and track pathway evolution by the sequence of lab observations. Moreover, if large enough sample is available, we should limit study subjects to be patients whose treatment data include all visits from the first to the last before patient progress to ESRD. This will likely allow us to build more comprehensive clinical pathways. Furthermore, although we did capture the duration of pathways in this study, temporal factor was not used to cluster patients. Temporal factors, such as pathway duration and the differences in time between actual practice and the consensus guidelines, should be explored in future analysis. This is an important objective that should be pursued with guidance from clinicians, so we may learn dividing points in the pathways that differentiate outcomes of treatments. Finally, and most importantly, rigorous evaluation by clinicians of the learned pathways is crucial to identify unrealistic transitions and courses of disease progression.

5. Conclusion

CKD is a costly and complex health condition with high mortality, and affects millions of adults worldwide. In this study, we aim to learn practice-based clinical pathways for CKD through which we seek an understanding of the major treatment pathways in the evolution of the disease. Our analysis of patient data from an EHR yielded 6 patient subgroups after applying hierarchical clustering on the sequences of office visits. Each subgroup has distinct characteristics, and captures commonly known combination of comorbidities in CKD, such as CKD stage 3, hypertension and diabetes. Also, patients who may experience hospital treatments, or progress faster than others, have been identified in subgroups. We observe that multiple paths of disease evolution exist even within each patient subgroup, confirming CKD's diverse course of development. Moreover, significant differences in the distribution of age, race and sex were found among subgroups. Clinical pathways learned from our study can be instantiated for any patient to enable shared decision making between clinicians and patients, so patients may gain insights into their projected clinical pathway based on demographics and earlier visits. At the same time, our study can serve as a practice management tool used by clinicians, to review their practice against current consensus guidelines for CKD, and identify care models that may lead to improved outcomes.

Acknowledgements

We are grateful to the physicians and staff of the community nephrology practice who generously provided data from their Electronic Health Record for this study. We particularly thank Dr. Teredesai, MD, Dr. Xie, MD, PhD, Dr. Patel, MD, and staff, L. Smith and A. Barletta, who gave us important clinical and technical information about the data and the key characteristics of CKD and its treatment. This study was designated as Exempt by the Institutional Review Board at Carnegie Mellon University.

PubMedMiner: Mining and Visualizing MeSH-based Associations in PubMed

Yucan Zhang, PhD[1,2], Indra Neil Sarkar, PhD, MLIS[1,3,5], Elizabeth S. Chen, PhD[1,4,5]

[1]Department of Computer Science, [2]Plant Biology, [3]Microbiology & Molecular Genetics, [4]Medicine, [5]Center for Clinical & Translational Science, Univ. of Vermont, Burlington, VT

Abstract

The exponential growth of biomedical literature provides the opportunity to develop approaches for facilitating the identification of possible relationships between biomedical concepts. Indexing by Medical Subject Headings (MeSH) represent high-quality summaries of much of this literature that can be used to support hypothesis generation and knowledge discovery tasks using techniques such as association rule mining. Based on a survey of literature mining tools, a tool implemented using Ruby and R – PubMedMiner – was developed in this study for mining and visualizing MeSH-based associations for a set of MEDLINE articles. To demonstrate PubMedMiner's functionality, a case study was conducted that focused on identifying and comparing comorbidities for asthma in children and adults. Relative to the tools surveyed, the initial results suggest that PubMedMiner provides complementary functionality for summarizing and comparing topics as well as identifying potentially new knowledge.

Introduction

The MEDLINE citation database represents a major source of references to biomedical literature, containing over 20 million citations dating back to the late 1940s with 2000-4000 citations added daily[1, 2]. MEDLINE is the primary component of PubMed that provides access to over 23 million citations[1] where each record is associated with a set of metadata that includes title, abstract, and Medical Subject Headings (MeSH) descriptors that are used to index MEDLINE citations and enable searching in PubMed. With the exponential growth of published biomedical research available in resources such as PubMed (especially MEDLINE), it can be challenging for clinicians and researchers to keep current with findings on a topic of interest and to discover connections between seemingly unrelated concepts (e.g., as represented by MeSH descriptors) across multiple disciplines[3-5].

A number of systems have been developed that build upon the search capabilities provided by PubMed[4, 6, 7], including biomedical literature mining tools that incorporate information retrieval, entity recognition, information extraction, text mining, and data integration methods[8, 9]. As part of the literature-based knowledge or relation discovery process, a first step is the identification of biomedical concepts or entities such as diseases, drugs, and genes. While some studies have involved extracting concepts from titles and abstracts in PubMed or the full-text of articles in PubMed Central, others have focused on MeSH descriptors that are arranged in a hierarchical structure thus allowing for searching at different specificity levels (e.g., using a broader descriptor such as "Respiratory Tract Diseases" versus a more specific descriptor such as "Asthma")[7, 10-14]. These latter studies include those that have used MeSH descriptors to identify co-occurring biomedical concepts as well as those involving use of association rule mining techniques to discover putative relationships between biomedical concepts[15, 16]. There are more than 27,000 descriptors in MeSH that are continually revised and updated[17]. Since MeSH descriptors are applied to MEDLINE records by trained subject matter experts with domain knowledge, they can be seen as representing standardized and high-quality summaries of a particular publication[18]. Thus, MeSH descriptors may offer a useful window into the full text for information retrieval, extraction, and other high-level functions, and potentially allow for further automation of the discovery process.

The goal of this study was to build upon prior efforts and develop an open-source literature mining tool ("PubMedMiner") for identifying and visualizing relationships between MeSH descriptors in MEDLINE. The findings from a survey of literature mining tools that incorporate MeSH descriptors were used to guide the development of PubMedMiner to include functionality for PubMed searching, MeSH descriptor extraction, Unified Medical Language System (UMLS) semantic type filtering, basic statistical analysis and visualization, as well as association rule mining and visualization. In order to demonstrate how PubMedMiner could facilitate hypothesis generation and knowledge discovery, a case study is presented for exploring and comparing comorbidities for asthma in children and adults. A discussion of limitations of the current prototype system, challenges in its development, and planned enhancements to the system are then provided.

Background

Various literature and text mining tools have been developed to improve information retrieval and infer relationships between biomedical concepts[6, 12, 19, 20]. In this section, findings from a survey of literature mining tools including MeSH-based functions are summarized and association rule mining is described as a technique for exploring MeSH-based relationships.

Survey of Literature Mining Tools

Numerous studies have successfully revealed interesting scientific discoveries from biomedical literature in MEDLINE using a variety of knowledge discovery tools that incorporate different terminological systems (e.g., MeSH[5, 21], UniProt protein/gene names[22], or the UMLS[23]) and algorithms for discovering or predicting relations[24]. For example, literature-based discovery (LBD) approaches have been used to discover new knowledge and generate hypotheses based on findings in the literature, such as identifying connections between the beneficial effects of fish oil in treating Raynaud's syndrome and the causal effect of magnesium deficiency on migraines, both of which were later validated[25-28]. LBD studies have integrated MeSH descriptors as part of the knowledge discovery process[5, 21]. Other studies have focused on using MeSH descriptors to improve information retrieval and identify relationships between entities[25, 26, 29-31]. For example, relationships such as drug-gene, drug-effects, protein-protein, and gene-gene, have been explored using statistical co-occurrence methods[29, 31-33].

A survey of literature mining tools was conducted to identify and compare those that incorporate MeSH descriptors. Based on searching publications, Google and Google Scholar Web searching results, and specific resources (e.g., the National Network of Libraries of Medicine, National Center for Biotechnology Information, and Arrowsmith project sites), a total of 80 tools was identified[2, 4, 6, 12, 19, 34]. Of these tools, links for about one-third were found to be no longer active. For the remaining tools, those satisfying the following criteria were included: (1) is maintained and available to the public; (2) focuses on literature mining in the biomedical domain and builds upon basic PubMed functions; and, (3) incorporates MeSH descriptors in the implementation of advanced functionalities, such as basic statistical analysis and association rule mining. The 14 eligible tools after applying these criteria were found to use MeSH descriptors in their main functions besides searching and were categorized into three groups according to their most notable features: (1) filtering or clustering search results using MeSH: BibliMed[35] (2011; Private); (2) describing search results with basic statistics for MeSH: LigerCat[36] (2009; Academic), PubAnatomy[37] (2009; Academic), Anne O'Tate[38] (2008; Academic), GoPubMed[39] (2005; Private), MedSum[40] (2005; Academic), and PubMed PubReMiner[41] (2004; Academic); and, (3) exploring associations among MeSH: KNALIJ[42] (2012; Private), PubAtlas[43] (2009; Academic), AliBaba[44] (2006; Academic), BITOLA[45] (2005; Private), PubNet[46] (2005; Academic), XplorMed[47] (2001; Academic), and MEVA[48] (2001; Private).

The first group whose major feature is filtering or clustering search results using MeSH descriptors includes only one system (BibliMed) that provides a more focused search but no other advanced functions for information extraction[19]. Several systems in the other groups also have a clustering function, such as Anne O'Tate and XplorMed. Systems in the second group accept standard PubMed queries for literature search and perform frequency analysis on MeSH descriptors from retrieved records (Table 1). However, only one or two systems support search result export, statistical analysis, or visualization. LigerCat[20] was the only open-source system identified in this survey. In the third group (Table 1), systems either carry out association rule mining directly among MeSH descriptors or find connections between publications through common MeSH descriptors. Systems such as KNALIJ and AliBaba visualize associations as a network between extracted entities, whereas systems such as PubAtlas visualize associations as a two-dimensional table. While XplorMed and MEVA do not allow for direct PubMed searching, users can upload files produced from external PubMed searches that are used for subsequent analysis. Only a few of the surveyed systems allow users to adjust parameters for association rule mining, and some tools cannot visualize discovered associations.

None of the systems in the second group was found to perform statistical analysis of UMLS semantic types associated with MeSH descriptors and only two of the tools from the third group have implemented the feature of filtering MeSH descriptors by semantic type. UMLS semantic types are hierarchical subject categories for categorizing concepts in the UMLS Metathesaurus[49] and have been used to cluster or filter search results. There are 133 semantic types currently and each MeSH descriptor can be associated with one or more semantic type(s)[17, 50]. This allows users to focus on associations between MeSH descriptors of interest.

Table 1. Tools with basic statistical analysis and association rule mining functions using MeSH descriptors.

Tool	Query format	Filtering with semantic types	MeSH as entity	Search result export	MeSH frequency	Semantic type frequency	Statistics visualization	Association rule mining	Rule strength cutoff adjustable	Association visualization	Related article links	Analysis result export

Association Rule Mining

The concept of association rule mining was proposed by Agrawal, *et al.* in 1993[51] in the context of market basket analysis, but has since been widely adapted to other domains[30, 52-54]. An association rule is defined as an implication of the form: $X \rightarrow Y$, where $X, Y \subset I$, $X \cap Y = \varnothing$, X, Y are sets of items ("itemsets"), I is the set of total items, and $X \rightarrow Y$ means that when X occurs, Y also occurs with a certain probability. Agrawal and Srikant proposed an algorithm for mining association rules based on identifying frequent itemsets, known as the *Apriori* algorithm[55].

The strength of an association rule is typically measured using metrics referred to as support and confidence[51]. The *support* of an itemset X represents the fraction of transactions containing itemset X. The *confidence* of a rule is the probability of finding transactions containing the consequent of a given rule that also contain the antecedent of the given rule. Commonly, in order to obtain association rules with statistical significance and certain strength, minimum support and confidence values are specified[51]. Many other measures of interestingness have been proposed, such as the chi-squared (χ^2) statistic, lift measure, and Gini index[56, 57]. Of note, the χ^2 statistic has been shown as an efficient measure of the strength of a set of association rules based on co-occurrence[30, 58, 59] and found to outperform other measures such as support, confidence, lift, and conviction[60].

A number of open-source tools are available that provide a wide variety of statistical and graphical techniques for generating and visualizing association rules, such as R[61], Tanagra[62], and Weka[63, 64]. R is a widely used free software environment for statistical computing and visualization that can be extended using over 5000 packages available at the Comprehensive R Archive Network (CRAN) package repository[65, 66]. Compared with R, Tanagra lacks advanced graphical features and Weka is weaker in calculating classical statistics[64, 67, 68]. The R package "arules" implements the *Apriori* algorithm for association rule mining and can calculate various interestingness measures for generated rules[69]. The "arulesViz" R package visualizes association rules in different formats such as scatter plot, grouped matrix, and graph-based association network[70].

Materials and Methods

Overview

In this study, the combined functionality provided by the aforementioned literature mining tools was used to guide the development of an open-source literature mining tool ("PubMedMiner") to include: PubMed searching, MeSH descriptor extraction, UMLS semantic type filtering, basic statistical analysis and visualization, association rule mining and visualization, as well as results exporting. With standard searches in PubMed, MeSH descriptors extracted from retrieved literature reflect the contents of the corresponding articles. Filtering by UMLS semantic types is one way to focus on particular MeSH descriptors of interest. Basic statistical analysis such as frequency counts helps to

identify the most common concepts and semantic types to inform mining and visualization of associations among selected MeSH descriptors.

The general workflow of PubMedMiner involves four phases (Figure 1): (1) searching and retrieving MEDLINE records associated with a particular topic from PubMed; (2) filtering MeSH descriptors by UMLS semantic type(s); (3) generating basic statistics for MeSH descriptors and UMLS semantic types; and, (4) mining and visualizing association rules between filtered MeSH descriptors. Results associated with each phase are made available as plain text (ASCII), XML, or PDF files.

The Ruby scripting language was used to develop the interactive, command-line version of PubMedMiner that is configurable at each phase. For the statistical analysis component, the R environment for statistical computing and graphics[71] was integrated into PubMedMiner using the RinRuby[72] Ruby gem. Functionality for basic statistics and association rule mining was enabled through the use of the "arules"[66] and "arulesViz"[66] R packages.

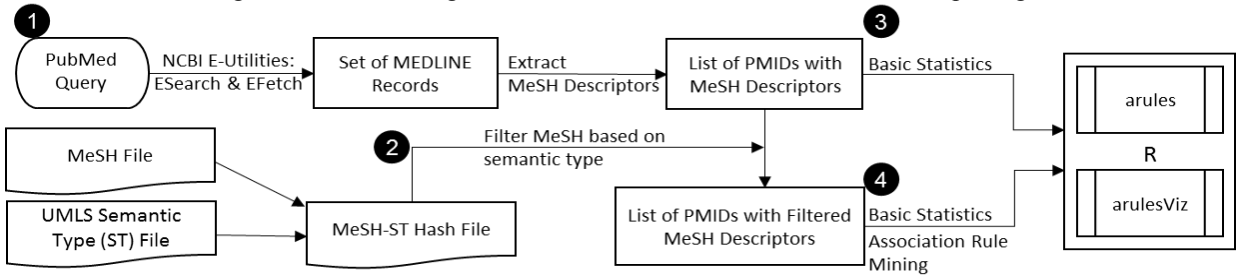

Figure 1. Overview of PubMedMiner development process.

Searching and Retrieving MEDLINE Records

PubMedMiner makes use of the National Center for Biotechnology Information Entrez Programming Utilities (NCBI E-Utilities)[73] to search and retrieve records in MEDLINE format from PubMed. Within PubMedMiner, a user can enter a PubMed query to search and retrieve MEDLINE-formatted records and is notified if no matching articles are found. At the end of a search, PubMedMiner parses each retrieved MEDLINE record and extracts the PMID and MeSH descriptors based on the corresponding PMID and MH metadata fields. Only the PMID and all associated MeSH descriptors along with subheadings are saved into a new text file for the next phase.

Filtering MeSH descriptors by UMLS Semantic Types

UMLS semantic types are used by PubMedMiner to filter MeSH descriptors for subsequent association rule mining. This step removes irrelevant associations and only focuses on association rules between MeSH descriptors corresponding to the set of semantic types specified by the user. Each MeSH descriptor and associated UMLS semantic types are extracted and stored as a hash table in a YAML (YAML Ain't Markup Language) text file, which links the semantic type codes to their full names according to a downloadable list of UMLS Semantic Groups that specifies the semantic types included in each group[74]. For example, the MeSH descriptor "Asthma" is associated with the UMLS semantic type code "T047" for "Disease or Syndrome."

Generating Basic Statistics for MeSH Descriptors and UMLS Semantic Types

The PMID-MeSH and PMID-semantic type data are transformed into the requisite formats that enable them to be analyzed in R using the "arules" package (version 1.0-15)[66]. Both absolute counts and relative frequencies of each MeSH descriptor and UMLS semantic type are saved in a text file in a tabular format. The visualization of frequencies as histograms is also implemented using "arules." The user can specify the number of MeSH descriptors or UMLS semantic types to be viewed in the histogram graphs (e.g., top 10 or top 25). Since each MeSH descriptor may correspond to multiple UMLS semantic types, duplicates of the same semantic type can exist for a single MEDLINE record. To accommodate for this, statistics are obtained for semantic types both with and without duplicates. PubMedMiner can perform statistical analysis and visualization on MeSH descriptors and UMLS semantic types both before and after filtering.

Mining and Visualizing Association Rules

In PubMedMiner, the "arules" R package that implements the *Apriori* algorithm is used for generating association rules among selected MeSH descriptors[66, 69] and the "arulesViz" R package is used for visualizing these rules (version 0.1-7)[66, 70]. Before the rule mining step, the selected MeSH descriptors are transformed into the appropriate format for R. The user needs to specify minimum support and confidence values at the beginning of the mining process.

Association rules are generated with 17 different interestingness measures that include support, confidence, χ^2, and Gini index, which are made available in a pipe-delimited text file. In addition, links to PubMed are generated that includes the consequent and antecedent of each rule as search terms in the query: "<rule consequent>"[mh] AND "<rule antecedent>"[mh]. Rules can be visualized and saved as PDF files in five different formats: (1) scatter plot; (2) matrix-based visualization; (3) group matrix-based visualization; (4) graph-based visualization with itemsets as vertices; and, (5) graph-based visualization with items and rules as vertices. For the graph-based visualizations, users can specify the number of rules to include (e.g., all or top 20). To view larger amounts of rules (maximum 1000 rules), a GraphML formatted file is generated that can be opened and modified by visualization tools such as Gephi and Cytoscape[75, 76]. Users can choose whether or not to re-run the rule mining function with adjusted parameters (i.e., support and confidence) if previously defined values did not give meaningful results.

Results

PubMedMiner

PubMedMiner is available under a GPL2 license at: https://github.com/UVM-BIRD/pubmedminer. The PubMedMiner tool provides several modes that cover functions for searching, filtering, statistics before and after filtering, and association rule mining. Each mode represents a combination of different functions and the user can specify which set of functions to be executed by the system. There are three main modes: (1) search, filter, and rule mining (includes statistics); (2) filter and rule mining (includes statistics); and, (3) rule mining only. The first main mode covers the whole process of the pipeline while the other modes only execute part of the process. Four additional modes provide individual functionality: (1) search only; (2) filter only; (3) statistics only (before filtering); and, (4) statistics only (after filtering). A PubMedMiner log file retains a record of the timestamp, selected mode, and configuration details such as the user-specified search query, UMLS semantic types, and other parameters for the basic statistical analysis and association rule mining.

Case Study: Exploring and Comparing Comorbidities for Asthma in Children and Adults

To demonstrate the use of PubMedMiner, a case study is presented here for how the tool can be used to facilitate exploration and comparison of comorbidities for asthma in either a pediatric or adult population. The respective queries (performed on February 13th, 2014) for these patient populations were:

- Pediatric Asthma: "asthma"[mh] AND ("infant"[mh] OR "child"[mh] OR "adolescent"[mh]) NOT "adult"[mh]
- Adult Asthma: "asthma"[mh] AND "adult"[mh] NOT ("infant"[mh] OR "child"[mh] OR "adolescent"[mh])

The first main mode, as described above, was used by PubMedMiner for both queries where the tool performed the PubMed search, filtered and analyzed extracted MeSH descriptors, and generated association rules. The pediatric asthma search returned 23,448 results containing 6,524 unique MeSH descriptors with 123 semantic types; whereas, the adult asthma search returned 22,839 articles containing 8,688 unique MeSH descriptors with 127 semantic types. Absolute counts and relative frequencies for all MeSH descriptors and UMLS semantic types were calculated, and the top 25 MeSH descriptors and top ten semantic types ordered by frequency were chosen to be displayed as histograms in separate PDF files. MeSH descriptors were subsequently filtered by the following three UMLS semantic types in the UMLS Semantic Network: (1) "Disease or Syndrome," (2) "Mental or Behavioral Dysfunction," and (3) "Neoplastic Process," where the latter two are children of the first[50]. After the filtering step, 669 MeSH descriptors were left for pediatric asthma and 948 MeSH descriptors remained for adult asthma. The tool carried out basic statistical analysis again on these filtered MeSH descriptors and further generated association rules using user-specified parameters. To maximize the rules generated by PubMedMiner, a minimum support of 0.01, minimum confidence of 0.01, and maximum rule length of 3 were specified as the settings for both example runs in this study.

According to the statistical analysis of the extracted UMLS semantic types, most semantic types in both sets of articles had similar frequencies (< 2 fold difference). For example, both sets of articles included the same top five UMLS semantic types ordered by absolute count without duplicates: "Age Group," "Population Group," "Human," "Disease or Syndrome," and "Organism Attribute." Several semantic types had frequencies with greater than a two-fold difference. For example, the frequency of the semantic types "Family Group," "Environmental Effect of Humans," "Conceptual Entity," "Organization," and "Regulation or Law" were higher in publications related to pediatric asthma; whereas "Anatomical Abnormality," "Organophosphorus Compound," "Body Substance," "Cell Function," and "Neoplastic Process" appeared more often in articles for adult asthma.

Similarly, the frequency patterns of MeSH descriptors after filtering differed between the two sets of articles. Table 2 presents a selection of MeSH descriptors that had relative frequencies greater than 2%. The fold differences of relative

frequencies were calculated for MeSH descriptors that were higher than 0.5% between the two sets, and fold differences greater than two are highlighted in Table 3, which shows MeSH descriptors with fold difference greater than five. Several MeSH descriptors were more frequently mentioned for pediatric asthma such as "Attention Deficit Disorder with Hyperactivity," "Virus Diseases," and "Respiratory Syncytial Virus Infections," and "Bronchiolitis, Viral" was only found in publications related to pediatric asthma. Some descriptors were more frequent for adult asthma such as "Asthma, Occupational," "Pulmonary Disease, Chronic Obstructive," "Hypertension," "Lung Diseases, Obstructive," and "Churg-Strauss Syndrome" (Table 3). This type of analysis enables one to explore potential asthma-related diseases and reveals those that are more studied relative to the two patient populations (children and adults).

Table 2. MeSH descriptors after filtering by UMLS semantic types.

Pediatric Asthma			Adult Asthma		
MeSH Descriptor	**Absolute Count**	**Relative Frequency**	**MeSH Descriptor**	**Absolute Count**	**Relative Frequency**
Asthma	9761	97.61%	Asthma	9692	97.20%
Dermatitis, Atopic	390	3.90%	Pulmonary Disease, Chronic Obstructive	738	7.40%
Rhinitis, Allergic, Perennial	389	3.89%	Occupational Diseases	667	6.69%
Acute Disease	357	3.57%	Bronchial Hyperreactivity	521	5.23%
Rhinitis, Allergic, Seasonal	329	3.29%	Chronic Disease	408	4.09%
Bronchial Hyperreactivity	311	3.11%	Rhinitis	310	3.11%
Respiratory Tract Infections	299	2.99%	Acute Disease	300	3.01%
Chronic Disease	292	2.92%	Rhinitis, Allergic, Perennial	270	2.71%
Rhinitis	275	2.75%	Rhinitis, Allergic, Seasonal	246	2.47%
Eczema	259	2.59%	Eosinophilia	214	2.15%

Table 3. Comparison of MeSH descriptor frequencies for pediatric asthma and adult asthma.

Pediatric Asthma		Adult Asthma	
MeSH Descriptor	**Fold Difference**	**MeSH Descriptor**	**Fold Difference**
Attention Deficit Disorder with Hyperactivity	53.00	Asthma, Occupational	83.00
Virus Diseases	18.80	Occupational Diseases	47.64
Respiratory Syncytial Virus Infections	14.33	Pulmonary Disease, Chronic Obstructive	29.52
Bronchiolitis	8.00	Hypertension	13.57
Eczema	7.40	Lung Diseases, Obstructive	11.67
Dermatitis, Atopic	6.61	Churg-Strauss Syndrome	10.50
Respiratory Tract Infections	5.34	Lung Neoplasms	8.43
Bronchiolitis, Viral	*	Drug Hypersensitivity	7.05
		Aspergillosis, Allergic Bronchopulmonary	5.20

* MeSH descriptor "Bronchiolitis, Viral" is only associated with pediatric asthma.

With a minimum support value of 0.01 and minimum confidence value of 0.01, 35 and 34 association rules were generated for articles related to asthma in children and adults respectively. The resulting text file included the rules along with the different interestingness measures sorted by χ^2 value in descending order and links to PubMed (e.g., http://www.ncbi.nlm.nih.gov/pubmed/?term="Dermatitis, Atopic"[mh] and "Asthma"[mh] for the rule "Dermatitis, Atopic => Asthma"). The five types of graphs were generated along with the GraphML file for visualizing the rules. Figure 2 shows the grouped matrix-based visualization of all the association rules where rules with the top *k* (user-specified) consequent (Right-Hand Side [RHS]) MeSH descriptors sharing common antecedents (Left-Hand Side [LHS]) are grouped together. If the LHS contains more than one MeSH descriptor, only the most frequent MeSH descriptor is shown in the column label and the number of other descriptors is shown as "+*N*" where *N* represents the number. Size and color represent support and χ^2 value respectively. The columns and rows are ordered according to the χ^2 value that is decreasing from top down and from left to right so that the group of most interesting rules according to χ^2 value are shown in the top-left corner of the plot. Numbers below LHS represent the number of rules containing the corresponding LHS MeSH descriptors.

In the graph-based visualization in Figure 3, MeSH descriptors and rules are represented as vertices, where the size of the rule vertex represents the support value of the rule and color denotes the χ^2 value (e.g., darker shades corresponds to higher values). Bi-directional association rules are identified between pairs of associated MeSH descriptors; the graph contains two rules for each pair with the same strengths in opposite directions. This type of graph emphasizes the composition of the rules and shows which MeSH descriptors share the same rule. Examination of disease-disease

associations from articles for pediatric asthma and adult asthma further highlights several diseases as possible common comorbidities of asthma in both populations such as "Bronchitis," "Bronchial Hyperreactivity," and "Rhinitis," whereas several diseases may be more common in one population than the other, such as "Eczema," "Dermatitis, Atopic," and "Food Hypersensitivity" in children, and "Airway Obstruction," "Churg-Strauss Syndrome," and "Eosinophilia" in adults. In addition to these pairwise relationships, the visualizations for pediatric asthma reveal relationships between "Rhinitis, Allergic, Perennial" and "Dermatitis, Atopic" as well as triple associations such as between "Asthma," "Rhinitis, Allergic, Seasonal," and "Rhinitis, Allergic, Perennial".

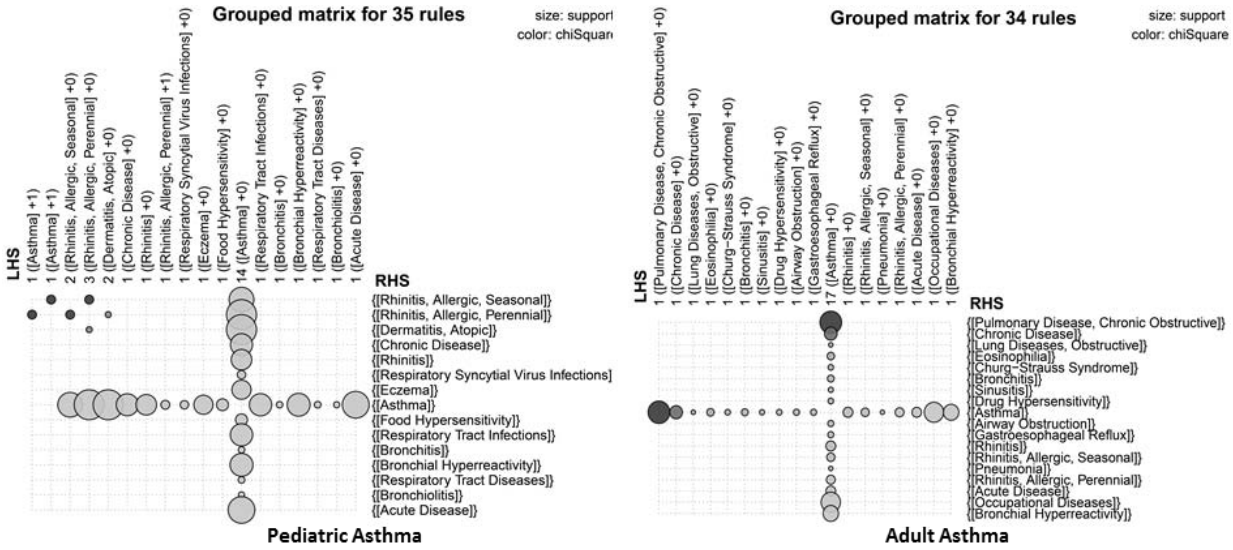

Figure 2. Grouped matrix-based visualization of all association rules for pediatric and adult asthma.

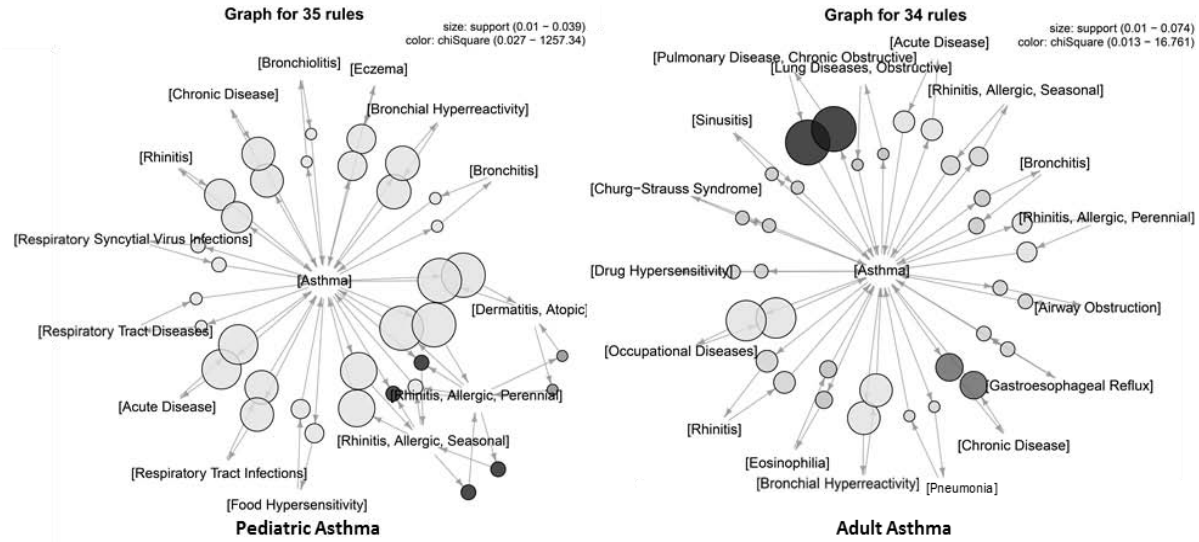

Figure 3. Graph-based visualization with items (i.e., MeSH descriptors) and rules as vertices of all association rules.

Discussion

PubMedMiner was developed as a prototype literature mining tool for MeSH descriptor extraction, basic statistical analysis, and association rule mining of biomedical literature for a given topic. There are several currently available literature mining tools that are capable of advanced literature retrieval and literature-based discovery. Based on the survey and comparison of existing tools including functionality for MeSH descriptors, a command line version of PubMedMiner was developed, which incorporates PubMed searching, MeSH descriptor extraction and filtering, basic statistical analysis, association rule mining, and visualization.

PubMedMiner can be used to explore MeSH descriptors and UMLS semantic types of interest for enhancing focused literature search as well as to validate existing and potentially discover new clinical knowledge. This latter functionality could be valuable for assisting clinicians and researchers keep up-to-date with changes in disease knowledge (e.g., disease-disease and disease-drug) over time. The case study demonstrated a more advanced use of this tool in which it helped highlight the similarities and differences between two PubMed searches for asthma in children and asthma in adults. This example shows how PubMedMiner may be used to facilitate a comorbidity analysis of asthma in different populations. While these searches excluded articles that include MeSH descriptors for both children and adults, further analysis could involve comparing comorbidities based on asthma articles for both children and adults (e.g., "asthma"[mh] AND "adult"[mh] AND ("infant"[mh] OR "child"[mh] OR "adolescent"[mh])). In addition, future work may include formally evaluating the results from such analyses with domain experts (e.g., clinicians and biomedical researchers) to confirm if the associations represent known or unknown knowledge, exploring how this tool may be beneficial for providing highly summarized domain knowledge for researchers and clinicians, guiding studies on particular conditions such as asthma in different populations, and validating results from clinical data mining studies (e.g., comorbidities based on data from the electronic health record).

For a given topic, there could be thousands of MeSH descriptors associated with a set of retrieved MEDLINE citations. PubMedMiner can carry out association rule mining among all MeSH descriptors or only filtered ones according to user-specified UMLS semantic types. Continued development of PubMedMiner will include advanced filtering functions such as incorporating hierarchical information (e.g., enabling the selection of MeSH descriptors for sub-categories of a specified UMLS semantic type) and considering other groupings of MeSH descriptors (e.g., leveraging the MeSH hierarchies or UMLS Semantic Groups). Additionally, the filtering functionality of PubMedMiner may be further enhanced by allowing users to filter out particular MeSH descriptor(s) before generating the statistics and rules in order to highlight relationships between other descriptors (e.g., excluding the original search descriptor "Asthma" and its descendants to highlight other co-morbidities). Other statistical approaches like TF-IDF could also be used to filter out frequently occurring MeSH descriptors (e.g., check tags such as "Humans," "Adult," and "Child").

Limitations include exclusion of newer citations due to the delay in assigning MeSH descriptors[77] and potential bias of selected MeSH descriptors due to consistency issues between different indexers[78, 79]. Besides MeSH descriptors, there are many other metadata fields in MEDLINE records, such as authors, publication types, titles, and abstracts. A number of tools have incorporated such metadata into their functionalities such as PubReMiner that calculates basic statistics on year, author, journal, and substances[19], and KNALIJ that generates and visualizes associations between authors, journals, and latest citations[42]. Future extensions to PubMedMiner may include combining basic statistics with association rule mining using other metadata for a given topic, and enhancing the current association rule mining functionalities by exploring biomedical concepts in titles and abstracts.

Using open-source technologies reduced the costs in terms of labor and time for implementing PubMedMiner. Association rule mining and visualization have been implemented in the "arules" and "arulesViz" R packages. In order to exploit the functions of these packages, R was integrated into Ruby (using the RinRuby Ruby gem) in the implementation of PubMedMiner and several limitations were encountered. Since the generated graphs are not self-descriptive, one motivation for creating the PubMedMiner log file was to record details about each use of the tool, including the user-specified parameters for creating all the graphs. Graphs have to be manually labeled when one needs to compare the same type of graphs generated with different queries. In addition, incomplete labels might be shown on graphs due to the size limitation when visualizing relatively large amounts of information. Twenty or fewer rules give the best resolution of node labels in the network graphs saved in PDF format and network graphs saved in the GraphML file format can be used to visualize up to 1000 rules. Future improvement of this tool may include enhancing interactive features by allowing users to set the font of node labels as well as the title of each graph. Furthermore, current rule metrics include 17 different interestingness measures that can assist users in selecting the most significant association rules. However, visualization of generated rules is implemented with only support, confidence, and χ^2 values. In future development, the tool could allow users to specify what set of measure(s) to use in visualization and incorporate a preview function based on user needs.

For the asthma case study, the frequency of MeSH descriptors was compared manually by calculating the fold difference of the same MeSH descriptors in two different queries. Allowing users to compare results from different queries is an additional functionality that may be included as a future enhancement in PubMedMiner. Although the command line version of PubMedMiner may satisfy many of the needs of studies such as described here, a graphical user interface (GUI) would likely be more desirable for the interactive process. The prototype system developed in this study has provided the foundation for implementation of a web-based GUI version of PubMedMiner (e.g., using MySQL and Ruby on Rails) that is publicly accessible and includes enhanced functionality.

Conclusion

MeSH descriptors can be seen as high quality summaries of biomedical literature and have been used as a window to literature indexed in MEDLINE. Guided by a survey of currently available MeSH-based literature mining tools, a command line prototype system (PubMedMiner) was developed that includes functionality for PubMed searching, MeSH descriptor extraction, UMLS semantic type filtering, basic descriptive statistics, association rule mining, and visualization. Based on a case study of comparing pediatric and adult asthma literature, PubMedMiner was able to identify association rules that may represent characteristic comorbidities.

Patient-Centered Case Management System (P-CMS)

Keith Butler, PhD[1], Andrew Berry[1], Amy Walker, PhD, MSN[1], Nikki Pete[1], Yi-Chen Sung[1], Craig Harrington[2], Jodie Haselkorn, MD[3], Paul Nichol, MD[4], Mark Oberle, MD[1], Lucas McCarthy, MD[3], & Mark Haselkorn, PhD[1]

1. University of Washington, Seattle, WA; 2. University of Texas, Houston TX; 3. VHA MS Center of Excellence, West, Seattle, WA; 4. Office of Informatics and Analytics, VHA, Washington, DC

ABSTRACT: P-CMS addresses an important gap in HIT for case management of multiple sclerosis (MS) with a design based on the workflow of MS care, the information clinicians actually use, and innovation to analyze the tacit, cognitive work of case management for effective HIT support. MS is one of many chronic diseases where clinicians spend excessive time on clerical tasks for the information they need to manage complex cases and coordinate treatment plans. The tacit nature of this care activity, however, made it difficult to understand how HIT should be applied. This demonstration will illustrate how an analysis of the conceptual work products[1] of case-management provided requirements and design concepts for an effective solution. P-CMS works with key use-cases of case management to form a measurably better workflow. The web-based prototype was implemented for usability testing, simulation of impact on workflow, and technical feasibility evaluation. The results indicate P-CMS will improve awareness of patients' treatment plans, increase timeliness of order completions, while eliminating many clerical tasks for time-savings of about 1-hour per shift. We will review the cognitive strategy of its design, progress towards an alpha test version, and generality of the design for other chronic diseases.

INTRODUCTION: Seventy-five percent of U.S. health care dollars are spent on chronic illness and the cost is growing with population aging. MS is an example of chronic illness where case managers play an important role coordinating and monitoring complex treatment plans that unfold over months for outpatients. The number and duration of orders, combined with the complexity of conditions, require a wide variety of information to manage cases and coordinate care. Using information from a wide variety of resources can impose burdensome clerical tasks to access it, integrate it manually, then keep the ad-hoc collection current, on top of doing patient care. Without an information system that is well-designed specifically for case management these overhead tasks can be daunting, disrupt timely coordination, and risk needless errors. The specific purpose of P-CMS is to provide a single tool that integrates needed information in a highly usable, effective user interface to improve awareness of the progress of patients' orders and conditions, while eliminating the wasted overhead of clerical information tasks.

P-CMS: Organizes needed information into layers based on an effective cognitive strategy[1] of management by exception against time-based milestones for each type of order. The home page displays a list of all patients with color coding for quick visibility of any patient whose progress has fallen behind one or more milestones. Any patient's order summary can be opened with one click, and any patient can be retrieved by name. Selectable column headers allow users to re-sort the list of patients with one click by:

- Any patients with new or changed orders, displayed by oldest to newest
- Any patients with order milestones that are late, displayed from most behind to least
- Patient's next appointment date, displayed by nearest to furthest
- Patient's last appointment date, displayed by most recent to oldest

All the page views provide color coding to identify patients with exceptions to expected progress.

STATUS: A functional prototype was implemented in HTML with anonymized patient data in a SQL database for usability testing and technical feasibility. Usability results with seven experienced nurses indicate it is highly learnable and easy to use for all use-cases. The Northwest VA regional data warehouse patient-level database was successfully linked to the P-CMS database for feasibility analysis of daily surveillance of clinical orders, lab results, radiology results, consult and appointment tracking.

Pajekto3DStereo: Enabling Generation and Interaction with 3D Stereo Networks

Bryant Dang BS, Suresh K. Bhavnani PhD
Institute for Translational Sciences, University of Texas Medical Branch, Galveston, TX

Abstract

Although 2D networks have been useful in revealing complex associations in a wide range of biomedical applications, they are often too dense to comprehend. In such situations, a 3D layout of the same network provides an extra degree of freedom in the z-plane, often resulting in a more accurate representation of the associations in the data. However, 3D layouts displayed in 2D occlude nodes that are further away in the z-plane, and therefore require the network to be rotated in order to view the nodes and comprehend their relationships in 3D space. Unfortunately, this rotation leads to disorientation and therefore requires a stereo version of the 3D layout to enable rapid comprehension. Because tools to develop such 3D stereo layouts are either proprietary or expensive, we developed *Pajekto3DStereo*, a simple interface in R that enables researchers to convert a 3D network layout into a format that can be used by a freely available stereo-visualizing tool called VMD. *Pajekto3DStereo* has enabled the discovery of a complex pattern related to two intersecting biological pathways that was missed using a 2D network layout.

Introduction

Numerous projects have demonstrated the utility of 2D network layouts to help researchers comprehend complex multivariate relationships[1]. However, network layouts are often too dense, resulting in the infamous "hairball" network with apparently no discernable pattern. In prior research[2,3] we have argued that because 3D network layouts provide an extra degree of freedom on the z-plane, force-directed algorithms[1] such as *Fruchterman Reingold* (FR) generate network layouts that more accurately reflect complex associations in the data. However, 3D network layouts displayed in 2D lead to node occlusion or disorientation when the model is rotated to view the occluded nodes. Such networks need to be displayed in 3D stereo which enables comprehension of the 3D layout without having to rotate the model. Here we describe a tool that enables the rapid generation of 3D stereo network models.

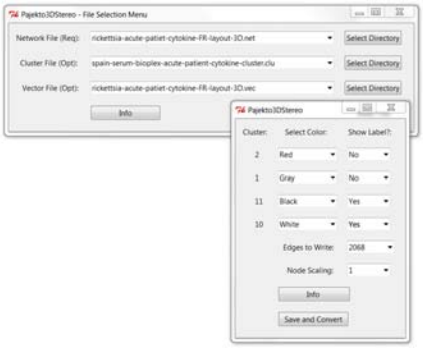

Figure 1. Dialog boxes in *Pajekto3DStereo*

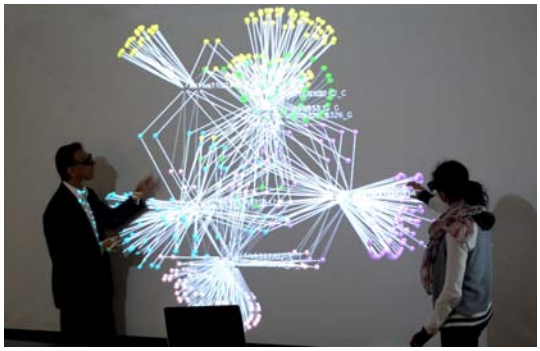

Figure 2. Output of *Pajekto3DStereo* being viewed in stereo through the use of VMD and stereo glasses

Method and Results

As shown in Figure 1, we have developed a tool in R called *Pajekto3DStereo* which takes as input a network layout file containing the X,Y,Z coordinates of nodes laid out by a 3D network layout algorithm (e.g., FR available in Pajek[1]). Through this interface, the user can also specify (1) color and size of the nodes, (2) number of edges to be displayed, and (3) display parameters that are critical for a high fidelity layout. *Pajekto3DStereo* then converts the network layout data into a format that can be read by VMD (a well-known freeware used to display molecules, nodes, and edges in stereo). As shown in Figure 2, the converted file can then be displayed and interacted with in 3D stereo. Such visualizations generated with *Pajekto3DStereo* have enabled the discovery of a sub-topology that was missed when using 2D network layouts[2]. In future research we intend to expand the features provided by *Pajekto3DStereo*, and user test the interface with the goal of enabling a wide range of researchers to freely and rapidly convert 2D network data into 3D stereo views that enable discoveries in complex multivariate data.

Big Data for Critical Care with Cloud-based In-Memory Database

Mengling Feng, PhD[1], Mohammad Ghassemi, Msc[1], Thomas Brennan[1],PhD, John Ellenberger, Msc[2], Ishrar Hussain, PhD[2], Roger Mark, M.D. PhD[1]
[1]Massachusetts Institute of Technology, Cambridge, MA; [2]SAP Research, Burlington, MA

Abstract

MIMIC is an open-access database, which holds clinical data from over 60,000 Intensive Care Unit (ICU) stays, with over 7,000 records matched with time-series physiological data. MIMIC is valuable Big Data research resource, which is over 4TB in size and currently has over 1,000 users around the globe. Analyzing large database like MIMIC is, however, computationally expensive due to its high dimensionality and vast volume. We have been exploring the in-memory database as a solution. In collaboration with SAP, our industrial partner, we will showcase how Big Data analytics can be effectively conducted with HANA, a Cloud based in-memory database system from SAP. Different from traditional databases, HANA is capable of storing the whole database in the main memory for fast and dynamic querying. We will have a live demonstration to showcase the advantage of HANA over traditional databases in terms of query speeds. We will also showcase how data extraction and statistical analysis of Big Data like MIMIC can be conveniently accomplished as one integrated process with HANA, which fully integrates SQL with R, the statistical analytic language.

MIMIC: An Open Big Data for Critical Care:

Our lab and partners have built and been maintaining the Multi-parameter Intelligent Monitoring in Intensive Care (MIMIC) database [1] since 2003. MIMIC is the largest open Big Data resource for critical care, and it currently has over 1,000 users around the globe. This open-access database, which now holds clinical data from over 60,000 stays in the BIDMC ICUs, has been meticulously de-identified and is shared online with the research community via PhysioNet (www.physionet.org). In this demonstration, we will guide the audiences to navigate through both the clinical component (400 GB) and the time-series (4 TB) components of MIMIC. The clinical component includes structured data, such as demographic data, lab & microbiology test results, medication & fluid records, diagnoses, hourly nurse-verified vital sign readings and patient mortality data. MIMIC also contains rich unstructured text data, which includes notes, reports and summaries. The time-series component of MIMIC consists of continuous high resolution (8-bit,125Hz) physiological waveforms data and trend data that were sampled at 1 data point per minute.

Big Data Analytics Empowered by In-Memory Database

Analyzing large database like MIMIC is computationally expensive due to the high dimensionality and large volume of the data. Performance and scalability issues of traditional databases often limit the usage of more sophisticated and complex data analytic models. In addition, a complete data analytic task requires multiple tools across various software platforms. Exporting and importing large amount of data across platforms requires a tremendous amount of computation and I/O resources. We have been exploring the in-memory database as a solution. SAP has recently developed an cloud-based in-memory database, named HANA, which is capable of storing the large volumes of data in the main memory, instead of the disk drives. HANA can dramatically reduce the time needed for data queries by eliminating the disk seeking, reading and writing. We will conduct a live demonstration to showcase the computational advantage of HANA over traditional databases by comparing their query speeds over the MIMIC data. Another great advantage of HANA is that it is fully integrated with R, the open source statistical analytic language, which has rich data mining and machine learning libraries. We will also demonstrate how researchers can conveniently conduct both data extraction and statistical data analysis under one single HANA platform.

Current System Development Status

HANA has already been deployed on an AWS cloud instance and can be easily launched by users. In the cloud instance, the in-memory database together with R has been implemented and populated with the MIMC data.

Narrative Event and Temporal Relation Visualization Tool

Sean P. Finan[1], Piet C. De Groen[2], Guergana K. Savova[1]
[1]Children's Hospital Boston Informatics Program, Harvard Medical School, Boston, MA;
[2]Mayo Clinic College of Medicine, Mayo Clinic, Rochester, MN

Abstract

Extensive critical patient information typically is in an unstructured, free text format – the clinical narrative – that can only be accessed by reading the full text. However, the amount of information within the Electronic Medical Record (EMR) of a single patient is expanding beyond the ability of someone to read within a typical appointment slot. New Natural Language Processing (NLP) methods allow automated extraction of medical events and temporal relations among those events from clinical narratives. In order to display the clinically relevant events from a complete life span of a patient, we created a novel visualization tool that allows scrolling and zooming in time while maintaining an overview of the entire timeline within a single frame. We selected four key features of a typical clinical encounter as the main content of a medical timeline: (1) signs and symptoms; (2) tests and procedures; (3) diseases and disorders; and (4) medications. Within these four features, more detailed subset timelines are allowed. We will demonstrate our prototype graphical user interface and discuss some of the challenges unique to the visualization of unstructured clinical narratives as well as our solutions.

Description of the System

NLP systems can pull a substantial amount of temporal information from text, including events from patient - physician discussions and activities of daily living, along with event modifiers such as negation and uncertainty. Although several excellent timeline visualization tools exist, they are geared towards rendering data from the structured part of the EMR and could not easily be extended to display information from the clinical narrative[1,2,3]. In addition to the new approaches listed in the abstract, our tool uses a unique combination of symbols, coloring and shading to expressively display nuanced event-time relations, event properties, and time span attributes. A marked-up representation of the source note allows convenient comparison between the graphical representation and text.

Statement of Use

A prototype is being tested as part of the Temporal Histories of Your Medical Event (THYME) project[4]. It will soon be integrated into Apache clinical Text Analysis and Knowledge Extraction System (cTAKES) and as such will be available through the Informatics for Integrating Biology & the Bedside (I2B2) platform[5,6]. Use of the tool will also play a part in an upcoming project in the oncology domain funded by the National Cancer Institute (NCI).

Acknowledgments

This work is partially supported by THYME (R01LM010090) and I2B2 (U54LM008748) from the National Library of Medicine. Parts of our schema stem from discussion held during our presentation at the 30th Annual Human-Computer Interaction Lab (HCIL) Symposium[7].

Using Electronic Medical Record Time and Quality Metrics to Identify Provider-Specific Training Opportunities

Anupam Goel, MD, MBA, Advocate Health Care, Oak Brook, IL; Bonnie Dean, Cerner, Kansas City, MO; Harlen Hays, Cerner, Kansas City, MO

Abstract

Time in the electronic medical record (EMR) provides a single dimension into inpatient provider behavior with the EMR. Coupling EMR time metrics with other metrics (*e.g.*, number of patients seen, percent of orders canceled, document quality) could help a clinical informatics department better identify opportunities to either adjust training opportunities or prioritize enhancements to help improve end-user EMR efficiency for large groups of users.

Introduction

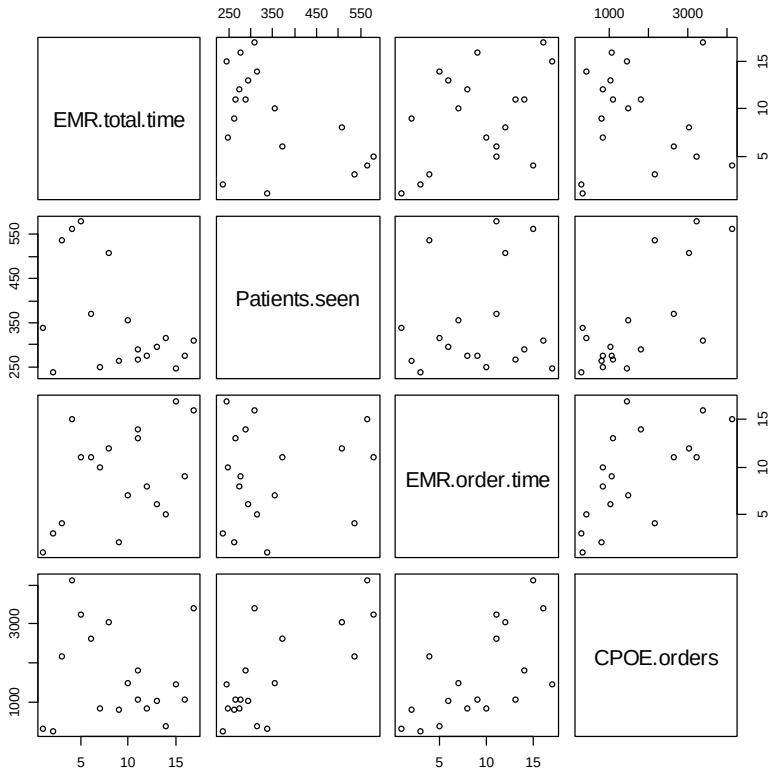
Some EMR vendors can provide time metrics to help clients identify users who may spend too little or too much time in the electronic medical record. A more appropriate measure of inpatient provider EMR behavior would balance time in EMR against other metrics including patient volume, EMR adoption and appropriate EMR use.

Methods

Advocate and Cerner developed a user dashboard including three different domains of time spent in the EMR (chart review, ordering and documentation) along with measures of EMR adoption (orders directly entered into the EMR [CPOE], clinical documents directly entered into the EMR) as well as measures of appropriate EMR use (percent of orders canceled, documentation quality).

Preliminary Results

The figure on the right describes the relationships between average daily time in a patient's chart, the number of patients seen during the month, the average time spent entering orders per patient per day and the number of CPOE orders among providers who saw at least 200 patients in two consecutive months at one hospital. Without additional information beyond time spent in the EMR, it would be difficult to identify opportunities for improvement.



Conclusions

A combination of EMR-generated provider metrics, EMR adoption and appropriate EMR use can assist a medical center identify specific opportunities to improve the EMR experience beyond time-based measures.

Demonstrating A Public Health Terrain Data Visualization System

Jeremy Keiper[1], Shiaofen Fang, PhD[1], Yuni Xia, PhD[1], Mathew Palakal, PhD[2], Shaun Grannis, MD[3], Thanh Minh Nguyen[1], Sam Bloomquist[1], Anand Krishnan[2], Weizhi Li[1]

[2] School of Informatics, Indiana University – Purdue University, Indianapolis;
[3] Regenstrief Institute, Indianapolis, IN

Abstract

Use cases for public health data visualization systems indicate a need for an interactive system, a wide variety of filters for narrowing scope, and visualizations in both geospatial and logical domains. A public health study not only involves relationships between individuals within a given community, but also considers correlations among attributes of diseases. These correlations are not inherently obvious unless one has prior domain expertise, and exploration of these relationships can be tedious even with complex statistical analysis tools. Ultimately, public health officials seek simplified datasets providing the minimum factors necessary to illustrate a problematic scenario. Through a combination of specific health data sources and innovative text and data analyses, we created a visualization engine allowing public health officials to quickly define, assess, and address potential epidemics. Our innovations include unique text and data mining techniques for discovering relationships spanning multiple domains, and innovative interactive visualizations providing comprehensive knowledge transfer to the user.

Introduction and Background

Public health researchers need access to relationships within communities to understand the details of an epidemic. Individuals can be connected to others by geographic proximity, shared community spaces, common treatments, or other shared personal traits. Most current work in health visualization focuses on analyzing individual patients. Our goal was to provide access to large, cohort-based indicators along multiple dimensions, allowing an epidemiologist to find outbreaks and disease patterns without requiring prior knowledge of dataset characteristics.

Our visualization interface provides multiple intelligent visualizations of regionalized health data, allowing users to see relationships at varying levels of granularity, as shown below: a navigable weighted graph demonstrating disease relationships; a geospatial heat map showing population density of selected diseases; a ring graph depicting patient-disease relationships and demographic grouping over time; a 3D geographic visualization for interactive exploration of cumulative disease occurrences; and a theme river used to show disease occurrence comparisons over time. We tailored the user interface for quick access to data filtering controls and snapshots of multiple alternative visualizations, surrounding a main interactive window that can assume the entire window on demand.

Unique data sources and analysis techniques coupled with interactive visualizations comprise the core of our innovations. The Notifiable Condition Detector (NCD) system at Regenstrief Institute informs public health officials by identifying lab tests indicating any reportable conditions, as defined by the state of Indiana. We use outcomes from the NCD to preselect patients of interest in our dataset. We then align these patients with discharge notes from hospitals in the Indiana Network for Patient Care, and process all of the free-form data through text mining analysis to identify additional diseases and other relevant attributes. Our system detects correlations across domains, including patients, diseases, and related attributes, and prepares this metadata for interactive visualization.

To investigate an outbreak, an epidemiologist could: search for the disease (filter sidebar); visualize a network of highly related diseases (association graph); select other closely related diseases to include in the visualizations (multiple interfaces); find the geographic distribution for multiple diseases, or a single disease over time (chloropleth, 2D or 3D); and look for patterns over time for patients contracting the disease multiple times or in sequence with its comorbidities (ring graph), exploring each visualization interactively to narrow focus.

As of this writing, our system is still under development and will not be deployed publicly unless so determined by its funder. This project is supported by the Department of the Army, award number W81CWH-13-1-0020.

Implementation of a Population Health Record in Montreal, Canada

Maxime Lavigne BEng, Lam Dang-Duy BEng, Eugene Fiziev, Catherine Ghassemian BEng, Alexis Hamel, Anya Okhmatovskaia PhD, Mojtaba Peyvandy, Arash Shaban-Nejad PhD, David L Buckeridge MD PhD

McGill Clinical and Health Informatics, McGill University, Montreal, QC, Canada

Abstract

In response to a critical lack of population health information, the Institute of Medicine has called for systems that use a determinants-of-health approach to integrate health and non-health data and provide easy access to health indicators. We have developed and implemented in the Montreal region a Population Health Record (PopHR), which computes indicators relevant to diabetes automatically from health and non-health data, allows access to indicators through free-text queries, and contextualizes indicator values using existing epidemiological knowledge.

Background

Local, state, and national decision-makers lack sufficient information to make important choices about the health of their communities [1]. This lack of information is particularly troubling in the context of the massive and growing burden of non-communicable diseases, which in 2010 were responsible for 83% of Disability Adjusted Life-Years in Developed countries [2]. To address this critical lack of population health information, the Institute of Medicine (IOM) recommends development of public health systems that link health and non-health data using a determinants of health approach to provide transparent and easily understood information in a timely manner for all levels of geography [1]. Current web-based information portals do not meet these requirements. Building on concepts advanced by the AMIA Board of Directors [3], we have developed a Population Health Record (PopHR) [4], which meets the requirements proposed by the IOM to address the pressing need for population health information [1].

System Description

The PopHR is a web-based, ontology-driven software platform that automates the retrieval and integration of heterogeneous data from health and non-health sources, and supports intelligent analysis and visualization of these data using knowledge of the determinants-of-health. Focused on improving decision-making related to the planning and evaluation of population health interventions, the PopHR addresses common limitations of existing web portals for population health information [1] through the following features:

- *Automated computation of health indicators from regularly updated sources of health and non-health data.* The PopHR integrates at a high spatiotemporal resolution individual-level data from administrative and clinical sources with small-area data on upstream health determinants from government and commercial sources.
- *Natural language interface enabling free-text queries.* Domain knowledge, usage data, and default values are used to provide query suggestions and auto-completion options. The limited use of filtering and stratification controls allows for iterative query refinement without cluttering the interface.
- *Contextualization of health indicators using existing knowledge about the determinants of health*. We have developed a suite of OWL ontologies to encode epidemiological knowledge about causal pathways for chronic diseases. The PopHR semantic framework uses this knowledge to reveal meaningful links between multiple health indicators, customize visualization, and support the development and evaluation of population health interventions.

The PopHR is currently implemented in the greater Montreal area (population 3.8 million) with an initial focus on diabetes [5]. Together with collaborators at the Montreal Health Department, the Quebec Public Health Institute, and the Quebec Ministry of Health, we are refining the PopHR in preparation for evaluation through controlled trials in public health and health system administration settings in Quebec.

SMART on FHIR®

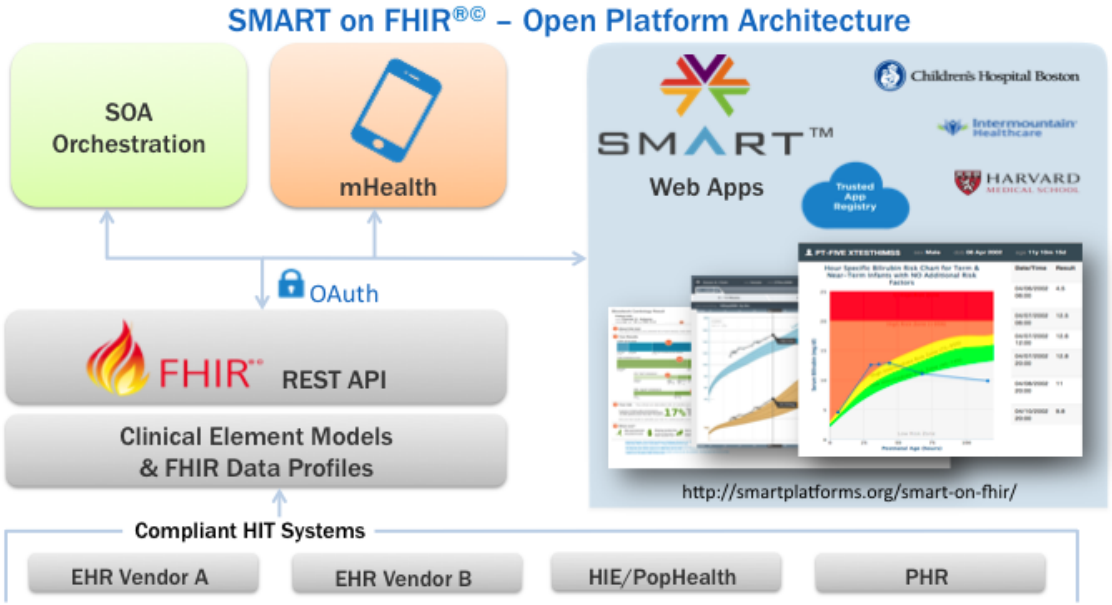
David P. McCallie Jr, MD[1], Joshua Mandel, MD[2], Stanley M. Huff, MD[3], Kenneth Mandl, MD, MPH[2], Isaac Kohane, MD, PhD[4]

[1]Cerner Corp., Kansas City, MO; [2]Boston Children's Hospital, Boston, MA; [3]Intermountain Healthcare, Salt Lake City, UT; [4]Harvard Medical School, Boston, MA

Abstract: *Kohane and Mandl first proposed the development of "substitutable apps" for healthcare systems in a widely discussed 2009 New England Journal of Medicine article. SMART on FHIR represents a vendor-neutral, standards-based, real-world implementation of that vision in support of an "app store" for healthcare. SMART on FHIR implements an open architecture to support interchangeable Web applications that can be "plugged in" to any compliant EHR or health data container. Clinical data are exposed using an Application Programming Interface (API) defined by Fast Healthcare Interoperability Resources (FHIR), an emerging HL7 standard. Semantic data interoperability is achieved using a set of FHIR Profiles that constrain a set of core Resource definitions using a comprehensive open-source library of Clinical Element Models, developed at Intermountain Healthcare. We will demonstrate multiple independently-authored applications running against commercial EHRs as well as other health information technology systems. We will show applications that visualize clinical data, provide decision support, and integrate clinical data with external sources including population health and HIE data.*

Purposes of the System: Modern EHRs are complex systems that can be thought of as "platforms" that provide support for core services such as documentation, order-entry, workflow, decision support, and data persistence. However, it is unlikely that any single vendor can provide support for all of the interactions and services desired by providers. SMART on FHIR defines a standards-based, vendor-neutral way to allow application developers to extend any compliant EHR platform. These extensions can address enhanced decision support, sophisticated data visualizations, and data integration from external sources. SMART on FHIR also offers a clear path for academic informaticists to develop, test, and deploy innovations, without the need to control the underlying EHR software.

Deployment Status: Pilot demonstrations have shown two commercial apps and four open-source apps running against four FHIR service hosts, including a commercial EHR and an open-source VistA implementation.



The HealthITxChange: A Community Infrastructure for Clinicians, Educators, Researchers, and Health IT Professionals focused on Ambulatory EHR Implementation and Use.

Helga E. Rippen, MD, PhD, MPH, FACPM [1], Christoph Ulrich Lehmann, MD, FAAP, FACMI[2], Ejim Mark, MD, MPH, MBA [1]

[1]Rockville Institute, Rockville, MD and Westat, Rockville, MD; [2]Vanderbilt University, Nashville, TN

Abstract

The HealthITxChange (www.HealthITxChange.org) is a collaborative effort between Rockville Institute, AMIA, ANA, AHIMA Foundation, and HL7 to provide a free, online community for educators, researchers, clinicians, and other health IT professionals to share their knowledge, lessons learned, and resources with a focus on ambulatory EHR implementation and use. Individuals responsible for implementing EHR systems often reach out to listservs, follow blogs, search the web, and go to conference sessions promising actionable information and lessons learned in order to find solutions to barriers they are facing or to increase their likelihood of success. Often, information in these sources is limited in scope and/or perspective, difficult to access and potentially biased. In an attempt to address these challenges an infrastructure to support an online community sharing timely, "unbiased" lessons learned on EHR implementation was created. The HealthITxChange also leverages "web harvesting" techniques to provide links to other websites, e.g., PubMed, CMS)] and discussion threads. Finally, to reduce bias and to set clear community expectations around behavior, members agree to abide by a Code of Conduct and the peer review process. This Collaboration is governed by the Executive Committee made up by representatives from Rockville Institute, AMIA, ANA, AHIMA Foundation, and HL7.

Purpose of the System

The purpose of the HealthITxChange is to provide an online community for clinicians, educators, researchers, health IT professionals, to share and access lessons learned, external links, comments, and resources. This online community will provide an environment to share knowledge and to accelerate learning around ambulatory EHR implementation and use.

Innovations

The system is innovative in that it

- provides a national and international learning community around ambulatory EHR implementation and use;
- minimizes the overwhelming nature of complex information by organizing it around the implementation process and tailoring it to the user's characteristics;
- provides a peer review process to mitigate bias and enhance quality;
- allows for community assessment of the usefulness of the information;
- provides links to relevant external links through a uniquely applied deep web harvesting technique tagged to topics;
- enables discussion tagged to a concept and social medial enabled sharing;
- provides a resource for training; and
- enables the community to identify gaps in areas such as policy, marketplace, and knowledge.

Degree Deployed

The site was made available online – www.HealthITxChange.org - on February 20, 2012. The site is focusing its efforts on developing a strong community and providing an infrastructure for researchers. Currently there are 360 individual members and 10 peer-reviewers with over 720 lessons learned, 100 resources, and 40,000 links. One academic center has used it as a core infrastructure for a grant submission and at least two health informatics courses include it as a resource for students in the course syllabus. There are over 17,511 unique visitors over the last year with 375 registered members representing over 40 countries.

An Electronic Health Record for Google Glass: A System Demonstration

Presenter and Developer: Karandeep Singh, MD[1,2]
[1]Brigham and Women's Hospital, Boston, MA; [2]Harvard Medical School, Boston, MA

Abstract

Though Google Glass (also known as "Glass") has been used to record and live stream surgical procedures, its use as an EHR platform has been largely overlooked. This system demonstration will review the basic principles of Google Glass development, demonstrate a novel functioning electronic health record (EHR) for Glass, and discuss potential use cases. The first part of the presentation will cover the strengths and limitations of Glass as a platform for development and clinical use. The second part will walk through the process of developing a simple Google Glass application using web technologies such as HTML5, jQuery, and the Adobe Phonegap framework. The third part will focus on demonstrating a functioning EHR application that interfaces with the Longitudinal Medical Record EHR at Brigham and Women's Hospital. Several input methods including voice commands, accelerometer-based scrolling, QR code recognition, and touch-based gestures will be used to access the EHR through Glass.

Description

The mobile use of electronic health records (EHRs) has been primarily confined to smartphones and tablets. Though EHRs aimed at mobile devices offer a convenient way for healthcare practitioners to interact with the medical record, their use is limited by the fact that they are not hands-free devices. The Google Glass provides a unique platform by which a user can access data hands-free in real-time. This system demonstration will describe the process of developing a Google Glass-based application and demonstrate a functioning Glass EHR at Brigham and Women's Hospital.

Developing for Google Glass

Google Glass is a mobile device worn on in place of (or as part of) eyeglasses that contains a transparent display visible to the wearer's right eye. The device runs on the Android operating system and can directly access wireless internet through a built-in wireless chip and can connect to a user's smartphone using Bluetooth. Using web technologies in conjunction with Adobe's Phonegap framework, building an application for Google Glass is fast and flexible. For the first part of the demonstration, I will cover the strengths and limitations of Glass as a platform for development and clinical use. Next, I will walk the audience through the process of starting a Phonegap project and building an HTML5-based Google Glass application that displays "Hello, World." I will review relevant plugins that facilitate data entry on Glass, including how to capture touchpad and accelerometer input, read QR codes, and implement speech recognition for capturing voice commands.

Demonstrating An Electronic Health Record on Glass

The Google Glass-based EHR demonstration will show a novel and functional EHR application that uses each of the different input methods described earlier to simplify the process of retrieving electronic patient data from the Brigham and Women's Hospital Longitudinal Medical Record EHR. I will demonstrate the following features:

- Selecting a patient using the swipe and tap gestures on the touchpad
- Scanning a QR code to securely input a patient medical record number
- Using voice commands for queries (e.g. "show me the meds", "what is the trend for PTH?")
- Using Glass in conjunction with a smartphone (e.g. "text me the number for the primary care doctor")
- Scrolling through large lists using accelerometer input to guide the scrolling speed

Deployment

A functional Glass EHR application has been built and is in pre-clinical use at Brigham and Women's Hospital. We are in the process of planning a trial of the application on the inpatient dialysis unit.

An EMR Designed for Teaching and Educational Research Based on Regenstrief Institute's Gopher System

Blaine Y. Takesue, MD[1,2], John T Finnell, MD[1,2], Jon D. Duke, MD, MS[1,2]

[1]Regenstrief Institute, Indianapolis, IN

[2]Indiana University School of Medicine, Indianapolis, IN

Abstract

Recognizing a significant gap between what students are taught in medical school and what physicians need to know in the modern practice of medicine, many experts have called for medical schools to improve student skills in areas including multidisciplinary teamwork, data analytics and electronic medical records. To help align medical education with a skillset future physicians will require, the Regenstrief Institute recently developed a standalone version of its Gopher computerized physician order entry system designed expressly for use in teaching environments. The system, known as tEMR, combines a rich patient database with the Gopher's clinical decision support architecture to deliver lessons and assess learners' interaction with the system.

Background

While US medical schools matriculate students with a depth of scientific knowledge, it is recognized that these same students graduate with inadequate training in subjects including health economics, health policy, and medical informatics. Adding to this gap is a trend within medical school hospitals that limits medical student access to electronic medical records at a time when electronic health records are becoming more central to patient care.[1] The Regenstrief Institute, with the support of the AMA's "Accelerating Change in Medical Education" (ACE) initiative, created a standalone version of its homegrown EMR (known as Gopher[2]), called the teaching EMR (tEMR) which will help close the gap. The tEMR was designed to support the revised curriculum at the Indiana University School of Medicine. Within the tEMR, students are not involved in patient care so the privacy and security issues which limit student access in production EMRs are not a concern. However, the tEMR does deliver a real world EMR experience; 1) as a branch of an in-use production EMR and 2) through the use of a synchronized, de-identified database of real patient data. The tEMR leverages functionality created for the production EMR to deliver customized education content and to assess students' critical thinking processes.

System demonstration

After discussing the tEMR's infrastructure and patient database, we propose to demonstrate several unique features of the Regenstrief tEMR. First, we will show the novel application of Gopher's clinical decision support architecture to deliver 'educational alerts' to students in a customized, contextual manner. We will demonstrate, using Regenstrief's RAVE rule-authoring platform, how educators can create this custom content. We will demonstrate a novel implementation of OpenInfoButton[3] also designed to deliver customized content for students. Finally, we will demonstrate how detailed logs of student interaction with the system, including data review and clinical orders, are used to assess critical thinking skills.

Relevance

The software developed for this project will be released open-source. One of our principle design objectives is to develop software that can be used at medical schools across the country as well as for the education of non-physician learners. We believe attendees will find a variety of use cases—both didactic and research—for which the tEMR will be of benefit

Doxy.me- A simple, free, and secure telemedicine solution for health care and research participation

Brandon M Welch, M.S., Ph.D.
Biomedical Informatics Center, Medical University of South Carolina, Charleston, South Carolina

Abstract

To address the need for a free and easy-to-use telemedicine solution needed for a clinical research trial, informaticists at the University of Utah developed Doxy.me, a simple and free Web-based video communication solution. Doxy.me is simple; downloads or plugins are not required and patients do not register or login. Several useful features are available to support clinical workflows such as a virtual waiting room, patient check-in and queue, and meeting controls. Furthermore, interest among clinical researchers at the Medical University of South Carolina has also led to the development of virtual eConsent capabilities to support research study participation using the Doxy.me platform. This system demonstration will: (1) demonstrate the capabilities and features of Doxy.me that are available to clinicians, researchers, and patients; (2) describe how the application complies with relevant security and privacy laws; (3) learn how clinicians can use Doxy.me to provide Web-based telemedicine for patients; and (4) understand how clinical researchers can use Doxy.me for virtual eConsent. At the conclusion of the presentation, participants should understand the capabilities and benefits of using Doxy.me for telemedicine and research. Doxy.me is freely available to all clinicians and researchers to use for telemedicine at no cost.

Introduction

In early 2013, the University of Utah Program in Personalized Health and Department of Obstetrics and Gynecology developed a new remote care delivery model for low-risk pregnant woman to take their own clinical measurements (e.g. blood pressure, fetal heart rate, weight) at home, enter the results into Epic MyChart, and have a virtual clinical visit with her clinician from home or work[1]. In the effort to identify a simple and free telemedicine solution for use in the study, the research team was faced with a lack of satisfactory telemedicine options. The research team felt that traditional telemedicine solutions (e.g. Cisco, Polycom) were expensive and too complicated for patients to use from home, and easy-to-use video communication solutions such as Skype or FaceTime were not permitted for telemedicine by the local institution because of privacy concerns. As a result, informaticists at the University of Utah developed Doxy.me ("doc see me"), a Web-based, HIPAA-compliant telemedicine solution that is also simple and easy-to-use.

Solution

Doxy.me is a simple, free, and secure telemedicine solution that allows clinicians to meet with patients at home or work over the internet. Doxy.me provides an encrypted, peer-to-peer, high-quality audio and video connection using technology built into widely used internet browsers and computers. As a result, to use Doxy.me, users do not need to download additional software or plugins. Furthermore, the patient does not need to register for an account or login to meet with her clinician; rather she simply enters the clinician's customized room URL (e.g. https://doxy.me/DrWelch) into her browser to join a virtual meeting with her clinician. Doxy.me also includes many useful features aimed at supporting a telemedicine workflow, such as a customizable virtual waiting room, patient check-in and queue, chat, video controls (e.g. mute, hold, audio only), meeting history, and more. Doxy.me also provides an enterprise version that allows organizations to use their own branded version of Doxy.me (e.g. https://utah.doxy.me) with additional features, including room analytics, clinician room sharing, three-way meetings, and admin controls to add and remove users. Because of the simplicity and ease-of-use of Doxy.me, the Medical University of South Carolina (MUSC) sponsored the development of virtual eConsent capabilities to support research study recruitment and enrollment at remote sites using Doxy.me.

Deployment

Doxy.me has been used by clinicians and patients in the prenatal care study for over a year. Doxy.me is now free and available for any clinician to use for telemedicine, as a result clinicians all over the country have registered for a free account and use Doxy.me in their clinical practice. There is no cost use and registration is quick and simple. Furthermore, efforts are currently underway to use Doxy.me for participant recruitment and enrollment at MUSC. These eConsent capabilities will also be available to any registered user of Doxy.me.
