ESN consisted of two independent reservoirs (ESN1) which served as a control for the experiment. This architecture consisted of two ESNs time-synchronized and running in parallel with no connections between the networks. These reservoir sizes were determined experimentally as discussed later. The second coupled reservoir architecture (ESN2) was similar to the first architecture. However, the nodes in both reservoirs were connected to each of the output nodes. The learning of the hidden to output weights were specific to the error generated by the corresponding waveform. For example, only the error between the predicted and actual ECG waveforms was used to update the W_{hidden_out} connection to the ECG output node. Both reservoirs were initialized synchronously with their corresponding waveform. It was interesting to investigate if the predictions of one reservoir could benefit from the other reservoir with this architecture, and whether two separate reservoirs would make the overall network more robust to limitations associated with the randomly assigned weights.

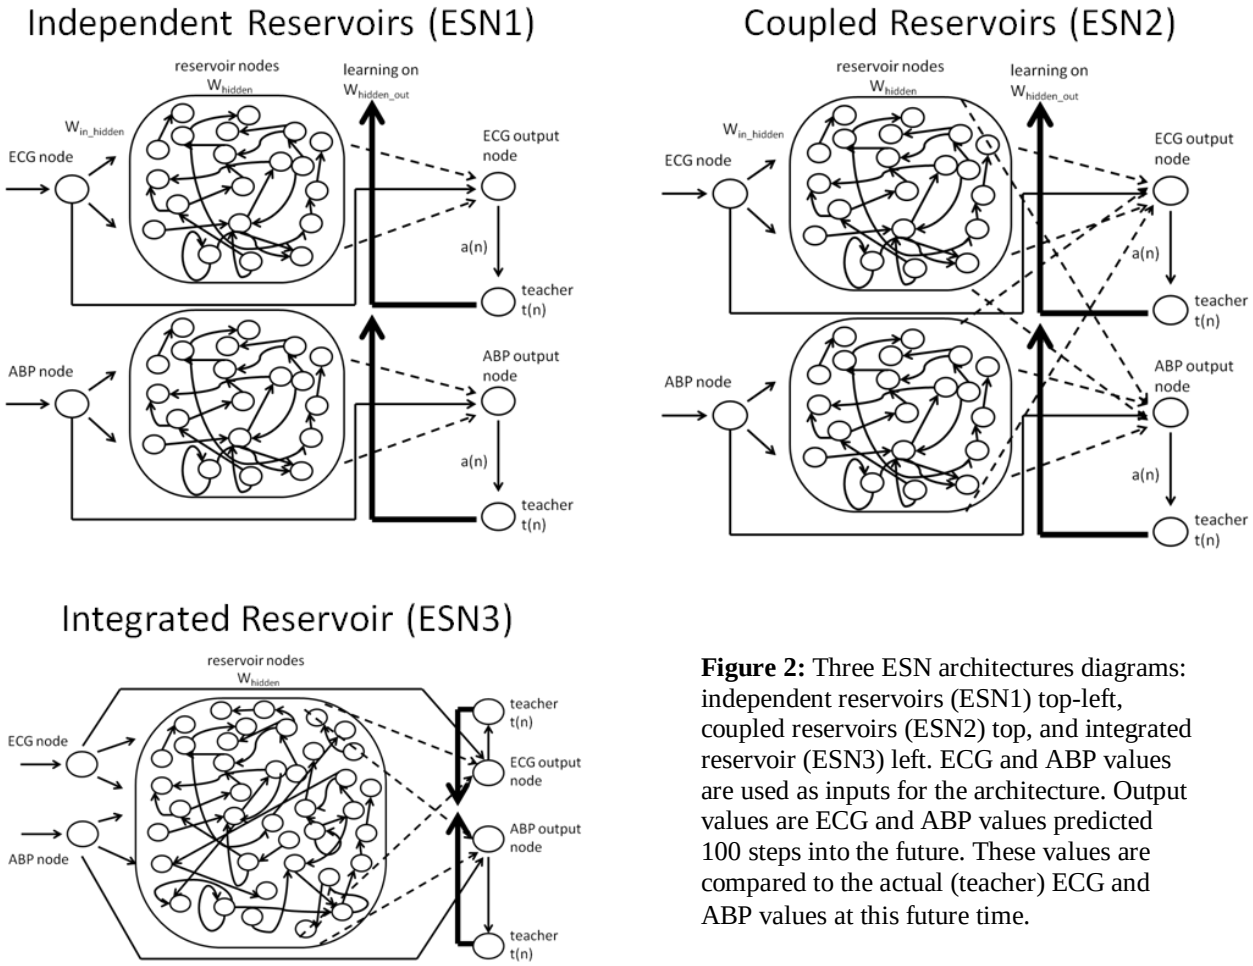

Figure 2: Three ESN architectures diagrams: independent reservoirs (ESN1) top-left, coupled reservoirs (ESN2) top, and integrated reservoir (ESN3) left. ECG and ABP values are used as inputs for the architecture. Output values are ECG and ABP values predicted 100 steps into the future. These values are compared to the actual (teacher) ECG and ABP values at this future time.

The third architecture consisted of one large integrated reservoir network (ESN3) with two input and two output nodes. This architecture was chosen to investigate how single reservoir systems compared to multiple reservoir systems when predicting multiple related waveforms. It was interesting to test if initializing and training one reservoir with two related waveforms could lead to better performance. To be consistent with the independent and coupled reservoirs, both the inputs and outputs were fully connected to the hidden nodes but inputs were only connected to their corresponding output waveform node. The other network parameters, such as spectral radius, W_{hidden}, sparsity, were the same with the independent and coupled reservoirs architectures. This ensured that the analysis would primarily focus on differences resulting from the network architecture. The integrated reservoir network was initialized with both waveforms, and similar to coupled reservoirs architecture, the fully connected

weights from the hidden to each output node were different and were trained based on the error associated with their corresponding predicted waveforms.

3.3.1 Determining Model Parameters

Experiments were first completed to identify some useful ESN parameter ranges for the ECG and ABP waveform data, especially reservoir sizes and learning rates. Identifying which parameters to set and the ranges of interest made the comparisons of different ESN architectures more appropriate. Two separate ESNs with similar architectures to the ESN mentioned above were used to predict ECG and ABP waveforms 100 time-steps into the future. These models were evaluated on MSE and maximum prediction error (max error). Different combinations of reservoir sizes and learning rates were tried because of their influence on how the waveforms were represented, decomposed, and learned by the system.

3.3.2 Methods for evaluation

The performance of these three architectures was assessed on MSE and the maximum prediction error (max error) between the performance and the actual waveform for both ECG and ABP data. A 10,000 time-step sample from patient record a41278 was used for this analysis. The data was divided into initializing (1-5,000), training (5,001-8,000), and testing segments (8,001-10,000). Initialization, training, and testing with all the networks followed the sample protocol. The Kolmogorov-Smirnov (KS) test was used to assess both the ECG and ABP MSE results for normality. This test is necessary to determine which statistical tests would be appropriate to use. Assuming normality, the ECG and ABP MSE and max error would be evaluated using one-way analysis of variance (ANOVA). This was used to determine if there were statistically significant differences between the ECG and ABP MSE and max error for the different architecture types (ESN1, ESN2, ESN3-900, ESN3-800, ESN3-700). Lastly, randomly sampled data from five individuals (a41325, a40416, a40076, a40432, and a41563) were used to evaluate the consistency and performance of the largest integrated reservoir network (ESN3-900).

4. Results

4.1 Model Parameters

To determine useful learning rates and reservoir sizes for the ESNs, a cursory assessment was first completed with the ECG data, varying the number of hidden nodes (100, 500, 750, and 1000) and the learning rates (0.01, 0.001, and 0.0001). The data was divided into initializing (1-5,000 time-steps), training (5,001-8,000 time-steps), and testing segments (8,001-10,000 time-steps). The data was tested 10 times for each combination. As shown in Table 1, reservoirs with nodes ranging between 100 and 750 and learning rates ranging from 0.001 and 0.0001 had on average better performance, prompting additional investigation as follows.

Table 1: ECG MSE test results (standard deviations)

MSE test	100	500	750	1000
0.01	3.78e42 (6.55e42)	7.83e7 (1.26e8)	4.1e13 (7.1e13)	4.6e76 (8.0e76)
0.001	0.026 (0.023)	18.39 (31.07)	1.42 (2.32)	1.6e6 (2.7e6)
0.0001	0.013 (0.0018)	0.02 (0.0029)	0.043 (0.031)	0.11 (0.14)

Reservoir size and learning rate ranges were further investigated with higher fidelity. The network ran ten more times with randomly initialized weights with new combinations of reservoir sizes (100, 200, 300, 400, 500, 600, and 700) and learning rates (0.001, 0.0005, and 0.0001). The results suggested that learning rates of 0.0001 and reservoir sizes of 500 or less than 300 tended to have better performance. A learning rate of 0.0001 and a reservoir size of 500 were used for the ECG components of the test ESN architectures. A reservoir size of 500 was chosen because it had slightly less variability in the results compared to sizes of 300 nodes or less. A similar analysis, conducted using ABP data, suggested a learning rate of 0.0001 and a reservoir size of 400 for the ABP components of the test ESN architectures. As a result, ESN1 and ESN2 both had two separate reservoirs with 500 and 400 nodes for the ECG and ABP waveforms respectively. Furthermore, we investigated the ESN3 architecture with three different reservoir sizes (700, 800, and 900 nodes) because a single reservoir system can perform differently based on its size.

4.2 Evaluating ESN Architecture Designs

The five ESN models were run thirty times with randomly initialized weights. Figures 3 and 4 show data from a training and testing run of ESN1 (independent reservoirs). The networks were evaluated on their prediction/test MSE and the maximum error values for both ECG and ABP waveforms. We found that the ESN architectures were able to predict ECG and ABP waveforms with varying levels of accuracy. We summarize the MSE results from both the ECG and ABP predictions in Figures 5 and 6 respectively. Outliers (results greater than three standard deviations from the mean) were most likely caused by poor randomly initialized weights and were removed, approximately five in each factor level, for the remainder of the analysis.

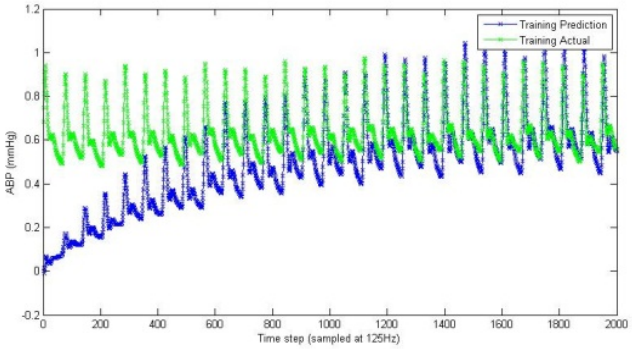

Figure 3: Sample ABP training run

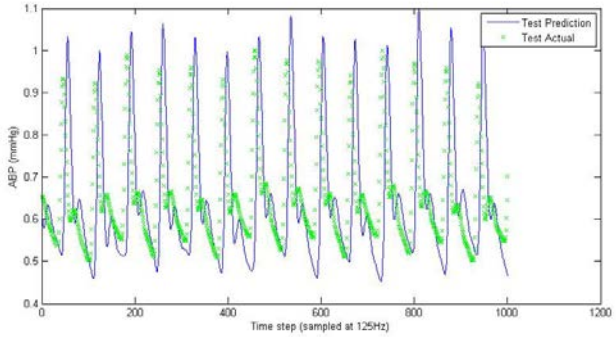

Figure 4: Sample ABP test prediction

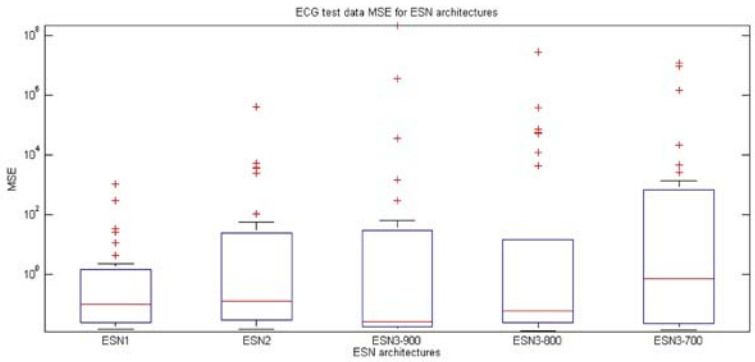

Figure 5: ECG MSE results for the different ESN architectures

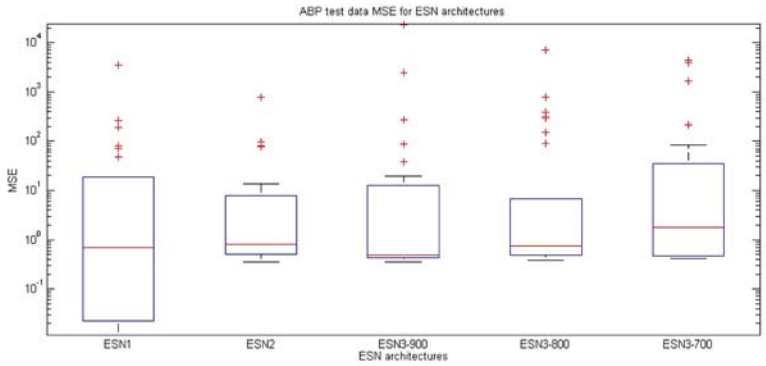

Figure 6: ABP MSE results for the different ESN architectures

Although the KS values for the ECG and ABP distributions were 0.5 and 0.53 respectively, parametric statistical tests could still be applicable considering the sample size. One-way ANOVAs were used to evaluate the MSE and max error of the predictions, Table 2. The factor levels were the different architectures (ESN1, ESN2, ESN3-900, ESN3-800, and ESN3-700).

Table 2: ANOVA results when evaluating ECG and ABP predictions using MSE and max error metrics

F-value (p-value)	ECG	ABP
MSE	1.48 (0.21)	1.19 (0.32)
Max Error	1.65 (0.17)	2.22 (0.071)

The results from the ABP max error analysis tended to be more meaningful (p-value = 0.071) compared to other metrics. The ABP max error results were mostly driven by the poor performance from ESN3-800 and ESN3-700 (integrated reservoir) as shown in Figure 7. We also noted that ESN3-900 (the largest integrated reservoir) tended to predict ECG waveforms slightly better than the independent and coupled reservoirs, Figure 7. However, ESN3's performance decreased with less hidden nodes. This may be due to the inability of the reservoir to correctly learn the two waveforms. In general, the independent reservoirs gave a much better prediction for the ABP waveform, although ESN3-900 had comparable performance in terms of ABP max error predictions. These results showed that there was no significant difference in the architectures at predicting two related waveforms together. There may also be increases in performance when combining waveforms in a single reservoir that is approximately similar in size to the ESN1 and ESN2. This showed the potential benefits of combining reservoirs to predict different but related waveforms.

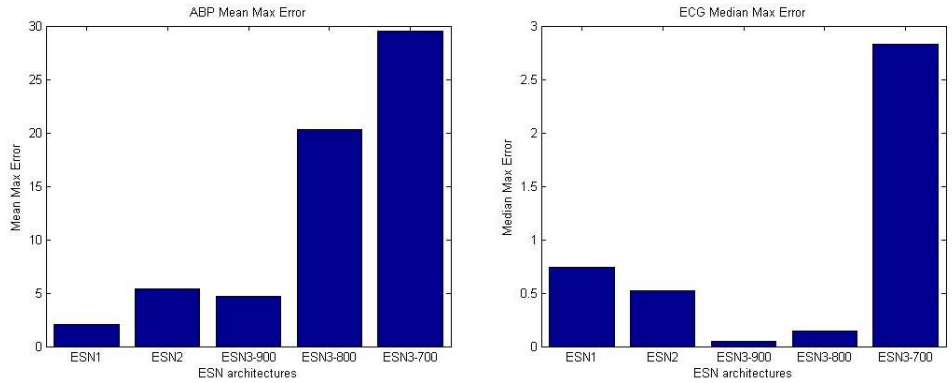

Figure 7: ABP mean max error (left) and ECG median max error (right).

4.3 Evaluating Across Individuals

Lastly, ESN3-900 (the largest integrated reservoir) was tested and compared using randomly sampled data from five individuals. ESN3-900 was chosen because its performance was similar to the basic independent reservoir architecture and it was faster to implement. The results showed that the ECG and ABP, Figure 8, performance across subjects were fairly similar, with the exception of patient 3. Though further work is needed, these results suggest that this architecture may be robust enough to be applied to different patients with little customization.

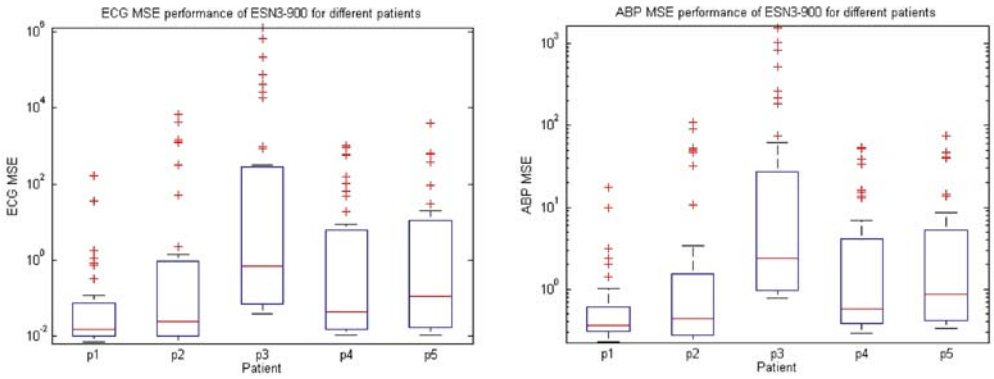

Figure 8: ECG MSE and ABP MSE results (left and right respectively) from five randomly selected patients

5. Discussion

The ability to predict and classify the ECG and ABP waveforms of patients is extremely important for the medical staff in Intensive Care Units. This paper approached this problem by demonstrating the effectiveness of different ESN architectures at predicting ECG and ABP waveforms. Although there was little significant difference in performance when predicting ECG and ABP waveforms between the different architectures, our results suggest that integrated reservoirs tended to have slightly better performance, especially when predicting the ECG waveform. Integrated reservoirs were also tested with different individuals with comparable results.

The ESN architectures in general tended to have much better performance at predicting ECG compared to ABP. This might be because the ECG waveforms have higher frequencies than the ABP waveforms. The loosely coupled subsystems in the reservoir might resonate or echo better at higher frequencies compared to lower frequencies. Furthermore, the ability of one larger reservoir to predict the waveforms was dramatically reduced as the size of the reservoir decreased. As the reservoir size decreased, the performance degradation was much more apparent with ABP then with ECG. This might also suggest that any coupling of ECG and ABP waveforms is biased toward the faster waveforms. This is an area that will require further investigation.

Furthermore, analysis of the largest integrated reservoir with five different individuals showed that this network architecture could be adaptable to different subjects. Without changing the parameters of the model, the largest integrated reservoir resulted in similar performance for four of the five randomly selected patients. Having a model that can be applied to different patients with little or no tailoring is attractive, and could be very beneficial in developing a predictive system for hospitals.

Although this research was exploratory, it does highlight some potential advantages of having one large reservoir for learning and predicting two related waveforms. The performance of the largest integrated reservoir was comparable to independent and coupled reservoirs, and was easier to implement. This analysis hints at interactions between how these waveforms are learned and stored in the reservoir. This could be investigated further and in more detail, perhaps starting with simpler, less chaotic waveforms. There are many questions to ask: for example, could initializing two reservoirs separately and then combining and reinitializing them lead to more robust internal subsystems in the reservoir? These and other queries can help further the understanding of Echo State Networks and make them more applicable for bioengineering and other applications.

There are limitations associated with this exploratory work, primarily concerning the limited predictive time-steps and the number of unique patients tested. This work aimed at exploring the application of ESNs for ECG and ABP waveforms. Although, these waveform predictions were limited to 100 time-steps, which may be too small to clinically trigger alarms, this work demonstrated the utility of this approach and could be refined in future work. It

would also be helpful to try different combinations of waveforms (not just the ECG II and ABP waveforms) and evaluate the models with more data from different patients. Furthermore, the parameters for each network (besides the learning rates and reservoir sizes) could be optimized. This would greatly increase the number of factors to control for, but a detailed factor level analysis of the network parameters would be very insightful. Expanding these models to predict higher level alarm states would be helpful. In addition, data transformations of the results might provide more normalized data. However, more research is needed to understand what these transformations mean intuitively for the results before applied.

A model that can predict ECG and ABP waveforms can naturally be extended to classify other waveforms and predict alarms. A model that can forecast the accuracy of ECG alarms or classify false alarms based on predicted waveforms might be extremely beneficial to medical staff, especially those in the ICU. There are several types of alarms in the ICU, each with unique waveform patterns, and this work can be extended to investigate the differences between predicted waveforms during a false alarm and a true alarm. Models that can extrapolate what a patient's waveforms will be like even a few seconds after an alarm can help medical staff and hospital systems better understand and classify alarms, with the ultimate goal of reducing false alarms, alarm fatigue, and improving patient care.

6. Conclusion

Alarm fatigue caused by bedside machines is a serious issue in Intensive Care Units. Part of this problem is the inability of these machines to accurately predict and classify a patient's ECG and ABP waveforms. In this study, we explored and demonstrated the ability of different Echo State Network architectures for predicting ECG and ABP waveforms with varying levels of accuracy. The most accurate predictions were generally by the largest integrated reservoir and the independent reservoirs architectures, which often had comparable results. Furthermore, results showed potential benefits for applying large integrated ESN reservoirs for different individuals. This paper also discussed limitations of this research, as well as suggestions for future work, and in particular the investigation of one versus two reservoir interactions and applications for predictive alarm classifications.

Evaluation of RxNorm for Medication Clinical Decision Support

Robert R. Freimuth, PhD[1,2], Kelly Wix[3], PharmD, RPh, Qian Zhu, PhD[1], Mark Siska, RPh[3], Christopher G. Chute, MD, DrPH[1]

Abstract

We evaluated the potential use of RxNorm to provide standardized representations of generic drug name and route of administration to facilitate management of drug lists for clinical decision support (CDS) rules. We found a clear representation of generic drug name but not route of administration. We identified several issues related to data quality, including erroneous or missing defined relationships, and the use of different concept hierarchies to represent the same drug. More importantly, we found extensive semantic precoordination of orthogonal concepts related to route and dose form, which would complicate the use of RxNorm for drug-based CDS. This study demonstrated that while RxNorm is a valuable resource for the standardization of medications used in clinical practice, additional work is required to enhance the terminology so that it can support expanded use cases, such as managing drug lists for CDS.

Introduction

Clinical decision support systems (CDSS) have emerged as an essential component of clinical information systems and electronic medical records (EMRs). Not only do CDSS serve a variety of functions to assist clinicians provide better care and prevent adverse events, but also they are required to meet regulatory requirements including the Meaningful Use measures of the American Recovery and Reinvestment Act (1). A number of health care organizations have described positive outcomes associated with deploying CDSSs and have leveraged their capabilities as a strategic tool for attaining institutional quality and safety improvement goals and objectives (2-4). Despite the growing advantages associated with CDSS, however, significant challenges impede its widespread adoption and the development of even more sophisticated computerized alerts and types of CDSSs (5). Sittig et al. identified ten grand challenges associated with CDSSs, which included improving the user interface to streamline clinical workflow and disseminating best practices for CDS design, development, and implementation (6). Fine-tuning CDS rules to deliver the most useful information at the appropriate time without causing alert fatigue remains a significant challenge, particularly when medications are involved (7).

One of the primary challenges related to the implementation of a robust, scalable CDSS for medications is the development of a comprehensive knowledge base that effectively accommodates maintenance and interoperability, supports rigorous data quality management principles, and enables the development of "free form" rules that are EMR-agnostic and accessible to ancillary medication management and supporting systems (8). In an effort to more effectively manage our medication-related CDS rules, including those related to pharmacogenomics, across the diverse systems within the Mayo Clinic enterprise we sought to adopt a standard, vendor-neutral drug terminology that would support interoperability and allow us to manage a single drug list for each CDS rule that is implemented. This manuscript describes our evaluation of RxNorm to better understand its capabilities and limitations in the context of a prototypic use case: the management of the drug list for an existing, active CDS rule.

Motivating Use Case: CDS Rule for Deep Vein Thrombosis (DVT) Prophylaxis

The following scenario illustrates a motivating use case for this study. To minimize the maintenance of drug-based CDS rules as formularies change, medications are referenced by generic drug name. To minimize alert fatigue and improve the specificity of the rules, the route of administration is used as an additional criterion for the rule trigger.

A CDS rule was developed to ensure that hospitalized inpatients receive deep vein thrombosis (DVT) prophylaxis. Providers receive a pop-up alert in the ordering system if no DVT prophylaxis was ordered.

The rule scans the active order list to determine if an order for heparin exists, using an RxNorm identifier (RxCUI) for heparin injectable solution. Testing reveals the rule is not identifying some orders for heparin subcutaneous injection. After detailed review of the data, it is determined that the RxCUI used for heparin injectable solution is not used for heparin in a prefilled syringe.

In this example, a logical assumption was made that all products that were injectable solutions for a given drug would have that corresponding defined relationship. In reality, drugs that were available in prefilled syringes were assigned a different relationship than those that were not in prefilled syringes. Regardless of the reason for this difference, this example emphasizes the necessity of knowing the intricacies and limitations of the data source, especially when used for clinical applications.

Background

RxNorm is a standard terminology developed by the National Library of Medicine (NLM) that provides normalized names for clinical drugs (9). It is intended to be used to facilitate the exchange of medication-related information among clinical systems and it is part of the federal Meaningful Use standard. RxTerms is a drug interface terminology that is derived from RxNorm, intended to facilitate medication order entry. It contains a pruned set of drugs from RxNorm that are anticipated to be most useful in a prescribing environment (10).

The Veterans Affairs National Drug File Reference Terminology (NDF-RT) is developed by the Department of Veterans Affairs (VA) Veterans Health Administration (11). The NDF-RT contains information about drug characteristics, including ingredient(s) and dose form. Concepts in the NDF-RT are organized into taxonomies, which represent generalization relationships between concepts hierarchically. As of June 2010, the NDF-RT has been integrated into RxNorm.

The RxNorm and NDF-RT terminologies have been used extensively for the normalization of drug data (12-15). Many of these efforts focused on developing methods for mapping terms from local drug coding systems to the reference terminologies and assessing the overall coverage of content. In contrast, in this study we evaluated the ability of RxNorm, with associated data from relationships to NDF-RT and RxTerms, to provide standardized representations of drug name and route of administration to facilitate management of drug lists for CDS rules.

Materials and Methods

Data Sources

The RxNorm full monthly release dated February 3, 2014 was downloaded from the NLM Unified Medical Language System (UMLS) web site (16). The RxTerms data files, version 201401, were also downloaded (17). The RxNorm and RxTerms data were loaded into a local MySQL database using a custom version of the loader scripts that were provided. The "rxnconso" and "rxnrel" tables were cloned and populated with subsets of the original data from the respective tables to facilitate complex queries that required multiple joins across these tables.

Terms from the NDF-RT "Dose Forms" (NUI N0000010010) hierarchy that had the NDFRT_KIND property of "DOSE_FORM_KIND" were downloaded via the NLM NDF-RT REST API using http://rxnav.nlm.nih.gov/REST/Ndfrt/allconcepts?kind=DOSE_FORM_KIND. The NDF-RT unique identifier (NUI) was extracted for each term. Since the term "Dose Forms" contains two child hierarchies, "Drug Delivery Device" (NUI N0000177905) and "Orderable Drug Form" (NUI N0000135762), the BioPortal web interface (18, 19) was used to browse the NDF-RT terminology and determine the branch to which each dose form term belonged. The concept terms, codes, and hierarchical branch name were loaded into a custom table in the local database.

Identification of Clinical Drugs and Related Attributes

To evaluate RxNorm for our motivating use case, we needed to identify the term types (TTY) that corresponded to generic drug name and route of administration. The RxNorm technical documentation was used to determine which entities and relationships were most pertinent to this study (20, 21). We chose the Semantic Clinical Drug (SCD) to represent orderable drugs using generic drug name(s). The SCD also contains strength and dose form. The local RxNorm database was queried for all SCDs (TTY = "SCD") that did not have a "suppress" attribute of "O", "Y", or "E". This list of drugs was used as the starting point for evaluation.

By browsing the RxNorm data using the RxNav user interface (22), several attributes were found to contain information related to route of administration: "Dose Form" and "Dose Form Group" from RxNorm; "rxn_dose_form", "new_dose_form", and "route" from RxTerms; and "Dose Form" from NDF-RT (**Figure 1**). The NLM was contacted to clarify the relationship between these attributes. RxNorm Dose Form was originally based on HL7 vocabulary group dose forms. RxNorm Dose Form was equivalent to RxTerms rxn_dose_form, which was used to derive RxTerms route and new_dose_form. RxTerms route was used as the basis for RxNorm Dose Form Group. NDF-RT Dose Form was "initialized from RxNorm" but equivalency was not determined. Based on this

information, the attributes RxTerms rxn_dose_form and RxNorm Dose Form Group were omitted from the analysis but the other attributes were retained and used for comparison.

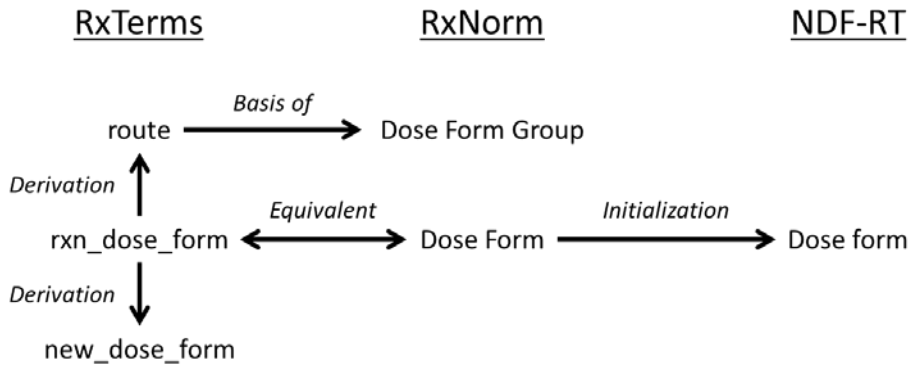

Figure 1: Attributes containing route of administration. The figure shows the attributes from each of the three data sources that were found to contain information related to route of administration, as well as the relationship between those terms.

Extraction and Evaluation of Defined Relationships

Instances of RxNorm Dose Form (TTY = "DF", source abbreviation (SAB) = "RXNORM") were obtained for each SCD using the RxCUI of the SCD and the relationship (RELA) "has_dose_form" (**Figure 2**). Terms for RxTerms route and new_dose_form were extracted directly from the RxTerms data using the RxCUI of the SCD. Terms for NDF-RT Dose Form (TTY = "PT", SAB = "NDFRT") were obtained for each SCD using the RxCUI of the SCD and the relationship (RELA) "dose_form_of". The resulting data set from each source was checked for missing or multiple terms for each SCD. All related terms were stored in new tables in the database to simplify subsequent analysis and exported to a spreadsheet for manual review of inter-source semantic consistency.

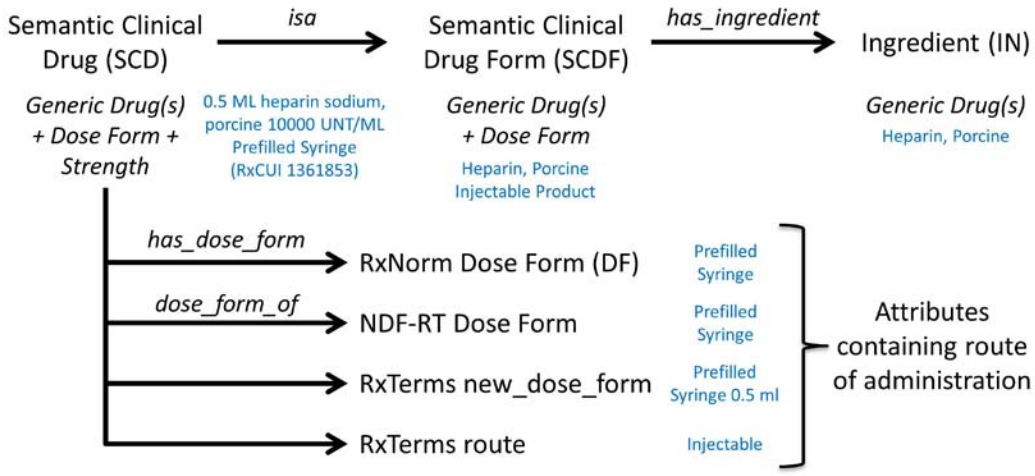

Figure 2: Drug entities, attributes, and relationships. The figure shows the entities, attributes, and relationships that are relevant to this study. Terms corresponding to the heparin use case are shown in blue text, as examples.

The Semantic Clinical Drug Form (SCDF) was used to compare dose forms for a given set of ingredients. The SCDFs (TTY = "SCDF"; "suppress" attribute not "O", "Y", or "E") associated to each SCD were obtained using the RxCUI of the SCD and the relationship (RELA) "isa". Ingredients (TTY = "IN", SAB = "RXNORM") for each

SCDF were obtained using the relationship (RELA) "has_ingredient". An ordered, concatenated form of ingredients was created for each SCD. Similarly, an ordered, concatenated list of dose forms was generated for each concatenated ingredient.

Results

Identification of Clinical Drugs and Related Attributes

The SCD contains generic drug name(s), strength, and dose form, and as such it serves as a convenient entity in RxNorm to which orderable drugs can be mapped. We found 20,268 SCDs in RxNorm, which were used as the starting point for the subsequent evaluation.

The authoring and maintenance of drug lists for CDS rules is most efficiently performed using the ingredient generic name and route of administration; therefore, it was necessary to obtain these attributes for each SCD. Generic ingredients were clearly represented within the RxNorm data model (TTY = "IN") but information about the route of administration was found in several entities (**Figure 1**). Two of these were eliminated from further consideration. Specifically, RxTerms rxn_dose_form was found to be redundant with RxNorm Dose Form, and was excluded from further analysis. Similarly, RxNorm Dose Form Group was defined as "a term type that serves as a grouping of dose forms (TTY=DF) related by route of administration (i.e., Topical) or dose form (i.e., Pill)" (23) and was also excluded since it was a less primitive concept than its source concepts, which were already included in the analysis.

Extraction and Evaluation of Defined Relationships

The RxNorm Dose Form was identified for each SCD in the data set. A total of 20,268 Dose Form terms were found, one for each SCD. No SCD had more than one RxNorm Dose Form and no SCDs were missing a related Dose Form. There were 104 different terms represented; the most frequently used terms are shown in **Table 1**.

RxCUI	Dose Form	Frequency
317541	Oral Tablet	4223 (20.8%)
316949	Injectable Solution	4215 (20.8%)
316965	Oral Capsule	1950 (9.6%)
316968	Oral Solution	1439 (7.1%)
316945	Extended Release Tablet	723 (3.6%)
721656	Prefilled Syringe	594 (2.9%)
316982	Topical Cream	589 (2.9%)

Table 1: RxNorm and NDF-RT Dose Form. The most frequently used terms are listed for RxNorm and NDF-RT Dose Form.

The terms for RxTerms route and new_dose_form were extracted for each SCD. Only 15,077 SCDs had related terms from RxTerms (exactly one route and new_dose_form each); 5191 SCDs (25.6% of the SCDs in the data set) were missing corresponding terms from RxTerms. The most frequently used terms for route and new_dose_form are shown in **Table 2**; a total of 39 and 170 distinct terms were found, respectively.

route	Frequency
Oral Pill	6167 (40.9%)
Injectable	3754 (24.9%)
Topical	1584 (10.5%)
Oral Liquid	1510 (10.0%)
Chewable	305 (2.0%)

new_dose_form	Frequency
Sol	4820 (32.0%)
Tab	3954 (26.2%)
Cap	1667 (11.1%)
Susp	564 (3.7%)
Cream	396 (2.6%)

Table 2: Terms from RxTerms. The most frequently used terms are listed for RxTerms route and new_dose_form.

NDF-RT Dose Form terms were extracted for each SCD. Although we expected at most 20,268 results, 20,417 related terms were found. Further investigation revealed that 55 SCDs were related to two NDF-RT Dose Form terms and 47 SCDs were related to three terms. The 251 terms related to these 102 SCDs were instances of only 7 different terms that represented three distinct concepts: mouthwash, toothpaste, and topical cake (**Table 3**). Specifically, 47 SCDs were related to the NDF-RT orderable drug form "mouthwash", but they were also related to similar terms from two other NDF-RT hierarchies (pharmaceutical preparations and chemical ingredients). Similarly, 54 SCDs were related to the orderable drug form "toothpaste" as well as the chemical ingredient "toothpastes". A single SCD contained relationships to two terms from the orderable drug from hierarchy: the concept "cake" and its child concept "topical cake".

NUI	Concept	Location in NDF-RT Hierarchy
N0000029230	MOUTHWASHES	Pharmaceutical Preparations => Drug Products by VA Class => Dental and Oral Agents, Topical
N0000135733	Mouthwash	Orderable Drug Form => Liquid => Solution => Oral Solution
N0000011404	Mouthwashes	Chemical Ingredients => Biomedical and Dental Materials
N0000135791	Toothpaste	Orderable Drug Form => Solid => Paste
N0000171562	Toothpastes	Chemical Ingredients => Biomedical and Dental Materials => Dentifrices
N0000135686	Cake	Orderable Drug Form => Solid
N0000184140	Topical Cake	Orderable Drug Form => Solid => Cake

Table 3: Terms for NDF-RT Dose Form. The table lists groups of terms for NDF-RT Dose Form that were related to a single SCD.

All SCDs were related to a single term for Dose Form that was in the orderable drug form hierarchy, except for one SCD that contained relationships to both "cake" and "topical cake". When the extraneous terms from the pharmaceutical preparations and chemical ingredients hierarchies, and the parent concept "cake", were excluded from the query 20,268 results were obtained. Each SCD was found to contain exactly one term for NDF-RT Dose Form. There were 104 different terms represented; the terms and their frequencies were identical to those for RxNorm Dose Form (**Table 1**).

Since each SCD was related to at most one term of each type (RxNorm Dose Form, RxTerms route and new_dose_form, NDF-RT Dose Form), the results of the individual searches were merged into a single table that was indexed by SCD. The semantic consistency of the terms from each data source was reviewed by examining all 296 unique combinations of terms. Only 88 combinations were found to be consistent, which was defined to allow for some semantic precoordination of concepts. In 125 cases the terms from RxTerms were narrower than those from RxNorm and NDF-RT due to the explicit inclusion of route, count, and/or quantity information (**Table 4**). The remaining 83 combinations, corresponding to 5191 SCDs, were missing terms from RxTerms. In all cases, the terms for RxNorm Dose Form and NDF-RT Dose Form were identical.

RxNorm Dose Form	NDF-RT Dose Form	RxTerms route	RxTerms new_dose_form
Dry Powder Inhaler	Dry Powder Inhaler	Inhalant	DPI 60 puff
Extended Release Capsule	Extended Release Capsule	Oral Pill	24 HR XR Cap
Augmented Topical Lotion	Augmented Topical Lotion		
Augmented Topical Lotion	Augmented Topical Lotion	Topical	Lotion (Augmented)
Buccal Tablet	Buccal Tablet		
Buccal Tablet	Buccal Tablet	Buccal	Tab
Medicated Shampoo	Medicated Shampoo		
Medicated Shampoo	Medicated Shampoo	Shampoo	Medicated Shampoo

Table 4: Examples of semantic consistency among terms. The first two rows illustrate the inclusion of qualifiers (e.g., "60 puff", "24 HR") in the terms from RxTerms that are not present in those from RxNorm or NDF-RT. The remaining rows show pairs of term combinations that contain identical values for RxNorm and NDF-RT but differ overall because one of the entries is missing terms from RxTerms.

Of the 83 combinations that lacked terms from RxTerms, 76 were found to have an equivalent entry based on RxNorm and NDF-RT values that also contained terms from RxTerms (**Table 4**). These 76 instances corresponded to 5065 SCDs, which accounted for 97.6% of SCDs that were missing terms from RxTerms and 25.0% of all SCDs in this data set. For the remaining 7 combinations, which corresponded to 126 SCDs, a corresponding entry either was not found or could not be assigned due to ambiguity as a result of the semantic precoordination of route, count, or quantity (**Table 5**).

# SCDs	RxNorm Dose Form	NDF-RT Dose Form	RxTerms route	RxTerms new_dose_form
1	Crystals	Crystals		
2	Metered Dose Inhaler	Metered Dose Inhaler		
1	Ophthalmic Cream	Ophthalmic Cream		
1	Otic Ointment	Otic Ointment		
13	Prefilled Applicator	Prefilled Applicator		
107	Prefilled Syringe	Prefilled Syringe		
1	Rectal Solution	Rectal Solution		

Table 5: Missing terms from RxTerms. Term combinations that were missing terms from RxTerms. These combinations did not have an unambiguous corresponding entry that could be used to obtain these terms.

To evaluate the consistency of related terms at the drug level, generic ingredients (IN) were obtained for each SCD. Since there was no direct relationship between SCD and IN, the SCDF was used as an intermediate step. The SCDF, which contain generic drug name(s) and dose form but not strength (**Figure 2**), was obtained for each SCD. Each SCD had exactly one SCDF; 8717 distinct SCDFs were retrieved. The majority of SCDFs (4763, 54.6%) were utilized by a single SCD, which indicated that only one strength was available for the drug in the specified dose form (**Figure 3**). Another 1705 (19.6%) SCDFs were used by two SCDs.

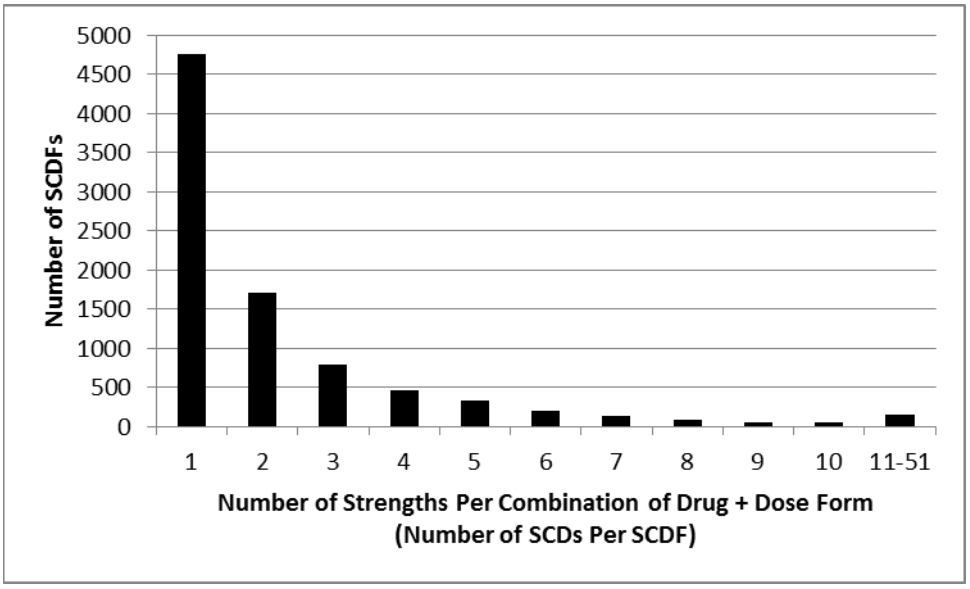

Figure 3: Relationship between SCDs and SCDFs. Most combinations of drug + dose form were mapped to a single SCDF but a small proportion of SCDFs represented many SCDs, indicating a large number of strengths available for the given combination of drug and dose form.

On the other end of the spectrum, 158 (1.8%) SCDFs were used by more than 10 SCDs each. The top 25 SCDFs (0.3%) were utilized by more than 20 SCDs each, representing 698 SCDs in total. The three most highly utilized SCDFs were "Menthol Lozenge" (RxCUI 374544), "Amylases / Endopeptidases / Lipase Enteric Coated Capsule" (RxCUI 402754), and "Guaifenesin / Phenylephrine Extended Release Tablet" (RxCUI 373391). The "menthol lozenge" SCDF was used by 51 SCDs that had strengths ranging from 1 mg to 18 mg. The "amylases/endopeptidases/lipase enteric coated capsule" SCDF was used by 45 SCDs that had varying combinations of strengths of the three ingredients. The "guaifenesin/phenylephrine extended release tablet" SCDF was used by 44 SCDs, distinguished not only by varying combinations of the two ingredients but also by different uses of the qualifier "12 HR". In fact, 24 of the 44 SCDs in this SCDF were identical pairs of drugs with the same strengths and dose form, but one specified "12 HR" and the other did not.

An ordered, concatenated list of ingredients was developed for each SCD. This list contained 8717 unique combinations of concatenated ingredients and dose form, which was expected based on the number of SCDFs. The list was grouped by ingredient(s) and the NDF-RT dose forms within each group were identified. Examples of the results are shown in **Table 6**. A total of 5021 unique combinations of ingredients were found.

Ingredient(s)	NDF-RT Dose Form(s)	NDF-RT Dose Form Type(s)
1-octacosanol	Oral Capsule	Orderable Drug Form
4-Aminobenzoate	Oral Capsule + Oral Tablet	Orderable Drug Form
4-Aminobenzoic Acid + Arginine	Topical Cream	Orderable Drug Form
Acetaminophen + Aspirin	Oral Powder + Oral Tablet	Orderable Drug Form
aclidinium	Dry Powder Inhaler	Drug Delivery Device
adalimumab	Injectable Solution + Prefilled Syringe	Drug Delivery Device + Orderable Drug Form

Table 6: NDF-RT Dose Forms, by Drug. The table lists examples of ingredient combinations and their respective related terms from NDF-RT Dose Form.

The type ("Drug Delivery Device" and/or "Orderable Drug Form") of dose form(s) available for each combination of ingredients was determined based on the NDF-RT hierarchy. The majority of ingredients (4702, 93.6% of the 5021 combinations) were related to one or more concepts from Orderable Drug Form only; these represented 15,776 SCDs. There were 47 (0.9%) ingredients representing 81 SCDs that were related to one or more concepts from Drug Delivery Device only. Interestingly, 272 (5.4%) ingredients were related to one or more concepts from both hierarchies, indicating inconsistency in how terms for dose form were related to a given drug. These cases represented 4411 SCDs, or 21.8% of the SCDs in this data set. Examples of drugs that were related to concepts from both hierarchies are shown in **Table 7**.

Ingredient(s)	NDF-RT Orderable Drug Form(s)	NDF-RT Drug Delivery Device(s)
ciclesonide	Inhalant Solution	Metered Dose Inhaler + Nasal Inhaler
Cromolyn	Inhalant Powder + Inhalant Solution + Nasal Solution + Nasal Spray + Ophthalmic Solution + Oral Capsule + Oral Solution	Metered Dose Inhaler + Nasal Inhaler
fluticasone	Inhalant Powder + Inhalant Solution + Topical Cream + Topical Lotion + Topical Ointment	Dry Powder Inhaler + Metered Dose Inhaler + Nasal Inhaler
heparin, porcine	Injectable Solution	Prefilled Syringe
Leuprolide	Injectable Solution + Injectable Suspension	Drug Implant + Prefilled Syringe

Table 7: NDF-RT Dose Forms, by Type and Drug. The table lists examples of drugs that were related to concepts from both NDF-RT Dose Form hierarchies.

Discussion

In this study we evaluated the potential ability of RxNorm to facilitate management of drug lists for CDS rules by providing standardized representations of generic drug name and route of administration. Generic drug name was clearly represented as ingredients. Anecdotal evidence suggested several different term types might contain information related to the route of administration. This study found route data in values of three attributes: RxNorm Dose Form, RxTerms route, and NDF-RT Dose Form. None of the value sets used by those attributes contained only route of administration, however, which presented a challenge when determining which to use to facilitate management of CDS rules.

The documentation for NDF-RT Dose Form indicates that the attribute is "initialized from RxNorm and is periodically resynchronized by computer algorithm" (11), which implies that some divergence may be anticipated over time. Nonetheless, we found this attribute to be identical to RxNorm Dose Form, with the caveat that some SCDs contained relationships to multiple terms from NDF-RT Dose Form. All but one of those related terms were outside the Dose Form hierarchy with similar spellings as the corresponding Dose Form term. This could suggest that those terms may have been introduced in error, a risk we recognized previously (24), and subsequently escaped the resynchronization process. The NUI codes for these terms are included in **Table 3** so they can be manually excluded from searches, if desired.

We found the content of the four term types was consistent between sources, although there was some variability in the semantic precoordination of concepts used by each attribute. In many cases the RxTerms new_dose_form attribute contained additional qualifiers that were not present in the other attributes, such as those which specified count (e.g., number of puffs for an inhaler), time-release (e.g., 12 HR), or volume (e.g., 1 ml). For example, the RxNorm/NDF-RT Dose Form "Prefilled Syringe" could not be mapped unambiguously to RxTerms new_dose_form, as the latter included a qualifier to indicate the volume of the syringe. In this case, there were 58 different values in RxTerms new_dose_form that map to "Prefilled Syringe", from "Prefilled Syringe 0.09 ml" to "Prefilled Syringe 125 ml". The inclusion of a volume metric within the term for dose form caused a significant expansion of the value set, which could complicate the management and use of these terms for CDS rules.

More than one quarter of the SCDs in the data set were missing relationships to RxTerms. The vast majority of them could be inferred, however, by using the RxTerms terms that were related to other SCDs that have the same value for RxNorm/NDF-RT Dose Form. Relationships for the remaining instances could not be assigned using this method largely due to ambiguity caused by count or volume qualifiers. In particular, most of those SCDs had a Dose Form of "prefilled syringe", which includes a specified volume in RxTerms. Without access to the algorithms used to assign RxTerms relationships, we could not ascertain the reason why so many relationships were missing from this data set. This may be partly due to the fact that RxTerms intentionally omits some drugs to improve query performance (10). Regardless, any query that uses terms from RxTerms as a parameter is likely to return incomplete results, which complicates or even prevents the use of RxTerms for the management of drug lists for CDS rules. We believe it would be better to define relationships for all drugs and allow implementers to filter the data set.

Our initial observations regarding injectable heparin suggested that the same drug could be classified as both an Orderable Drug Form and a Drug Delivery Device, based on the value of Dose Form. This study confirmed that observation and demonstrated that while this phenomenon affected a relatively small proportion of ingredients, those ingredients comprised nearly 22% of the SCDs in this data set. We were not able to find any documentation that describes the process by which relationships are assigned. Without a clear understanding of this process it would be difficult to confidently use those relationships for the management of drug lists used in CDS rules.

Finally, we observed extensive semantic precoordination of orthogonal concepts within the value sets used for each of the attributes in this study (RxNorm/NDF-RT Dose Form, RxTerms route, RxTerms new_dose_form). **Table 1** and **Table 2** illustrate terms that contain concepts for dose form, route, and/or drug delivery device, such as "oral tablet" and "topical cream". This precoordination complicates the computational use of these terms for managing drug lists and makes it difficult to use those terms appropriately.

Although RxNorm is intended to "assist with medication-related clinical decision support" (9), it was primarily developed as a standard for data exchange and semantic interoperability so it is not surprising that the data model may be more suited to this use case. In particular, the current structure and content for representing route of administration and dose form is not optimal for CDS. This is not unexpected, however, as the content and organization of biomedical ontologies may enable them to meet some use cases better than others (15, 25). As

RxNorm is adopted more widely it is likely that additional use cases will arise that will require extensions to the terminology.

Limitations

The limitations of this study include restrictions due to its scope. Specifically, we limited our evaluation to attributes that pertained to drug name and route of administration, and omitted analysis of RxNorm Dose Form Group (DFG) and Semantic Clinical Drug Form Group (SCDG). While it is possible these elements may be relevant to our use case, they are computational derivations of the attributes that were already included in the study. Similarly, we explored the hierarchy of NDF-RT Dose Form while evaluating semantic consistency but we did not investigate other classification schemes from that terminology. In particular, drug class would be relevant to drug-based CDS; this topic has been explored previously (24, 26, 27).

Finally, we intentionally scoped this evaluation to RxNorm, as it is a nationally-recognized standard that meets Meaningful Use requirements. Other terminologies with cross-references to RxNorm content might address some of the issues that were identified in this study. For example, the Drug Ontology (DrOn) is derived in part from RxNorm and follows formal ontological principles (28). It may be possible to extend RxNorm with data from other ontologies to meet the needs of our use case.

Conclusions

In this study we evaluated the potential ability of RxNorm to facilitate management of drug lists for CDS rules by providing standardized representations of generic drug name and route of administration. Generic drug names were clearly represented as ingredients. It was more difficult to find a robust representation for route of administration, however, and we explored several attributes to determine which might be most appropriate for our use case. None of those attributes provided an ideal, semantically "pure" form of route of administration.

In the course of these investigations we discovered several issues related to data quality, including erroneous or missing defined relationships, and the use of different concept hierarchies to represent the same drug. We also identified examples where the use of qualifier terms and the semantic precoordination of orthogonal concepts would complicate the use of the data.

This study demonstrates that while RxNorm is a valuable resource for the standardization of medications used in clinical practice, additional work is required to enhance the terminology so that it can support expanded use cases, such as managing drug lists for CDS. We encourage the NLM, content developers of drug knowledge bases, and the scientific community to continue to evaluate and collaboratively extend RxNorm for a variety of clinical uses.

Acknowledgements

This work was supported by the NIH/NIGMS (U19 GM61388; the Pharmacogenomics Research Network) and the Mayo Clinic Office of Information and Knowledge Management. The authors would like to thank the NLM staff that support RxNorm for providing critical clarifications regarding the content and relationships represented in the data set.

Abstract

Small numbers of patients are a special challenge for rare diseases research. Electronic health record (EHR) data can facilitate research if patients with rare diseases can be reliably identified. We estimate the coverage of the names of a set of 6,519 rare diseases. Using the UMLS, 697 (11%) diseases were matched to ICD-9-CM, 1,386 (21%) to ICD-10-CM and 2,848 (44%) to SNOMED CT. Using published mappings from SNOMED CT to ICD, we further estimate additional broader matches of 2,569 (39%) rare diseases to ICD-9-CM and 1,635 (25%) to ICD-10-CM. The number of codes that match one and only one disease are 1,081 (62%) for ICD-9-CM, 1,403 (73%) for ICD-10-CM, and 3,311 (85%) for SNOMED CT. Our findings confirm that SNOMED CT has the greatest coverage and specificity needed to identify patients with a rare disease from EHR-data, and can facilitate research and evidence-based care.

Introduction

Rare diseases are defined in the US as conditions that affect less than 200,000 Americans and in the European Union as those with a prevalence of 5 per 10,000 or less. They are largely, but not exclusively, genetic disorders. Because of the variation in definition, there is no globally authoritative list of rare diseases, but the number of recognized rare diseases is between 6-7,000 diseases.[1-4] Although each condition is uncommon, collectively rare diseases are more common. The National Organization for Rare Disorders estimates that up to 30 million (or 1 in 10) Americans are affected by a rare disease.[3] Consequently, rare diseases have emerged as priority research topics in both the US and the EU. Advances in genetic testing and the emergence of personalized medicine increase the number of subtypes of common diseases, further motivating development of research methods for rare diseases.

To identify sufficient numbers of rare diseases patients for research, multiple clinical sites and countries are often required and electronic health record (EHR) data can facilitate the identification of rare disease patients across multiple sites. Phenotype definitions that leverage widely adopted administrative terminologies (such as ICD-9-CM and ICD-10-CM) can potentially enable the consistent identification of patients with rare diseases from different providers and organizations. Our collective national capacity for rare diseases research, therefore, depends upon adequate coverage of rare diseases in these administrative terminologies. On the other hand, according to the "meaningful use" incentive program for the use of EHRs, clinical terminologies (such as SNOMED CT) are required for the encoding of clinical information in the EHR.[5] The encoded clinical information will in turn drive the EHR-embedded information and decision support (e.g., InfoButtons[6], clinical practice guidelines) and consumer health information (e.g., MedlinePlus Connect) functionalities. To comprehend the national capacity for rare diseases research, EHR-enabled clinical decision support and patient education, we estimate the coverage of rare diseases in ICD-9-CM, ICD-10-CM, and SNOMED CT for a set of 6,519 rare diseases, and explore the granularity of rare disease terms in these terminologies. We examine in detail the matches found for a set of rare diseases that are being studied in the national Patient Centered Outcomes Research network (PCORnet), recently established this year to create a national infrastructure for observational and clinical research in diverse and distributed healthcare organizations. [7]

Background

Rare diseases have become an increasingly important topic in health care research and policy contexts. Rare diseases are explicitly represented in important federally-funded research initiatives, such as the Rare Diseases Clinical Research Network[8] and the Clinical and Translational Science Awards (CTSA) program. Despite differences in

disease etiology and affected populations, there are common logistical challenges for research that can be addressed in part with data standards and informatics expertise and tools.[9-12] Generalizable research methods that address issues specific to rare diseases can impact the investigation of thousands of rare conditions and hundreds of thousands of Americans. With increased adoption and meaningful use of EHRs, there is renewed effort in leveraging EHRs for research. The Patient-Centered Outcomes Research Institute (PCORI) was funded from the Affordable Care Act to examine real-world treatment decisions.[13] PCORI network is specifically tasked to conduct observational and interventional research on the comparative effectiveness of various treatments using distributed and heterogeneous healthcare organizations and various EHR systems. PCORI currently supports the research for approximately 50 rare diseases (see appendix). The motivation for this paper was to explore the coverage of rare diseases in standard terminologies in order to characterize the current capacity for EHR-based research on those diseases, and to suggest strategies that will increase the national research capacity for all rare diseases.

There are several initiatives that have complete or partial inventories of rare disease names and terms. The Office of Rare Diseases Research (ORDR) of the National Center for Advancing Translational Sciences (NCATS) in the U.S. and Orphanet in the E.U. recognize 6 -7,000 disorders as rare diseases and support various efforts to link these disease names to standard terminologies. The ORDR also supports the Genetic and Rare Diseases Information Center (GARD), a web-based information resource for the public on more than 6,000 rare diseases.[14] The Genetics Home Reference, maintained by the National Library of Medicine, includes a smaller set of approximately 800 genetic diseases, most of which are rare. The NLM has identified and validated SNOMED CT codes for these 800 diseases to supports public retrieval of information. Orphanet, an EU-wide advocacy and information organization funded by national and European public institutions and patient organizations, foundations and corporations, provides information to the public on approximately 7,000 rare disorders on its web-based Portal for Rare Diseases and Orphan Drugs.[1] Orphanet also sponsors OrphaData, which provides the scientific community with data and tools to support the identification, quantification, and research of rare disorders. As part of this effort, Orphanet recently developed a rare disease ontology (ORDO) which serves as an inventory and classification of rare diseases, cross-referenced with OMIM, ICD-10, and SNOMED-CT and with genes in HGNC, OMIM, UniProtKB and Genatlas.[15, 16]

Existing standard terminologies, such as ICD and SNOMED CT are important components for EHRs and rare diseases research. Over 3,000 distinct concepts (including diagnoses, findings, treatments and procedures) from 4 medical centers were used to evaluate the content coverage of these and other clinical coding systems.[17] Although no coding system captured all concepts, SNOMED was the most complete. The authors concluded that both ICD-9-CM and ICD-10 fail to capture substantial clinical content, and warned that analytic conclusions that depend on these coding systems may be suspect. ICD-10 is critical for global surveillance of rare diseases. The Clinical Modifications (CM), e.g., ICD-9-CM and ICD-10-CM are critical for billing and reimbursement in the U.S. SNOMED CT is becoming increasingly adopted as a supporting clinical terminology in EHR systems worldwide[18], and gaining attention in the US since being named as a reporting standard for problem lists.[5] Previous studies have shown significant inclusion of rare diseases in SNOMED CT[19, 20], and anecdotally the IHTSDO (International Health Terminology Standards Development Organisation) is committing to increasing this coverage. SNOMED CT plays an important role in context-aware knowledge retrieval applications (i.e., InfoButtons) and the identification of patient-directed consumer information from the various information resources such as the Genetic Home Reference and MedlinePlus.

There are different approaches to identifying rare disease names in standard terminologies. Rare disease names from the Office of Rare Diseases have been mapped to the Unified Medical Language System (UMLS) to facilitate coding in other systems such as Medical Subject Headings (MeSH) for medical literature, ICD for public health surveillance, and SNOMED CT for use in clinical records documentation and clinical decision support.[19] In 2010, the NLM mapped 8,435 rare disease names (collected from ORDR, Orphanet, and the National Organization for Rare Disorders, a patient advocacy and voluntary health organization in the US) to the UMLS, and found different levels of coverage for Medical Subject Headings (MeSH) (5,663 ; 67%), Online Mendelian Inheritance in Man (OMIM) (3,802 ; 45%), SNOMEDCT (4,192 ; 50%), and ICD-10 (1,029 ;12%).[20]

In this investigation, we re-examine the current coverage of rare disease names in standard coding systems to support two use cases: 1) the identification of rare disease patients from EHR data for research, and 2) the identification of appropriate rare diseases information, including published medical literature, clinical practice guidelines for providers and authoritative consumer-directed information for patients, using coded data from EHRs.

Further, we explore differences in granularity between various terminologies, all in the context of how EHRs can support the consistent and reliable identification of rare disease patients, to enable evidence-based care and multi-site research.

Methods

Estimating the Coverage of Rare Diseases

We estimated the coverage of rare diseases in the three terminologies: ICD-9-CM, ICD-10-CM and SNOMED CT. To do this, we used two resources: the UMLS and the published maps from SNOMED CT to ICD-9-CM (developed by IHTSDO) and ICD-10-CM (developed by NLM). We first matched the 6,519 ORDR rare diseases by their names to the UMLS using lexical matching, utilizing both exact and normalized string matches, followed by semantic group validation (with restriction to the Semantic Group Disorders). Through the UMLS concept structure, we identified matches to SNOMED CT, ICD-9-CM and ICD-10-CM codes (we call these *UMLS-identified matches*). We anticipated that the UMLS-identified codes were mostly equivalent matches, since the UMLS concept structure is based on synonymy (i.e., not broader or narrower matches). For ORDR rare diseases with UMLS-identified SNOMED CT match but no ICD match, we further used the SNOMED CT to ICD-9-CM and ICD-10-CM published maps as an alternative path to match to ICD-9-CM and ICD-10-CM codes (we call these *map-identified matches*). (Figure 1) The published maps enabled us to identify matches other than equivalent matches, since the ICD map targets could be broader (often) or narrower (seldom) than the SNOMED CT concept. Since the published maps did not cover all of SNOMED CT, we extrapolated the results to estimate the number of map-identified matches that we could potentially find if all SNOMED CT concepts were included in the published maps.

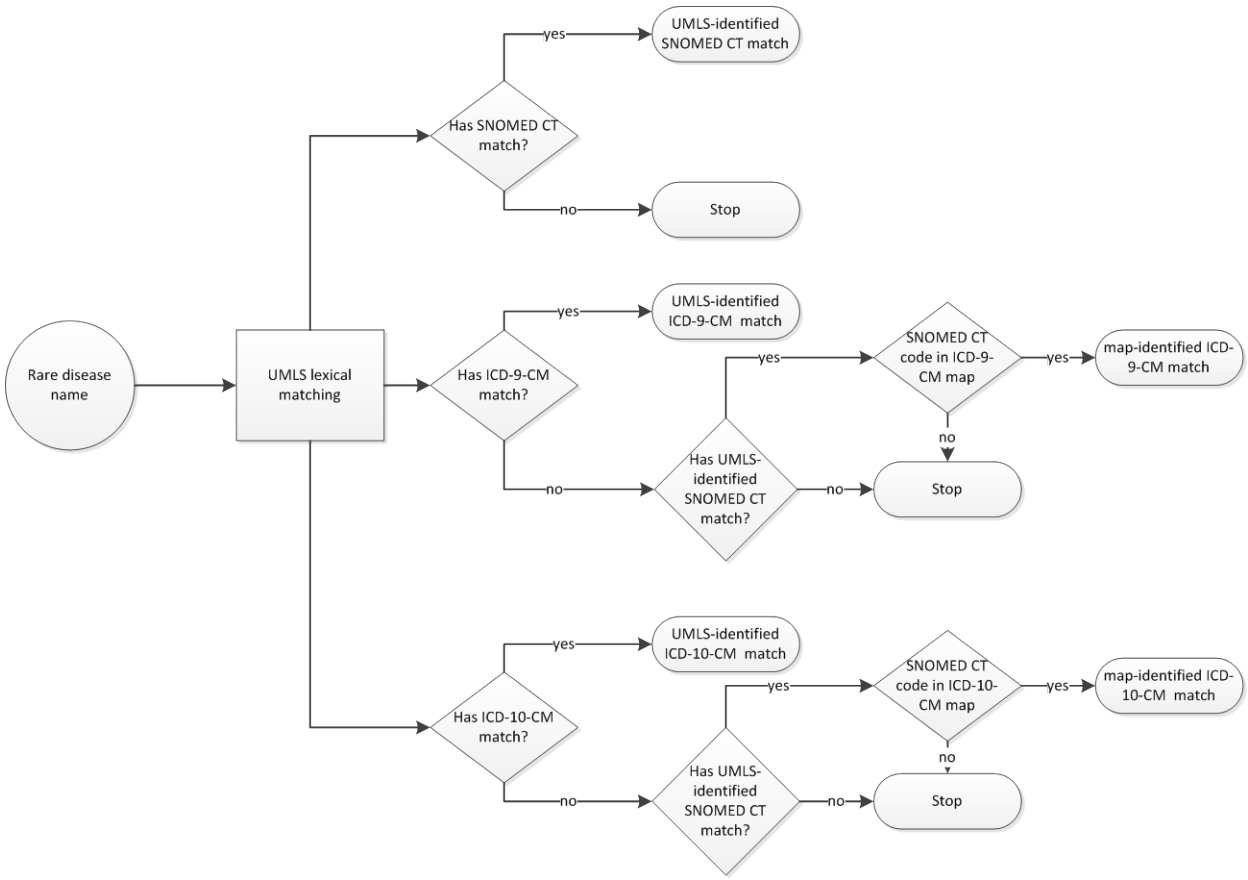

Figure 1. Overview of matching methods.

Estimating the Granularity of Matches for Rare Diseases
To study the impact of lack of equivalent matches for rare diseases, we looked at the ability of a specific code in the three terminologies to identify a specific disease. Using the matches identified above, we calculated the extent to which multiple rare diseases were included in a single code in the three terminologies.

Manually Validating a Sample of Matches
We reviewed a small set of rare diseases to validate our matching methods. We identified 46 rare disease categories under study in the PCORnet, specifically those diseases listed on applications for the 11 funded Clinical Data Research Networks (CDRNs) and 15 funded Patient Powered Research Networks (PPRNs).[7] We exploded some disease categories like 'vasculitis' and 'primary immunodeficiency diseases' to include specific diseases, such as Churg-Strauss Syndrome and Severe Combined Immunodeficiency.

The matches in the three terminologies found for the PCORnet rare diseases were reviewed by two authors (RR, medical informatician; KWF, physician) familiar with medical terminologies. Specifically, each assessed whether the match for the PCORnet diseases was an equivalent, narrower (more precise), broader (less precise) or related match. Where there was discrepancy between reviewers, consensus was reached through discussion.

As a general reference for comparison, we also calculated the coverage and granularity for the Orphanet's ORDO, based on the accompanying SNOMED CT mappings in the ontology.

Results

Estimating Rare Diseases Coverage
Using the names and synonyms of the 6,519 ORDR rare diseases for lexical matching in the UMLS, 697 (11%), 1,386 (21%) and 2,848 (44%) diseases were matched to ICD-9-CM, ICD-10-CM and SNOMED CT respectively. These were the UMLS-identified matches.

Among the 5,822 rare diseases with no UMLS-identified match to ICD-9-CM, 2,783 SNOMED CT matches were found, of which 80% (2,448 SNOMED CT codes) were included in the ICD-9-CM published map. This yielded map-identified matches for 2,055 (32%) diseases to ICD-9-CM. If all SNOMED CT concepts were included in the published ICD-9-CM map, the projected map-identified matches for ICD-9-CM would be 2,569 (39%) diseases. Similarly, among the 5,133 rare diseases with no UMLS-identified ICD-10-CM match, 1,841 SNOMED CT matches were identified, of which 56% (1,035 SNOMED CT codes) were included in the ICD-10-CM published map, which yielded map-identified matches for 919 (14%) diseases. The projected map-identified match for ICD-10-CM was 1,635 (25%) diseases. (Table 1)

As a comparison, Orphanet's rare disease ontology (ORDO) contained 6,750 diseases, among them 1,446 (21%) diseases were accompanied by matches to SNOMED CT.

Table 1. Coverage of rare diseases in the three terminologies.

	UMLS-identified match	Map-identified match (found)	Map-identified match (projected)
ICD-9-CM	697 (11%)	2055 (32%)	2569 (39%)
ICD-10-CM	1386 (21%)	919 (14%)	1635 (25%)
SNOMED CT	2848 (44%)	n/a	n/a

Estimating the Granularity of Matches for Rare Diseases

Using the matches identified above, we calculated the extent to which multiple diseases were included in a single code in the three terminologies. (Table 2) We define a *unique match* as a code that matches to only one rare disease,

and a *multiple match* as a code that matches to more than one rare disease. The number and proportion of unique matches were 1,081 (62%) for ICD-9-CM, 1,403 (73%) for ICD-10-CM, and 3,311 (85%) for SNOMED CT. Overall, 672 (38%) of the matched ICD-9-CM codes were multiple matches, which was lower for ICD-10-CM (n=526, 27%) and lowest for SNOMED CT (n=598, 15%). As for the cardinality of the broader matches, the maximum number of diseases matched to a SNOMED CT code was 5 diseases. The highest number of diseases matched to a single code was 208 for ICD-9-CM and 23 for ICD-10-CM. There were 117 ICD-9-CM and 40 ICD-10-CM codes matching to more than 5 diseases.

In Orphanet's ORDO, 1,446 rare diseases were matched to 1,748 SNOMED CT codes. Most of the SNOMED CT codes (1,735, 99%) were matched to a single disease, and 13 SNOMED CT codes were matched to two diseases.

Table 2. Number of Rare Diseases Included in Matched Codes from Source Terminologies.

# rare diseases matching to a code	# ICD-9-CM codes (% of total codes)	# ICD-10-CM codes (% of total codes)	# SNOMED CT codes (% of total codes)
1 (unique match)	1081 (62%)	1403 (73%)	3311 (85%)
2	319	328	478
3	125	88	84
4	68	45	33
5	43	25	3
> 5	117	40	0
# codes matching to > 1 disease (% of total codes) (multiple match)	672 (38%)	526 (27%)	598 (15%)
Examples	208 rare diseases matched to *759.89 Other specified congenital anomalies*	22 rare diseases matched to *Q82.8 Other specified congenital malformations of skin*	5 rare diseases matched to *28835009 Retinitis pigmentosa*

Table 3. Manual review of PCORnet rare diseases matches.

		ICD-9-CM	ICD-10-CM	SNOMED CT
UMLS-identified matches (% of all UMLS-identified matches)	equivalent	14 (93%)	13 (68%)	46 (74%)
	broader	0 (0%)	3 (16%)	2 (3%)
	narrower	1 (7%)	2 (11%)	9 (15%)
	related	0 (0%)	1 (5%)	5 (8%)
	total	15 (100%)	19 (100%)	62 (100%)
Map-identified matches (% of all map-identified matches)	equivalent	1 (2%)	9 (25%)	n/a
	broader	45 (87%)	23 (64%)	n/a
	narrower	4 (8%)	3 (8%)	n/a
	related	2 (4%)	1 (3%)	n/a
	total	52 (100%)	36 (100%)	n/a
# diseases with equivalent match (% of total diseases)		15 (28%)	22 (42%)	43 (81%)
# diseases with no equivalent match		30 (57%)	23 (43%)	2 (4%)
# diseases with no match		8 (15%)	8 (15%)	8 (15%)
Total # diseases		53 (100%)	53 (100%)	53 (100%)

Manual Review of Matches

Among the UMLS-identified matches, the proportions of equivalent matches were 93%, 68% and 74% for ICD-9-CM, ICD-10-CM and SNOMED CT respectively. Among the map-identified matches, 87% of the ICD-9-CM

matches and 64% of the ICD-10-CM matches were broader matches. Overall, 8 (15%) of the 53 diseases could not be matched to any of the three terminologies. Among the 45 diseases that could be matched, an equivalent match could be found for 15 (28%), 22 (42%), 43 (81%) diseases for ICD-9-CM, ICD-10-CM and SNOMED CT respectively. (Table 3)

Discussion

We first estimated the coverage of ORDR rare disease names in ICD-9-CM, ICD-10-CM, and SNOMED CT by lexical mapping to the UMLS. As expected, we found increasing coverage from ICD-9-CM (697; 13%) to ICD-10-CM (1,386; 26%), with the highest coverage for SNOMED CT (2,848; 53%). This is consistent with previous findings on the higher general clinical coverage of SNOMED CT. [17] The coverage of rare disease names in SNOMED CT is slightly lower than the 50% coverage seen in 2010, [20] although the earlier study used a larger set of rare disease names from multiple sources. As shown by the manual review, most of the UMLS-identified matches are equivalent matches.

This study differs from earlier work by Pasceri [20] in that we did not stop at lexical matching by the UMLS. In view of the low coverage of rare disease names in ICD-9-CM and ICD-10-CM, we explored new ways to match to these terminologies. We made use of the published maps from SNOMED CT to ICD-9-CM and ICD-10-CM to provide a cross-walk to the ICDs via SNOMED CT. This could considerably increase the matching rates to ICD-9-CM (from 11% to 50%) and ICD-10-CM (from 21% to 46%). However, most of these additional matches were not equivalent matches, and were either broader (majority) or narrower/related (minority) matches, as confirmed by the manual review. While these non-equivalent matches may still be useful in some use cases, e.g., to narrow down a large cohort of patients to those who may be suffering from a rare disease, they may not be precise enough to support direct patient care e.g. offering specific advice on the treatment of a particular disease.

Our work specifically supports use cases related to the use of EHRs to support the consistent and reliable identification of rare disease patients to enable evidence-based care and multi-site research. When searching health system data for rare disease patients, fine-grained and specific codes are preferable. Our data show that SNOMED CT has more codes (than ICD-9-CM or ICD-10-CM) that relate to one and only one disease. Due to the need to support statistical analysis in ICD-9-CM and ICD-10-CM, grouper concepts are more prevalent. This will cause problem when a code is required to identify a specific rare disease, such as linking an entry in the EHR to some disease-specific information. Our analysis shows that a higher percentage of ICD-9-CM and ICD-10-CM codes (38% and 27% respectively) lead to more than one rare disease, compared to 15% for SNOMED CT. One ICD code can lead to hundreds of diseases while the number is much smaller in SNOMED CT.

Although the PCORnet rare diseases that we explored in detail are not necessarily representative of all the rare diseases, these conditions are important in that they are being studied now. The proportion of diseases with equivalent match for the PCORnet list is considerably higher than what we saw for the 6,519 rare diseases overall. It is possible that the PCORnet funded research addresses more well-known or important diseases, so that more of them make their way into standard terminologies. Even if the small set of rare diseases that we used for validation are not representative of other rare diseases, their association with the PCORnet national research network that is actively exploring the use of EHR data in observational and interventional research will make them exemplars for refining strategies to increase the national capacity for rare diseases research and evidence-based care.

Limitations of our study include the following. We only focused on one source of rare disease names (ORDR). We did not do a comprehensive review of all the matches found in the three terminologies. The PCORnet rare diseases that we reviewed might not be representative of all rare diseases. Using the published maps to cross-walk to ICD-9-CM and ICD-10-CM was only possible for those diseases with UMLS-identified SNOMED CT matches.

The Way Forward

ICD and SNOMED CT are designed for very different purposes, and the rare disease community can benefit from knowing this distinction. As a classification system, ICD by definition includes categories that are designed to be exhaustive and mutually exclusive. For statistical purposes (in epidemiology and billing use cases) the idea of

"multiple counting" (e.g., classifying a disease in two different hierarchies) is discouraged, and residual categories (e.g., some diseases 'not elsewhere classified') can be meaningful. In fact, one reason for the residual categories is to avoid the need to assign codes to diseases with very low prevalence (i.e. rare diseases) and to maintain statistical balance of the coding categories. On the other hand, SNOMED CT as a clinical terminology is designed to support the representation of any concept to be stated about the patient. In the context of a terminology, "multiple counting" is desirable, and residual categories are meaningless. For example, for a patient suffering from Laurence-Moon syndrome, the diagnostic label "Other specified congenital malformation syndromes, not elsewhere classified" will not be useful in finding disease-specific patient education information or clinical practice guidelines. Another advantage of SNOMED CT is its shorter update cycle of 6 months, compared to yearly updates for ICD.

There is great potential benefit in the use of SNOMED CT as a source terminology in EHRs. Using a robust and fine-grained terminology such as SNOMED CT, clinicians can document patient data once at the point of care with fidelity to the clinical situation, at the appropriate level of granularity and certainty or uncertainty. These data, encoded in SNOMED CT, could be re-used for automated decision support and accessing customized information at the point of care. Others have shown that coarse disease classifications, such as ICD, are insufficient for these purposes, and our data indicate that SNOMED CT has higher proportion of fine-grained, or highly specific, codes for each disease. The use of SNOMED CT in the EHR can enable clinicians to record data only once at the point of care. Then the mappings of SNOMED CT to ICD classifications can be used to leverage these data for epidemiologic purposes, health system management, and billing. This would avoid duplicate effort of double-coding and potentially avoid the skewing of clinical data for billing purposes. To see how this will work for ICD-10-CM take a look at the I-MAGIC demo tool at NLM's website. [21]

Rare disease advocates should work to include rare diseases specifically in SNOMED CT. In future, a tighter integration between SNOMED CT and ICD-11 is anticipated. Concepts in SNOMED CT will then find a natural path into ICD, avoiding the risk of code translation or mapping errors. This is in line with Orphanet's exhortation for inclusion of more rare diseases in ICD.

Conclusions

To support patient care, patient education and research in rare diseases, adequate coverage of rare diseases in standard terminologies is essential. Existing coverage in SNOMED CT is higher than ICD-9-CM and ICD-10-CM, and with higher precision. More work is needed to improve coverage.

Appendix. List of rare disease categories (46) studied in PCORI networks and grant awards.

Adrenoleukodystrophy	Granulomatosis with Polyangiitis	Phelan-McDermid Syndrome
Aicardi Syndrome	Hepatitis	Primary Immunodeficiency Diseases
alpha-1 antitrypsin deficiency	Hypoplastic left heart syndrome	Primary Nephrotic Syndrome (Focal Segmental Glomerulosclerosis)
Alström syndrome	Hypothalamic Hamartoma	Pseudoxanthoma elasticum
Amyotrophic Lateral Sclerosis	Inflammatory breast cancer	Psoriasis
Becker muscular dystrophy	Joubert syndrome	Pulmonary fibrosis
Chronic Granulomatous Disease	Juvenile Rheumatic Disease	Rare Cancers
Churg-Strauss Syndrome	Kawasaki Disease	Selective IgA Deficiency
Co-infection with HIV and hepatitis C virus	Klinefelter syndrome and associated conditions	Severe Combined Immunodeficiency
Common Variable Immunodeficiency	Lennox-Gastaut Syndrome	Severe Congenital Heart Disease
Cystic fibrosis	Membranous Nephropathy	Sickle Cell Disease
DiGeorge Syndrome	Metachromatic leukodystrophy	Sickle cell disease; Recurrent C. Difficile colitis
Dravet Syndrome	Microscopic Polyangiitis	Tuberous Sclerosis
Duchenne muscular dystrophy	Minimal Change Disease	X-Linked Agammaglobulinemia
Dyskeratosis congenital	Multiple Sclerosis	
Gaucher disease	Pediatric Transverse Myelitis

Validating Health Information Exchange (HIE) Data For Quality Measurement Across Four Hospitals

Nupur Garg, MD[1], Gil Kuperman, MD, PhD[2], Arit Onyile, MPH[1], Tina Lowry, MS[1], Nicholas Genes, MD, PhD[1], Charles DiMaggio, PhD[2], Lynne Richardson, MD[1], Gregg Husk, MD[3], Jason S Shapiro, MD[1].

Abstract

Health information exchange (HIE) provides an essential enhancement to electronic health records (EHR), allowing information to follow patients across provider organizations. There is also an opportunity to improve public health surveillance, quality measurement, and research through secondary use of HIE data, but data quality presents potential barriers. Our objective was to validate the secondary use of HIE data for two emergency department (ED) quality measures: identification of frequent ED users and early (72-hour) ED returns. We compared concordance of various demographic and encounter data from an HIE for four hospitals to data provided by the hospitals from their EHRs over a two year period, and then compared measurement of our two quality measures using both HIE and EHR data. We found that, following data cleaning, there was no significant difference in the total counts for frequent ED users or early ED returns for any of the four hospitals ($p<0.001$).

Introduction

Health information exchange (HIE) is an important complement to electronic health records (EHRs), providing much needed outside clinical information to providers at the bedside.[1] Although comprehensive HIE at a state or national level is far from being fully realized, it is increasingly identified as a key element of our nation's approach to providing 21st century healthcare.[2-4] The Health Information Technology for Economic and Clinical Health (HITECH) portion of the American Recovery and Reinvestment Act (ARRA) has promoted the "meaningful use" (MU) of EHRs through three stages, each of which defines standards and provides incentives to compliant hospitals and providers. Whereas stage 1, meaningful use, focused on the technical ability to get information into a shareable electronic form, stages 2 and 3 focus on actual clinical use and driving improved outcomes with a progressively increased focus on HIE.[5]

HIE is not without challenges, facing questionable financial sustainability, adoption, and usage in many settings. [3,4,6-8] That said, the trend towards HIE use has continually increased,[6] with several recent studies showing that the *primary clinical use case* of clinicians reviewing the records of individual patients at the bedside can help prevent admissions, decrease testing, and ultimately save money.[7,9,10] However, studies showing that quality and safety are actually improved by HIE are still needed.[3,4,11,12]

As HIE expands, and we begin sharing data more broadly, health data is increasingly aggregated into ever larger nodes as we work toward a vision of national HIE. Through this progression, HIE data will increasingly serve as a data source for *secondary use cases* including care coordination,[13] population management,[14] public health surveillance,[15] broad community-wide quality measurement,[16] and research.[17] Ultimately these secondary uses may be a strong driving force for improving the safety and quality of patient care.

Because of the context-dependent nature of HIE data quality, meaning data may be of sufficiently high quality for one use case but not for another, HIE data that are "fit for use" in the primary clinical use case may not be "fit

for use" in secondary use cases.[18] As these secondary uses begin to test the limits of HIE data, the importance of ensuring HIE data quality should not be underestimated.

Background

Currently, EHRs are a common source of electronic data for quality measurement, many of these quality measurements are mandated by state and federal reporting requirements for research and for other secondary uses.[5,15,19,20] Because of this, the need for data quality analysis in the setting of EHRs has been recently described, and various methods have been explored for generating and rating data from EHRs to ensure a level of data quality.[18,21,22] For HIE, data quality assessment may be even more challenging, since aggregation of multiple data sources into an HIE multiplies the potential for data quality issues.

HIE networks are often initially formed to support the primary clinical use case, without much consideration for secondary use cases at their inception. HIEs often contain both clinical data from ancillary systems (e.g., lab results, diagnostic reports, clinical notes) and registration data from admission, discharge and transfer (ADT) registration systems (e.g. visit dates, patient demographics and other identifiers). For primary clinical use, these data are incorporated from multiple sites so that an individual clinician can view data belonging to an individual patient from multiple provider organizations. Initial HIE implementations may involve minimal validation, cleaning, or transformation. Testing may focus on interfaces between systems, and on assuring the proper display of clinical data at the presentation layer for individual patient data. Because HIE networks are usually designed around the primary clinical use case, data transformation to leverage the deep semantics at each site, mapping to appropriate terminologies to translate the meaning of data across sites, and detailed data quality and validation may be neglected. Once we begin to apply scenarios for the secondary use of HIE data, data quality issues are often discovered.[23,24]

In this analysis, we describe approaches to data cleaning, measuring data concordance before and after data cleaning, and validation of the secondary use of HIE data for two specific quality measures: identification of frequent emergency department (ED) users and early (72-hour) ED returns.

Methods

Setting

Healthix is a regional health information organization (RHIO) providing HIE to the New York metropolitan area and Long Island.[25] Healthix formed in 2012 through the merger of the Long Island Patient Information Exchange (Lipix) and the New York Clinical Information Exchange (NYCLIX).[26] Since then, the Brooklyn Health Information Exchange (BHIX) has also merged with Healthix,[27] and Healthix now has 9.2 million unique patients, > 6,500 users performing > 10,000 searches per month, and 107 participating organizations with 383 facilities comprising 29,946 acute and extended care beds as of January 2014.

To date, Healthix has enabled HIE primarily through the use of standard HL7 2.x messages,[28] written to a common specification, to send data from source systems at multiple provider organizations to edge servers at each site built with a common data structure. Registration information from each site's ADT system, including patient demographics and master patient index (MPI) functions, is housed in a centralized location.

As part of each site's implementation of HIE with Healthix, end-to-end interface testing was conducted. Artificial data was entered into test patient records in the site's source systems, and then followed downstream through the HIE interface, into the edge server, and finally to the display level in the HIE's portal viewer. Each step of the way, the data was checked for validity based on the source system, which consisted of making sure the interfaces were sending data properly and that the information was being properly displayed for clinicians. While this sort of testing is a standard aspect of HIE implementation, it may not detect problems that do not affect data display in the primary use case. For example, missing discharge date/time stamps might not be detected if all that is being tested is the ability to display laboratory and radiology results, but if the data are later employed for secondary use in measuring frequent ED users and early (72-hour) ED returns, then these missing data become much more important. As another example, free text diagnosis data might display properly during testing, but if analyses that require ICD-9 codes are attempted later, they may fail.

Data

EHR and HIE data elements from four hospitals were obtained for all ED visits from 3/1/09 to 2/28/11, including visit number (denotes a unique encounter), medical record number (MRN – denotes a unique patient), admission and discharge date and time, date of birth, and gender. All data were de-identified in accordance with HIPAA prior to analysis by the research team, and the protocol was reviewed by the Mount Sinai Program for the Protection of Human Subjects and given a not human research determination.

Analysis

HIE and EHR data for each site were merged on hashed visit numbers to evaluate concordance of unique encounters, and on hashed MRNs to evaluate concordance of unique patients. In this case, concordance is defined as having a unique match. Next, age, gender and the time-stamps for admissions/discharges were also tested for concordance. In order to adjust for differences between the EHR and HIE data for these latter four parameters, various data cleaning rules were systematically applied. These data cleaning techniques were derived from observation of the major areas of discrepancy noticed when concordance between the two data sets was tested, and through expert evaluation of workflow issues that were likely to have caused these discrepancies at each site. The three data cleaning techniques used were as follows:

1) Age was considered to match if the date of birth was less than or equal to one year difference between the HIE and EHR data.

2) Gender was considered to match if it was specified in either the EHR or HIE, and recorded as the same or "unknown" in the other system.

3) Admit and discharge times were considered to match if the difference in date/time was less than 6-24 hours. The number of hours from 6-24 was chosen on a site-specific basis by extending the data cleaning factor by the smallest multiple of 6 hours in which the concordance of encounters first became greater than 98%. This particular data cleaning technique was necessary because differences in clinical and registration staff workflows likely led to small but frequent discrepancies between the two data systems in which admit and discharge times were entered. For instance, when a clinician discharged an ED patient, a date/time stamp was immediately entered in the EHR but the registration staff member may wait until the end of his or her shift to remove the patient from the ADT system, causing the ADT date/time stamp to lag behind by a small number of hours.

The last part of the data analysis included measuring frequent ED users (patients with ≥ 4 visits in 30 days) and early (72-hour) ED returns (patients who return for a second ED visit within 72 hours of being discharged). The counts for each of these quality measures were then compared for statistically significant similarity between HIE and EHR datasets for each hospital using Chi square.

Results

Adjusted values (following data cleaning) were not significantly different between site-specific HIE and EHR datasets (Table 1). There was a high degree of concordance for unique encounters and patients between HIE and EHR data sets, so no data cleaning was employed.

Table 1	**Site 1**		**Site 2**		**Site 3**		**Site 4**	
	Unadj % Matched	Adj % Matched	Unadj % Matched	Adj % Matched	Unadj % Matched	Adj % Matched	Unadj % Matched	Adj % Matched
Unique Encounters (Visit #)	99.45	N/A	99.27	N/A	99.25	N/A	99.98	N/A
Unique Patients (MRN)	99.32	N/A	99.31	N/A	99.31	N/A	99.84	N/A
Age	99.71	100	97.61	100	97.69	100	97.94	100
Gender	99.25	100	99.16	99.91	99.16	99.91	99.61	99.63
Admit Date/Time	0.13	99.53	5.00	99.99	2.76	99.99	53.86	100
Discharge Date/Time	2.47	98.05	49.27	99.89	47.42	99.86	94.42	99.96

Table 1 shows the level of concordance between the EHR and HIE of the various data elements in the left column before and after adjustments were applied across all four sites. N/A signifies not applicable as no data cleaning was employed for these parameters.

The unadjusted match rate for age and gender ranged from 97.61% to 99.71% across sites (std. dev. 0.87%), and once the adjustment criteria were applied, all match rates increased and were greater than 99.6%. The admit and discharge date/time did not match well in the unadjusted data (range 0.13% to 94.42%, std. dev. 34.6%). Data cleaning adjustment allowed for a match in greater than 99.5% of admissions and 98% of discharges. The lowest discharge date/time unadjusted match rate was at Site 1, but only a six hour data cleaning time frame was needed to get the match percentage over 98%. Site 2-4 required a 24 hour adjustment of the time frame, and after adjustment had greater than 99.85% match rates across all sites.

When we measured the number of frequent ED users (patients with ≥ 4 ED visits in 30 days) and early (72-hour) ED returns, we found a high degree of concordance between HIE and EHR data sets (Table 2). All four sites have EHR counts that do not differ significantly from the HIE counts (p-value < 0.001).

Table 2	**Site 1**		**Site 2**		**Site 3**		**Site 4**	
	EHR Count	HIE Count	EHR Count	HIE Count	EHR Count	HIE Count	EHR Count	HIE Count
Frequent Users	1,204	1,221	1,060	1,035	1,746	1,708	936	924
72 Hour Returns	8,299	8,456	7,237	7,093	12,243	12,045	5,476	5,431

Table 2 shows the agreement between the EHR and HIE when the quality measures of the frequent ED users and the 72 hour returns were applied. EHR and HIE counts are not significantly different with a p-value < 0.001.

Discussion

In preparation for a project measuring frequent ED users and early (72-hour) emergency department (ED) returns across an HIE, this analysis was performed to validate the use of HIE data by comparing it to the electronic health record (EHR) data, since EHRs are often the source of data for these ED quality measures, and much of the encounter data in the HIE comes from ADT source systems. Our analysis shows that through some simple data cleaning and transformation, the level of concordance between EHR and HIE data sources for multiple data elements across four separate hospitals was very high. Furthermore, when we compared the performance of our two specific ED quality measures we found no statistical difference between EHR and HIE data.

There are several likely reasons that concordance between the data sets for demographic and encounter data exist, and the counts for frequent ED users and early (72-hour) ED returns were not identical. First, the data in the date and time stamps for the EHR are generally captured by clinicians directly as part of their EHR workflow, and the date and time stamps for the HIE were generally captured by registration staff in the sites' ADT source systems as part of their registration workflow. Differences in the timing of these two workflows likely led to some of the discrepancies. Second, age and gender data are generally captured by registration staff in ADT source systems, and then flow to both the sites' EHRs and to the HIE. It is possible that subsequent changes were occasionally made directly in the EHRs and not in the ADT systems, causing some of these discrepancies. Third, it is possible that some of the HL7 messages from various sites did not make it to the HIE due to occasional interface downtimes or other malfunctions, causing some small number of HL7 messages to be either dropped or altered. This may help explain why three of the four hospitals have lower counts for frequent ED users and early returns of ED patients from the HIE data than the EHR data. Some of the HIE cases were missing a discharge date/time, and in those we are unable to calculate a 72 hour return, so the counts would be lower. Regardless, the discrepancies between the HIE and EHR datasets was minimal in most cases, and in other cases could be addressed by simple data cleaning approaches.

This study has several important limitations. First, these analyses were performed on only a small subset of sites participating in Healthix (four out of more than 50 hospitals with EDs), and without further analysis of more sites, there is no way to determine if similar data quality issues would be encountered at the other sites, or if the data

cleaning techniques employed here would suffice. Also, the ED has traditionally been the focus of HIE interventions, but future studies should investigate data quality issues for inpatient and ambulatory domains. Second, some of the data quality issues here might be unique to this geographic region, though similar problems are likely to exist more broadly. Further analyses in other settings would need to be performed to make this determination. Finally, the analyses performed here were limited to HIE taking place using standard HL7 2.x interfaces. There is currently much work being done using newer XML-based continuity of care document approaches in HL7 Version 3 in RHIOs[28] and Integrating the Healthcare Enterprise protocols to exchange data between separate HIE networks.[29] There will likely be new and different data quality issues and data cleaning requirements that arise when these newer data transport standards are employed.

Secondary use of data gathered in electronic health records is increasing, raising the need for standardized data quality assessment. Without this, the validity of secondary uses that leverage electronic data may be questionable. Some of these secondary uses include quality measurement, chronic disease management and care coordination, population management, public health surveillance and observational comparative effectiveness research.

Health information exchange presents an appealing data source for these secondary uses of electronic data, and has the distinct advantage over EHR data in that it includes data from multiple provider organizations in a region. Patients often visit more than one provider organization, causing their healthcare data to become fragmented.[30-32] The use of HIE data for these secondary purposes therefore may more accurately reflect the manner in which patients interact with the healthcare system when compared to individual EHRs as a data source. However, the need for standardized data quality assessment and data cleaning is even greater when HIE serves as the data source because data from multiple sites are aggregated in an HIE, compounding data quality issues evident in individual EHRs. Further work should be done to determine if standardized data assessment and data cleaning techniques in the setting of an HIE can be developed, and if they differ from similar work that is being done at the level of the EHR.

Abstract

Emergency department (ED) visits due to allergic reactions are common. Allergy information is often recorded in free-text provider notes; however, this domain has not yet been widely studied by the natural language processing (NLP) community. We developed an allergy module built on the MTERMS NLP system to identify and encode food, drug, and environmental allergies and allergic reactions. The module included updates to our lexicon using standard terminologies, and novel disambiguation algorithms. We developed an annotation schema and annotated 400 ED notes that served as a gold standard for comparison to MTERMS output. MTERMS achieved an F-measure of 87.6% for the detection of allergen names and no known allergies, 90% for identifying true reactions in each allergy statement where true allergens were also identified, and 69% for linking reactions to their allergen. These preliminary results demonstrate the feasibility using NLP to extract and encode allergy information from clinical notes.

Introduction

Allergic reactions result in over 1 million visits per year to emergency departments (ED)[1]. Foods and antibiotics are among the most common causes of these visits with an estimated 525,600 and 112,116 visits annually[2, 3]. Adverse drug events (ADEs) due to a patient receiving a medication to which they were known to be allergic is present in both the inpatient[4] and outpatient[5] settings. Careful documentation and encoding of patient allergies is critical to patient safety and ensuring drug allergy checking and clinical decision alerts are triggered. Natural language processing (NLP) has shown promise in this domain[6], yet few have adapted its use to detecting allergies from clinical notes, which often contains allergy information both within and outside the allergy section of the chart. This paper presents our early experience and preliminary findings in developing an allergy module for a general NLP system, named Medical Text Extraction, Reasoning, and Mapping System (MTERMS), to extract and encode allergy information from clinical text. We assessed the system performance of the MTERMS in processing free-text ED notes for allergen names and associated allergic reactions.

Background

Emergency physicians are often at the forefront of treating and managing acute allergic reactions. Their clinical notes typically convey the allergen, the patient's reaction and their response to treatment. While allergy information is usually recorded in the allergy section, it may not be included in the allergy section at the time of presentation or it may be located elsewhere (e.g., medical decision making or ED course). Additionally, the physician's narrative may include important details reflecting their certainty the patient is having an allergic reaction and the treatment given. As such, pertinent allergy information may be buried in clinical text, raising a concern for patient safety, as this information is not interoperable with computerized drug-allergy alerting or drug-drug interaction checking.

Most NLP applications to date have focused on other specific domains including clinical problems[7], medications[8], vaccination reactions[9], suicide ideation[10], smoking status[11], or ADE detection[12], etc. While allergy (a type of adverse event) is an important domain, it has not yet been widely investigated. In cTAKES[13], a NLP system by Savona et al, allergies to a given medication are handled by setting the

negation attribute of that medication to "is negated". In MedLEE, terms such as "allergy" or "toxic" are captured and assigned to the semantic type "reaction"[14]. Melton et al[15] used MedLEE[16, 17] to identify 45 adverse event types (e.g., loss or impairment of bodily functions) using discharge summaries. A set of computerized queries implemented the inclusion and exclusion logic for each event and identified the adverse events against the NLP output. Melton's approach achieved an overall sensitivity of 28%, specificity of 98.5%, and PPV of 45%. Most ADE detection algorithms use simple keyword search methods that search notes for relevant trigger words[14]. In general, these studies have reported low sensitivity (69%[18], 23%[19]) and PPV (7%[20], 12%[21], 52%[18], and 41%[19]). One study[14] searched keywords (e.g., "error," "mistake" or "iatrogenic") to detect medical errors in discharge summaries, residents' transfer of service notes, and outpatient visit notes with PPVs ranging from 3.4% to 24.4%, depending on the keywords used. Apart from performance issues, one major limitation of a keyword searching method is that it only considers a limited set of terms, hence most of these tools are unable to automatically extract and encode important clinical information (such as medications and symptoms). This lack of detailed clinical information as a part of the structured output limits its usage in further analysis or other research purposes.

Several studies[6, 22] using NLP techniques have been conducted on analyzing allergy repositories. Skentzos et al[22] developed NLP software to identify cholesterol lowering statin drug side effects documented in narrative provider notes and achieved a recall of 86.5% and precision of 91.9%. The Skentzos algorithm was further utilized to conduct a retrospective cohort study to determine the factors associated with documentation of statin side effects in a structured allergy repository[23]. Recently, a study by Epstein et al[6] evaluated the use of NLP to encode free-text food and drug allergens and mapped identified allergens to RxNorm. Epstein's study focused only on allergens within the patients allergy list and did not include reactions and environmental allergens. To date, no comprehensive NLP systems have been evaluated for processing allergy information in clinical notes with dynamic mapping to standard terminologies.

Automated encoding of allergy information is challenging as it requires the integration of multiple standard terminologies[24]. Initial standard terminology recommendations for encoding allergy have been put forth by the health information standards panel (HISTP). These include, SNOMED CT[25] for allergy/adverse reactions, RxNorm[26] for medications, National Drug File Reference Terminology (NDR-RT)[27] for drug classes and the Unique Ingredient Identifier[28] for food and substance allergens[29, 30]. The National Council for Prescription Drug Programs (NCPDP)[31] has proposed allergy value sets for encoding allergy that includes RxNorm as the source terminology. The Centers for Disease Control (CDC) has released a value set for encoding allergies that includes food, drug and environmental allergens, each mapped to SNOMED CT[32]. The coverage of five terminologies (RxNorm, SNOMED CT, UNII, NDF-RT and MedDRA) for encoding common allergies was recently evaluated by Goss et al who found SNOMED CT and RxNorm can satisfy most criteria for encoding common allergens with sufficient content coverage[24].

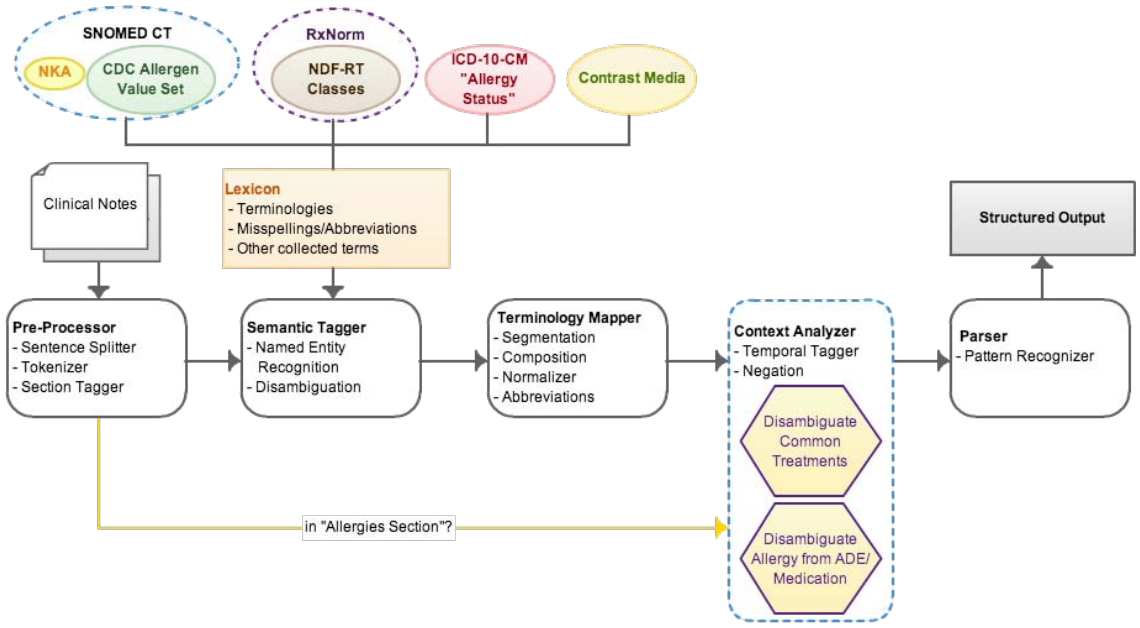
We have developed a generic NLP application, called Medical Text Extraction, Reasoning and Mapping System (MTERMS)[33], which is initially used for encoding medication information for medication reconciliation and for mapping between medication terminologies[33, 34]. MTERMS processes free-text entries into a structured XML output using a pipeline approach that includes a Pre-Processor, Semantic Tagger, Terminology Mapper, Context Analyzer, and Parser. The Terminology Mapper of MTERMS maps free-text medical concepts to multiple standard terminologies (e.g., SNOMED CT, RxNorm, NDF-RT, etc.) instead of a single specific terminology and where necessary, establishes dynamic mapping between these terminologies. In this study, we extended MTERMS by adding an allergy module for processing free-text allergy information.

Methods and System Design

System Design

The NLP allergy module is built on the MTERMS platform, and consists of a new lexicon for allergy concepts, an updated context analyzer consisting of new disambiguation algorithms, and updates to the XML output schema (Figure 1). MTERMS provides dynamic mapping of concepts across each terminology in its lexicon.

Figure 1: MTERMS system architecture for allergy module.



Lexicon Development

Our lexicon uses multiple recommended standard terminologies for encoding allergy concepts[24, 30] as well as local terminologies. For drug allergens, we use RxNorm and the same method to create the medication concept database described by Zhou et al[34]. We compiled a list of medications typically used to treat allergic reactions (e.g., Benadryl, Solumedrol) from allergy experts. Drug classes are inherited from NDF-RT (e.g., Ace Inhibitors), using those present in RxNorm and from ICD-10-CM "Allergy Status" terms (e.g., Antibiotics)[35]. For food and environmental allergen names, we use an available allergy value set from the CDC (Public Health Information Network Vocabulary Access and Distribution System (PHIN VADS)) as well as a subset of terms collected from the sub-tree (subClassOf) "allergen class" of SNOMED CT. Contrast media concepts were compiled from RxNorm and allergy experts. We use the 2014 versions of RxNorm, SNOMED CT, UNII, and the 2011 allergy value set from the CDC (Public Health Information Network Vocabulary Access and Distribution System (PHIN VADS)). To facilitate the integration of updates released from terminology sources, separate SQL tables were allocated to lexical variants or common misspellings.

For reaction names, we use a subset of terms compiled from the most frequently observed allergy reactions within Partners Enterprise-wide Allergy Repository (PEAR), a longitudinal allergy database shared within the Partners provider/hospital network[23]. These reactions were then mapped to SNOMED CT.

Search and Disambiguation Algorithms

Drug, food, and environmental agents mentioned in the clinical text can have different meanings. A drug may be a treatment for a condition or environmental agent may be the setting a patient was surrounded by. Since allergens and associated reactions can be found anywhere in a clinical note, our algorithms conduct disambiguation by considering contextual information. For example, when inside of the allergies section, our algorithms search and encode all matches to our lexicon for allergens and reactions due to the context of the section. Outside of the allergy section, our algorithms identify allergens and reactions using a set of rules (regular expressions) that search for the presence of indicators (e.g., allergic, allergy, caused, "started after", "likely due to"). If the pattern is recognized as being one indicating an allergy, then we add the annotations for the allergen and associated reactions. An example of a pattern outside of the allergies section is shown in Figure 2.

Medications used as common treatments for allergic reactions and their symptoms (e.g., hydrocortisone, Pepcid) often show up in the same sentence as the drug allergen, and thus need to be disambiguated. We

use a set of rules based on indicators (e.g., resolved, treated, relieved) taking into account position of indicator with treatment drug, relative to the reaction and allergen. These rules are applicable both within and outside the Allergies section of the clinical note. Our current disambiguation algorithms are limited to the sentence level.

We also compiled a subset of reaction terms or conditions that indicate an allergy (e.g., anaphylaxis, hives, Stevens-Johnson Syndrome, urticarial rash) to aid in disambiguation of allergic reactions from common reasons to visit the ED that are not necessarily immune-mediated (e.g., rash, itch). When any of these allergic reactions or conditions are found in the text, MTERMS will assert an allergy even if an allergen was not mentioned.

Allergy Module Structured XML Output Design

The allergy observation module was adapted from the HL7 allergy and intolerance working group model[36] and used to develop an XML schema for representing some of the key elements within an allergy observation (e.g., type of allergy, allergen, reaction). A simplified example of our XML representation from the NLP tool is shown in Figure 3.

Figure 2: XML representation of an allergy to Augmentin (the free-text input was mentioned in the Assessment section of an ED note)

Free-text within Assessment section:
"My impression is this is an allergic urticarial rash possibly from Augmentin"

NLP output:

```
<Allergy SectionText="Assessment ">
   <Allergen RxCUI="151392" SAB="RXNORM" SAB_Code="151392" TTY="BN"
   AllergyIndicator="allergic">augmentin</Allergen>
   <Reaction DESCRIPTIONID="369545012" DESCRIPTIONTYPE="Synonym"
   CONCEPTID="247472004" IndicatesAllergy="True">urticarial rash</Reaction>
</Allergy>
```

Evaluation Methods

Corpus

We evaluated free-text emergency department (ED) notes, which are often the initial point of care for treatment and management of acute allergic reactions. ED notes were randomly selected from years 2011 and 2012 from Brigham and Women's Hospital. A random set of 500 ED notes from 2011 were set aside for training the MTERMS allergy module. The notes were then processed by the NLP tool and the output reviewed by four reviewers (LZ, FG, DS, and JL). We estimated that 15-25% of our sample notes contain allergy information and sample size of 187 was calculated using Stata[37]. We used a larger test set than the calculated sample size, which consisted of 400 randomly selected ED notes from 2012, in order to incorporate a variety of allergy cases and statements. The test set was created by a non-study staff member and all developers were blinded to it. This study was approved by Partners Institutional Review Board (IRB).

Gold Standard Annotation Schema

We used Protégé to create an annotation schema for identifying and classifying allergy information. The annotation schema included the type of allergy (food, drug, contrast media or environmental) as well as "no known allergies" (NKA). We also captured reactions to allergy statements even if the allergen was not specified.

Verification of System-Extracted Allergy Concepts

Using the testing set of 400 randomly selected ED notes, FG and DS manually reviewed and annotated each note using the annotation tool Knowtator[38]. To create the gold standard, the annotations were merged, reconciled and Inter-annotator agreement (IAA) was determined using the Knowtator IAA calculator. We then processed the testing corpus of clinical notes with MTERMS and compared its XML output to our

gold standard. The capability of MTERMS to detect different types of allergens as well as reactions was evaluated.

Our initial evaluation was on the ability of MTERMS to detect the correct reactions identified to a true positive allergen within the clinical text. Second, we evaluated if the reaction was correctly associated with the allergen identified. False positive reactions as a result of a false positive allergen were not considered in this study.

Results

MTERMs overall F-Measure for encoding allergen names and no known allergies was 87.6% with a recall of 91.0% and precision of 84.4%. The inter-annotator-agreement on the testing sample of 400 notes was 98%. Results by allergen type (Table 1) demonstrate that different types have varying system performance. Recall was highest for the drug allergens (92.5%) and lowest for environmental allergens (68.8%). Precision was highest among food, environmental, and NKA. Overall F-measure was highest among NKA and lowest for drug allergens.

Table 1. MTERMS System Performance on Processing ED Notes for Allergen Names and No Known Allergies

Allergen Type	**Total #**	**Recall (%)**	**Precision (%)**	**F-Measure (%)**
Drug	86	92.5	71.1	80.4
Drug Class	34	87.2	87.2	87.2
Environmental	11	69	100	82
Food	10	74	100	85
Contrast Media	6	86	100	92
Subtotal	147	87.2	78.6	82.7
No Known Allergies	70	100	100	100
Total	**217**	**91.0**	**84.4**	**87.6**

For reactions corresponding to a true positive allergen, we assessed the recall, precision, and F-measure (Table 2). We achieved an F-measure of 90% for identifying true reactions in each allergy statement where true allergens were also identified. When taking into account allergen/reaction association (e.g., reaction correctly paired to allergen), the recall increased to 85% but the precision decreased to 58% with a lower F-measure of 69%. Additionally, MTERMS correctly identified two instances of a true positive reaction, "urticaria," where no allergen (true negative) was identified.

Table 2. Reactions for True Positive Allergens*

Reaction	**No association**	**Association****
Total #	11	13
Recall	82%	85%
Precision	100%	58%
F-Measure	90%	69%

* Reactions associated with true positive allergens identified by MTERMS when allergen is present.

** Evaluates the number of associations present and the ability of MTERMS to correctly associate the reaction to the identified allergen (Note that there are cases in which a single reaction is linked to multiple allergens).

Common issues identified within MTERMS are shown in table 3. These included lexical variants that were not accounted for in our lexicon (e.g., lexicon contained NSAIDs but not NSAID and fish-dietary but not fish). These were common across all types of allergens (food, drug, contrast media and environmental). There were also instances where concepts were combined, resulting in only one of the two potential allergens being identified (e.g., MRI and CT contrast – missed MRI contrast).

Reasons for false positive allergens captured by MTERMS have been summarized in Table 4. There was one incidence of a medication falsely tagged as an allergen because it was written in the allergy section

(e.g. Motrin); however, the context suggests it might be a treatment rather than allergy. Outside of the allergy section, medications were most often falsely tagged as allergens when the medication was associated with treatment of a condition (where the condition can also be regarded as an allergic reaction by the NLP tool). For example, Coumadin is often used for the treatment of patients who have atrial fibrillation. There were also several incidences of medications falsely tagged as allergens near unrelated conditions or symptoms (e.g. antibiotics and hyperglycemia).

Table 3. Issues with MTERMS: False Negatives Allergens & Reactions

Issue	**Examples**
Not in lexicon (Drug)	"nitro" | "skin wipe"
Not in lexicon (Class)	"NSAID" | "statin" | "ace inhibitor" | "known drug allergies" | "multiple drug allergies"
Not in lexicon (Food)	"cherries" | "fish"
Not in lexicon (Environmental)	"seasonal allergies" | "bee stings" | "chemical exposure of unclear etiology" | "cold air" | "dry weather"
Not in lexicon (Reaction)	"GI upset" | "tight throat"
Disambiguation between allergy and medication	"Benadryl"
Combination of Terms	"MRI and CT contrast" misses MRI contrast
Pattern not supported	"She is noted to have a heparin allergy where she has itchy rash when she had been injected in the past"

Table 4. Issues with MTERMS: False Positives Allergens

Issue	**Examples**
Medication in allergy section header	"ALLERGIES: None. She has had some musculoskeletal pain relief with the Motrin she has been taking previously"
Medication associated with condition	"Coumadin/atrial fibrillation | antibiotics/fever | albuterol/asthma"
Conditions or symptoms near medications	"Given his comorbidities with his hyperglycemia, I had multiple conversations with strongly recommending observation stay for IV antibiotics" False Positive: Antibiotics | hyperglycemia

Discussion

The MTERMs allergy module achieved an overall F-measure of 87.6% for identifying allergens within ED clinical notes. Recall for medication names (92.5%) was comparable to Zhou et al[33] for free-text notes (90.6%). However precision was lower (71.1% vs. 90.3%) as the tool picked up medications associated with conditions that are not immune-mediated (Table 4). For reactions to true positive allergens, MTERMS had an overall F-measure of 90%. The F-measure dropped to 69% when analyzing if the reaction was correctly clinically paired with the allergen. This drop reflects the increase of false positive associations and lower precision.

Recent efforts on use of NLP to detect allergies have been undertaken by Epstein et al[6] who developed an algorithm to identify ingredient to which patients had allergies in a perioperative information management system. Epstein's system splits multi-allergen entries into multiple entries for processing and mapped allergies to RxNorm. Epstein's system noted a high precision (99.83%) but lower recall (72.82%) when evaluating unique strings from free-text and non-standard drop list allergy entries. The high precision is expected as the corpus essentially corresponded to only the allergy entries. In contrast, MTERMS had a lower precision (84.4%) but higher recall (91.0%), which is what we would expect given the need to find free-text allergy information from clinical notes and disambiguate an allergy from a treatment or home medication. Additionally, MTERMS attempts to encode and associate allergens with reactions.

MTERMS showed improvement in comparison to previous ADE studies[14, 18-21]. On a clinical level, MTERMS is able to identify true reactions when true allergens are also identified (e.g., fentanyl patch/rash, codeine/itching). Additionally, the correct reaction would be associated with the allergen (fentanyl

patch/rash); however, additional reactions (e.g., itching) from other allergens found (e.g., codeine) would also be listed, making it difficult to discern the correct allergen and reaction association. Disambiguation is a challenge because allergies and reactions are not always written in a one-to-one statement: multiple reactions can be listed for a single allergen or a single reaction can be listed for multiple allergens. MTERMS currently associates reactions based on proximity which allows it to correctly associate multiple reactions to a single allergen. However, MTERMS lacks sufficient logic to handle allergy relationships in close proximity or sentences with multiple sets of allergens and reactions. Identifying association indicators and a better understanding of the spatial relationship of allergens to reactions may help to create better association logic. Additionally, there was large variation in how clinicians document the allergy and while it is expected that only pertinent information related to allergies exists in the allergy section, we found some instances where other types of information was entered in the allergies (e.g., Motrin for musculoskeletal pain). Disambiguating false positive allergens associated with a medication used for treatment of a condition but contained in the allergy section or symptoms closely associated with medication (e.g., antibiotics/hyperglycemia) will also require further refinements to the context analyzer.

The lexicon for MTERMS is based on a subset of terms from standard terminologies that were compiled by expert review. MTERMS missed some common singular or pleural concepts (e.g., NSAID, statin, Seasonal Allergies). Common foods (e.g., fish) were also not identified as not all organism concepts from SNOMED CT were incorporated into the lexicon nor included in the PHIN allergy value set from the CDC (which includes the term "fish – dietary"). Misspelling errors continue to be an issue. Further pre-processing capabilities and lexicon development will be necessary to account these findings.

With the persistence of free-text entry, efficient NLP tools and/or machine learning methods are needed to bridge the gap between free-text and standard terminologies. Pick lists can help facilitate the entry of structured data but the preferred and most efficient method of data entry by clinicians is still often free-text. The benefits of structured data entry are clear with respect to drug-allergy and drug-drug checking and other forms of clinical decision support. Challenges ahead include further refining the allergy module of MTERMS and exploring methods of integration of NLP tools within an EHR and clinicians workflow.

One main limitation of our study is the testing sample consisted of ED notes from a single institution's EHR system, thus our results may not be generalize-able to other departments or institutions. For example, primary care physicians may encounter patients with more mild allergic reactions that are not immediately life threatening compared to patients in the ED. We expect documentation by allergy specialists to include much more detailed descriptions of the allergen and reactions, additional allergy elements regarding desensitization status, and certainty whether the allergic reaction was immune mediated through testing. Conclusions on the tool's ability to handle reactions and the challenges of disambiguating between treatments and allergies are also limited. While our sample size was chosen to provide sufficient examples of true allergies, allergic reactions may not have been well represented. We observed even fewer incidences of a true positive allergic reaction where the allergen was unknown or absent. Further analysis of PEAR, a large allergy repository, may improve our contextual understanding the associations between allergens and their reactions.

Conclusion

We present our preliminary findings for an allergy module for the Medical Text Extraction, Reasoning, and Mapping System (MTERMS) natural language processing (NLP) tool, and evaluated it's performance using free-text ED clinical notes. We found it is feasible to extract and encode allergy information from clinical notes using standard terminologies and contextual analysis.

Abstract

Mining the free text of electronic medical records (EMR) using natural language processing (NLP) is an effective method of extracting information not always captured in administrative data. We sought to determine if concepts related to homelessness, a non-medical condition, were amenable to extraction from the EMR of Veterans Affairs (VA) medical records. As there were no off-the-shelf products, a lexicon of terms related to homelessness was created. A corpus of free text documents from outpatient encounters was reviewed to create the reference standard for NLP training and testing. V3NLP Framework was used to detect instances of lexical terms and was compared to the reference standard. With a positive predictive value of 77% for extracting relevant concepts, this study demonstrates the feasibility of extracting positively asserted concepts related to homelessness from the free text of medical records.

Introduction

Homelessness, especially among Veterans, is a matter of national importance to the United States. The US Department of Veterans Affairs (VA) has committed to ending homelessness among Veterans[1]. Providing appropriate services for those who are experiencing homeless and, of equal importance, early interventions to those at risk are key components of this initiative. An essential element of preventing homelessness among Veterans is a systematic approach to identifying those at risk.

Current methods of identification of Veterans with any of these risk factors from within the VA consist of mining administrative databases for ICD-9-CM codes associated with these diagnoses [2, 3]. The reliability and validity of using administrative data is domain specific and has been shown to be useful in several domains [4-8]. However, this method is unlikely to be either timely or complete enough to be useful for planning interventions. Additionally, many factors of a social and behavioral nature are not captured completely by ICD-9-CM codes and so these may offer only a limited view of a patient's needs or risk factors.

References to risk factors as well as evidence for homelessness are often found only in the free text of medical records written by VA providers and possibly precede the formal identification of Veterans as being homeless[9]. Homelessness also serves as an ideal use case for identifying a wide range of psychosocial risk factors that may be documented in the free text during visits to the health care system [10]. The value of these text data has been shown in several clinical and biomedical domains including bio-surveillance, adverse event detection, and quality improvement [11-14].

Mining the free text of electronic medical records requires informatics-based methods such as natural language processing (NLP) to reliably extract appropriate and relevant information of interest, often referred to as concepts [12, 14]. These concepts can be single words, phrases, or larger spans of text. In general, NLP systems function by parsing sentences, identifying words or phrases, and mapping those to standardized vocabularies or ontologies such as the Unified Medical Language System (UMLS) Metathesaurus. In the absence of a formal ontology or in a situation where it is not known how domain-specific concepts are represented in clinical documents, an intermediate step would be to develop a lexicon or vocabulary of relevant concepts in the domain of interest. The lexicon could then be used as a dictionary in an NLP system for identification and extraction of appropriate concepts.

With no existing literature, reference standard, or lexicon to refer to in the specialized domain of homelessness, the goal of this study was to develop an NLP pipeline to extract positively asserted concepts related to homelessness

from the free text of VA medical records. The primary objective was to describe the positive predictive value (PPV) of the extraction process. We first describe the development of a lexicon of concepts related to homelessness through an iterative process. This lexicon was then used in an NLP pipeline to extract the concepts of interest. The performance of the extraction process was evaluated against a reference standard of free text clinical documents that were classified at the document level by human review to have evidence of homelessness along with a control group of documents with no evidence of homelessness. The prevalence of different categories of concepts in this reference standard is described using the NLP pipeline.

Methods

Setting and data sources

This study was performed using Veterans Information and Computing Infrastructure (VINCI), a central repository of VA-wide databases available for research including administrative, pharmacy and laboratory data, and free-text clinical documents [2]. For this study, a cohort of Veterans was identified who had at least one encounter within the VA health care system during the calendar year 2009 in two of four VA national regions. A corpus of free text clinical documents from outpatient encounters for this cohort of Veterans was extracted from VINCI databases and made available for this concept extraction project.

Developing a lexicon for concepts related to homelessness

A review of available concepts and variant lexical terms covering risk factors for homelessness and homelessness status was determined to be sparse and incomplete within available and frequently used controlled clinical vocabularies. It was determined that the traditional NLP extraction using UMLS based terminology needed to be augmented with additional concepts and terms that are missing.

There were several stages involved in lexicon development. The initial list of terms and phrases was constructed from a literature review for known risk factors for homelessness in general and Veterans in particular [15]. Next, a think-a-loud session was held, where the members of the research team, many of whom have experience with health care for the homeless, reviewed charts from known homeless Veterans and enriched the lexicon with concepts identified from the free text notes written by various VA providers including medical, mental health and social work providers.

The lexicon was refined using an iterative process. A panel of domain experts reviewed documents pre-annotated by NLP to determine if relevant concepts were identified, make modifications to annotations, add missing annotations, or reject annotations found to be incorrect or irrelevant. Concepts found within the notes that were relevant but not currently in the lexicon were added to it. An additional 154 variant forms of the terms were added through the use of NLM's lexical variant generation tools[16] coupled with additional human curation. The final list was adjudicated by a group of clinicians, social workers as well as homeless shelter providers to ensure generalizability in both the VA and external settings. A further refinement of the lexicon was performed by manual review of the documents for false negatives after processing by the NLP pipeline.

The resulting set of 356 terms were categorized into eight broad categories: direct evidence, "doubling up", mentions of mental health diagnoses, behavioral factors, social stressors, sexual and other trauma, medical comorbidities, and other risk factors.

Establishing a human-reviewed reference standard of text documents for homelessness

The premise for choosing text documents was based on discussions with VA clinicians and service providers who care for Veterans experiencing homelessness. The rationale was that barring a self-declaration of homeless status by the Veteran, the most direct reference to a Veteran experiencing homelessness is likely to be in the free text notes of VA providers.

From the text documents generated from VA facility encounters during the calendar year 2009, a random sample of 500 documents was extracted without regard to VA facility or any Veteran characteristic. Another random 500 documents were extracted with the word 'homeless' in the note title. This step was taken to enrich the text document

corpus for homelessness as a random sample of documents is likely to have a low prevalence of homelessness and concepts of interest.

Using the official US Government definition for homelessness [17], a written guideline was developed for human review of text documents. Reviewers were instructed to read a document and then classify the document as either (1) having *positive* documentation for evidence of current or past homelessness or risk factors associated with homelessness (ever homeless/at risk) or (2) *no* evidence of homelessness. Three reviewers were recruited to perform the classification. As part of the training to establish and achieve high agreement, each reviewer was instructed to classify 4 sets of 20 documents (total 80) with review and discussion among reviewers of concordantly and discordantly classified documents. Once the set of 80 'human training' documents were completed, reviewers were assigned sets of 20 documents till the corpus was exhausted (total corpus of 862 documents). The classification task was performed using a general purpose annotation tool called eHOST, in which documents were displayed in human-readable format similar to the VA electronic medical record [18]. The file format for the documents was based on Knowtator, a widely used annotation tool [19].

Researching available electronic resources to map concepts related to homelessness

In an effort to map the terms in our lexicon to existing ontologies, two steps were taken. First, a search for concepts related to homelessness was conducted using the NCI Metathesaurus browser [20]. This resource is described as a wide-ranging biomedical terminology database that covers most terminologies used by NCI for clinical care, translational and basic research, and public information and administrative activities. It is an extensive dictionary of concepts from over 75 sources including the Unified Medical Language System (UMLS) Metathesaurus.

In addition, an effort was made to map the lexical concepts to established ontologies by utilizing BioPortal (http://bioportal.bioontology.org) to ensure uniformity and to avoid duplication of efforts in converting unstructured free text to structured data. BioPortal is an open source Web repository enabling access to terms from about 372 biomedical ontologies and data sources [21, 22]. However, in addition to clinically-related ontologies, BioPortal includes genomic-associated ontologies, such as cell line ontology, as well as other organism ontologies, such as mouse genome. The 372 ontologies as of year 2013 were manually curated in order to limit our lexical search to clinically-related data sources. A total of 98 ontologies and terminologies were considered for concepts mapping and two searches were performed on the lexicon created for this project: an exact match term search and an "at least one" term search (wildcard search strategy). The results of both search types were retrieved and manually curated by three people, with one adjudicating the review results of the other two. UMLS Concept identifiers were also generated for each term in the lexicon via term to concept mapping tools [23]and human judgment for those that did not map. UMLS concept ids are provided as attributes for the 84 terms that were mapped. These efforts provide an additional semantic locality entry point that could be used for classification from different perspectives.

Natural language processing (NLP) pipeline: V3NLP

The basic premise of an NLP pipeline is to take unstructured free text and convert the text to machine-readable 'structured' elements. The V3NLP Framework, used for this project, is a UIMA [24] based set of tools, annotation label guidelines, annotators, readers and writers designed to aid VINCI NLP developers to build out applications. The V3NLP Framework evolved initially from HITEx [25], CTAKEs [26], and MetaMap[23], which are NLP systems that have been applied across a wide variety of use cases.

The pipeline created for this task involved term lookup utilizing the lexicon developed for this project along with negation detection. Additional modules were developed and employed for this task to address boilerplated text such as Slot: Value, check boxes, and question structures. The slot:value pipeline component and the question pipeline component were employed to identify concepts that fall within these structures so that the concept assertion status is updated [27]. Concept assertion semantics are different for each of these boilerplated structures. For example, checkbox structures of the form *Homeless: Y N* was observed within Homelessness Survey records. It is necessary to recognize that this is a check box structure, and that the assertion status for the *homelessness* concept rests on the dependent content, to the left of the delimiter. If only *Y* appears, or any positive variant, the concept is asserted. Any other dependent content value would cause the concept to be tagged with negated. A tail end module was created to turn the homelessness terms into annotations in 8 named categories as described above.

Error analysis for training NLP pipeline

False positive error analyses were performed by two human reviewers on a subset of 50 documents that were classified by the human reference standard as "positive" evidence of homelessness and 50 documents with "no" evidence of homelessness. The task was to review all the concepts extracted by the NLP pipeline (true and false positives) and classify the concept as either positively asserted or not, thus establishing the true positive rate which is the positive predictive value, PPV). This was performed using eHost and reviewing text documents highlighted with concepts identified by the NLP pipeline [18]. The false positive analysis was used to identify problem areas in the text such as templates (such as question/answer formats) and refine the NLP pipeline in an iterative manner. As an initial review of false positives were noted to be due to negation and boilerplated text such as check boxes and questions, modules to address these issues were added to the NLP pipeline (Negex for negation and slot:value and question for boilerplated text).

Further, false negative analyses were performed by reviewing the text of the documents to identify additional concepts related to homelessness that were not already identified by the NLP algorithm. These words, terms or phrases were then included in the lexicon to be used in the next iteration of the NLP algorithm.

Positive predictive value of the NLP pipeline for extracting positively asserted concepts

An agile review of 50 documents from the homeless and non-homeless category was used to improve the overall PPV of concept extraction in an iterative manner. The final, refined iteration of the NLP pipeline was used to determine the instances of positively asserted concepts in eight categories in the 862 documents of the reference standard. After excluding the 100 documents used above for the error analysis and training of the pipeline, the remainder 762 documents were reviewed by two human reviewers to determine the true positivity or PPV of the concepts identified by the NLP pipeline.

The rationale for determining the PPV or precision alone as opposed to precision and recall (sensitivity) as is often reported in the informatics literature is due to the low prevalence of concepts of interest and the resulting high number of documents that are expected to be negative with regard to concepts.

Data extraction and analyses was performed using SAS (Version 9, SAS Institute Inc., Cary, NC) and R software (Version: 2.15.0, The R Foundation for Statistical Computing, Vienna, Austria). This study was approved by the Institutional Review Board of the University of Utah and Research Review Committee of the VA Salt Lake City Health Care System. The research protocol was granted waiver of authorization and waiver of consent to access existing electronic medical records in VA research databases.

Results

Lexicon of Concepts Related to Homelessness

The final version of the manually created lexicon contained 202 high-level psychosocial and homelessness related concepts, divided in to the eight categories already mentioned. Table 1 lists the categories and examples of the terms and concepts included in each one.

Reference standard of free text documents for concept extraction

Starting with a corpus of 1000 documents, our annotators reviewed a total of 862 documents for the reference standard after removing 138 documents due to training and for logistic reasons. Of these, 424 were classified as having evidence of homelessness at the document level (Homeless) and 438 as having no evidence of homelessness (Not Homeless). Reviewers had 98% overall inter-rater agreement in classifying the documents.

The top 5 document types in terms of frequency as determined by the note title in the "Homeless" group were: HCHV Healthcare for Homeless Veterans, Homeless Program Initial Assessment (X), Homeless Program/OPC/SOAP/Social Work, Homeless Program Intake, and Healthcare for Homeless Veterans. The top 5 most frequent document types in the "Not Homeless" group were: Addendum, Discharge Summary, Primary Care, Ambulatory Outpatient Care Note, and Primary Care Clinic Notes.

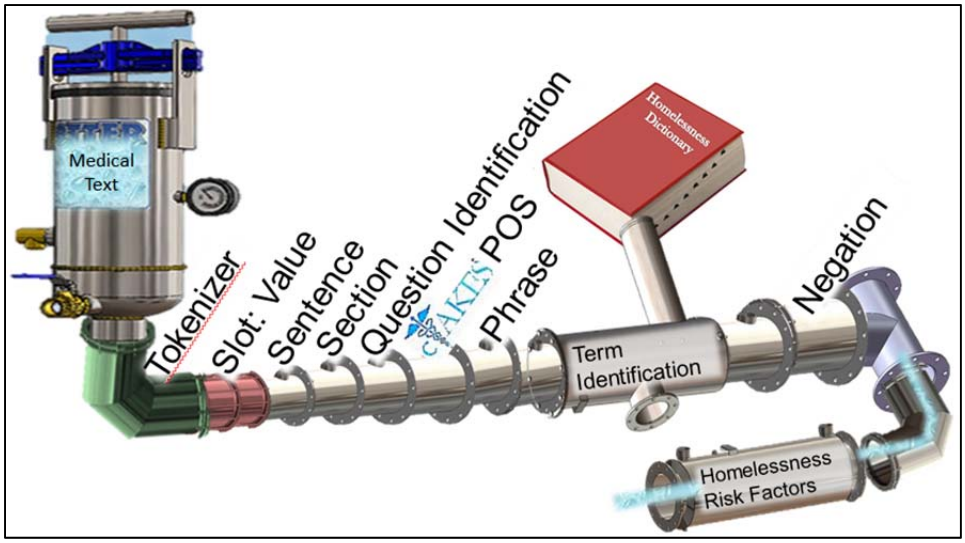

Figure 1: Homelessness psychosocial risk factors NLP pipeline

Table 1. Lexicon concept categories and examples of terms.

Concept Categories	Examples
Behavioral Health	Addiction, alcohol/drug abuse or dependence, detox, DUI, pathological gambling, violent behavior
Direct Evidence	Homeless, living on streets, sleeping outdoors, lack of housing, V60.0
Doubling up	Doubled up, couch surfing, lives with parents/significant other/sibling, crashing at friend's house
Medical Comorbidities	Hepatitis C, frostbite, HIV, gangrene
Mental Health	Axis II, poor coping skills, social isolation, paranoia, schizophrenia, depression, anger
Other Risk Factors	Emergency medical services, at risk ethnic or racial groups, no ID, needs ID
Sexual & Other Trauma	Sexual abuse/trauma, childhood abuse/trauma, domestic violence, military sexual trauma (MST)
Social Stressors	No or poor family support, recent divorce, death of close family member, job loss, legal issues

UMLS and BioPortal searches

The search for 'homeless' and 'homelessness' on the NCI Metathesaurus revealed one unique concept of homelessness with several synonyms (concept unique identifier, CUI C0237154). A review of the relationships of this concept to others in the form or parent, child and sibling relationships (representing hierarchies of relationships between associated concepts) reveals mapping to several risk factors related to homelessness. For example, parent concepts include social problems; child concepts include temporary shelter arrangements; sibling concepts include social behavior and substance abuse disorders. The challenges in directly applying NLP algorithms that map free text to unique concepts in the Metathesaurus is the problem of one term mapping to several different related concepts and the lack of knowledge of how these concepts are represented in the electronic medical record by diverse types of providers in a healthcare system.

The Bioportal search resulted into 648 terms or phrases that were mapped to the initial 201 high-level concepts. This included similar terms from mostly SNOMED, LOINC and Medical Subjects Headings. The results were manually reviewed by two reviewers and ultimately, 185 concept unique identifiers (CUIs) that are psychosocial and homelessness related were retrieved. However, about 62% of the initial concepts did not result into any mapping from Bioportal.

Prevalence of concepts in document corpus

The iterative development of the NLP pipeline based on an agile review of false positives in 50 documents each of homeless and non-homeless resulted in improvement of the positive predictive value (PPV) of concept extraction. (Table 2). While several iterations resulted in improvement in PPV of extracted concepts, some iterations resulted in degradation of PPV in certain concept categories. Table 2 shows three representative steps of the iterative process with corresponding numbers of hits from NLP and associated PPV.

The final iteration of the NLP pipeline (version 10) was then applied to the entire reference standard corpus (Table 3). A total of 4251 concepts were identified from the 862 documents. Among the documents with 'homeless' in the note title, 403 out of 417 (97%) contained at least one concept. Based on a human review of the false positive concepts, the overall positive predictive value (PPV) for extracting homeless-related concepts from this set of documents was 76%. Among the random sample of documents, only 150 out of 455 (33%) contained at least one concept, with an overall PPV of 77%.

Table 2. True positive (Positive Predictive Value) during NLP pipeline iterations based on error analysis

		Documents with evidence of homelessness (N=50 documents)				**Documents with no evidence of homelessness (N=50 documents)**			
		Concept Categories Number of True + False Positives (PPV%)				Concept Categories Number of True + False Positives (PPV%)			
	Error Analysis Comments	Direct	Mental Health And Behavioral	Social Stressors	All others	Direct	Mental Health And Behavioral	Social Stressors	All others
NLP Version 6 Key word; Negation with phrasal span	False positives noted in templated questions; acceptable PPV	1323 (85)	881 (84)	558 (87)	57 (72)	80 (73)	109 (85)	46 (80)	20 (65)
NLP Version 8 Templated question/answer sections ignored	Decrease in overall positivity due to ignoring template question/answer; decrease in PPV	850 (72)	344 (72)	208 (82)	16 (63)	36 (44)	50 (68)	20 (70)	10 (40)
NLP Version 10 Recognize template question/answer; also template with colon (:) and[]	total all 3690	1557 (76)	1005 (61)	681 (91)	66 (79)	14 (71)	239 (80)	79 (95)	49 (69)

In addition, the "homelessness" documents had an average of 8 concepts per document, as compared to 2 concepts per document in the random sample. Table 2 contains additional information related to the prevalence of concepts, including concepts per category, PPV by category, and most frequent concepts from each category.

False positive analysis

The human review of documents for false positive and false negative analyses was conducted using eHOST (Figure 2).
The most common reason for false positivity was that the concept was part of a templated question, such as "How long have you been *homeless*?' In addition, the context of the word or alternate meanings of a word or abbreviation lead to several false positives. For example, the abbreviation SA is often used to refer to substance abuse and was included in the lexicon. However, in the context of a medication list, SA TAB refers to sustained action. The phrase *rule out* is commonly used in medical records to literally indicate that the providers were trying to rule out a particular condition or diagnosis. This had to be added as a term to insure the negation module picked it up as one unit within one phrase to appropriately negate the rest of the phrase.

Table 3. Prevalence of concepts related to homelessness in reference standard document corpus (Total N=862 documents, Total positively asserted concepts = 4251)

	Documents with evidence of Homelessness (N=403 documents)* Total concepts = 3309 Average 8 concepts per document, range 1 to 34, median 8			Documents with no evidence of Homelessness (N=150 documents)** Total concepts = 320 Average 2 concepts per document, range 1 to 13, median 1		
	Number of Concepts (Positive Predictive Value %)	**Most Frequent Concepts**	**Most Frequent Document Types**	**Number of Concepts (Positive Predictive Value %)**	**Most Frequent Concepts**	**Most Frequent Document Types**
Direct Evidence	1557 (76)	shelter, homelessness, hchv, homeless program, rehabilitation	homeless, social work, mental health program notes	**20 (70)**	shelter, rehabilitation, halfway house, housing program	psychiatry nursing assessment, mental health
Mental Health and Behavioral Factors	1016 (62)	detox, heroin, drug use, etoh, alcohol abuse	homeless, social work, discharge summary and mental health program notes	**195 (77)**	etoh, alcohol use, withdrawal, alcohol abuse, substance abuse,	discharge summaries, general mental health note, follow-up primary care
Social Stressors	681 (91)	divorced, unemployed, separated, prison, jail	homeless, social work, discharge summary and mental health program	**66 (95)**	divorced, unemployed, lives alone, prison, jail	mental health, , discharge summaries, history & physical
Other	55 (75)	trauma, hep c, mst	homeless, medical progress and social work program	**39 (67)**	mst, trauma, hep c	primary care, medical clinic, mental health note

* **14 of 417 (3%) documents with evidence of homelessness had 0 concepts**

** **305 of 455 (67%) documents with no evidence of homelessness had 0 concepts**

hchv = health care for homeless veterans; etoh = alcohol; hep c = hepatitis c; mst = military sexual trauma

False negative analysis

In the first round of review, the most common terms that represented concepts related to homelessness that were found in the free text and were missing from the lexicon were terms related to alcohol use. For example, a template used in screening for alcohol use, the phrase used was 'how many drinks containing alcohol do you consume each day?'; similarly several creative variations on the theme of heavy drinking were noted in the free text including the terms 'problem drinker'. Other examples of missed concepts were due to misspelling and the use of different cases (capital vs. lower case) in a non-standard fashion. For example, typically the usage for the Housing and Urban Development, VA Assisted Housing is represented as HUD-VASH; in some instances, the provider used a non-standard mix-up of upper and lower case letters such as Hud-Vash which was not recognized by the NLP program as a variant (even though NLP programs have a case insensitive algorithm built in).

Discussion

Using the VA electronic record and informatics methods, this study demonstrates the feasibility of extracting positively asserted concepts related to homelessness from the free text of medical records. Sub-optimal mapping of concepts to existing ontologies demonstrated the necessity for developing a customized lexicon for concepts related to homelessness. Homelessness may be considered a 'non-medical' condition and as such this represents an interesting use of NLP to extract non-medical concepts from medical records. It is important to note that the established risk factors for homelessness (as denoted by the different categories in Table 1) are very much part of the medical domain and are expected to be found in medical records.

The potential applications of the lexicon and NLP algorithm are to study the prevalence of these concepts among those who have evidence of homelessness versus those who are not. These analyses may also play a role in

determining associations of concepts with the onset of homelessness and in the ideal situation, provide a means of identifying early warning indicators of risk of homelessness, prior to the formal 'diagnoses' through ICD-9-CM codes for homelessness or known risk factors. This could be achieved by applying the algorithm on longitudinal electronic medical records of Veterans. With the use of available ontologies and vocabularies, this work could be extended to other medical domains.

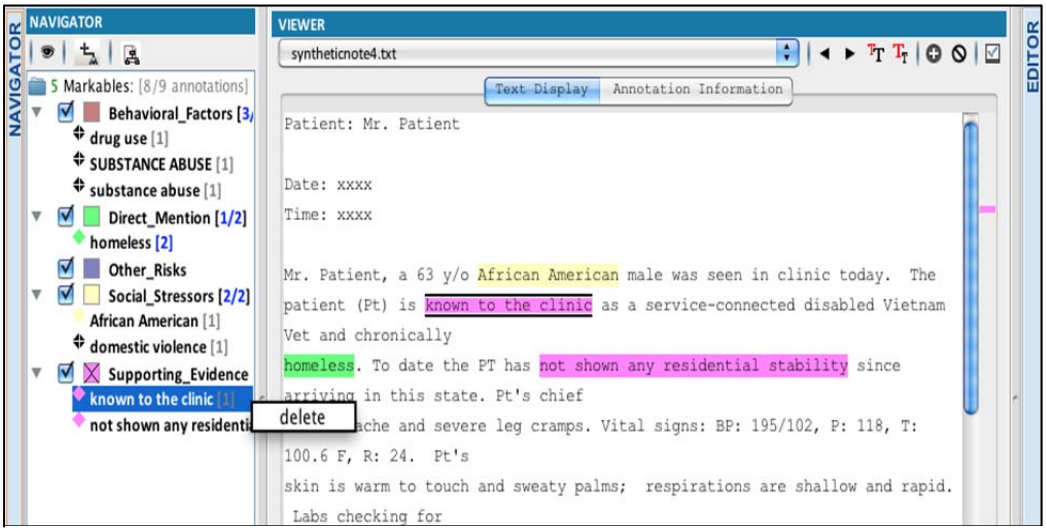

Figure 2. Synthetic record containing mentions of homelessness as displayed in eHost, the annotation tool used.

The issue of templates in VA medical records has been shown to be a major factor in poor performance of information extraction algorithms[27], as demonstrated by the use of a version of this pipeline in a study of extracting psychosocial factors from large electronic medical record corpora [10]. This study demonstrates the feasibility of successfully processing question/answer and other formats of templates to extract positively asserted concepts to increase yield (hit rate of concepts) and PPV. This has broad applicability in the field of NLP as templated medical records are used in many settings to document patient-related information both by providers (forms and checklists in the EMR) and by patients (in-clinic, through kiosks and on-line surveys and questionnaires).

The iterative process by which the lexicon was developed and made available for use by the NLP algorithm reinforces the challenges of 'teaching' computers to read human language. The myriad variations possible in terms of spelling, meaning and abbreviations, the variation noted in text written by different types of providers and regional variations lead one to conclude that this likely represents a sub-language of its own.

We note several limitations. Based on our experience, the lexicon for homelessness concepts is neither exhaustive nor complete. Thus we would consider the current lexicon to be a living document. We did not attempt to add to the lexicon using automated or 'self-learning' methods. It is likely that there are variations in use of concepts related to homelessness based on sub-language differences among various clinical providers or based on geography (by state or region of the US). Thus, it would be important to study such variations to look at iso-semantic concepts. A more detailed mapping of our lexical terms to available vocabularies and ontologies is necessary and ongoing as it is desirable to convert all NLP-derived phenotypes to structured data. We applied the NLP pipeline to a small subset of VA records in this study. A version of the pipeline has been applied to a large corpus with acceptable performance [10]. While this pipeline has been developed using VA medical records, the principles are generalizable and adaptable to the EMR of other large health care systems.

Concept assertion status including asserted, negated, hypothetical, historical, and not relating to the patient are ever present sources of failures within the NLP process. NegEX2 [28]was used for this study to determine asserted/negated status. Future iterations will incorporate a refined version of ConTEXT to determine assertion status with more granularity and precision[29].

Concepts of interest extracted from the NLP pipeline are not sufficient to make a homelessness classification for a given patient. On-going work involves using concepts of interest extracted from reference documents as features to train a machine learning predictive model.

Conclusion

Extracting information related to a non-medical condition from the free text of medical records can be a challenge. In this use case involving concepts related to homelessness, it required the development of a specialized lexicon, as the concepts of interest were poorly covered by existing ontologies. This method can be applied to other areas of interest and relevance while mining the EMR.

Acknowledgements

This work is supported by VA HSR&D Merit Review Award # HIR 10-002 (PI: AVG). We would like to express our gratitude to the administration and staff of the VA Informatics and Computing Infrastructure (VINCI) for their support of our project. The project benefited immensely from an active advisory role by the VA SLC Health Care System's homeless service coordinator, Mr. Aldo Hernandez. We are deeply appreciative of the expertise and active participation in this project by our homeless service community partners in Salt Lake City, Utah: Fourth Street Clinic (Mr. Monte Hanks); The Road Home (Ms. Michelle Flynn and Ms. Michelle Vasquez), Volunteers of America (Ms. Jessica Fleming, Ms. Jamie Jones) and the State of Utah (Ms. Kathleen Moore). We would like to thank our colleagues at the National Center on Homelessness Among Veterans (Drs. Dennis Culhane, Steven Metraux and Jamison Fargo) for their discussions and advice. We gratefully acknowledge the support of our research team members: Mr. Thomas Ginter, Ms. Sarah Craig and Ms. Natalie Kelly. We also acknowledge other resources and facilities provided by the VA Salt Lake City Health Care System.

Cincinnati, Ohio

Abstract

Efforts to study relationships between maternal airborne pollutant exposures and poor pregnancy outcomes have been frustrated by data limitations. Our objective was to report the proportion of Ohio women in 2006-2010 experiencing stillbirth whose pregnancy exposure to six criteria airborne pollutants could be approximated by applying a geospatial approach to vital records and Environmental Protection Agency air monitoring data. In addition, we characterized clinical and socio-demographic differences among women who lived within 10 km of monitoring stations compared to women who did not live within proximity of monitoring stations. For women who experienced stillbirth, 10.8% listed a residence within 10 km of each type of monitoring station. Maternal race, education, and marital status were significantly different ($p<0.0001$) comparing those within proximity to monitoring stations to those outside of monitoring range. No significant differences were identified in maternal age, ethnicity, smoking status, hypertension, or diabetes between groups.

Background

Despite a steady decline over the previous two decades, the United States stillbirth rate of 6.0 per 1,000 births in 2006 remained substantially higher than that of other high income countries.[1-3] The national stillbirth rate (defined as fetal deaths occurring at or beyond 20 weeks of gestation) also remained 50% above the Healthy People 2010 goal of 4.1 per 1,000 leading to a revised goal for Healthy People 2020 of 5.6 per 1,000.[4, 5] While, obesity, maternal age, and smoking are significant modifiable risk factors for stillbirth, other clinical, genetic, socioeconomic, and environmental factors are also important contributors to a woman's risk of stillbirth.[6, 7] Although methodological limitations in previously reported studies have yielded mixed and inconclusive results, identifying the effects of maternal exposure to airborne pollutants on fetal development and birth outcomes remains a research priority.[8, 9]

The Environmental Protection Agency (EPA) lists six criteria pollutants representing agents harmful to public health.[10] These include carbon monoxide (CO), lead (Pb), nitrogen dioxide (NO_2), ozone (O_3), particle pollution, and sulfur dioxide (SO_2). Pollutants are monitored at regular intervals by stations at fixed locations, though exposures of individuals residing nearby may be approximated. Exposure estimates rely on linking data representing air quality with clinical and socio-demographic measures of individuals. Previous analyses of associations between the criteria pollutants and stillbirth have been limited in analytic design as a consequence of relevant data residing in incompatible systems.[11-17] Former study limitations include inadequate temporal and geographic granularity and insufficient controlling for socio-demographic risk factors. Additionally, previous efforts have typically focused on single pollutant exposures rather than considering exposures to multiple pollutants or the combined effects of multiple pollutant exposures.

A recent study utilizing a geospatial approach identified an association between stillbirth and maternal exposure to pollutants by linking vital records to data from the EPA Air Quality System.[18] However, this type of analysis may also be limited by proximity of mothers to EPA monitoring stations, particularly when conducting analysis of multiple exposure types. The fixed number of monitoring stations as well as the placement of stations near urban settings may limit the coverage and representativeness of population data obtained from the EPA.

The objective of this Ohio statewide study was to describe the coverage and utility of existing air monitoring data to support investigations of maternal pollutant exposures when integrated with vital statistics. This was achieved by 1) identifying among women who experienced a live or stillbirth, the proportion who resided within proximity to an EPA air monitoring station 2) characterizing clinical and socio-demographic differences among women who lived within range of all types of monitoring stations compared to women who did not live within proximity of any air

monitoring stations. This study builds upon previous efforts in developing maternal-child health data resources by integrating disparate data sets including vital statistics, hospital discharge data, geospatially-based measures from the American Communities Survey, and community-based program data.[19, 20] Integration of air quality data provides an additional dimension for investigating the complex interplay of factors contributing to stillbirth and other perinatal outcomes.

Methods

The geospatial population-based cohort study incorporated data from two primary sources, vital records and air monitoring measures. Vital records including fetal death records as well as live birth records were obtained from the Ohio Department of Health representing 4,622 stillbirths and 751,123 live births occurring in Ohio during 2006-2010. The study set was reduced to singleton births with documented gestational age between 20 and 42 weeks and with documented birth weight of at least 350 grams. Additionally, infants with confirmed chromosomal anomalies were not included in the final study set. Lastly, births occurring within Ohio corresponding to mothers reporting residence outside of the state were excluded resulting in a final study set of 3,090 stillbirths and 707,110 live births (Table 1). Basic demographic and clinical measures including maternal race and ethnicity, age, marital status, level of education, smoking status, and diagnosis of hypertension or diabetes were also obtained from vital records data.

TABLE 1. Study exclusion criteria and final sample

Exclusion Criteria	Stillbirths	Live births
Records of birth events within Ohio, 2006-2010	4,622	751,123
Missing gestational age, gestational sge < 20 weeks, or gestational age > 42 weeks	52	2,910
Birth weight <350 grams	954	366
Chromosomal anomalies	128	685
Multiple gestation	86	26,995
Residence outside of Ohio	113	13,057
Final study set	3,090	707,110

Measures of criteria pollutants were obtained from the EPA representing CO, Pb, NO_2, O_3, SO_2 and fine particulate matter measuring less than 2.5 μm in aerodynamic diameter ($PM_{2.5}$).[21] Data were obtained from Ohio air monitoring stations representing pollutant level measures at time periods ranging from hourly to every few days. Data were obtained for 2005 through 2010 to correspond with the pregnancy timeframes represented by the vital records data set. Each pollutant was measured by a unique set of stations, with a range of six to 59 locations in Ohio. Although some stations measured a single pollutant, other stations obtained multiple measures. In all, measures of pollutant levels for the six criteria pollutants were captured at 126 unique geospatial coordinates across the state. Using all measures captured for each pollutant at each location, monthly average measures were calculated for every calendar month of the study period.

Linkage between vital records and air pollution data was performed using ArcGIS 10.1 (ESRI, Redlands, CA). Station locations were geocoded with a latitude-longitude coordinate pair as were maternal residences reported at the time of birth. When specific address information was missing, residence was approximated using the centroid of the residence zip code. For each live or stillbirth record, the closest monitoring station was identified for each pollutant. Additionally, the distance to the nearest monitoring station of each pollutant type was calculated.

The number of birth events listing maternal residence within five, 10, and 15 km of a monitoring station was calculated for each pollutant. We also determined the set of women residing within proximity to monitoring stations for each of the six criteria pollutants as well as the set of women who were not within the proximity of five, 10, or 15 km of any criteria pollutant monitoring stations. Additional analyses were conducted for the women within proximity to all six monitor types compared to women outside of the coverage range of any monitoring station. Consistent with methods used in previous analyses, proximity for the additional analysis was defined as 10 km.[18, 22]

Statistical analysis and calculations were conducted using SAS version 9.3 (SAS Institute Inc., Cary, NC) software. Bivariate χ2- or *t*-tests analyses were performed to identify demographic and clinical differences between populations within proximity to all six pollutant monitors and those outside the proximity of any monitoring station. Because multiple tests were performed, a Bonferroni-Holm correction was implemented to determine significance.[23]

Next, estimated exposures to each pollutant were calculated for each pregnancy trimester and for the entire duration of pregnancy. The initiation of the pregnancy was estimated by subtracting the clinical estimate of gestational age from the documented date of delivery. The first trimester was defined as weeks 0 through 12, the second trimester as weeks 13 through 27 and the third trimester as weeks 28 through 42. Exposures were estimated by first identifying

the average monitoring station measure for the calendar month corresponding to each pregnancy month. Whole pregnancy and per trimester exposure estimates were calculated using monthly monitor measures for which the mother was pregnant for at least half of the calendar month, or for which the pregnancy trimester spanned at least half of the calendar month. For each pregnancy stage, mean population exposures for stillbirth and live birth outcomes were then calculated using exposure estimate calculations for individual mothers. The Ohio Department of Health and University of Cincinnati Institutional Review Boards approved this study.

Results

For both stillbirth and live birth sets, the mean and median distance from each residence to the nearest station monitoring each of the criteria pollutants is recorded in Table 2. For all six of the criteria pollutants, the average distances between residences and stations were inversely related to the number of monitoring stations.

TABLE 2. Number of monitoring stations for each pollutant and the average distance between stations and maternal residence at the time of live or stillbirth event.

Pollutant	Number of stations	Distance from stillbirth residence to nearest station (km) (mean, median)		Distance from live birth residence to nearest station (km) (mean, median)	
CO	17	36.1,	17.6	40.7,	19.8
Pb	20	24.8,	16.5	29.5,	17.7
NO_2	6	68.1,	49.1	72.3,	66.2

Table 3 lists the number of stillbirth and live birth events listing a residence within a 5, 10, and 15 km radius from each monitoring station. The proportion of the 3,090 stillbirths and 707,110 live births covered by each radius is also reported. Additionally, the number and proportion of births with residence within range of all six criteria pollutant monitoring station types is listed. Ozone and $PM_{2.5}$ monitoring stations had the best coverage with over 55% of stillbirths and nearly 50% of live births having a corresponding maternal residence within 10 km from a station. Just 10.8% of the stillbirth and 8.1% of the live birth population listed a residence within 10 km of each of the six monitoring station types. On the other hand, 33.6% of the stillbirth and 39.1% of the live birth population listed a residence that was more than 10 km from any of the six monitoring station types (Figure 1).

Characteristics of the stillbirth and live birth populations are listed in Table 4. Also in the table, clinical and demographic characteristics are further stratified into categories of women who reported a residence within 10 km of each of the six types of monitoring stations and women whose residence was more than 10 km from any station type. Among women who experienced a stillbirth, race, education, and marital status had significant differences between groups. However, no significant differences were identified in age, ethnicity, smoking status, hypertension, or diabetes between groups. Among the large live birth set, all comparisons yielded significance in comparisons between groups.

Exposures to each of the six pollutants are presented in Table 5 for both stillbirth and live birth data sets. Mean exposures are listed for each pregnancy trimester and for the pregnancy duration representing all estimated exposures having a residence within 10 km of the relevant station type. Only exposures to $PM_{2.5}$ exceeded EPA standards; however the high exposure rates affected both stillbirth and live birth populations.

Discussion

The linkage approach described in this manuscript has potential to enable powerful analyses of pollution effects on stillbirth as well as other pregnancy related outcomes. The final linked study data set joined measures from the EPA and vital record sets providing a data set containing socio-demographic measures at the individual person level along with pollution exposure approximations customized both temporally and spatially to each individual pregnancy. Exposure approximations for each trimester of pregnancy enable additional analyses about the stages of fetal development that may be most susceptible to high levels of pollutant exposure. This approach has already provided insight into the impact of high $PM_{2.5}$ exposure levels on stillbirth. In a previous analysis we found a 42% increase in stillbirth risk associated with increased $PM_{2.5}$ exposure during the third trimester of pregnancy.[24] Further, we estimated that up to 2.2 per 1,000 Ohio stillbirths are potentially attributable to high levels of $PM_{2.5}$ exposure.

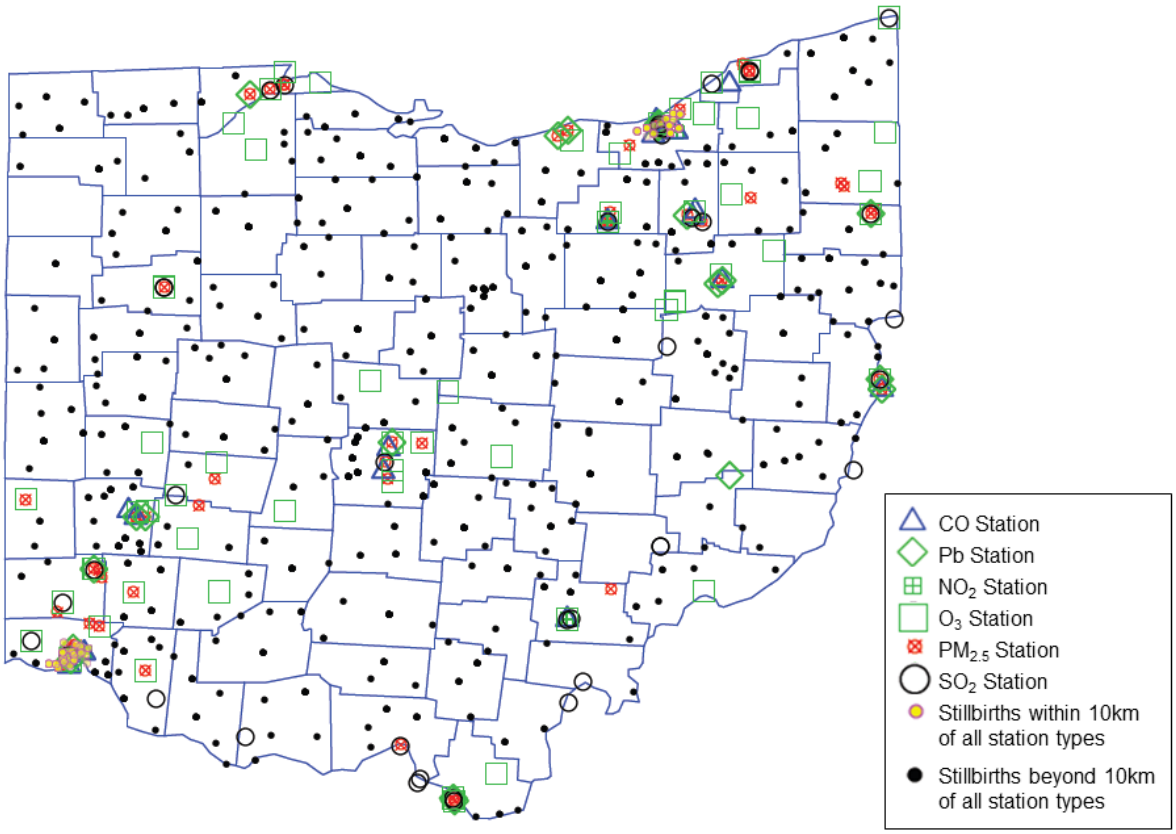

FIGURE 1. Locations of 126 monitoring station locations throughout Ohio along with points indicating stillbirths with residence within 10 km of all six criteria pollutants monitoring stations and with residence beyond 10 km from any monitoring station.

Efforts to use this approach to estimate pregnancy exposures to all six criteria pollutants using a maximum of 10 km distance between residence and monitoring stations would be limited to less than 11% of the Ohio stillbirth and about 8% of the live birth populations. Also the analysis would be restricted to residents of the urban Cincinnati and Cleveland regions. Although this geospatial approach for approximating exposure may be sufficient for single particulate analysis, reliance of residence in close proximity to air monitoring stations is a considerable limitation to the analysis of the effects of multiple pollutants. Having just six monitoring stations in the state of Ohio, NO_2 approximations are the most sparsely represented in the data set. Although it may be difficult to conduct representative analyses of simultaneous exposures to all six criteria pollutants, this geospatial approach could potentially support meaningful analyses of a subset of the criteria pollutants.

sd= standard deviation
ppm = parts per million
ppb = parts per billion

In the current analysis, although we found that coverage for estimating exposures to all six criteria pollutants was limited to urban populations, there were no significant difference in the prevalence of important stillbirth risk factors including maternal age, smoking status, hypertension, and diabetes between the rural and urban groups. While the distribution of clinical risk factors was consistent among those in close proximity to all monitoring stations as well as those outside the proximity of any monitoring station, there were significant differences in the socio-demographic makeup of the two groups. Women residing near all six types of monitoring stations were more likely to be black, unmarried, and to have attained a lower level of education than women listing a residence beyond the range of any monitoring station. Because many of these characteristics are associated with the stillbirth outcome, any study using our data management approach would need to make proper adjustment for these coexisting risk factors when conducting analyses and in reporting results.

The described approach has generalizability beyond analyses related to stillbirth. Other studies have focused on the effects of maternal exposure to pollutants on preterm birth[25-27] and autism.[28] Our approach would provide the same improvements to temporal and spatial granularity in the analyses of these and other clinical outcomes associated with maternal exposures. A separate investigation using our approach has identified an association between high levels of $PM_{2.5}$ exposure and preterm birth.[29] As all pregnant women are potentially at risk for negative outcomes resulting from pollution exposures, our methods have broad applicability and relevance in better understanding the true risks to fetal and infant health associated with in-utero exposures.

Although the use of maternal residence enables additional spatial granularity over cruder county- or state-wide exposure approximations, our approach does not capture spatial mobility throughout the course of pregnancy. Our approach utilized a residence provided at the time of birth; however, a more detailed residence history would enable further customization of individual exposure approximations throughout the pregnancy period. In addition, our approach was unable to adjust to variations in pollutant levels within the 10 km radius of each monitoring station. The described variations introduce the limitation of underestimated risk attributed to maternal exposure.

Conclusions

Using a spatial approach to linking measures of air quality to vital records, we were able to identify characteristics of women residing within the coverage range of EPA monitoring stations. Although women residing within range of stations were significantly different in regards to socio-demographic characteristics than women residing outside the coverage range of monitoring stations, groups expressed similar clinical risk factors for stillbirth. While the spatial approach supports analysis of single particulate exposures, the inclusion of additional pollutants in an analysis of combined exposure effects may be prohibitively restrictive of eligible populations. Although, researchers should consider potential limitations associated with populations in close proximity to air monitoring stations, the described approach has generalizability to support the study of the effects of pollutant exposures on various pregnancy and birth related outcomes.

Using Anchors to Estimate Clinical State without Labeled Data

Yoni Halpern[1], Youngduck Choi[1], Steven Horng MD MMSc[2], David Sontag PhD[1]

Abstract

We present a novel framework for learning to estimate and predict clinical state variables without labeled data. The resulting models can used for electronic phenotyping, triggering clinical decision support, and cohort selection. The framework relies on key observations which we characterize and term "anchor variables". By specifying anchor variables, an expert encodes a certain amount of domain knowledge about the problem while the rest of learning proceeds in an unsupervised manner. The ability to build anchors upon standardized ontologies and the framework's ability to learn from unlabeled data promote generalizability across institutions. We additionally develop a user interface to enable experts to choose anchor variables in an informed manner. The framework is applied to electronic medical record-based phenotyping to enable real-time decision support in the emergency department. We validate the learned models using a prospectively gathered set of gold-standard responses from emergency physicians for nine clinically relevant variables.

1 Introduction

Health information technology is an essential part of modern health care, providing health care professionals with critical information about patients and allowing them to make maximally informed decisions about a patient's care.

In order to accelerate the development of advanced clinical decision support tools, we seek to create a new middleware application layer consisting of hundreds of clinical state variables that summarize a patient's past and current state. These clinical state variables collectively form a patient phenotype that is continuously estimated throughout a patient's stay and can be used by decision support applications to better inform, guide, and expedite the workflows of clinicians. We define clinical decision support for this paper very broadly to include any functionality that helps a clinician to be better, whether this means more complete or efficient documentation, adherence to clinical guidelines, disease specific order sets, alerts and reminders, visualizations that summarize patient information, or contextual information retrieval, extraction, and summarization.

For example, nursing home patients have different clinical care needs and treatments than other patients in the emergency department. They are more likely to have resistant organisms to standard antibiotic therapy, and therefore must be empirically treated with broad spectrum antibiotics. They are also more likely to fall and therefore require special handling to minimize fall risk. Decision support tools can be used to remind clinicians to order broad spectrum antibiotics and warn them when they do not. They can also be used to alert ancillary staff such as patient transporters and radiology technicians to take appropriate fall precautions, a precaution that may not always be obvious. Although whether a patient is from a nursing home could be collected manually as structured data, there are hundreds of clinical state variables that would be valuable for decision support. Collecting all of these variables for all patients is not feasible. Previous systems that use this type of approach often fail to get the support of clinical users and are systematically not used.

Standard ontologies and knowledge representations are necessary but not sufficient to catalyze the development of advanced decision support and enable transferability of models across institutions. In particular, the patient's state may not be directly observable. Machine learning allows us to reason about patients in these settings. Previous approaches such as logistic regression, support vector machines, decision trees, and neural networks require domain experts to label a fairly large number of positive and negative examples which is time consuming (e.g. [1, 2, 3]). Even after this labeling work has been done, these learned classifiers often do not generalize well across institutions since the learned classifiers are highly dependent on the representation they are trained on. Retraining for each site can require repeating the labeling process, modifying the representation and adjusting rules (e.g. [4, 5]). A review of recent approaches to automated patient phenotyping from electronic records can be found in [6].

In this paper, we describe a methodology for learning to estimate a patient phenotype, consisting of hundreds of different clinical state variables, based on information available in the Electronic Medical Record (EMR). We

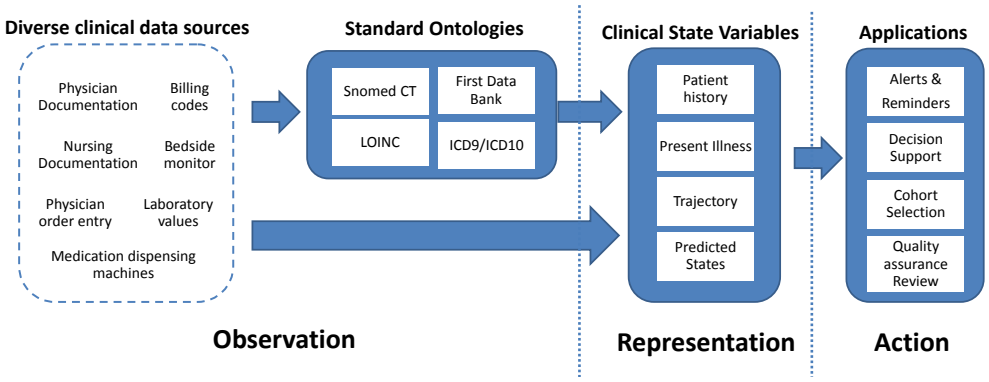

Figure 1: Schematic diagram of a middleware layer, reading inputs from the EMR and acting as an intermediate representation for applications. To improve generalization across institutions, we make no assumptions about the raw clinical data sources. Rather, we make use of existing standardized ontologies to specify anchors for each clinical state variable, and then use the anchors within each institution to learn classifiers to estimate the variables using previously collected, unlabeled, raw clinical data.

use a combination of domain expertise and vast amounts of unlabeled data, rather than relying solely on domain expertise or requiring labor-intensive manual labeling. To learn the models, we require only that certain highly informative variables that we call *anchor variables* be identified by an expert, and the rest is learned from large amounts of unlabeled data in an unsupervised manner. To promote transferability between institutions, we assume only that these anchor variables remain stable between institutions while the rest of the underlying observation model can change. Figure 1 presents a schematic view of such a system.

The main contributions of this paper are as follows:

1. We introduce the concept of anchor variables.
2. We show how to use anchors within an unsupervised machine learning algorithm to estimate each clinical state variable without any human labeling.
3. We describe a novel user interface developed to help with choosing a good set of anchors for each clinical state variable and for performing interactive cohort selection.
4. We evaluate our algorithm's performance using a prospectively gathered set of gold-standard responses from emergency physicians on nine different clinically relevant patient phenotyping tasks.

More broadly, this paper presents a novel approach to harnessing unstructured and structured data found in electronic medical records to estimate clinical state variables that can be used in a wide variety of settings, including both retrospective and prospective clinical care, research, administration, and quality improvement.

2 Anchor variable framework

2.1 Observed and latent variables in the EMR

We formalize anchor variables within the context of latent variable models. In our framework, variables are categorized as either *latent* or *observed*. In a model with m latent variables and n observed variables, each patient is described with a collection of latent variables $\mathcal{Y} = \{Y_1, Y_2, ...Y_m\}$ and a collection of observations $\mathcal{X} = \{X_1, X_2, .., X_n\}$. Here we focus on binary variables but the work can be readily extended to consider categorical variables as well.

Observed variables represent quantities that can be observed directly from the EMR. These include structured variables like age and sex, but also queries that can be computed on semi-structured or free-text data, such as *Does any of the free text contain the phrase "chest pain"?* or *Does the medication list include "GSN_004380" (aspirin)?* Here we assume a very general form of the EMR without making assumptions of which fields are present and what structure they take. These observations are represented in Figure 1 as the leftmost section of the schematic.

Observations from the EMR are inherently noisy and may miss important information. For example, if the note contains the short-form "cp" instead of chest pain, the chest pain observation would be negative even though

the patient may actually have the symptom. Our model addresses this by explicitly treating observations as noisy evidence about the clinical state variables of interest. Additionally, as we will see later on in more detail, we allow certain key observations to be trusted as true when they are *positive* but not when they are negative.

Latent variables represent quantities that **cannot** be observed directly from the EMR or computed as a simple query, but for which the EMR can provide information that would be useful to answer the question. These variables could be the answers to higher level questions such as *Does the patient have* $\{$*an infection, altered mental status, a history of alcoholism*$\}$*?* The answers to these higher level clinical state questions form a useful representation of the patient, shown in the middle section of Figure 1. In many cases, the answers can be found in the EMR, though they are usually found in free-text sections of the record. Formulating queries to extract this information directly from the free-text is notoriously difficult due to the vast number of ways each fact can be expressed [7]. In other cases, the answers may simply not be documented at all, either because they are not known or due to a failure to document. In all of these cases, even though it is impossible to observe the answers directly, it may still be possible to infer them based on all of the other data observable in the record. In our framework, the goal will be to learn a classifier to predict the value of the latent variables $\mathcal{Y}$ with only access to the observations $\mathcal{X}$.

2.2 Anchor variables

It is important to recognize that many different EMR systems exist and the set of observable variables in one system may not map directly to the set of observable variables in another [8]. Promulgation of standards in the form of ontologies to normalize the representation of observations as well as knowledge representation standards such as the Continuity of Care Document will help to reduce some of this effect. However, different vendors will continue to innovate beyond these standardizations and there will always be a structural differences in data representations. In our framework we assume that the set of observable variables can change from system to system as long as a few key informative observations are conserved. These observations are *anchor* observations with the following property:

Definition 1. *An observation X_j is an* anchor *for a latent variable Y_i if X_j is conditionally independent of all other observations, X_k $\forall k \neq j$, conditioned on the value of Y_i.*

In other words, anchor observations provide a direct, albeit noisy, view of the underlying latent variable we wish to predict. The key characteristic of an anchor is the conditional independence property which states once the value of the latent variable is known, no other observables provide additional information about the anchor variable. While anchors tend to provide strong evidence towards the value of the latent variable, it would not make sense to answer the questions simply based on the values of the anchors alone. However, our insight is that we can explicitly treat anchors as noisy labels and use them within a learning algorithm. Learning with noisy labels is a subject that has been studied extensively in machine learning literature (e.g. [9, 10]) and we leverage that work here. By using domain knowledge to identify these noisy labels in the data itself, we no longer require manual labeling of the data before it can be fed to a machine learning algorithm. The resulting method is extremely portable. As long as anchors can be shared between institutions, no new labeling work is required to train the classifiers for a new institution's data.

In the next section we describe an unsupervised method to learn decision rules to predict the values of latent variables, $\mathcal{Y}$, using all of the the observed variables, $\mathcal{X}$, when anchors for each latent variable have been specified. When transferring to a new system with a potentially different set of observed variables we can perform the same unsupervised training on the data available in the new system with no additional human input as long as the anchors are preserved or can be mapped into the new data system. In order to ensure that anchors are not particular to an institution, we can use standard ontologies when specifying the anchors.

2.3 Learning decision rules with positive anchors

Let $A \in \mathcal{X}$ be an anchor variable for Y_i. The collection $\tilde{\mathcal{X}} = \mathcal{X} \setminus A$ represents the observations $\mathcal{X}$ with the anchor removed. We describe a procedure for learning a single decision rule, trying to predict the value of a single latent variable Y_i from observed values X using a special type of anchor that we call *positive* anchors.

Definition 2. *An observation A is a* positive anchor *for a latent variable Y_i if it is an anchor for Y_i and $P(Y_i = 1|A = 1) = 1$.*

Intuitively, observing the anchor to be positive unambiguously reveals the state of the latent variable to be positive, while observing it to be negative does not reveal the state of the latent variable. This setting has previously been studied under the name *positive-only labels* [9] and a procedure for learning with positive-only labels is as follows (see [9] for a detailed derivation):

1. Learn a calibrated classifier (e.g. logistic regression) to predict $P(A = 1|\tilde{\mathcal{X}})$.
2. Using a validate set, compute $C = \frac{1}{|\mathcal{P}|} \sum_{k \in \mathcal{P}} P(A = 1|\tilde{\mathcal{X}}^{(k)})$ where $\mathcal{P}$ is the set of data in the validate set where $A = 1$.
3. For a previously unseen patient t, predict $\begin{cases} P(A = 1|\tilde{\mathcal{X}}^{(t)})/C & \text{if } A^{(t)} = 0 \\ 1 & \text{if } A^{(t)} = 1 \end{cases}$

Positive anchors have some appealing properties. First, the algorithm to learn with them is extremely simple and requires only the capability of learning logistic regression models, which are standard in most statistical packages. Second, positive anchors have an intuitive interpretation for the human providing the anchors. For positive anchors, the anchor should be a quantity that *can only be caused* by the latent variable being "on". Finally, the positivity of an anchor is easy to verify. If an expert is presented with examples of patients with a positive anchor, they can confirm that in fact all (or almost all) of the presented patients are positive for the latent variable of interest. Conditional independence is more difficult to verify and requires that an expert verify that the proposed anchor is truly completely explained by the clinical state of interest.

Anchors like this exist in medicine. For example, a positive rapid antigen test for Group A streptococci is very specific for strep throat and can serve as a positive anchor. The absence of a positive test result can be uninformative either due to the low sensitivity of the test, or due to the possibility that the test was never performed because the diagnosis was obvious and the patient was treated without testing [11]. In addition to carefully choosing anchors, data preprocessing can be performed to increase the amount of conditional independence between anchors and other observations. For example, in the Methods section we describe how common bigrams are represented in order to avoid obvious violations of conditional independence. In real use cases, no anchors will ever perfectly meet the criteria in Definitions 1 and 2, and missing data will not be completely at random. Nonetheless, approximate anchors can perform well on real data, as we demonstrate with experimental results for a range of clinical variables. The above definitions are still useful as they give theoretical principles by which to choose good anchors.

If multiple anchors are specified, they can be combined in a number of different ways. The simplest way is to create a composite anchor out of the union of all of the individual anchors. For example, if the diagnosis code ICD9-288.00 (neutropenia, unspecified) and the word "immunocompromised" are both anchors for the latent variable `isImmunosuppressed`, then we can create a single composite anchor which is present if *either* of these two observations is present. If the original anchors are positive as in Definition 2, then the new composite anchor is also a positive anchor. Using the composite anchor is advantageous compared to choosing a single anchor because it occurs more frequently, providing more positive examples for training.

3 Specifying anchors with an interactive display

In practice, specifying anchors can be challenging. In order to specify anchors, one must have sufficient domain knowledge to evaluate whether a variable fits the definition of an anchor. To ease the process of eliciting anchors from domain experts, we built an interactive interface to allow domain experts to specify anchor variables and visualize the resulting model learned with those anchors. Figure 2 shows a screenshot of the tool being used to specify anchors to identify HIV positive patients.

The interface is a general tool for specifying anchors and viewing the learned classifier. A user can add latent variables and specify anchors for them. After adding an anchor, the user can, in real time, update the learned model and view a ranked list of patients at the bottom of the screen. The ranking is generated according to the predicted likelihood of the latent variable being positive according to the model built with the current set of anchors. For each patient, a short summary is presented for easy viewing, and selected patients can be viewed in more detail in the middle pane. Patients can be filtered according to three different criteria: view only patients with anchors (to judge whether the anchors are catching the correct subset of patients), view patients that have the most recently added anchor (to judge the incremental effect) and view patients without anchors (looking at a ranked list of these patients provides an idea of how well the learning algorithm has *generalized* beyond simply looking for patients that have the anchors).

After learning a model, the tool additionally *suggests* new anchors by showing the observations ranked by weights of a linear classifier learned with a penalty on the L1 norm of the weight vector. The L1 penalty encourages the learned classifier to use a minimal number of variables, effectively selecting highly informative observations. The user then uses clinical judgment to decide whether or not each suggestion would make a good anchor, e.g. by including the new observation and seeing the incremental effect on the ranking, or by viewing the newly anchored patients. The result is a simplified active learning workflow with a human-in-the-loop. In this work we focus on

the basic task of learning classifiers with anchors, leaving more advanced active learning techniques like asking questions about specific patients in a maximally informative manner [12] and providing detailed performance feedback for the user to future work.

The ranking and filtering mechanisms provide feedback to the user, giving information about whether the model is being built reasonably or not. Figure 3 in Section 5 shows a user trace of a clinician using our interface to specify anchors to identify patients with a cardiac etiology. The feedback coming from patient rankings, viewing recently anchored patients and looking at suggested anchors is sufficient to allow him to incrementally build better models by specifying new anchors.

Anchors can be specified as words or phrases, and they are interpreted as queries on the free text portions of the medical record. Additionally, the interface allows for incorporation of anchors according to standardized hierarchical ontologies. For example, medications are grouped by families according to First Databank's Enhanced Therapeutic Classification (ETC) hierarchy, and diagnosis codes are grouped according to the ICD9 hierarchy. For these hierarchical structures, including a parent as an anchor automatically adds all of its children as well.

In addition to specifying anchors, the tool is useful for performing fast interactive cohort selection, allowing the user to quickly learn classifiers to find members of a target population using the anchor approach. The learned classifiers can be exported as well for use in real-time decision applications. The tool is freely available for download at `http://sontaglab.cs.nyu.edu/`.

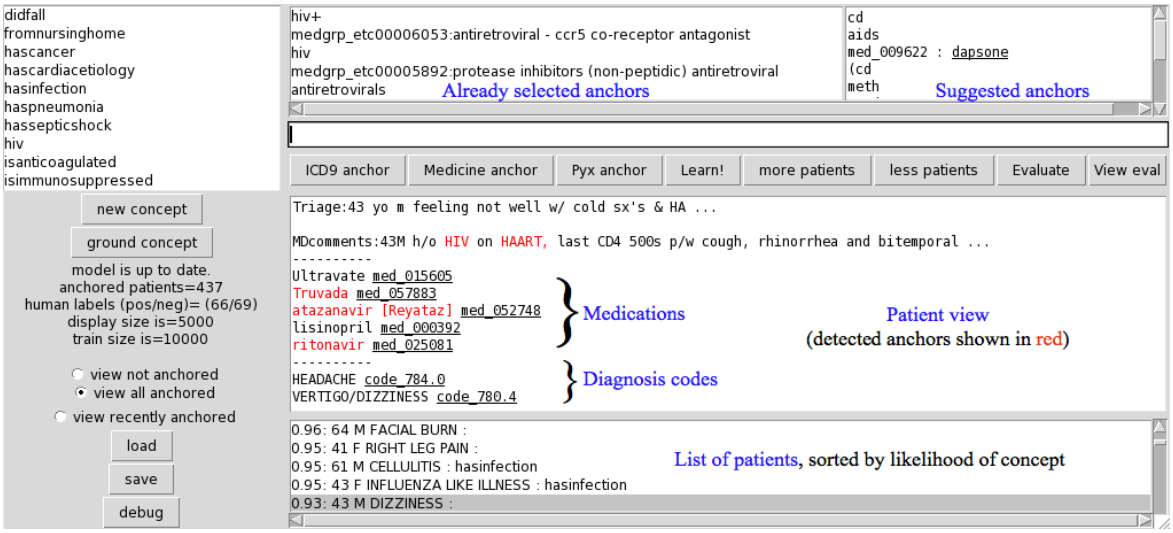

Figure 2: A screenshot of the anchor elicitation tool using deidentified patient information. Conditional highlighting emphasizes the presence of previously specified anchors in a note so that the physician can determine quickly whether its usage is as expected.

4 Methods

4.1 Data description

For training and evaluation we use a collection of 273,174 emergency department patient records collected from a 55,000 patient/year Level 1 trauma center and tertiary academic teaching hospital between 2008 and 2013. Each record represents a single patient visit. All consecutive ED patient visits were included in the data set. No visits were excluded. This study was approved by our institutional review board.

In order to evaluate the utility of the latent variable predictors learned, we collected gold standard labels from the primary clinical provider caring for a patient at the time of disposition from the emergency department, (admission, discharge, or transfer). As part of the routine clinical workflow of disposition, clinicians were asked a series of 2-3 questions chosen randomly from a rotating pool of questions. The answers serve as gold standard labels. These questions were entirely voluntary, but received an approximately 85% completion rate. As part of our quality assurance process, we routinely review random samples of cases to confirm the quality of data obtained using this technique and confirm that missing data occurs completely at random. Since only 2-3 questions were asked at any given time, it took approximately 2 years to collect the labels for this paper, in addition to labels for other unrelated research projects not presented here. Table 1 shows the clinical state variables and the associated disposition questions that we use for evaluation in this paper. Responses were collected for all consecutive patients

except for the `didFall` question which was only asked for patients who had a head CT scan. Clinicians reported responses using a five point scale with 1 being most negative and 5 being most positive. The `didFall` question used a three-point scale of "No", "Uncertain" or "Yes". When converting the labels to binary values we take 4 or above as positive. Responses labeled as "Uncertain" are treated as unlabeled.

Latent Variable	Disposition Question	Additional Information	Labels Collected	Fraction Positive
didFall	Did the patient fall from standing or lesser height?	None	9,831	0.118
hasCardiacEtiology	In the workup of this patient, was a cardiac etiology suspected?	None	17,258	0.068
hasInfection	Do you think this patient has an infection?	Suspected or proven viral, fungal, protozoal, or bacterial infection	62,589	0.213
fromNursingHome	Is the patient from a nursing home or similar facility?	Interpret as if you would be giving broad spectrum antibiotics	36,256	0.045
hasCancer	Does the patient have an active malignancy?	Malignancy not in remission; and recent enough to change clinical thinking	4,091	0.042
hasPneumonia	Do you think the patient has pneumonia?	None	9,934	0.073
isAnticoagulated	Prior to this visit, was the patient on anticoagulation?	Excluding antiplatelet agents like aspirin or plavix	1,082	0.047
isImmunosuppressed	Is the patient currently immunocompromised?	None	12,857	0.040
hasSepticShock	Is the patient in septic shock?	None	6,867	0.020

Table 1: Questions asked of physicians at disposition time to obtain a gold standard set of labels. Additional information was displayed in a clickthrough screen with a link from the main question page.

4.2 Representation and preprocessing

Patient records are represented as containing six distinct types of observable variables which come from semi-structured sections of the EMR: 1. ICD9 diagnosis codes (from billing information), 2. current medications recorded during medication reconciliation, 3. medications dispensed during the ED course as reported by medication dispensing machines (Pyxis), 4. free text sections formed by a concatenation of chief complaint, triage assessment and physician's comments, 5. Age, 6. Sex.

Deidentified free text was preprocessed using a modified version of NegEx [13, 14] and negated words were replaced by a new token (i.e. if the token "fever" was within the scope of a negation, it was transformed to a new token, "negfever"). A second step of preprocessing collected 1,500 significant bigrams and appended them to the text (i.e. the phrase "chest pain" was augmented to be "chest pain chest-pain" with an extra token representing the bigram). When learning with anchors, we remove the component words (i.e. "chest pain" is replaced by a single token "chest-pain"). We do this in order to increase the amount of conditional independence between anchors which are bigrams and the rest of the text. If the token "chest-pain" is chosen as an anchor, it will not be conditionally independent of the tokens "chest" and "pain" without the removal step. For training linear classifiers, the first representation is strictly more general, so it should not hurt the performance of our baseline algorithms.

Medications are represented by generic sequence number (GSN) and diagnosis codes by ICD9 codes. Age was discretized by decade with a binary indicator for each decade. Patients are represented as a binary feature vector representing the presence or absence of each distinct diagnosis code, current medication, dispensed medication, word, discretized age value and sex. Observations that occur in fewer than 50 patients in the entire dataset were discarded, leaving a final binary feature vector of size 20,334.

4.3 Anchor specification

A single emergency physician specified anchors for each clinical state variable using our custom anchor elicitation tool with access to a database of 20,000 unlabeled patients chosen at random from the full patient set. Figure 3 shows the evolution of the performance of the learned classifier as the physician specified anchors. Unless otherwise noted, results are reported using the final set of anchors specified by the physician. Note that the physician was not provided with explicit feedback about the performance of the model on the ground truth labels, but was able to use the interface to determine which anchors were useful and make progress. In order to accurately assess

the effort involved in specifying anchors for a new classification task and to avoid overfitting, each anchor-based predictive model was only built once with the exception of `hasCancer` which was used as an example for development purposes.

4.4 Machine learning

We compare the classifiers learned using anchors to a simple rule-based baseline and a supervised machine learning baseline which uses a subset of the collected gold standard labels for training. Evaluation is reported on nine separate estimation tasks, one for each clinical state variable in Table 1. We emphasize that unlike the supervised baseline, the anchor algorithm does not require ground truth labels for training.

The rule-based baseline simply predicts positively when at least one anchor is present and negatively otherwise. This approach also requires no training, and is evaluated on the entire labeled set.

Evaluation of the supervised baseline is reported using 4-fold cross validation in order to fully utilize the limited number of gold standard labels we have for some of our clinical state variables. In each experiment, the labeled patients are divided into four equal-sized test sets. For each test set, a classifier is trained using a portion of the 75% of patients which are not in the test set ("training patients") and then used to predict for the 25% of patients designated as test. The results are averaged across the four test sets, giving an estimate of the performance on the entire labeled dataset. Each classifier of the supervised baseline is learned using at most 3000 training patients, representing approximately 3 weeks-worth of patients at our institution.

The supervised baseline was learned with logistic regression using the scikit-learn package [15] in Python. We use 5-fold cross validation within the train set to choose parameters, trying all combinations of the regularization constant (options are $\{10^{-6}, 10^{-5}, ..., 10^{6}\}$) and the norm used in regularization. Choices for the norm are L1 (encourages the learned classifier to use a minimal number of features by penalizing the sum of absolute values of the regression weights) or L2 (avoids overly emphasizing any one feature by penalizing the sum of squares of the regression weights). For the supervised results for 100 and 200 labels, 5-fold cross validation is not viable, due to the low number of positively labeled samples for each disposition question. Hence, for these numbers of labels the parameters are chosen to be the default values in scikit-learn. Lastly, we reduce regularization of the bias parameter by setting the "intercept_scaling" parameter to 1000.

The anchor method is trained using the specified anchors and 200,000 examples chosen randomly from the unlabeled dataset, and tested on the entire labeled set. Scikit-learn is used to fit logistic regression models as in the supervised setting, but holding the regularization norm fixed as L2 and doing cross-validation over the regularization parameter. Since the logistic regression models learned in the anchor method are meant to predict the presence or absence of the *anchor* (as described in Section 2.3), the cross-validation technique to choose parameters also uses the presence or absence of the anchor to measure performance, requiring no ground truth labels.

We measure performance using area under the ROC curve (AUC), a measure of the overall quality of a ranking predictor. Estimating the constant C in step 2 of the anchor algorithm is not necessary to obtain a ranking, so we omit that step. In the rule-based approach, ties are broken by counting the number of distinct anchors present in the patient record. In the anchor approach, ties among patients with anchors are broken according to the predicted probability of the latent variable ignoring the presence of the anchors.

4.5 Real-time decision support evaluation

We evaluate a real-time decision support scenario where the estimation tasks are performed without access to diagnosis codes (i.e., diagnosis codes are excluded from the feature vector), as these would usually be assigned after the patient leaves the emergency department. The supervised baseline and rule-based approach simply ignore all ICD9 codes because they cannot incorporate extra information that is not available at test time. However, since the algorithms are meant to be trained on previous patients, it is reasonable to assume that diagnosis codes would be available at the time of training. Thus, the anchor algorithm uses ICD9 codes as *anchors* during training, even though the resulting prediction rules do not use them as features.

We also tested a retrospective setting where the algorithms have access to diagnosis codes, both at train and test time. This setting is meaningful since our algorithm can also be used in retrospective settings for tasks such as cohort selection, information retrieval and quality control. The results were qualitatively similar, so we only present the real-time setting here.

5 Results

In this section we present results comparing the performance of the anchor-based learning method to the baseline methods on the task of predicting the nine clinical state variables listed previously in Table 1.

First, we show the utility of the anchor-specification interface described in Section 3. Figure 3 shows the learning path for the `hasCardiacEtiology` clinical state variable, describing the changes to AUC as the clinician added and subtracted anchors from the model. It is noteworthy that using our interface, the quality of the model tends to increase as time progresses. We observed this trend for all of the clinical state variables. Table 2 shows some of the final anchors specified by the clinician who used the interface. Using our interactive tool, the total time to specify anchors for all nine models was approximately 5 hours.

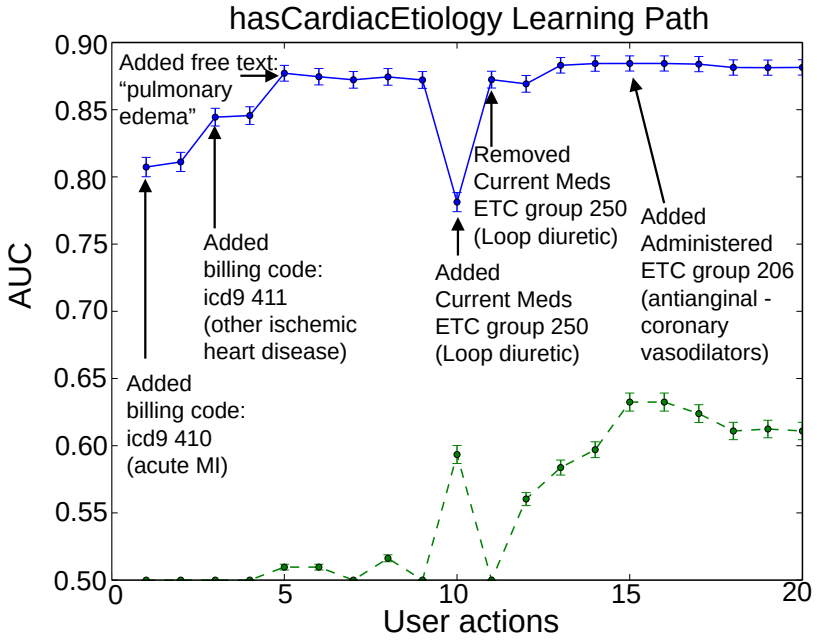

Figure 3: A learning path for one of the learned models (`hasCardiacEtiology`) as the interface is being used to build this model. On the x-axis are user actions, either additions to or deletions from the current set of anchors. On the y-axis is AUC evaluated on the gold standard collected labels. The dotted line shows the progress of the rules baseline which simply predicts 1 when an anchor is present and 0 otherwise. The rules baseline initially has an AUC of 0.5 since the earliest anchors are ICD9 codes and we consider the real-time setting where ICD9 codes are not available for the test set.

Clinical State Variable	Selected Anchors
didFall	Billing code [Accidental Falls] (ICD9 E880-E888), "slipped", "s/p-fall', "slip-fall", "fell down", "mechanical_fall", "witnessed-fall", ...
hasSepticShock	Billing code [septic shock] (ICD9 785.52) , Administered meds from [cardiac sympathomimetics] (ETC:00003064)
isimmunosuppressed	Current meds from [antineoplastic - antimetabolite - folic acid analogs] (ETC:00002881), "immunocompromised", ...
hascancer	Billing code [neoplasms] (ICD9 group 2), "breast-ca", "mets", "oncology", ...

Table 2: A selection of anchors specified by a clinical collaborator. Anchors that utilize structured variables such as diagnosis codes or medications (current or administered) are mapped to a relevant structured ontology.

Table 3 shows a comparison to supervised learning for the real-time setting described in Section 4.5. For many of the clinical state variables, the anchor algorithm outperforms learning with 3K labels, suggesting that it would take a non-trivial amount of time and human effort to collect the data necessary to train in a supervised setting with comparable accuracy. The `didFall` task was evaluated on a biased population since the question was only asked for patients with a head CT scan. The supervised method was trained on a similarly biased population, so it makes sense that the performance of the anchor algorithm underperforms in this setting.

To provide a comparison to a semi-supervised algorithm, we experimented with training using SVMlight in a transductive setting [16], using up to 20,000 visit instances (500 labeled, 19500 unlabeled) for the `hasInfection`

variable. Samples were reweighted to account for the class imbalance. However, we found that this semi-supervised approach did not improve AUC over the supervised baseline with 500 labeled examples.

Variables	Rules	Supervised						Anchors
		100	200	500	1K	2K	3K (min, max)	
didFall	0.725 ± 0.008	0.814	0.852	0.900	0.914	0.920	**0.924** (0.917,0.934)	0.883 ± 0.006
hasCardiacEtiology	0.611 ± 0.006	0.772	0.827	0.824	0.875	0.900	**0.906** (0.891, 0.920)	0.881 ± 0.006
hasInfection	0.723 ± 0.002	0.728	0.767	0.804	0.830	0.861	0.883 (0.881, 0.886)	**0.903± 0.001**
fromNursingHome	0.620 ± 0.005	0.725	0.792	0.822	0.869	0.894	0.891 (0.873, 0.906)	**0.918 ± 0.004**
hasCancer	0.822 ± 0.018	0.635	0.673	0.693	0.810	0.882	0.902 (0.880, 0.930)	**0.945 ± 0.01**
hasPneumonia	-	0.856	0.907	0.933	0.947	0.956	0.963 (0.954, 0.972)	**0.971 ± 0.003**
isAnticoagulated	0.849 ± 0.03	-	-	-	-	-	-	**0.930 ± 0.02**
isImmunosuppressed	0.650 ± 0.01	0.584	0.659	0.740	0.814	0.842	**0.862** (0.840, 0.877)	0.840 ± 0.009
hasSepticShock	0.738 ± 0.02	-	0.760	0.773	0.863	0.920	0.952 (0.928, 0.967)	**0.967 ± 0.008**

Table 3: Comparing AUC in the real-time setting. The supervised method is trained using logistic regression with a small number of gold standard labels. When the anchors are composed entirely of diagnosis codes, the rules approach cannot be meaningfully evaluated on the test set (in the real-time setting, diagnosis codes are not available at test time). When we had insufficient data to train, the supervised approach could not be evaluated. Best methods in each row are bolded. The anchor approach uses 200K *unlabeled* examples in training. Standard errors of the AUC for Rules and Anchors are computed using 1000 bootstrap samples of the test set. Min and max values for the 3K supervised baseline are from the 4-fold cross validation.

6 Discussion

Across the nine clinical state variables considered in our evaluation, our anchor-based unsupervised learning algorithm obtains prediction accuracy comparable to and in many cases better than a supervised prediction algorithm. It is important to note that the clinical states we are interested in are precisely those for which ground truth labels cannot be easily derived from diagnosis codes or from natural language processing on the clinical notes. Labeling data would be expensive, time consuming, and in many cases institution-specific since the learned predictors may not generalize.

Surprisingly, despite the physician not receiving explicit feedback about the performance of the model on the ground truth label, using our user interface he was able to determine when adding an anchor helped or hurt overall performance (as seen by a generally monotonic increase in AUC with each additional anchor specified). Our initial user interface also allowed the physician to label individual patients as positive or negative for a given clinical state variable. However, despite trying various ways of integrating this feedback into our learning algorithm, we found negligible gains in accuracy compared to only using the anchors.

There are several interesting directions for future work. Our current approach predicts each clinical state variable independently, but it would also be interesting to jointly model the clinical states. Doing so may provide a solution for the vexing problem of how to efficiently provide the learning algorithm *negative* feedback, which could be addressed by introducing additional variables (and anchors for them). We could then use negative correlations between clinical state variables to disambiguate commonly confused clinical states.

Although our algorithm can provide useful predictions without any labeled data, its use within a clinical setting presents opportunities to gather additional data to improve its performance. One direction for future work would be to develop a feedback mechanism (implicit or explicit) to learn from the algorithm's use. We also plan to integrate our predictions into an active learning algorithm to be used with the current system that asks questions prospectively at the time of disposition from the ED. We currently rotate through the questions asked so as to not overburden the clinician. Instead, we can carefully select which questions to ask for the specific patient at hand so as to best improve our prediction algorithms for a range of clinical state variables.

The most important next step will be to test the generalization of anchor-based learning in departments other than the ED and in other institutions. We are also continuing to use the user interface to specify anchors for dozens of additional clinical state variables, using these to enable new contextual user interfaces and to trigger decision support.

Abstract

Many academic medical centers have aggregated data from multiple clinical systems into centralized repositories. These repositories can then be queried by skilled data analysts who act as intermediaries between the data stores and the research teams. To obtain data, researchers are often expected to complete a data request form. Such forms are meant to support record-keeping and, most importantly, provide a means for conveying complex data needs in a clear and understandable manner. Yet little is known about how data request forms are constructed and how effective they are likely to be. We conducted a content analysis of ten data request forms from CTSA-supported institutions. We found that most of the forms over-emphasized the collection of metadata that were not considered germane to the actual data needs. Based on our findings, we provide recommendations to improve the quality of data request forms in support of clinical and translational research.

Introduction

Clinical and translational research is a growing priority of the United States (US) National Institutes of Health (NIH). To encourage greater advancements in this area the NIH has supported over 60 research institutions through the Clinical and Translational Science Awards (CTSA).[1] At the same time there has been a substantial increase in the adoption of electronic health records (EHRs), with nearly half of US hospitals now with one or more EHRs in place.[2] This concomitant investment in both the research enterprise and in health information systems that capture data electronically has presented unprecedented opportunities for advancing clinical and translational science, and is a necessary precursor for building the foundations of a broad-scale 'learning health system'.[3, 4]

Research tasks that were previously impractical, if not impossible, to perform with paper-based health records have now become achievable due to the large volumes of data stored in a 'readily accessible' electronic format. However, in addition to privacy and security constraints, numerous difficulties remain with respect to access and use of the data.[5] Compared to paper records, EHR data should be much easier to aggregate across large numbers of patients, but the complexity of the underlying systems, including the heterogeneity in metadata, data structures, and even the data itself, often hinders their computational reuse by a broad range of stakeholders.[6-8] Further, prior work has shown that it is not uncommon for a hospital to have hundreds of different IT systems.[9] Data from multiple health information systems are thus often aggregated into databases commonly referred to as data or information warehouses, data repositories, data marts, or data networks.[10-16] A major theme of the NIH roadmap has been the idea of "Re-Engineering the Clinical Research Enterprise",[17] and one of the recognized challenges has been providing the means to "facilitate access to research…resources by scientists, clinicians" and others.[18] However, two major barriers exist with respect to data access.

First, to help meet the needs of clinical and translational research, 'self-service' tools have been developed to provide a means for data access as well as analysis and visualization.[19-26] Many of these tools have been widely implemented and have achieved a good level of adoption. While self-service tools have been demonstrated to work well for various scenarios,[27] by nature of their intended simplicity for a broad user base, these systems often cannot handle all of the complex data needs that are required by biomedical research teams.[20, 28] Researchers usually do not have the database knowledge nor do they understand what is involved in data retrieval. In contrast, data managers or query analysts usually do not know how to ask questions to elicit data needs using non-technical language understandable by researchers.[29] Data need negotiation usually involves several "trial-and-error" iterations. As a

result, many institutions have recognized the need to invest in informatics or IT experts (often called data analysts or report writers) to serve as an intermediary between the complex data sources and the biomedical researchers, the latter of whom have significant domain expertise but often lack training in data access approaches such as the use of structured query languages (SQL). [29-31]

Second, for liability considerations and HIPAA or regulatory compliance, data owners need to carefully check the credentials and qualifications of data requesters, which usually involves lengthy review processes involving multiple institutional review offices. An important artifact, the *data request form*, is the nexus linking all the stakeholders in the process of providing data access for researchers. Such forms are generally meant to serve documentation and communication needs for multiple stakeholders, including researchers, query analysts, data owners, and regulatory officers.[32] They can provide a means for researchers to list their credentials and specify their needs through a formal request process. They also help data stewards verify if the appropriate regulatory approvals are in place and to help with other administrative bookkeeping. Importantly, data request forms are also meant to provide a means for research teams to communicate complex data needs in a manner that can be understood by a data analyst and converted into executable database queries for data retrieval.[33] It follows, then, that the manner in which these forms clearly, and unambiguously, define the data needs and sources can have major downstream consequences for the subsequent research on which the request is based. Yet there are no published standards for designing EHR data request forms, or even best practices about which an institution can turn to in constructing a form. It is therefore up to each institution to develop their own form with the hope that the right questions are being asked of data requestors in order to ensure that data needs are being met accurately and efficiently.

Therefore, the data request form plays an indispensable role in facilitating data access for researchers in many institutions. Motivated to provide better data access to the broad clinical and translational research community, we aim to understand (1) how the current forms efficiently collect information needed by data owners and effectively communicate data needs of researchers and (2) if they collect necessary and relevant information that cannot be extracted for reuse from existing institutional information systems. In this study we conducted a formal content analysis of data request forms from multiple academic institutions affiliated with a CTSA award. Our goal was to develop a deeper understanding of what questions are typically asked on the forms, and to help provide insights regarding whether current data request forms provide adequate coverage of salient details to capture data needs effectively. To achieve these goals, first, we obtained ten data request forms from CTSA-supported academic medical centers in the US. Then we developed a form annotation schema based on the consensus of two annotators and used this coding book to annotate the forms. On this basis, we conducted a detailed content analysis of the forms and identified information deficiencies as well as unnecessary workload imposed on researchers that exist across many forms in use today. Finally, we provided insights and recommendations from our analysis that could be used to improve the content of data request forms and, ultimately, improve the process for obtaining complex data from institutional repositories in support of clinical and translational research.

Methods

A. Collection of data request forms

Ten data request forms were obtained for this study. All forms were in use at CTSA-supported academic medical centers around the US as of February 2014. Four of the forms were obtained through personal contacts by the authors, whereas the remaining six were identified through an online search with the Google search engine using the strings “EHR data request” and “medical research data request.” The ten CTSA-supported institutions from which these forms were actively in use were: Boston University, Columbia University, Northwestern University, University of California - San Diego, University of California - San Francisco, University of Colorado Denver, University of Kansas, University of Michigan, University of Wisconsin, and Vanderbilt University. Note that these institutions are listed here in alphabetical order, which does not match the order in which they are presented in the results section, wherein only a letter is used to identify each form.

B. Development of a codebook

Five of the ten data request forms were randomly selected for developing the coding schema for the content analysis. Two reviewers (GH and DH) independently evaluated the five forms and developed a list of themes derived from the forms. These themes were based only on the actual questions asked on each of the forms, although several

Table 1. Form elements comprising the codebook for the content analysis of the data request forms, including examples of each type of element. When an element could be coded as Simple [S] or Extensive [E], an example of each is provided. Basic elements were only coded as Simple [S] if present; thus no Extensive example is provided.

Code	Name	Description	Example(s)
1.0	*Requester Metadata*	*Any form elements that describe the user requesting data*	*not a coding element*
1.1	Name	This element may include the name, and/or contact data of the requester	[S] Requester Name [E] Requester Name, Department, Email
1.2	PI/Supervisor/ Department Head	This element may include the name, and/or contact data of the requester's PI, supervisor and/or department head	[S] Supervisor Name [E] Supervisor Name, Department, Email
1.3	Billing/ Administrative	This element may include the name, and/or contact data of the requester's administrator or other billing information	[S] Administrative Name [E] Administrative Name, Department, Email
1.4	Other	Any other attributes associated with the requester, and not associated with the content of the request	[S] Are you a part of the CTSA?
2.0	*Request Metadata*	*Any form elements that describe the actual request*	*not a coding element*
2.1	Study Title/Request	This is a brief summation of the request.	[S] Project Title; Research Question
2.2	Existing/ New Request	This element specifies if the request is new or a modification to an existing request	[S] Is this a new request or a modification to an existing report
2.3	Funding Source	This element is asking who is financially supporting the use of this data.	[S] What are your funding sources? [E] Will funds be used to pay subcontractors; do funding sources have restrictions on the use of the data collected for this project?
2.4	Request Purpose	Concerns the use of the data being request. For example will it facilitate an internal administrative report, research or preparatory for research, cohort/Clinical trial recruitment?	[S] Will the requested data be applied to any of the following areas? Non-research, Patient Care, Operations, Research, etc.
2.5	Request Type	This element specifies the degree of data access the user requires.	[S] Multiple Choice: Self-service, Super user [E] Study Design Consultation, Research Navigator
2.6	Data Sources	Any element that asks the user to specify the source of data, for example this maybe a particular database, or a particular clinical site where the user thinks the data may originate.	[S] Sources of data? (Text Box) [E] Sources of data? (Multiple Choice)
2.7	Data Element Specification	This element refers to any description of the medical data elements the requester is after.	[S] Describe the data you need. [E] What is your selection criteria, From what time period… What data fields do you need?
2.8	Recurring Requests	This element is specific to the frequency of data delivery. A clinical trial that submits a request to aid recruitment may wish to receive a weekly dump of potential matches.	[S] Is this a one-time request or recurring?
3.0	*Compliance*	*Form elemenst related to a compliance attribute, such as IRB, PHI, internal regulations, or documentation requirements*	*not a coding element*
3.1	Institutional review board (IRB)	If the request is research, this element request details on the IRB number or if the protocol is IRB exempt.	[S] IRB number
3.2	IRB Proof	Elements that require IRB proof	[S] Please upload your approved IRB protocol
3.3	Protected Health Information (PHI)	Regardless of request purpose, this element specifies HIPAA compliance and asks to what level of identified data (if any at all) are needed.	[S] Will the data be identified or de-identified [E] Please select the type of data you will need: identified, de-identified, limited decedent, aggregate counts…
3.4	Compliance Other	This element concerns any type of compliance attribute, whether it be IRB, PHI, internal regulations, or documentation requirements that could not be classified elsewhere	[S] Provide your consent (or waiver of consent)
4.0	*Data Use*	*Refers to how the requester is going to use or share the data*	*not a coding element*
4.1	Internal Data Sharing	This element represents how the user is sharing the data within their team, where the data is going to be stored, how the data is to be delivered, or the format of the data.	[S] Please describe data storage and use plan [E] Who will have access to the data, where the data is to be stored, data delivery & format
4.2	External collab-orators data use agreement (DUA)	If the requester is sharing the information with an external collaborator, is there a formal data use agreement	[S] Is there a DUA? [E] Name non-affiliated project team members that will have access to the data; upload DUA.
4.3	Public Sharing of Original Dataset	This elements refers to the intent of the requester to publish the original dataset	[S] Will data be made publically available? [S] Do you plan on making this data publically available, how so?
4.4	Terms and conditions of use	This element refers to any mention of terms and conditions the requester must agree to for the release of the data to them.	[S] Please read/agree to these terms and conditions for the use of this data.
4.5	Data Use Other	This element includes items that were not specifically covered in the other data use categories	[S] Who is your intended audience for data reporting?
5.0	*Miscellaneous*	*Form element that cannot be categorized elsewhere*	*not a coding element*
5.1	Elements not classified elsewhere	Items that did not fit into other categories.	[S] Is this an emergency request due to a grant deadline [S] Will you be contacting patients?

research questions helped guide the analysis. These included (1) what high-level organizational categories can data request form elements be assigned to? (2) what percentage of metadata could potentially be obtained from source systems without asking research teams to copy it to a form? (3) how are request form items distributed between administrative data (i.e., 'bookkeeping') and actual data requests? (4) how much detail does each element on a form seek to obtain from a user completing the form?

The theme lists from both reviewers were then compared, discussed, and consolidated into a single list. A third reviewer (CW) evaluated the merged list and refined it further. Finally, two reviewers (GH and DF) compared two randomly selected forms to finalize the codebook and address additional gaps in code coverage. Similar themes were then grouped into logical categories (e.g., "Compliance", "Data Use") and numbered. This final list served as our codebook, which is shown in Table 1.

We also utilized a 'comprehensiveness' measure to indicate the breadth of each element: Simple (S) or Extensive (E). Simple elements were related to a very focused, narrow question on a form (e.g., "Your Name"), whereas Extensive elements had a much broader scope. For example, an Extensive element asked the requestor to "indicate all identifiers (PHI) that may be included in the study research record", followed by a list of all 18 HIPAA identifiers with a checkbox next to each. Examples of Simple and Extensive elements with respect to the codebook are also shown in Table 1. Note that some elements (e.g., codes 1.4, 2.1, 2.2 in Table 1) were judged by the team to only be coded using a Simple 'comprehensiveness' measure; others could be either Simple or Extensive.

C. Form annotation by two annotators

Each data request form was divided into individual, granular form elements based on the questions asked on each form. For example, one of the forms had a single numbered question comprised of two sub-questions, (1) "describe the data security procedures" and (2) "who will have access to the data". These were split into two distinct elements for coding. Each data request form element was then entered into the Coding Analysis Toolkit (CAT; Texifter, Amherst, MA). The CAT provided the capability for each element to be shown to an annotator on a computer screen along with the codebook so that all elements could be reviewed and coded efficiently. Using the CAT, two annotators (GH and DF) independently reviewed and coded all of the data elements from each of the ten data request forms, including whether each was Simple or Extensive in terms of comprehensiveness. Inter-rater agreement for each form was assessed with the kappa statistic. Coding disagreements were then discussed between the two coders and code assignment consensus was reached.

D. Content analysis of the ten forms

From the coded elements on each form we estimated the completeness of information about data needs captured in each form. This was done by assigning a numerical score to each element in the code book based on the comprehensiveness measure (Simple=1, Extensive=3) that represented the maximum score each item could be assigned. Forms that had ≥ 3 Simple elements assigned to the same code were considered to have an Extensive comprehensiveness measure of that code by nature of having multiple elements covering the same concept. We then computed the percent coverage of all possible elements by summing the scores per form and dividing by the total number of possible points a theoretical, all-inclusive form would have had. Finally, we assessed the form elements coded with either code element 2.1 and 2.7 for their ability to capture the salient details that would likely be necessary to capture the context and content of data requests in a reliable manner, which may serve as a communication channel between biomedical research teams and data analysts.

Results

The primary results from our analysis are shown in Table 2. There was substantial variation in how much detail each form covered and in the elements that were covered. Based on our metric of coverage, the top three forms (A, C, and J) had coverage of 52%, 48%, and 48%, respectively. Form B was much more sparse with only 11% total coverage. In general, forms that had more overall elements (or individual questions) also had better coverage, but the relationship was not completely linear. For example, Form A with the highest percentage of coverage (52%) only had 15 total elements whereas form F had 19 total elements but only 35% overall coverage. This discrepancy was most often due to either the number of Simple versus Extensive elements used on a form (e.g., fewer elements, but

Table 2. Summary of the coding analysis performed on the ten data request forms. If a cell is shaded it means that the specific code (row) was found to exist in the specific form (columns A-J). Additionally, the comprehensiveness measure of each element is shown with either an S (Simple, light shading) or E (Extensive, dark shading); those with ≥3 Simple elements on a form related to a single code were assigned an 'E' label even if it was not originally coded as being Extensive. The "Max Score" column represents the total number of points a form element could be assigned as a representation of its comprehensiveness. The total coverage of all elements for each form is shown at the bottom of the table as both a sum and percentage. Note that cells with an Extensive comprehensiveness label were given a score of 3 and those with a Simple comprehensiveness label were given a score of 1. The "# Forms with element" column is a sum of the number of distinct forms that had at least one element on the form that had the respective code in it. For example, nine forms contained code 2.1 ("Study Title/Request").

Code	Description	Max Score	Form										# Forms with element
			A	B	C	D	E	F	G	H	I	J	
1.0	*Requester Metadata*												
1.1	Name	3	E				E		E	E		E	5
1.2	PI, supervisor, department head	3	E	S	E	E		E			E	E	7
1.3	Billing/Administrative content	3			E		S	S				E	4
1.4	Other	1		S		S					S		3
2.0	*Request Metadata*												
2.1	Study Title/Request	1	S	S	S		S	S	S	S	S	S	9
2.2	Existing/New request	1	S		S					S			3
2.3	Funding source	3			E			S			S	S	4
2.4	Request purpose	1	S	S	S		S	E*	S		S	S	8
2.5	Request type	3		S		E					S		3
2.6	Data sources	3	E					S		S			3
2.7	Data element specification	3	E					E	S	S	S	S	6
2.8	Recurring requests	1	S		S								2
3.0	*Compliance*												
3.1	IRB	1	S					S			S	S	4
3.2	IRB proof	1	S									S	2
3.3	PHI	3	E				E						2
3.4	Compliance other	3	S				E		S			E	4
4.0	*Data Use*												
4.1	Internal data sharing	3			E			S	E	S			4
4.2	External collaborators DUA	3			E							S	2
4.3	Public sharing of original dataset	1							E				1
4.4	Terms and conditions of use	1	S								S		2
4.5	Data use other	1								S			1
5.0	*Miscellaneous*												
5.1	Elements not classified elsewhere	3	S		E	S	S	E		S	E	E	8
	Total Score	46	24	5	22	8	13	16	13	10	14	22	
	Percent coverage of all possible elements	100%	52%	11%	48%	17%	28%	35%	28%	22%	30%	48%	
	Total number of distinct form elements identified for coding		15	5	25	10	9	19	11	11	21	36	

***** This was labeled Extensive because there were 4 distinct Simple elements related to category 2.4; however, this category was considered to be a Simple category. Thus, in this row it still only counts as 1 towards the total score.

more extensive coverage by each element) or due to many elements disproportionately being related to only a handful of related questions (e.g., one form had four elements dedicated to the funding source).

Nine out of the ten forms asked about the title of the study/request, and this was the most common question asked across the forms. Other questions were less commonly asked. Only two forms (A and J) explicitly requested proof of study approval from an institution review board, and only one form (G) asked if there was a plan to share the original data set publically. At a category level, four forms did not have a single element related to "Compliance" and three did not have a single element related to "Data Use". All forms incorporated at least one element related to the categories of "Requester Metadata" and "Request Metadata", the latter of which is most important for understanding the actual data needs for a request. Within the "Request Metadata", codes 2.1 ("Study Title/Request")

and 2.7 ("Data element specification") were determined to be the most relevant for a data analyst to understand the specific needs of the research team. Therefore, we list the specific elements for codes 2.1 and 2.7 derived from all 10 forms within Table 3. Some forms asked detailed questions (e.g., five distinct elements coded 2.7 on form F) whereas others asked very basic questions (one element coded 2.1 on form C).

During the coding process we also came across form elements that stood out from the rest, based on the unusual or interesting nature of the questions. These are detailed in Table 4. This table also contains descriptions based on our consensus opinion on why those specific elements were noteworthy. Overall, coding the forms was challenging due to the highly variable manner in which questions were worded. For the ten forms in our analysis, the initial Kappa scores measuring the inter-rater agreement were quite variable, ranging from 0.14 to 0.86 (full list for the forms in the order presented in Table 2: 0.83, 0.86, 0.57, 0.14, 0.64, 0.65, 0.52, 0.55, 0.43, 0.76). Thus, some forms required considerable effort to reach consensus on the final coding of each element.

Table 3. Data elements related to codes 2.1 ("Study Title/Request") and 2.7 ("Data element specification"). These two codes were judged to be the most relevant for a data analyst to understand the information needs of the research team. Note that form D did not contain any elements for which these codes could be applied.

Form	Code	Comprehen-siveness	Element Header Excerpt	Element Question	Element Options
A	2.1	S	General Reason for Request	Brief description of intent for use of data and/or associated project	Text Box
A	2.7	E	Research Request Reason	Please included as applicable: Request Information (Please include Request Description and if known) - Data Elements, Date Range/Parameters, Sort Sequence, Included Population (e.g. nursing units, DRG codes), Excluded Population (exceptions to the included population), Associated Form (Eclipsys Use Only)…	Docu-ment Upload
B	2.1	S	Please provide the following information	I need the new report because…	Text Box
C	2.1	S	Data Type	Full Study Title	Text Box
E	2.1	S	If the purpose of your request is for Patient Care, Education, Administrative, Billing/Payment…complete the following	Give a brief description of your project in the space below:	Text Box
F	2.1	S	DATA REQUEST FORM	Study Title/Study Idea	Text Box
F	2.7	E	Data and/or Records Needed for Research Protocol: Include the following…	Selection Criteria (e.g., all patients with a visit with an ICD-9 780.3x and/or 345.x, English speakers whose age > 50 and age <= 75, etc.)	Text Box
F	2.7	E	Data and/or Records Needed for Research Protocol: Include the following…	Counts (if applicable): (e.g., number of patients seen by Firm A, B, C grouped by under 65 and 65 or older)	Text Box
F	2.7	E	Data and/or Records Needed for Research Protocol: Include the following…	Dates of Records: (e.g., January 1, 2004 March 31, 2005)	Text Box
F	2.7	E	Data and/or Records Needed for Research Protocol: Include the following…	Number of Records: (e.g., 2000 patients with specified diagnosis, 10% sample of patients with diagnosis, all patients admitted thru ED)	Text Box
F	2.7	E	Data and/or Records Needed for Research Protocol: Include the following…	List of Data Fields: (e.g., age, race, diagnosis, service area, PCP, etc.)	TextBox
G	2.1	S	complete the following questions	Describe the project for which the data is requested:	Text Box
G	2.1	S	complete the following questions	What is the purpose of the project or study?	Text Box
G	2.7	S	complete the following questions	Describe the data elements needed, such as cancer type (site and histology), geographic location and dates…	Text Box
H	2.1	S	What are the objectives of this project?	What question(s) are you trying to answer?	Text Box
H	2.1	S	What are the objectives of this project?	What problem(s) are you trying to solve?	Text Box
H	2.7	S	What are the data requirements?	How much historical data are needed to meet the targeted reporting scope?	Text Box
H	2.7	S	What are the data requirements?	How current do the data need to be to support the targeted reporting?	Text Box
I	2.1	S	Project Details	Project Title	Text Box
I	2.7	S	Project Details	Please explain below and describe, in detail, the nature of your request to BMI/ICTR. Please do not include any protected health information (PHI)	Text Box
J	2.1	S	General Question	Protocol Title	Text Box
J	2.7	S	General Question	Anticipated Enrollment	Text Box
J	2.7	S	General Question	Is your anticipated enrollment period greater than a year	Y/N/NA

Table 4. Noteworthy atypical form elements grouped from different forms.

Element	Why noteworthy
"I want to write my own SQL queries"	Allows for the possibility of self-service of the complex databases for advanced users. It is unclear what type of guidance or oversight is provided for such requests.
"Please specify what type of Biomedical Informatics Services you are requesting: REDCap, Velos…"	This form combined questions related to data requests and those related to data storage.
""Will you be contacting patients? ____No ____Yes. If yes, please justify the need."	This form seemed to conflate the role of data request fulfillment with that of an institutional review board (IRB). A judgment about the appropriateness of contacting patients is generally handled within the framework of an IRB.
"Principal Investigator: Degree(s):"	It is unclear what the need is for the academic degrees of the principle investigator. It is possible that some institutions limit data access to investigators with a terminal degree.
"What question(s) are you trying to answer" "What problem(s) are you trying to solve"	These questions appear to be aimed at developing a broader perspective about the specific needs and goals of the research term. This information could be useful to help the analyst better understand the context for the data request.

Discussion

Our analysis of research data request forms revealed several interesting findings. Foremost was the substantial variability in the content and comprehensiveness of the forms. This variability suggests that there is no universal or community-based consensus, even among CTSA institutions, about the optimal way in which a data request form should be designed, what the 'right' questions to ask are, and how they should be asked (i.e, expecting simple or extensive answers). This could cause downstream consequences including an inability to meet regulatory requirements (e.g., no record of IRB approval verification) or an inability to track research data use in trustworthy ways, as well as problems developing the right queries to meet the fine-grained needs of research teams.

Our analysis raised the important question about how well overall the forms were designed. Being able to answer this question adequately depends, in part, on how well the forms could capture complex data needs accurately and in a reproducible manner. Some forms were very vague or brief about asking researchers what was needed, whereas others asked about specific elements (Table 3). Yet we did identify one form that contained questions that seemed to be aimed at helping the analyst develop a deeper understanding of what data were being sought (Table 4, row 5) and this may be a useful approach to improve communication.

Because data request forms might serve as the first point of contact between a data management team and a research team, improvement of these forms could provide great benefit. It has been shown that work focused on redesigning pathology test request forms has been beneficial,[34-36] so it may be reasonable to extrapolate that similar benefits could be achieved with redesigned data request forms. The process of developing appropriate data queries from complex user needs can take multiple rounds of refinement,[29] but current forms do not appear to be designed to support this process well. It has been noted in the literature that adequately meeting the data needs of investigators for a single request can take a long time[37] so any efficiencies that can be gained would be welcomed.

Data requests forms have been mentioned in the literature[32, 38] (often as a side note) but little attention has been paid to their role in helping investigators obtain data accurately and efficiently. Relative to other form elements, our analysis indicates elements used to elicit the context and content of the requester's data need are lacking. The utilization of frameworks such as PICO (problem/population, intervention, comparison, and outcome) might prove to be advantageous in this setting.[39, 40] With PICO, requesters are encouraged to structure the information need along each of the four dimensions, which could help convey a more realistic description of the request.

Additionally, the effectiveness of forms could likely be improved by providing additional education to investigators about the nature of the data in the systems while at the same time helping to guide researchers through the request form in a more logical manner to ensure that all the important aspects are covered. It has been observed that familiarity with the database fields by research teams is essential even when working with data analysts[41] but the forms we analyzed did not provide such details. It is possible that some of the forms we reviewed were meant to be accompanied by additional descriptive documents, but we did not come across them in our search. We also did not identify any forms that discussed the issues about data in coded format versus free text narratives, or what types of data are generally found in either of those types of sources.

The forms that comprised our analysis appeared to be constructed to meet the needs of multiple stakeholders (researcher, compliance, IT, etc.). What was surprising, however, is that many forms were unbalanced and placed a greater emphasis on capturing administrative (i.e., bookkeeping) data rather than on the details necessary to execute an effective data query. At the large academic centers generally funded by CTSAs, it is likely that many of these data elements already exist in electronic format in administrative databases and might not even need to be transcribed onto a form. Additionally, asking about the degrees of the principal investigator (Table 4, row 4), for example, may be a reflection of a data governance concerns; that is, trainees or temporary employees without terminal degrees may not be granted access to the data at some institutions.

Future work should seek to understand what are the core set of elements that elicit actionable information related to common data requests. To this end, a careful analysis of actual data requests in order to be able to map the type of data needs to appropriate elements on existing forms, or to create new form elements when needed. Understanding these needs is a first step towards developing solutions to meet those needs.[42] Cimino *et al.* recently described their work related to understanding complex queries to better develop data retrieval capabilities in the self-service tool BTRIS (Biomedical Translational Research Information System) in use at the NIH.[20] Their goal was to better empower users to obtain the needed data rather than having to rely on data analysts to retrieve the data for them. Several of their observations could likely also improve the design of data request forms, specifically the recognition that the requirements from users "included types of data, constraints on data, and data sets formed from inclusion from multiple data sources."[20]

In addition, future work should seek to quantify the time it takes to complete the elements on a data request form, and if there may be a reasonable tradeoff between form length and the subsequent quality and efficiency of the data extraction. Additionally, observing investigators as they fill out the forms could provide insights about what form elements may be confusing or ambiguous.

From our analysis we are able to make several recommendations about future data request form development: (1) more effort should be made to standardize the types of questions being asked across institutions; (2) whenever possible, forms should de-emphasize the collection of administrative metadata and expand the scope of elements related to the request itself; (3) despite decrease administrative metadata, forms should capture enough information to ensure that regulatory requirements about data use, privacy, and human subjects protection are being met; (4) form design should match the data requirements of investigators--since this is not well described, further research will be needed to elucidate these requirements; (5) because data requirements may vary based on the intended use (e.g., research versus administrative), a 'one-size-fits-all' form may not always be ideal, and forms customized to various use cases may be more effective; and (6) forms should provide at least a minimal level of detail to ensure that users understand the selections and options, including details about data sources and data types.

Conclusions

To serve people we must first understand them. A data request form is meant to be a tool to facilitate an understanding between data owners and data requesters, rather than a burden on researchers serving bureaucratic purposes. This analysis of research data requests forms revealed considerable heterogeneity in form content, both in the breadth and depth of the topics covered. Additionally, most forms over-emphasize the collection of administrative metadata and under-emphasize the collection of important details necessary to communicate a complex data request to a reporting team. Future work should focus on better understanding the content and nature of data requests from the perspective of multiple stakeholders to help inform the design of new data requests forms that can better capture the complexity of clinical and translational research teams.

Abstract

Patient-generated health data (PGHD) offers a promising resource for shaping patient care, self-management, population health, and health policy. Although emerging technologies bolster opportunities to extract PGHD and profile the needs and experiences of patients, few efforts examine the validity and use of such profiles from the patient's perspective. To address this gap, we explore health interest profiles built automatically from online community posts. Through a user evaluation with community members, we found that extracted profiles not only align with members' stated health interests, but also expand upon those manually entered interests with little user effort. Community members express positive attitudes toward the use and expansion of profiles to connect with peers for support. Despite this promising approach, findings also point to improvements required of biomedical text processing tools to effectively process PGHD. Findings demonstrate opportunities to leverage the wealth of unstructured PGHD available in emerging technologies that patients regularly use.

Introduction

One of the most promising trends in health informatics is the rise of patient-generated health data (PGHD), ranging from patient-reported outcomes (PRO)[1-2] and observations of daily living[3] to quantified self[4] and qualitative illness narratives[5] collected outside of clinical care. Whereas traditional consumer health technologies focus largely on *pushing* resources to patients, emerging opportunities leverage existing PGHD for better care. Health information technology, including social media, provides a vital source of PGHD used as the basis of automated health profiling for targeted prevention[6] and treatment.[7-8] To promote social support in the context of online health communities, we leverage PGHD to automatically profile the health interests of online community members and then use those profiles to facilitate peer connections and support for cancer.[9]

Although PGHD has long been the prized treasure of online health communities,[10] it has become recognized as a critical tool for improving clinical care and population health by complementing traditional forms of data collected in the clinic.[1,11-12] For example, social support provided through narrative posts on online health communities promotes empowerment by improving psychological adjustment to cancer,[13] increasing social wellbeing, and helping patients feel better informed.[14] Electronic self-reported quality of life collected through structured PRO tools can reduce symptom distress and improve patient-provider communication.[15-16] Patient illness collected through a self-report tool was found to identify respiratory illnesses with greater sensitivity than chief complaint data used by traditional disease surveillance systems.[17] Growing patient engagement in health care highlights the important role that patient experience plays in policy, such as meaningful use criteria.[11,18] In particular, the Office of the National Coordinator for Health Information Technology initiated several activities to advance the application of PGHD in clinical workflows, research and development, and policy.[12]

Emerging technology (e.g., social media, mobile devices, sensors) bolsters the opportunity for using PGHD to profile the needs and experiences of patients, making this an important area for research and policy.[19] Thus, examining the validity of inferences extracted from PGHD is critical. Whereas progress has been made processing structured PGHD, such as PROs,[2] opportunities remain to leverage the wealth of unstructured PGHD in social media and other technologies that patients regularly use. Several studies benchmark the validity of inferences drawn from PGHD against clinical comparisons.[17,20] Yet few efforts examine the validity and use of health profiles extracted from PGHD from the patient's perspective.

Using automated text processing, we extract health-related terms from online community posts to summarize individual members' health-related interests.[21] Our long-term goal is to use the resulting **health interest profiles** to connect members with shared interests for peer support.[9] Our partnership with CancerConnect.com provides a unique opportunity to evaluate this approach with online community members. As a first step, we conducted a user

study to evaluate individualized health interest profiles with users based on their posts. In this work, we address two key research questions:

RQ1. How closely do health interest profiles extracted from PGHD align with members' stated interests?

RQ2. What are members' preferences for using health interest profiles to connect with peers for support?

Profiling users from PGHD in online health communities

Growth in health-related use of social media,[22] including online health communities, helps patients share experience and advice with peers (i.e., patient expertise).[23] Many individuals now use these tools more often to exchange information and advice than to obtain emotional support.[24] Yet, reading numerous posts to identify peers with shared interests takes time and effort. It can be difficult for community members to relate to the health experiences of other users[25] and build relationships that support rich exchange of patient expertise.[13]

Profiles about users and their interests provide a key means for exploring potential relationships in online communities. Most online communities encourage users to create a profile by manually entering a few key details, such as diagnosis or treatment. Detailed user profiles are invaluable for summarizing the experience and expertise of available from peers,[26] yet manual upkeep of detailed profiles takes time and energy away from managing a serious illness. We explore one possible solution that augments user profiles with details extracted automatically from community posts contributed by each user, such as treatments, tests, or other topics of interests.

Members of early online communities without user profiles were often limited to communicating their personal characteristics and interests through "signature line" descriptions at the end of message board posts. Today, user profiles are a fundamental component of modern social media that represent individual community members.[27] By aggregating distinctive features that characterize a user, a user profile provides a synopsis, typically through a combination of manually entered elements (e.g., personal interests) and semi-automatically generated elements (e.g., number of followers or friends). From these elements, users form "thin slice" impressions when establishing online connections.[28] Thus, user profiles help establish social context as conversation starters.[29]

In the health domain, some researchers enrich user profiles by dynamically leveraging PGHD. For example, Nuschke and colleagues[30] designed a community-based diet and exercise journal that dynamically illustrates progress towards health goals and community participation on user profiles. Similarly, profiles on PatientLikeMe.com summarize historical trends in PGHD that users post about their experience with treatments, symptoms, outcomes, and community participation with dynamic icons.[31] Temporal charts and graphs extend profiles to illustrate trends in these metrics over time. Although automatic extraction of PGHD can help users to build detailed profiles, this approach raises a number of questions about how machines might assist users–does automatic extraction produce more content than what users manually enter? How accurate is extracted content? Does automatic extraction capture interests and experiences that users do not otherwise enter?

In our work, we are enriching user profiles with health-related interests automatically extracted from a user's community posts.[21] The resulting health interest profile could efficiently summarize a user's experience through the health terms they discuss in posts as their community participation evolves over time. One could imagine extending such profiles with additional personal characteristics that members wish to share when forging connections with community members, such as demographics, education, livelihood, or connection to cancer as a patient, survivor, caregiver, or other role.[26] Despite the potential value of reducing the effort required for profile creation and maintenance, user perceptions about the accuracy and value of automated profile generation remain unknown.

Extracting Health Interest Profiles in CancerConnect Online Community

Within the context of CancerConnect (http://cancerconnect.com/), our partnering online health community, we examined the automatic extraction of individualized health interest profiles by processing the text of community members' posts. CancerConnect is an award winning resource for web-based cancer resources that facilitates peer support for cancer through forum-style community posts. Health interests profiles provide the basis for our broader effort aimed at peer matching to recommend "mentors" with shared interests.[9]

We developed a text extraction approach to automatically generate health interest profiles from online community text.[21] The profile is a vector of terms representing the health interests of an individual member based on all posts that user has contributed to the community. Our profile extraction pipeline includes MetaMap to support automatic extraction of health-related terms and sematic concepts that populate health interest profiles. MetaMap[31] is a natural language processing tool designed to extract health-related terms from biomedical text that map to concepts in the Uniform Medical Language System (UMLS).[33] The UMLS consists of more than 1.3 million concepts from over 100

biomedical vocabularies.[34] Each concept in the UMLS is classified into one or more semantic types.[35] Together, semantic types make up the UMLS Semantic Network that unifies the vocabularies within the UMLS, and thus, provide a means for grouping semantically similar terms. Because health terminology used by biomedical professionals can differ from the ways many patients express and think about health topics, researchers map patient-friendly terms to UMLS concepts in an effort to develop consumer health vocabularies (CHV).[36] Recent efforts include computer assisted updates that leverage social network data from PatientsLikeMe.com to identify new terms for inclusion in CHV.[37]

To generate a health interest profile for an individual community member, we collect all of the posts that member contributes to the community. We then process those posts to automatically extract health-related terms, which we refer to as "health interests." Since we wish to present those health interests to users, we were faced with a small dilemma. Do we present the user with an uncategorized set of extracted health interests? Or do we attempt to group health interests in some coherent way? We chose to group similar health interests using UMLS semantic types.[35] There are a number of strategies for grouping UMLS semantic types, such as maximizing semantic coherence.[38] Our aim was to present groups of terms relevant to the cancer experience that would be sensible to users who view health interest profiles. To do so, we considered a sample set of terms with their associated UMLS semantic types and created our own five categories that group similar semantic types (Table 1). Through this process, we populate a user's health interest profile with the health interests we extracted across the five categories (see example in Figure 1). This categorization enabled us to generate individualzed profiles that present information about uers in logical chunks, similar to user profiles they might find in any other online community.

Table 1. Health interest profile categories and associated UMLS semantic types

Category	UMLS Semantic type
Health problems	Neoplastic Process Disease or Syndrome Acquired Abnormality Injury or Poisoning Anatomical Abnormality Finding Sign or Symptom Pathologic Function Clinical Attribute Laboratory or Test Result
Treatments	Antibiotic Biomedical or Dental Material Medical Device Pharmacologic Substance Therapeutic or Preventive Procedure Hormone Vitamin
Diagnostics & tests	Diagnostic Procedure Research Activity Laboratory Procedure
Provider care	Health Care Activity
Genetics	Gene or Genome

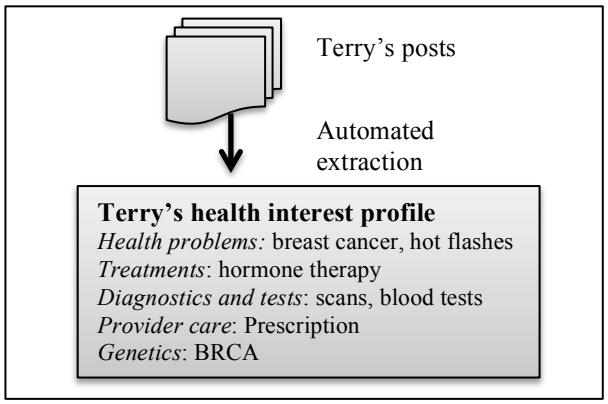

Figure 1. Example health interest profile populated with health interests extracted from community posts contributed by fictitious member "Terry"

We evaluate these individualized health interest profiles through a user study with community members. Our CancerConnect partnership enabled us to examine both the accuracy and perceived value of health interest profiles. We could generate health interest profiles for individual community members, and then ask those members to evaluate their own individualized profile. We were particularly interested in evaluating the accuracy of our automatically extracted health interest profiles compared to the stated health interests that community members could provide directly through manual entry (RQ1), as well as examining community members' perceived value of using those profiles to connect with other members for peer support (RQ2).

Methods

We conducted a web-based user study by recruiting members of CancerConnect to answer our two key research questions about the accuracy and perceived value of extracting health interest profiles from PGHD in online health communities. Before the study, we processed the text from all posts each community member contributed to the CancerConnect community. Using the extracted terms, we constructed individualized health interest profiles that summarize health-related issues each member discussed in their posts across our five categories (Table 1). To be

eligible for participation, members were required to have posted sufficient text to the CancerConnect online community over the past six months to extract a health interest profile with at least ten unique terms.

We used the individualized health interest profiles with participants during the two-part user study. To examine the alignment of health interests extracted from members' posts with members' stated health interests (RQ1), participants first completed a set of recall and recognition tasks during which they manually entered health issues of personal interest. Then, participants completed a set of preference ratings to describe their perceptions about using health profiles to disclose their personal interests and characteristics to other community members (i.e., "peers"), to learn about the interests and characteristics of peers in the community, and to be matched and interact with peers with shared interests and characteristics (RQ2). At the end of the study we collected participant demographics. IRB approval was granted from the University of Washington Human Subjects Division. We configured and administered the user study using Lime Survey (http://www.limesurvey.org/en/).

Part 1. Recall and recognition tasks

Each participant completed a sequential set of recall and recognition tasks to assess the accuracy of their individualized health interest profile. The participant first completed a free recall task in which they were asked to enter terms or phrases that describe the health issues they discuss within the community for as many of the five categories as they wished (i.e., health problems, treatments, diagnostics and tests, provider care, and genetics). Next in the recognition task, we primed the participant by showing the extracted health interests from their profile across the five categories. We asked the participant to add or remove terms and phrases until they were satisfied. Terms and phrases were shown as tags that could be easily added or clicked on to remove (Figure 2).

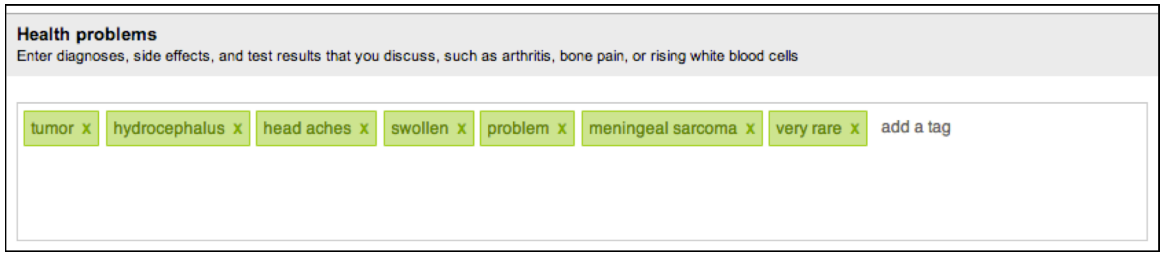

Figure 2. Example of recognition task to add or remove health interests for category "health problems"

At the conclusion of the recall and recognition tasks, we obtained three lists of health interests for each participant: (1) ***extracted terms*** making up the participant's health interest profile that we automatically generated, (2) ***recalled terms*** that the participant entered from memory during the recall task, and (3) ***recognized terms*** that resulted after the participant added and removed terms from their automatically generated health interest profile during the recognition task. We assessed the alignment of those lists of health interests using Wilcoxon sign rank to compare the number of terms between lists, as well as Jaccard index, precision, and recall to compare term similarity between lists. In particular, we examined the alignment between extracted terms from the health interest profile with the member's stated health interests through recall and recognition tasks (RQ1). This analysis enables us to examine how close a set of extracted terms can come to an acceptable set of profile terms. It also allows us to consider the similarity/differences between the health interests we can extract and the health interests users choose to enter.

Part 2. Preference ratings

Following the recall and recognition tasks, the participant provided structured feedback by rating their preference across a range of potential uses of their personal health profile (RQ2). We were particularly interested the perceived value of using profiles to share health interests with community members, as well as expanding profiles with other personal characteristics. Guided by our prior work,[25] we chose 10 personal characteristics which that could be used as the basis for peer matching and interaction including: all health interests, only common health interests, personality, participation level, demographics, education and livelihood, geographic location, common users followed, common groups followed, and common posts responded to. Preference ratings were made on a 5-point Likert scale (1="not at all" to 5="very") and covered four main areas: (1) ***comfort in disclosing*** personal interests and characteristics to other members of the online community on the profile, (2) ***interest in viewing*** personal interests and characteristics of other community members on their profiles, (3) ***importance of matching characteristics*** sought when connecting with online community members (e.g., someone with the same diagnosis or similar age), and (4) ***interest in interaction styles*** for connecting with online community members. Interaction styles included four types: (1) "one shot" anonymous interaction that is one-to-one, short-term, and impersonal, (2) one-to-one interaction that is personal, confidential, and sustained over time with a "buddy," (3) group interaction that

occurs regularly among individuals with a shared issue modeled after a "support group," and (4) group interaction that occurs as needed and focused on a topic of interest in a "group campaign."

We report preferences using descriptive statistics and comparisons based on Friedman chi square (X^2) and Wilcoxon signed rank (V) tests. We also offered participants the option to provide open-ended responses for concerns and suggestions regarding the use of health profiles to connect with community members, which we grouped qualitatively for emergent themes. This analysis enabled us to examine participants' attitudes regarding a range of potential uses of health profiles for sharing their health interests as well as broader personal characteristics for connecting with peers in the online community.

Results

Participants

A total of 34 CancerConnect members participated in the study with one participant completing only the recall and recognition tasks in part 1. The remaining participants ranged in age from 31 to 76 and are mostly female and white (Table 2). Table 3 shows participants' online community participation including average weeks worth of posts, posts per week, words per post, and extracted health interests per week.

Table 2. Demographics of participants

Age mean(sd) range	55(11) 31-76
Sex	85% Female 9% Male 6% na
Education	9% High school graduate 31% Some college 33% College graduate 24% Post graduate 3% na
Race/ethnicity	94% white 6% na
Social network size	24% Extensive 49% Moderate 18% Small 9% na
Geographic location	22% Western United States 15% Midwestern United States 27% South United States 27% Northeastern United States 9% na
Top personal interests/hobbies	Reading, exercise, cooking, gardening, television/movies

Recall and recognition: Profile validation

We report on alignment in the number and similarly of health interest terms we automatically extracted, terms participants freely recalled, and terms resulting after the participant completed the recognition task.

The number of terms that resulted following automated extraction, the recall task, and the recognition task are shown in Table 4. Compared to recalled terms, we extracted significantly more health problems (V=450, p=0.001) and treatments (V=444, p=0.004). Participants entered more terms than we extracted for diagnostics and tests, but that difference was not significant. Compared to what we automatically extracted, participants entered significantly more genetic terms and provider care terms (V=109, p=0.004). Automated extraction was limited for those two categories–we extracted provider care terms for 19 participants and extracted genetics terms for only three.

Table 3. Online community participation

	Mean (sd)	Range
Weeks worth of posts	32 (38.4)	0.1 - 129
Posts/week	3 (4.5)	0.1 - 14
% Initiating posts	20%	0 - 100%
% Replies	80%	0 - 100%
Mean words/post	105(55.0)	36 - 227
Mean extracted terms/week	13 (137)	0.1 - 49

In contrast, the difference in number of terms that resulted following automated extraction and the recognition task was much less striking. Participants removed an average of 2.4 health problems from the health interest profile, resulting in significantly fewer terms on the resulting recognized term list than we extracted (V=205, p=0.05). With the exception of treatments, participants added terms for remaining categories, resulting in more terms on the resulting recognized term list than we extracted for diagnostics and tests (V=21, p=0.02), provider care (V=34, p=0.008), and genetics (V=0, p=0.001). Table 5 shows numbers and examples of added and removed terms.

Table 4. Number of terms that resulted following the text extraction, recall task, and recognition task

	Extracted terms		Recalled terms		Recognized terms	
	mean (sd)	range	mean (sd)	range	mean (sd)	range
Health problems	13.15 (7.16)	3 - 26	6.94 (5.23)	1 - 23	11.74 (6.18)	2 - 26
Treatments	9.79 (7.80)	0 - 25	5.09 (3.82)	0 - 20	9.88 (7.41)	0 - 24
Diagnostics and tests	3.38 (3.23)	0 - 13	4.65 (4.85)	0 - 25	4.38 (3.61)	0 - 17
Provider care	1.82 (2.96)	0 - 13	4.15 (3.86)	0 - 17	3.00 (2.83)	0 - 12
Genetics	0.09 (0.29)	0 - 1	1.71 (1.73)	0 - 6	0.82 (1.14)	0 - 4

Table 5. Terms added and removed during recognition task

	Terms added		Examples of added terms	Terms Removed		Examples of removed terms
	mean (sd)	range		mean (sd)	range	
Health Problems	1.0 (1.8)	0 – 7	no side effects	2.4 (2.8)	0 – 10	alone, pain, HIV
Treatments	0.9 (2.0)	0 – 9	folfiri 5fu, nutrition	0.9 (1.2)	0 – 4	oxygen, procedure
Diagnostics and tests	1.4 (2.1)	0 – 7	ct scan, mri, blood test	0.4 (0.8)	0 – 3	hgb, research, color
Provider care	1.4 (2.1)	0 – 7	2nd opinion, exams	0.3 (0.6)	0 – 3	report, documented
Genetics	0.7 (1.1)	0 – 4	brca, family history	0.0 (0.0)	0 – 0	(none)

Findings on alignment of the number of extracted, recalled, and recognized terms demonstrate that automatic extraction can help users populate their profiles. This machine assistance was most effective for categories in which we extracted more terms (i.e., health problems and treatments). When given the opportunity, participants removed extracted terms they found inappropriate. Some removed health problems, such as "alone" and "clarity", point to limitations of extracting terms with MetaMap that do not seem health-related from the perspective of participants. Other removed terms were more clearly health-related, such as "pain" and "HIV," but participants chose not to keep them on their health interest profile. Categories with fewer extracted terms (i.e., provider care, genetics) required participants to add terms during the recognition task because extraction alone did not sufficiently populate their profile. Health problems that participants added, such as "no side effects", might be impossible to extract unless the user explicitly stated in a post. Thus the size of our categories varied and this had impact on our approach. These findings suggest that machines can help augment profiles through automated extraction, but that users should be provided the opportunity to edit extracted data. These findings also illustrate limitations of applying biomedical text processing tools to unstructured PGHD.

Term similarity between extracted terms and recognized terms was substantially higher than between extracted terms and recalled terms across all 5 categories of health interests (Table 6). With the exception of genetics, where terms were extracted for only 3 participants, overlap between extracted terms was recognized terms was substantial with Jiccard indices ranging from 0.48 to 0.79. When recognized terms served as the gold standard, the precision and recall of extracted terms was also high with worsening performance as categories become sparser moving from provider care to genetics. When we used recalled terms as the gold standard, overlap with extracted terms was much lower, including low precision and recall across all categories.

Table 6. Similarity between extracted terms and recognized terms, recalled terms

	Extracted (test) vs. Recalled (gold standard)		Extracted (test) vs. Recognized (gold standard)

Findings on term similarity further support our claim that participants appear largely satisfied with the accuracy of individualized health interest profiles we extracted and thus made few changes. Users are beginning to discuss emergent topics, such as genetics, which may be challenging to extract using tools like MetaMap. Such categories may be small with few terms, but that does not mean they are unimportant and users should be solicited to input terms. Further, lack of overlap between extracted terms and recalled terms suggests that users and machines might contribute different kinds of health interests to profiles. To further investigate this possibility, we compared the similarity

between recalled terms and the terms participants added during the recognition task (Table 7). The small term overlap and low precision and recall suggest that when participants are prompted with extracted terms, they add different kinds of terms than those they freely recall. This finding holds despite the lack of a washout period between sequential recall and recognition tasks. Our findings suggest a **valuable role for machines** to assist users not only in augmenting profiles with extracted terms that they are unlikely to recall and enter manually—by showing users the extracted terms, machines can also remind users of additional terms they are unlikely to recall on their own.

Preference ratings: Attitudes toward profile use

<u>Self-disclosure:</u> On average, participants expressed comfort in disclosing 10 types of personal interests and characteristics by publicly displaying them on their profile (Figure 3), with the greatest mean comfort expressed for disclosing common health interests and the least mean comfort disclosing geographic location. For participants without missing data (n=30), the difference in comfort level among types of personal characteristics was significant (X^2 = 19.7, p=0.02). Pairwise comparison between the highest level of comfort disclosing common health interests and lowest level of comfort disclosing geographic location shows a significant difference (V=93, p=0.005). Most participants (25/33) expressed no concerns about disclosing personal characteristics to other community members. When asked about concerns, 11 left their open-ended response blank and 14 responded with an explicit statement (e.g., no concerns). Concerns expressed by the remaining 8 participants included revealing personal information that could be used in unapproved ways (e.g., targeted advertising) (4/33), desire to choose with whom to share personal information (1/33), desire to keep personal information private (1/33), and creating stress (1/33) or embarrassment (1/33).

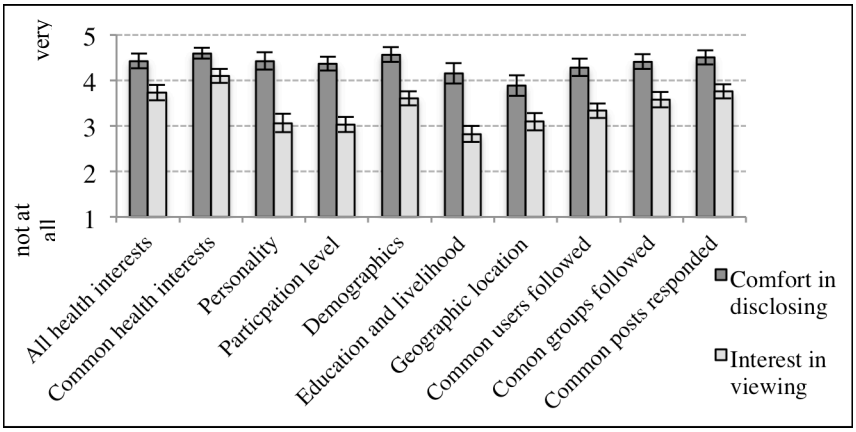

Figure 3. Comfort in disclosing vs. Interest in viewing personal characteristics

<u>*Viewing preferences*</u>: On average, participants expressed interest in viewing the 10 personal characteristics of other members on user profiles (Figure 3), but this interest level varied significantly among the 10 types (X^2=62 p<0.001). Participants expressed the greatest interest in viewing common health interests and the least interest in viewing education and livelihood. Pairwise comparison between the highest interest in viewing common health interests and lowest interest in viewing education and livelihood location shows a significant difference (V=210 p<0.001). Interest was significantly higher for viewing *common health interests* than any other personal characteristic except *common posts responded to*. Interest in viewing *education and livelihood* was significantly lower than other characteristics except *personality*, *participation level*, and *geographic location*. When compared to ratings for comfort disclosing personal characteristics, participants expressed greater comfort disclosing than interest in viewing all personal characteristics (Figure 3).

Matching preferences: When considering connecting with an online peer, participants rated the importance of a range of matching characteristics (e.g., *someone who…*). Figure 4 shows that on average participants rated some matching characteristics more important than others. For participants without missing data (n=19), this difference was significant (X^2=27, p<0.001). Matching characteristics rated highest include *someone who is* trustworthy, has experience with cancer as a patient or caregiver, and has a similar diagnosis. Characteristics rated least important include someone who lives nearby, who I already know, and who is of similar race/ethnicity. Pairwise comparisons between highest and lowest rated characteristics show significant differences at or below the 0.001 level.

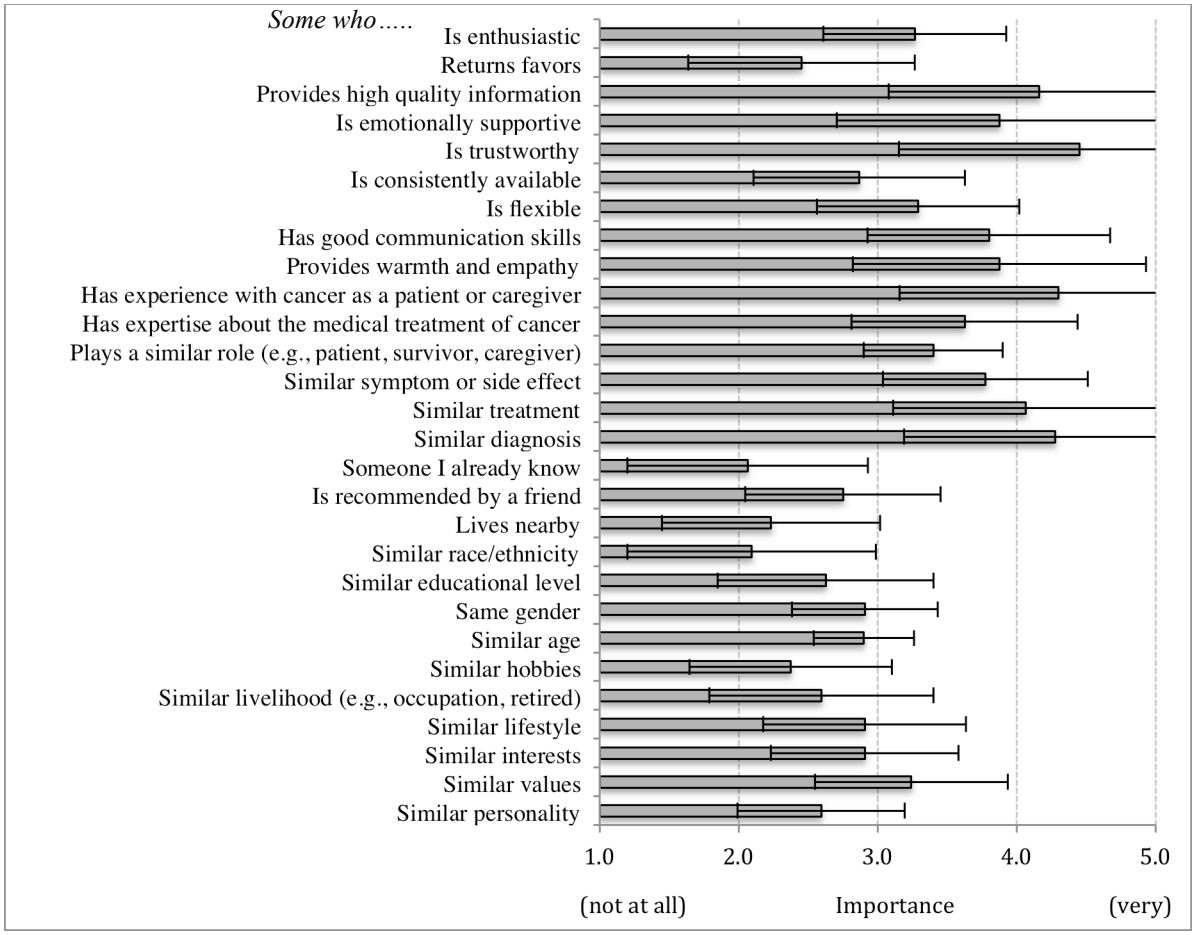

Figure 4. Mean importance of matching characteristics

Interaction preferences: On average, participants expressed interest in interacting with members across a range of styles (Figure 5). There was a significant difference in interest level among the four interaction styles (X^2=14, p<0.003). Pairwise comparisons show significantly less interests in "one shot" style, than other styles, including "buddy" style, "support group" style, and "group campaign" style. When asked about additional ways they wished to interact with online peers, participants reported email (33%), phone (25%), around specific topics (17%), through social media (17%), such as Pinterest or Blogger, and in disease-specific groups (8%).

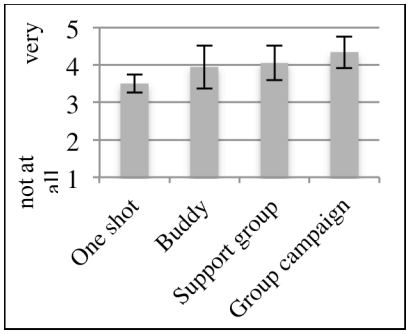

Figure 5. Mean interest level in interaction styles

Discussion and Conclusion

Substantial opportunities exist to leverage the wealth of unstructured PGHD available in emerging technologies that patients regularly use, yet few efforts examine the validity and use of health profiles extracted from PGHD from the patient's perspective. Although findings point to the perceived value of health interest profiles, we will evaluate their actual value in connecting peers in our future work. Findings from our user evaluation of health

interest profiles extracted from online community posts demonstrates value in augmenting detailed health profiles through text extraction applied to unstructured PGHD in multiple ways.

First, health interest profiles not only align closely with members' stated health interests, but expand upon those interests with little user effort. Automated extraction can populate profiles with content that community members accepted—when given the opportunity to add or remove health interests, few changes were made. Further, extracted content appears to overlap little with the content that members manually enter. This finding suggests that automated text extraction captures new and different kinds of interests and experiences than community members generally recall. In addition, extracted content appears to not only encourage members to refine their profile through manual removal of unsuitable content, but also act as a prompt for users to enter additional content they might not otherwise consider. Extraction is necessarily limited to the text users choose to post, which makes manual profile entry an important option for users. Thus machines can assist, but not necessarily replace, the user when processing PGHD.

Second, our findings illustrate positive attitudes of community members toward the use and expansion of health interest profiles with additional personal characteristics to connect with peers for support (e.g., common health interests). Community members expressed comfort in disclosing a number of personal characteristics to community members. They also expressed interest in viewing those characteristics of others. These findings provide support for expanding our automated extraction of detailed user profiles with additional characteristics of interest that can be used to facilitate peer matching and interaction. Important matching characteristics (i.e., someone who is trustworthy, has cancer experience, and has a similar diagnosis) and preferred interaction styles provide insight for future work in which we will use those profiles to match and help connect users for peer support. Although individuals with similar personal characteristics are likely to be attracted to each other (i.e., "birds of a feather flock together"), there may be merit in exploring "difference matching" (e.g., "opposites attract").

Although our findings provide new insight into the value of machine-assisted processing of PGHD, our text extraction was most effective when sufficient content, but not inappropriate content, was extracted. Finding this sweet spot poses a challenge. Whereas users can edit out irrelevant terms extracted by an overzealous machine, the inability of existing text extraction tools to capture important content is problematic. Topics such as provider care and genetics are clearly important to patients, but represent gaps in MetaMap and UMLS. Despite improvements in mapping UMLS to consumer-oriented terms,[36-37] effectively processing PGHD requires enhancements.

Emerging trends in PGHD present significant promise for shaping health care, self-management, population health, and policy. Our findings offer insights that speak to the value of processing PGHD from the patient's perspective. In particular, we illustrate one promising approach to leverage PGHD in the context of online communities. Substantial opportunities exist for capturing a wealth of unstructured PGHD available in emerging technologies that patients regularly use. As patient engagement in health grows and our desire to capture PGHD intensifies, it is critical that we prioritize development of technologies that can effectively process this unique and valuable resource.

Abstract

Natural language processing (NLP) technologies provide an opportunity to extract key patient data from free text documents within the electronic health record (EHR). We are developing a series of components from which to construct NLP pipelines. These pipelines typically begin with a component whose goal is to label sections within medical documents with codes indicating the anticipated semantics of their content. This Clinical Section Labeler prepares the document for further, focused information extraction. Below we describe the evaluation of six algorithms designed for use in a Clinical Section Labeler. These algorithms are trained with N-gram-based feature sets extracted from document sections and the document types. In the evaluation, 6 different Bayesian models were trained and used to assign one of 27 different topics to each section. A tree-augmented Bayesian network using the document type and N-grams derived from section headers proved most accurate in assigning individual sections appropriate section topics.

Introduction

A key focus in Biomedical Informatics is the use of computerized patient data to impact medical care at the bedside. A variety of tools have been developed that consume electronic data and produce information that can be used by clinicians to gain insight and to direct diagnostic and therapeutic interventions. These include systems that organize and summarize clinical information as well as decision support applications that deliver alerts, suggestions, and otherwise support the delivery of consistent, high-quality care.

To be compatible with the tools that mediate these information interventions, data in the electronic health record is best managed in a structured form whose semantics are captured through reference to standardized medical terminologies. Unfortunately, a large subset of the clinical documentation in electronic medical records consists of free-text reports. A recurring challenge in the use of electronic medical data to support clinical care is the need to extract relevant medical facts from these clinical documents. This can be accomplished through natural language processing (NLP) technologies[1]. However, the use of these technologies is made more difficult by the heterogeneous nature of these documents. Not only do different types of documents focus on different clinical information, but documents are typically divided into sections each of which focuses on a different category of medical data.

For these reasons, an initial step in clinical NLP is to identify these sections and to label each with a concept code representing the principal *topic* of that particular section. Labels such as "History of Present Illness", "Family History", "Allergies", and "Discharge Disposition" are used to represent these topics.

Typically, at this stage in processing a document, an initial parse based on structural features results in a collection of document sections each consisting of a section header followed by one or more paragraphs. The text in these paragraphs reflects those clinical facts relevant to a particular medical topic. Unfortunately, while clinicians generally organize clinical documents using semantically similar component sections, they do not necessarily use a standardized collection of section headers to distinguish among these sections. The topics involved must be discovered through an initial processing effort. In the document collection we describe below, sections containing similar concepts are entitled with a surprising number of different headers. Both the text from each section's header and the text from within the section content can be used as input to a system that assigns a topic as a canonical label for each section. This system is called the "Clinical Section Labeler".

The algorithms described below are designed to assign a coded descriptor to each section. This descriptor tells what the section is about (i.e. the section's *topic*). Section topic labeling is the initial step in information extraction for many types of documents. When NLP systems are focused on extracting particular types of information, this information will typically be located in specific sections within the document. If each document is initially processed by a section labeler that can effectively assign a standardized topic to each section, further processing can be restricted to only those sections in which the required information is likely to be found. This can result in more accurate overall output since, for instance, an NLP system extracting current medications will look in the "Medications" section and not in the "Allergies" section, thereby avoiding mistakes and reducing processing effort.

The character of sections and section topics has been, to some extent, formalized in the HL7 Draft Standard for Trial Use (DSTU) describing the Consolidated Clinical Document Architecture (CDA)[2]. This standard describes approximately 60 different section types and their representation through section templates. Identifiers for these sections generally come from the Logical Observation Identifiers Names and Codes (LOINC) system[3].

The challenges and goals described above have been addressed. Several approaches to automatically assigning canonical section topics have been described in the literature. Denny, et al developed a complete system design to automatically identify section boundaries and to label the sections.[4] This system was designed to find sections with section headers as well as "implied" sections where section headers were absent. The algorithm used a combination of NLP techniques. These included spelling correction, Bayesian components (used to score section headers), and terminology-based rules.

In a more focused effort, Ying et al described a tool specifically for identifying sequences of section types[5]. They applied Hidden Markov Models (HMMs) to this task. They used simple bigrams as features and compared the HMM-based approach to models restricted to a naïve Bayesian algorithm. The version of the system based on HMMs proved significantly more accurate than the naïve Bayesian process.

Approach

In order to develop and test a system to assign topic labels to the sections of clinical documents, we began by collecting a group of medical reports. These reports were chosen to support training and testing for a section topic recognition system. This dataset consisted of 3483 clinical reports extracted from Intermountain Healthcare's Enterprise Data Warehouse (EDW). The distribution of the reports used is indicated in table 1.

Table 1: Reports used in Section Topic analysis.

Report Type	Number of Reports
Consultation Report	491
Discharge Summary	499
Operative Report	499
Surgical Pathology Reports	499
History & Physical Report	497
ED Physician/LIP Report	499
XR Chest 2 Views (Frontal/Lateral)	499

We used a combination of automated and manual annotation to break the text in these reports up into four categories. These were 1) section headers, 2) section content, 3) labels, and 4) values. Labels and values generally occurred as pairs such as labeled dates ("Date of Service: 12/5/2012"), although values occasionally appeared independently.

Combinations of section header and section content define the individual sections and were the targets for further analysis. Occasionally, headers did not have complementary sections. This typically occurred when a header was

followed by sub-headers each of which could then have independent content. In these cases, we collapsed all subordinate sub-headers and their content into a single instance of section content.

The sections defined this way were manually labeled with topic identifiers designed to represent the basic documentation goals of each of these report components. These named identifiers were expected to express the principal documentation goal of each section. To accomplish this, identical section headers were grouped together with links back to section content. A physician reviewed the section groupings using the section content as necessary to confirm membership of different headers in a semantic class. This effort provided the annotated dataset.

Section Topic Identifiers

Once we had identified the topics that we would target, we developed and compared a group of algorithms designed to assign an appropriate topic to each combination of section header and section content found. These systems were alike in two aspects: each used features generated through extraction of N-grams (uni-grams, bi-grams, and tri-grams) from the text of the section headers and/or section content and each employed models for identifying topics which were constructed using Bayesian-network-based approaches[6]. These Bayesian networks (BNs) were designed to use both the document type and the generated N-grams in assigning a topic for each section.

The Bayesian models differed in two aspects. First, for two of these models, N-grams were derived exclusively from the text of the section content in each section's header/content pair; for two models, N-grams were derived exclusively from the text of the section header in each section's header/content pair; and for two models, N-grams were derived from a combination of the text in both the header and content of each section.

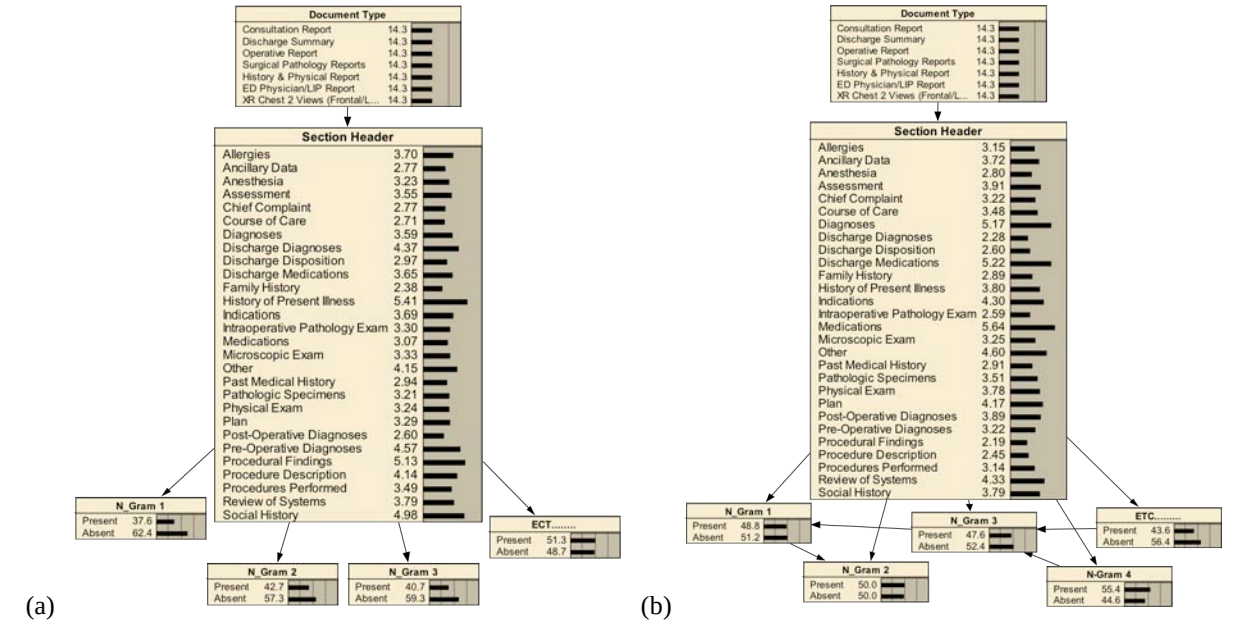

Figure 1: Bayesian networks were used to recognize section topics. In three cases (a), the core of the network employed a naïve Bayesian model. N-grams generated from 1) the section headers, 2) the section content, and 3) a combination of header and content were used to detect the topics of the individual sections. In the three additional cases (b), the network used these same feature sources but applied a tree-augmented naïve (TAN) Bayesian model. In all cases, the network was extended by adding a node representing the document type being processed.

The second way in which these models differed was that three were produced using an extended version of the naïve Bayes paradigm and three were developed using an extended version of tree-augmented naïve (TAN) Bayesian networks[7]. In developing these networks we extended the standard Bayesian paradigm by adding a node

representing the document type. This allowed for the differing distributions of section topics in the various document types to be easily captured by the algorithm. Table 3 (below) indicates the different algorithms tested.

The use here of Bayesian network techniques reflects our continuing interest in this technology. We have previously used BN-based systems in a number of NLP experiments. These include systems to extract findings from chest x-ray reports[8,9], systems to extract interpretations from ventilation/perfusion lung scan reports[10], and tools for syndromic detection[11]. A description of a system (MPLUS) that uses this approach to NLP can be found in Christensen et al[12]. Our enduring enthusiasm for this technology reflects its ability to incorporate information from multiple linguistic sources and to provide graphical tools through which to develop and inspect the resulting semantic models.

Analysis

We analyzed the different algorithms described above by employing a 10-fold cross validation technique. In this approach, the sample was divided into 10 parts, and for each part, the algorithm was trained with 90% of the sample and tested with the remaining 10%. The results are aggregated at the end of the procedure.

In this testing we looked at three different measures of parsing accuracy. We calculated the F-statistic and the standard one-versus-all area under the ROC curve (AROC) (for each topic, the analysis compares it to the combination of all competitors). However, when choosing a topic with this method, we actually choose the most likely topic from a list of 28. Therefore, we also calculated the pair-wise AROC[13] designed for multiclass classification problems.

Results

Within the initial dataset, 27,645 sections were identified. This had been reduced from 40,441 sections by the collapse of sub-sections into the parent sections. Ninety-eight different topics were assigned during annotation. These ranged in frequency from two instances (Nutrition Status, and Post-Operative Course) to 2933 instances (History of Present Illness). We determined to focus our efforts on topics with a frequency greater than or equal to 1% in the total corpus. Those topics whose frequency was less than 1% were collected into a category called "Other". This reduced the number of distinct topics to 27 plus the broad category of “Other”. These are listed in table 2.

In this way we narrowed the number of distinct section topics for consideration to 27. As anticipated, a review of the documents showed that these semantic labels were associated with a broad range of section header text. The 27 topics corresponded to 584 different text strings used as headers for sections from these clinical documents. For example, the single topic, “Medications”, was assigned to 1355 different sections; 53 different textual representations were found among these section headers ranging from “ADMISSION MEDICATIONS” to “She has been taking the following medications:” Across the range of topics we noted high variability in the headers produced during routine medical documentation. Interestingly, although it was not our intent, 23 of the 27 topics lineup well semantically with the section types described in the Consolidated CDA DSTU.

The goal of the Clinical Section Labeler is to use the N-grams from the section headers and content to appropriately label each section with a topic representing a principal category for the medical facts represented within that section. To accomplish this, we developed a tool that 1) extracted N-grams from section content and/or section headers, 2) executed a feature selection algorithm to identify subsets of N-grams able to discriminate among the different section topics, and 3) trained the Bayesian models described above to identify the appropriate topic for a section from among the 28 choices. The feature selection algorithm applies the Chi-square statistic to identify and discard the subset of features whose contribution to topic assignment is anticipated to be minimal. Researchers can inspect the distribution of Chi-squares and choose a threshold that will exclude irrelevant features.

Inspection of the N-grams generated by processing the section headers indicated that all useful information for topic detection could be gleaned using the top 800 N-grams. However, for topic detection using text from the section content or the text from the combination of section headers and contents, the number was larger. Over 1 million N-grams were generated from these sources and Chi-square testing suggested that a large subset of these could

contribute to topic detection. We chose to use the strongest 4000 of the N-grams produced for the topic identifier based on the section content text and the strongest 3000 of the N-grams produced for the identifier designed to process the combined section header and content. (Initial efforts with the combination of header and content N-grams (approximately 5000 total N-grams) proved disappointing; reducing the combined number appeared to give better results.)

Table 2: Section topic selected for analysis.

Section Concept	Case Count
Allergies	1269
Ancillary Data	1189
Anesthesia	417
Assessment	1865
Chief Complaint	1286
Course of Care	407
Diagnoses	817
Discharge Diagnoses	538
Discharge Disposition	418
Discharge Medications	378
Family History	934
History of Present Illness	2933
Indications	341
Intraoperative Pathology Exam	502
Medications	1355
Microscopic Exam	448
Other	2319
Past Medical History	2020
Pathologic Specimens	564
Physical Exam	1455
Plan	703
Post-Operative Diagnoses	473
Pre-Operative Diagnoses	695
Procedural Findings	663
Procedure Description	538
Procedures Performed	723
Review of Systems	1180
Social History	1215

Six section topic identifiers were built and tested using the 10-fold cross validation procedure described above. They ranged in raw accuracy from 61.77% to 98.96%. Table 3 displays results from these 6 different models. Shown are their accuracy (percentage of section topics correctly classified), the one-versus-all area under the receiver operating characteristic curve (AROC), the pairwise AROC, and the F-measure.

Based on these results, it appears that, for this population of documents, processing the section header with an extended, tree-augmented naive Bayesian model is most likely to provide an appropriate topic for the section. However, the measures reported are averages (weighted for AROC and F-measure) across all topics. For a tool of this sort, one hopes for consistent accuracy across the range of topics included in the model.

Table 3: Preliminary results of analysis of 6 topic-identification models.

Topic Identification Algorithms	Accuracy	AROC	Pairwise AROC	F-Measure
Naïve BN/Header Only	95.83%	0.9986	0.9992	0.9590
Naïve BN/Content Only	61.77%	0.9317	0.9551	0.6245
Naïve BN/Header + Content	84.08%	0.9801	0.9869	0.8400
TAN BN/Header Only	98.96%	0.9996	0.9997	0.9869
TAN BN/Content Only	67.55%	0.9578	0.9714	0.6792
TAN BN/Header + Content	90.90%	0.9911	0.9950	0.9116

Therefore, to further characterize the accuracy of the TAN BN using header text only, we evaluated its accuracy across the 27 individual topics (plus "Other"). Table 4 shows the most ("Pathologic Specimens") and least ("Course of Care") accurate topics identified with the TAN BN-based model using features from the section headers alone. We had anticipated that "Other" would be the least accurately identify topic, but were mistaken as indicated in the table.

Table 4: Statistics for the most and least accurate topics identified using the TAN BN model and the section header text.

Topic	Recall	Precision	F measure (95% confidence Intervals)	AROC (95% confidence Intervals)
Pathologic Specimens (Most accurately detected topic)	0.9982	1.0	0.9991 (0.9966, 1.0)	1.0 (1.0, 1.0)
Course of Care (Least accurately detected topic)	0.9165	0.9739	0.9443 (0.9266-0.9607)	0.9999 (0.9998-0.9999)
Other	0.9621	0.9339	0.9477 (0.9411, 0.9539)	0.9977 (0.9968, 0.9986)

Discussion

The documents used in this evaluation represent a typical collection of the kinds of reports produced when clinicians operate in a flexible authoring environment. Transcription and dictation, speech recognition, and manual authoring with and without templates all played a part in creating the medical documentation represented here. We expect a high degree of variability in the *content* of many of the sections that appear in medical reports. Patient characteristics are highly variable and this will be reflected in descriptions of their conditions.

However, we had originally hoped to take advantage of consistent section headers to help us find those locations in the document where specific types of information can consistently be located. Unfortunately, section headers also showed wide variability. We therefore chose to treat them like other medical concepts, which must be derived from strings of text in medical documents.

In electronic record systems where clinicians compose their text within a standard report template, section headers can be restricted to those provided by the template system. In these cases, where clinicians used standardized headers for sections, the challenges of automated section topic recognition are reduced. But in EHRs with flexible authoring systems, different wordings and formats occur frequently for section headers. Yet these variable representations can still be mapped to a common set of underlying medical concepts. This is the goal of the Clinical Section Labeler: to assign topics to sections that guarantee the semantic character of similarly labeled sections to be

consistent from report to report. Information about medications is to be grouped in a “Medications” section, and information about physical exam or past medical history tends to be found in “Physical Exam” or “Past Medical History” sections.

The Clinical Section Labeler succeeds in this to a degree. However, a review of the documents in this collection suggests that this modeling effort failed to accommodate a valuable group of document components. Many of the documents sections contained subsections, each with its own sub-heading. The initial semi-automated annotation tagged these sub-headings as headings, but then appropriately generated a pointer back to the relevant parent section heading. During the initial annotation, commonly encountered subsections (such as those representing the components of the physical exam) were assigned their own topic labels. The goal was to be able to independently identify subsections such as "Cardiovascular Exam" or "Eye Exam". However, subheadings and subsections were used erratically in many of the documents. For example, in some of the documents discharge diagnoses were used as subheadings and the subsections were descriptions of the evaluation and course of the individual diseases. As a result we decided to focus on labeling top-level sections. Future efforts will need to accommodate more complex document models where subheadings may be either identifiers for the subcomponents of a typical section or may represent individual clinical conditions used as alternative organizing foci within the documents.

Additional observations include the following:

- N-grams have limitations in large and complex document collections. We have anticipated this and plan to approach section labeling with other feature generation techniques in the future. None-the-less, we continue to find N-gram-based feature generation useful as an initial, brute force technique for configuring NLP systems.
- The use of Bayesian networks looks promising. In this experiment, we were able to develop both naïve Bayesian and TAN Bayesian models from our annotated data with relative ease. Extending the model with a network node reflecting document type was also simple. In the future, additional opportunities to extend the model are available. These include incorporation of new ways to combine information from the section headers and content using a different BN structure or, perhaps, adding an HMM component to the model to take advantage of the typically consistent sequences of section topics seen in medical documents.
- Our current section topic annotations will require revision. The current collection of topics represents an initial categorization driven in part by inspection of the documents extracted from our enterprise data warehouse. The goal was to investigate the existing “wild-type” section authoring process. In future work, we will refine this system. The focus will be on an organization of these concepts in the way that best supports extraction of key clinical information for specific care delivery and research activities. The section topics suggested as a part of the Consolidated CDA will help guide this revision. We envision capturing this organization in an ontology that can assist in future natural language processing efforts.
- Any approach that standardizes the use of section headers will ease the section labeling problem. Our next generation of EHR tools is expected to allow us to standardize many of our templates for collecting this data. None-the-less, research that wishes to exploit the several decades worth of collected reports in our EDW will continue to face the challenge of variable document structure and section heading expression.
- The reference standard for this project may have introduced an element of bias into the analysis. Not all of the 3483 documents were read through by the annotator. Instead, texturally identical section headers were grouped and examples of section content were reviewed to make sure the topic assigned was consistent with section semantics. It is apparent that some section content in fact belonged to different semantic categories than the header would indicate. Indeed, this is frequently seen when, for instance, elements of the “Social History” or “Family History” are included in the “History of Present Illness” due to their apparent relevance to the patients presenting complaint. To the extent that this occurs, it may explain the reduced accuracy of section identifiers that include section content. Another contributor to this reduction in accuracy is the huge number of n-grams generated for the section content. The Bayesian algorithms could

accommodate only a few thousand features, whereas accurate assignment of these sections to their semantic categories would have required tens of thousands or perhaps hundreds of thousands of N-gram-based features.

Conclusion

In this report, we have focused on tools to identify the semantic character of sections commonly found in medical documents. We describe this as assigning "topics" to these sections. The technology tested appears promising for this task and can be leveraged for other recognition tasks in natural language processing as well. We will continue to refine it and to study other approaches appropriate to semantic labeling tasks.

This work focuses on achieving accuracy in assigning topics to previously identified document components. In the future, we will embed this technology into a system designed to completely automate the identification of report components. This system will use both the text of medical documents and local document formatting characteristics to locate section headers and content. Subsequently, the tools described here will assign topics to these sections. Further processing of these labeled documents can then take advantage of an automatically generated document map to determine where relevant clinical information might be found. The ability to focus targeted natural language processing in those sections where relevant information is likely to be found should assist us in developing natural language processing systems that are both efficient and accurate.

The information extracted from medical documents has substantial value. It can contribute to research into the character and course of human illness and, in the future, will inform decision support systems capable of participate in clinical decision making at the bedside. We hope and expect that tools designed to identify sections in clinical text will help to realize the benefits of natural language processing systems.

This research was made possible by funding from the Strategic Health IT Advanced Research Projects (SHARP) Program (90TR002) administered by the Office of the National Coordinator for Health Information Technology.

Security Concerns in Android mHealth Apps

Dongjing He, Muhammad Naveed, Carl A. Gunter, Klara Nahrstedt
Dept. of Computer Science, University of Illinois at Urbana-Champaign, Urbana, IL

Abstract

Mobile Health (mHealth) applications lie outside of regulatory protection such as HIPAA, which requires a baseline of privacy and security protections appropriate to sensitive medical data. However, mHealth apps, particularly those in the app stores for iOS and Android, are increasingly handling sensitive data for both professionals and patients. This paper presents a series of three studies of the mHealth apps in Google Play that show that mHealth apps make widespread use of unsecured Internet communications and third party servers. Both of these practices would be considered problematic under HIPAA, suggesting that increased use of mHealth apps could lead to less secure treatment of health data unless mHealth vendors make improvements in the way they communicate and store data.

1. Introduction

The mHealth trend is evident: as of March 2013, Research2Guidance reported that there were about 97,000 mHealth apps across 62 app stores[1]. According to a report from MarketsandMarkets, the global mHealth market is predicted to grow from $6.21 billion in revenue in 2013 to $23.49 billion by 2018 at a compound annual growth rate (CAGR) of 30.5 percent over the five-year-period from 2013 to 2018. The mobile fitness and wellness market is expected to grow at a CAGR of 36.7 percent from 2013 to 2018[2]. This rising mHealth market threatens changes in the way significant amounts of health data will be managed, with a paradigm shift from mainframe systems located in the facilities of healthcare providers to apps on mobiles and storage in shared cloud services. This trend is paralleled by a new openness in which devices that were once only available in hospitals become widely available to individuals while flexible mHealth applications tempt clinicians away from the hospital-based systems they used in the past. This popular market will disruptively challenge traditional approaches by being cheap and accessible.

Security and privacy of health data could be significantly affected by this trend. Freed from the bonds of HIPAA, mHealth apps are free to handle data using lower assurances than those typically applied to HIPAA entities. However, the data they handle is often as sensitive as the data handled by HIPAA entities. Typical Google Play apps such as Self-help Anxiety Management, iCardio, Epocrates CME, and Clinical Advisor provide assistance with mental health concerns, activity monitoring, and information services that reveal user interests in particular symptoms or diseases. It is important to develop guidelines for the security and privacy of mHealth apps that suit a dynamic market while assuring that the growth of mHealth does not lead to a cavalier vendor attitude toward personal data. New security and privacy risks particular to mobile computing and communications technology abound in mHealth apps[3, 4]. The aspects of mHealth make it different from other health information systems: First, mHealth apps allow a much larger amount of data being collected from the patient, as mobile devices can collect data over extended periods of time. Second, a much broader range of health-related data is being collected, as many mHealth apps collect patient activities and lifestyle, not only physiological data, but also include physical activity, location tracking, eating habits and diet details, social interactions and so on. Third, the nature of communications technology and mobile computing exposes many new attack surfaces to the outside world.

The goal of this paper is to carry out a three-stage study of the security and privacy status of free mHealth apps offered on Google Play. In the first study, the top 160 free mHealth apps in Google Play are classified and examined to formulate a list of attack surfaces that need attention in this area. These are shown in Table 1. Then a random sample of 27 apps is selected from the top 1080 apps and analyzed with respect to these seven attack surfaces. Significant issues are found in three attack surfaces: *Internet, Logging,* and *Third Party Services*. Since our concern about *Logging* will be addressed to a significant degree by deployment of a new version of Android, we focus our attention on the other two: *Internet* and *Third Party Services*. A random sample of additional 22 apps is taken involving Internet communications. Examination confirms that many of these 22 apps display significant risks to security and privacy on these two attack surfaces. Our primary conclusions are that the mHealth apps in Google Play commonly send sensitive data in clear text and store it on third party servers whose confidentiality rules may not be as strong as they need to be for the type of data being stored.

Table 1. Description of attack surfaces.

Attack Surface	*Description*
Internet	Sensitive information is sent over the Internet with insecure protocols, e.g. HTTP, misconfigured HTTPS, etc.
Third Party	Sensitive information is stored in third party servers
Bluetooth	Sensitive information collected by Bluetooth-enabled health devices can be sniffed or injected
Logging	Sensitive information is put into system logs where it is not secured
SD Card Storage	Sensitive information is stored as unencrypted files on SD card, publicly accessible by any other app
Exported Components	Android app components, intended to be private, are set as exported, making them accessible by other apps
Side Channel	Sensitive information can be inferred by a malicious app with side channels, e.g. network package size, sequence, timing, etc.

The remainder of this paper is organized as follows. We first discuss background and related work, then describe our methods for the three experiments. The next three sections describe the three studies respectively. We end with discussion.

2. Background and Related Work

In recent years, we have seen an increased adoption of mobile health applications by patients and physicians as well as the general public[1, 2]. Mobile computing and communications technology bring about new security and privacy concerns[3, 4]. The main objective of our study is to systematically investigate the security and privacy risks in mHealth apps on the Android platform. To the best of our knowledge, our study is the first study for classifying Android mHealth apps and summarizing their security and privacy risks.

2.1. Related Work

Recently, researchers have been actively involved in mHealth research. Mosa et al.[5] review articles discussing the design, development and evaluation of mHealth apps and discuss the differences between apps for healthcare professionals, for medical and nursing students, and for patients. Martínez-Pérez et al.[6] review on commercial mHealth apps for the most prevalent health conditions in the Global Burden of Disease list provided by the World Health Organization. Kotz[4] develops a taxonomy of the privacy-related threats to mHealth. Through an extensive survey of the literature, Avancha, Baxi, and Kotz[3] develop a conceptual mHealth privacy framework and discuss the technologies that could support privacy-sensitive mHealth systems. Aarathi et al.[7] investigate patients' privacy concerns about sharing their health information collected from mHealth devices with their family, friends, third parties and the public. Our goal is to review commercial mHealth apps from Google Play in order to classify, analyze and demonstrate their security and privacy risks.

2.2. Android Operating System

Our work focuses on researching the security and privacy risks on Android platform. Android is an open-source platform supported by Google that has become the most common OS for mobile devices. A report by F-Secure[8] shows that Android attracts much more malware attacks than iOS, which is another popular mobile platform. There are many mHealth apps and solutions have been built for the Android platform[9, 10, 11, 12]. Android is based on Linux for mobile devices. It provides a rich application framework to allow developers to build apps written in Java. App components are the essential building blocks of an Android app. There are four different types of components: Activity, Service, Content Provider and Broadcast Receiver. Android uses *Intents* for inter-component communication. Intents are used to start an Activity, to start a Service, or to deliver a Broadcast message. An *Intent Filter* is an expression composed from action strings that specifies the types of Intents a component would like to receive. Android provides a *permission* mechanism to enforce restrictions of inter-component communication and access to system resources.

3. Methods

This paper investigates the security and privacy risks in Android mHealth apps. More specifically, we will investigate such threats in three studies:

Study 1: What are the potential attack surfaces?

We review 160 apps identified by selecting the top 80 free apps in Health & Fitness category and another top 80 free apps in Medical category from Google Play. In order to get a sense of the context of Android mHealth apps, we first divide the 160 apps into two groups with regard to their target users and classify them into eight categories according to their functionalities. To develop a list of attack surfaces that are most representative, we review research papers[13, 14, 15, 16, 17] and documents[8, 18], and we analyze the 160 mHealth apps to find evidence of threats. Based on this review, the following seven attack surfaces represent areas that need protection: *Internet, Third Party Services, Bluetooth, Logging, SD Card Storage, Exported Components,* and *Side Channels*.

Study 2: How widespread is the threat?

After identifying the potential attack surfaces, Study 2 takes a further step to learn how widespread these attack surfaces are. The top 1080 free apps are identified from the Medical and Health & Fitness categories on Google Play, 540 from each. By using a random number generator without replacement through random.org, 27 apps are selected for the dataset for Study 2. Of these apps, we analyze them one by one in detail with respect to the seven attack surfaces identified in Study 1. Three attack surfaces are identified as important ones: *Internet, Third Party Services* and *Logging*, because the majority of the 27 apps evidence issues with these attack surfaces. Figure 1 shows how we include and exclude apps for Study 2.

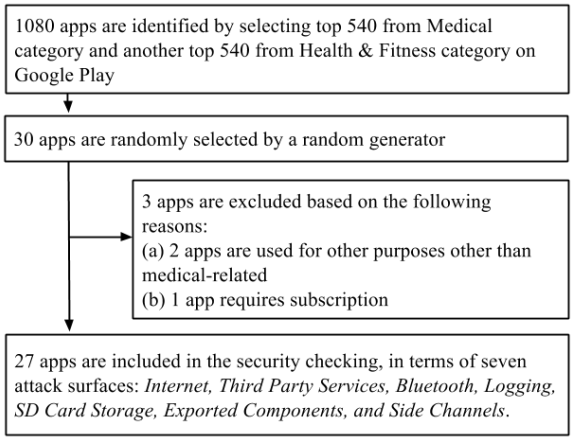

Figure 1. App selection flow graph for Study 2

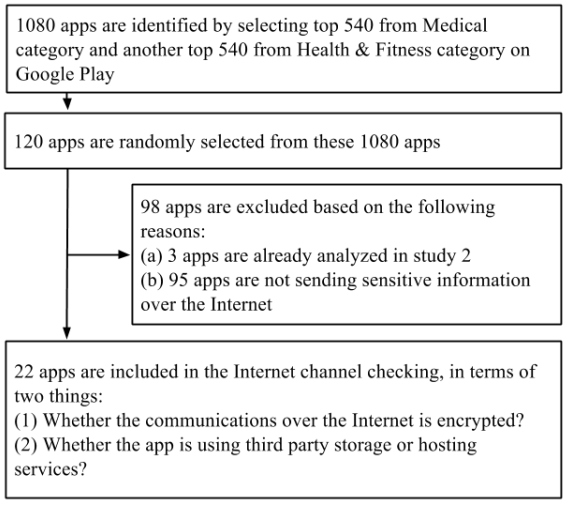

Figure 2. App selection flow graph for Study 3

Study 3: How serious is the threat?

Since security concerns in *Logging* will be addressed significantly by an Android version upgrade, we focus our attention on the other two attack surfaces, *Internet* and *Third Party Services*. The app selection process in Study 3 is similar to that of Study 2, but only apps that are sending sensitive information are selected. We randomly select 120 apps from the top 1080 free mHealth apps from Google Play. Then we use purposive sampling: the apps that have already been studied in Study 2 are excluded and the apps that are not sending sensitive information over the Internet are also excluded. In the end, 22 apps are included and analyzed in details to understand how serious the threat involving *Internet* communications is. Figure 2 shows how we include and exclude apps for Study 3.

4. Results

4.1. Study 1: What are the Potential Attack Surfaces?

To investigate the potential attack surfaces, we first want to understand the context of Android mHealth apps. By studying the 160 apps collected as described in the Section 3, we developed the classification system for Android mHealth apps shown in Table 2. We divide the top 160 free mHealth apps into two groups by their expected users. *Patient* apps are the ones mainly used by the individual whose health is being monitored. In most cases, the monitoring is done by the individual herself. *Healthcare Professional* apps are the ones mainly used by physicians, nurses, medical students, and other healthcare professionals to support their activities, which includes the monitoring

of patients. According to their functionalities, eight categories are used. Categories targeted at Patients include: *Lifestyle Management, Sensor-based Health Monitoring, Medical Contact, Medication and Disease Management,* and *Personal Health Record (PHR) Management*. Categories targeted at Healthcare Professionals include: *Medical References, Medical Training,* and *Clinical Communication*. A mHealth app may be useful for both Patients and Professionals (*e.g.* a pill identifier app can be used by patients to organize pills or by pharmacists to prevent errors in dispensing medications). Also, a mHealth app may belong to more than one category, since it may serve multiple functionalities (*e.g.* a fitness tracking app can monitor lifestyle data as well as manage PHR).

Table 2. Classification of popular free mHealth apps on Google Play.

Target users	*Category*	*Functionality Examples*	*Modules Used*	*Number of Apps (%)*
Patients	Lifestyle Management	Count calories; track eating habits, exercise, sleep, period, pregnancy, and etc.	Accelerometer, Gyroscope, GPS, Network	96 (60%)
	Medical Sensor-based Monitoring	Monitor health metrics such as: heart rate, blood pressure, blood glucose, insulin, cholesterol, and etc.	Externally connected health devices, Network	15 (9.38%)
	Medical Contact	Contact registered nurses, doctors or hospitals	Network, Phone call, Email	14 (8.75%)
	Medication and Disease Management	Manage prescription records; identify pills; shop medication online; look up symptoms; manage chronic diseases	Network	27 (16.88%)
	PHR Management*	Manage and/or synchronize PHR with health services	Network	75 (46.88%)
Healthcare Professionals	Medical References	Look up drug, disease and condition; anatomy tool; medical calculator; medical dictionary	Network	26 (16.25%)
	Medical Training	Aid medical students studying medical theories	Network	9 (5.63%)
	Clinical Communication	Emergency alert; photo sharing	GPS, Network	2 (1.25%)

* Here we define PHR management as patients syncing and managing user health information with an online health service provider.

Most of the applications in the categories are appropriate for our study but we exclude one app because it lacks a medical or healthcare purpose, and we exclude another app because its language is not English. Among the included 158 apps, we have 129 (81.65%) that are Patient-facing, 32 (20.25%) that are Professional-facing, and 3 (1.90%) drug identifier apps that are both. All the Patient-facing apps are from the Health & Fitness category and 41.03% of the apps from the Medical category are Professional-facing. In Table 2, the majority (60%) of the most popular Android mHealth apps are in the Life Management category. Nearly half (46.88%) of the apps manage and synchronize user health information to online service providers. The average rating score for the Patient-facing apps is 3.92, which is less than 4.18, the average score for the Professional-facing apps. However, the Patient-facing apps have almost 4 times more user installations, whose average is 502,263, than that of the Professional-facing apps, whose average is 139,125.

By studying previous literature[13, 14, 15, 16, 17] and online documents[8, 18], many different attack surfaces on Android apps have been identified. We study the 160 selected apps to have an understanding of what commercial mHealth apps are doing and whether risks exist in these attack surfaces. Real security issues are found within these Android mHealth apps, and the seven attack surfaces in Table 1 were identified as the most important ones. Here we use four specific examples in Android commercial mHealth apps to demonstrate the attack surfaces can lead to realistic and serious consequences.

Case 1 (Unencrypted Internet): Many mHealth apps send unencrypted information over the Internet. For example, both Doctor Online[19] (patients can talk to doctors online) and Recipes by Ingredients[20] (patients can search recipes according to their illness or ingredients suitable for their diseases), send unencrypted sensitive information,

including the user's email and password, in clear text over the Internet. Figure 3 shows the network traffic from Doctor Online captured by WireShark that contains user's name, email and password.

Figure 3. Network traffic from Doctor Online containing sensitive information.

Case 2 (Logging Sensitive Information): Many mHealth apps put sensitive user information into logs. For example, CVS/pharmacy[21], a popular app with millions of installations on Google Play, puts user login credentials and personal medical information in its log messages. Figure 4 shows the log messages with sensitive information from CVS/pharmacy. In the Example 1, CVS/pharmacy logs the prescription refill details from use inputs, including name, email address, store number, and Rx number. In the Example 2, CVS/pharmacy puts user login credentials in a debug log message. With this information a malicious party can view user profile and prescription history, which could support medical identity theft. A malicious party can even do pharmacy online shopping with users' stored credit card information.

Example 1: I/HttpDataClient(21039): https://native.usablenet.com/mt/ws/cvs.com/v2/refill?first=**tina**&last=**fey**&mail=**tina.health.droid%40gmail.com**&store=**24536**&orig=prod&rx1=**1524949**

Example 2: D/LOGIN (21039): https://native.usablenet.com/mt/ws/cvs.com/v2/login?username=**tina.health.droid%40gmail.com**&password=**password**&orig=prod

Figure 4. Log messages from CVS/pharmacy containing sensitive information.

Note that in both cases, the sensitive information is contained in the query strings of HTTPS URLs. Some developers may have a misconception that all HTTPS requests using GET or POST are sent over encrypted TCP connections so that sensitive information can be safely put into HTTPS URLs. However, even if sensitive information is not seen during transit, it remains visible in other places, such as mobile app logs, server logs, browser history and so on. Developers should avoid as far as possible including sensitive information in logs since it may be hard to know or control who is able to access the logs.

Case 3 (Exported components): Several apps in our study have component exposure threats. For instance, Noom Weight Loss Coach[22], an app with more than 10 million installations, exposes its Content Providers to external apps, which means any app can access the exposed Content Providers without declaring any permission. After searching for "content://" paths in the manifest and decompiled source code, we get a list of content URIs defined in the app. By using Drozer[23], an automatic security analysis tool, we attempted to access sensitive information with each content URI. Figure 5 shows the ability to read user workout history stored in the app's Content Provider with the content URI "content://com.wsl.noom.exerciseinfo".

dz> run app.provider.query content://com.wsl.noom.exerciseinfo

accessCode	key	timestamp	exerciseType	duration	caloriesBurnt	isManual	stepsCalories
WUX2G6EF	0	1393052360350	Walking	50892	0.484559	0	0
WUX2G6EF	1	1393009200000	Running	1800000	262	1	175

Figure 5. Access Noom Weight Loss Coach's user workout history by using Drozer.

Case 4 (Unencrypted SD card storage): Some sleep monitoring apps, such as SnoreClock[24] and Sleep Talk Recorder[25], record the sleep sounds of users and store them as unencrypted audio files on an external storage. For instance, the Sleep Talk Recorder explicitly stores sleep-recording unencrypted audio files on the SD card with name format YYYY-MM-DD-HH-MM-SS.wav. With read storage permission, a malicious app can read a user's sleep recordings; with internet permission, it can further send this information to remote servers. Another example is that Urgent Care[26] stores system logs in an unencrypted file on SD card, potentially leaking symptom lookup history.

4.2. Study 2: How Widespread is the Threat?

The complexity of the Android system has led to numerous potential attack surfaces that could be exploited by a malicious party to gain unauthorized access to sensitive data in mHealth apps and cause serious consequences. Analyzing these attack surfaces can help security specialists do security assessment and help mHealth users and developers understand and manage security risks. In Study 2, we analyze these attack surfaces with a new set of 27 random selected Android mHealth apps. The process of selecting these apps is described in Section 3.

Internet: Android mHealth apps access the Internet for various purposes, including to transfer information to a remote server and to retrieve ad to display to users. The information transferred over the Internet to a remote server

includes sensitive health information and ideally all such communication with the remote server should be encrypted. The 27 randomly sampled apps are analyzed to study why they require the Internet access (i.e. to transfer information or to display ads). Furthermore, we analyzed if the encrypted communication is used in network transmission.

Any app can get access to the Internet with Andoid's INTERNET permission. To study if the apps are using Internet for displaying ads or transferring information to the remote server, we study the description of the apps and check the functionality of the apps by installing and using them on a Samsung Galaxy SII phone. As a result, 85.2% (23/27) of the apps have the permission to access the Internet. 70.4% (19/27) use the INTERNET permission to display ads, while 29.6% (8/27) of them use it to communicate user information over the Internet.

To study whether the communication with remote servers is encrypted we installed and ran each of the apps while capturing network traffic using the "Shark for Root" Android app, and used WireShark to see if the traffic is encrypted. The result shows 7.4% (2/27) of the apps allow the users to use the blog or social network associated with the app via the Internet but only one of the apps used encrypted communication. We found that 25.9% (7/27) transmit medical information to the remote server, 57.1% (4/7) use encrypted communication, and 42.9% (3/7) use unencrypted communication to transfer the sensitive health related information.

We analyzed if the three apps sending unencrypted data over the Internet are actually sending sensitive information. The first app searches for nearby pharmacies, doctors, etc. The second app tracks exercise workouts, and the third (Doctor Online from Spain) facilitates finding and talking to doctors online. Doctor Online sends email, username and even password unencrypted over the Internet.

Third Party Services: Android apps use storage and hosting services such as Amazon instead of maintaining their own infrastructure. This is an economical as well as scalable solution for mobile apps. But storing sensitive health information on these third party services can have serious implications even for large and widely-trusted services like Amazon. We study if these seven apps communicating with remote servers are hosted on the cloud or on-premises servers owned by the app vendors. To this end, we analyze the IP addresses of these apps in the communications with their respective servers. IP addresses have a publicly available record of whom it belongs to and we use this to find out where the traffic is going. We found that 85.7% (6/7) apps are hosted on third party servers. Three of them are hosted on Amazon and rest on other hosting services. We were not able to tell if data on the remote third party servers is stored in encrypted fashion such that the hosting companies do not have access to this data. However, the four apps mentioned in the previous Internet section are using encryption for the communication only.

Bluetooth: Many mHealth sensing apps primarily use Bluetooth to collect data from health sensors to mobile devices. One app (3.7%) of the 27 apps in our dataset connects to a Bluetooth health device to collect personal health information. Supporting Bluetooth devices is more common among the 160 most popular Android mHealth apps, where 15/160 (9.5%) provide Bluetooth connectivity to collect health data. 12 of the 15 apps declare and use both BLUETOOTH and BLUETOOTH_ADMIN permissions, so that they can use Bluetooth to connect and collect data from external health sensors, while the remaining three of them collect health data via the Internet or by connecting with other apps. The apps collect various types of health information, including heart rate, respiration, pulse oximetry, electrocardiogram (ECG), blood pressure, body weight, body temperature, quality of sleep, exercise activities. Apparently, Bluetooth is a major communication technology for sensor-based health monitoring in Android mHealth apps. Naveed et al.[14] present a problem of external-device misbonding (DMB) for Bluetooth-enabled Android devices and health sensors. They show how a malicious app can stealthily collect user data from an Android device or spoof a device and inject fake data into the original device's app. One app of the 27 apps connects to external health sensors and uses default PIN code 0000, which makes it vulnerable to the DMB attack. To defend against the Bluetooth-based threats on mHealth apps, Naveed et al.[14] propose an OS-level protection, which generates secure bonding policies between a device and its official app and enforces these rules when establishing and terminating Bluetooth connections.

Logging: the Android logging system enables developers to collect and view debugging output for apps. The logging facility allows a system-wide logging, including both application information and system events. If an app is granted READ_LOGS permission, the app is allowed to read the low-level system log messages. With the READ_LOGS permission, a malicious app may be able to extract sensitive information from log messages. To find such logging vulnerabilities we used a tool called logcat from the Android Debug Bridge (ADB) shell to view system log messages.

In our dataset, 9 out of the 27 apps (33.3%) put sensitive information in log messages. Among the 9 aforementioned apps, two (22.2%) disclose GPS coordinates, three (33.3%) disclose Facebook friend information, and one (11.1%) divulges more sensitive data such as user sign up data, which includes name, location and profession of the user. Three (33.3%) apps leak disease and drug browsing history in the app logs. From the study on our dataset, it indicates a large number (33.3%) of the mHealth apps leak sensitive information in system logs that could support cause serious attacks such as medical identity theft.

SD Card Storage: Each Android app gets a dedicated part of file system where it can write its private data. However, if an app writes files to an external storage, such as an SD card, the files are not guaranteed to be protected. With READ_EXTERNAL_STORAGE or WRITE_EXTERNAL_STORAGE permissions, any app can read or write files from an external storage. Before API level 19, the READ_EXTERNAL_STORAGE permission is not enforced and all apps still have access to read from an external storage.

In our dataset, 66.7% (18/27) of the apps declare the WRITE_EXTERNAL_STORAGE permission, which means they write data to external storage that can be read by any app with the READ_EXTERNAL_STORAGE permission. We used Dex2jar[27] to decompile the application package (apk) files for these 27 apps to get their Java source code. We searched this code for the "ExternalStorage" and "ExternalFiles" keywords in the source code to construct all possible paths for files stored on SD card. Then, we executed all possible operations with the studied apps and exhaustively went through the resulting directories to check their file contents. This search did not reveal evidence that any of the apps store sensitive information in external storage files.

Exported Components: Android app developers can specify if a component (Activity, Service, Broadcast Receiver, or Content Provider) is public to external apps. A component can be declared as *exported*, or public, if its declaration sets the EXPORTED flag or includes at least one Intent Filter without permission protection. However, setting a private component improperly as *exported* enables a malicious app to send unwanted Intents to the component, which can cause security problems with broadcast injection, activity launch or service launch[17]. In addition, if the Content Provider is exported, a malicious app can read or write the exported Content Provider without declaring any particular permission. The Content Provider supports the basic "CRUD" (create, retrieve, update, and delete) functions and the data in a Content Provider is addressed via a "content URI". Knowing the "content URI" from an exported Content Provider, a malicious app can retrieve or modify the data according to the Content Provider's schema. An example we gave earlier in our discussion of Study 1 illustrates an unauthorized access to an exported Content Provider to read the app's sensitive information.

Side Channels: All the attack surfaces discussed above are using explicit channels in Android system, where a malicious party has chance to directly read sensitive data from the attack surfaces. Besides the explicit channels, side channels can be exploited by a malicious party to infer sensitive information from apps, even if they are well-designed and implemented by their developers. Zhou et al.[13] find a correlation between network payload size, which is publicly accessible in Android system, and the disease condition a user selects on WebMD mobile[28]. With this correlation even an app with no permissions, a "zero-permission" malicious app, can monitor WebMD's network payload in the background, and map their monitoring results to the disease condition that a user searches on WebMD. Side channel information leakage has also been discovered from motion sensors, such as accelerometer and gyroscope[15, 16]. Fine-grained motion sensor monitoring can be used to infer keystrokes, such as 4-digit PIN codes, on touch screen smartphones with only soft keyboards.

To circumvent the network-payload-based side channel attack, Zhou et al.[13] present a mitigation mechanism which enforces limitations to accessing Android public resources (*e.g.* network payload size) by modifying the Android kernel. MHealth developers can pad blank information to network packets to ensure they are fixed-length, or develop offline strategies for downloading sensitive data. For the motion-sensor-based side channel attack, Adam *et al*.[15] propose disabling untrusted access to motion sensors whenever a trusted input function (*e.g.* password entry) is being performed.

4.3. Study 3: How Serious is the Threat?

Three vulnerabilities in Study 2 are revealed to be common and serious: sending sensitive information unencrypted over the Internet, storing it on third party services, and including it in logs. Since logging can be addressed by an Android version upgrade, we focus our investigation on the other two threats, Internet traffic and third party services.

As only seven apps in Study 2 are actually sending sensitive information over the Internet, we carried out Study 3 to understand the prevalence of these threats with a larger number of apps using the Internet. Another 120 apps are

randomly sampled from the 540 top Health and Fitness apps and another 540 top medical apps (1080 in total) from Google Play. These apps are then manually analyzed to rule out those not sending any sensitive information over the Internet. After the filtering, 22 apps are found to be sending sensitive data over the Internet (some apps requiring subscription are filtered out as well). To analyze their Internet traffic, we installed these 22 apps and captured their traffic using the same methods described in Study 2. The results reveal that 63.6% (14/22) of these apps are sending unencrypted data over the Internet and 81.8% (18/22) are using third party storage and hosting services such as Amazon's cloud services. One of our randomly selected apps (Fitbit) uses encryption over the Internet, but is also using third party storage and hosting services. The four apps that are using their own servers to store and host their apps are big companies such as Aetna, United Healthcare, Caring Bridge and US Dept. of Health and Human Services. We were not able to obtain ground truth about whether apps encrypt data when they store it with third parties, but one may conjecture that apps that do not encrypt data over the Internet probably also do not encrypt it on third party storage. Even though the data might be hosted in an isolated environment (e.g. on an isolated VM in the cloud), storing unencrypted data on third party storage makes the data vulnerable to insider attack, where the service provider is malicious.

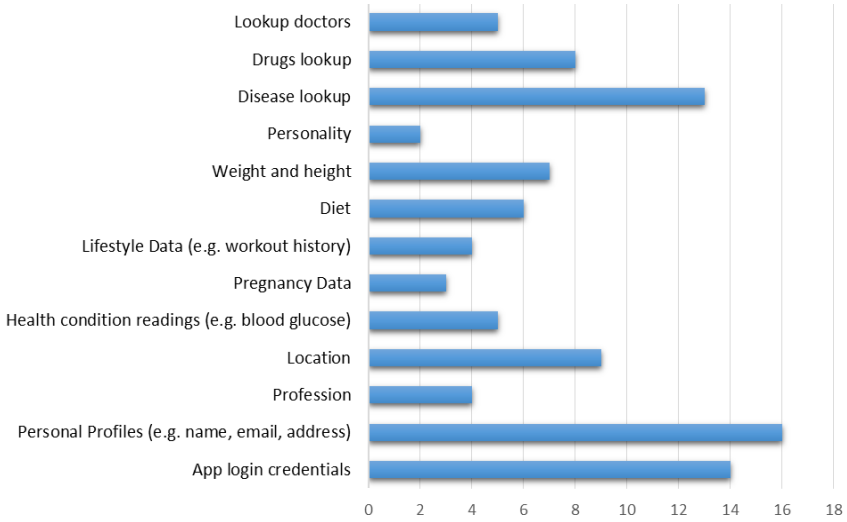

Figure 6. Sensitive information distribution in the 22 apps dataset for Study 3.

When used as intended, a variety of sensitive user data are collected, stored, and transmitted through these Android mHealth apps. Figure 6 shows the distribution of sensitive information in the 22 apps (x axis means the number of appearances of sensitive information in the 22 apps). Based on our study, the information includes at least personal profiles, health sensor data, lifestyle data, medical information browsing history, and third-party app data (*e.g.* Facebook account information). Depending on the type, sensitivity, and volume of mHealth data breaches, disclosure or tampering with these sensitive data may lead to serious consequences, such as profiling, medical identity theft, and healthcare decision-making errors. According to the information collected from World Privacy Forum[29], thefts have used stolen medical information for a resourceful collection of nefarious purposes. For example, a Colorado man whose Social Security number, name and address had been stolen received a bill for $44,000 he presumably owed to a hospital because his identity had been used by a thief to get medical services in his name. In another case, another identity thief in Missouri used the personal data of multiple victims to establish false driving licenses and was able to use them to obtain prescriptions in the victims' names at a regional health center.

5. Discussion

5.1. Summary of Findings

Our three-stage study raises many concerns and shows some serious problems with Android mHealth apps. The major issue is unencrypted communication over the Internet and use of thirty party hosting and storage services. Our study shows that a significant number of the apps in the top health related apps from the Google Play market have these issues. These issues need attention and are not easily fixable because they require extra effort and security expertise from developers and computational capabilities from platforms. Third party cloud and hosting services

provide a very economical solution for hosting app services and storing data and many app vendors may feel it is not economical to maintain their own servers or even encrypt stored data on the third-party services.

5.2. Compliance Recommendations

The increased use of mHealth results in greater risks to health-related information on mobile devices. Developers and healthcare service providers would be wise to make efforts to ensure that mHealth apps facilitate security compliance even if they are not legally required to do so (at the current time). Based on our study on the risks from mHealth apps, here are some important compliance recommendations: encryption is essential to secure personal data stored on mobile devices; when accessing web-based services, TLS/SSL should be deployed throughout the Internet transmission session; even though the network transmission session is protected and encrypted, using third party services to store users' sensitive data must be closely reviewed and users should be informed when it is happening; developer guidelines or training can be helpful in avoiding many of the common mistakes that are rooted from development with poor security practices; risk assessment provided by authorities can further minimize the security risks that may harm users. Experience with Happtique, which was forced to suspend app certifications after some of the apps it certified were found to have some of the problems above, provides evidence of strong incentives for better security and privacy practices[30]. A report from Symantec also raises questions about security risks in self-tracking devices and apps[31]. A good possible direction is for mHealth app developers to create a set of security and privacy guidelines that offer a baseline for protections.

5.3. Limitations of the Study

Android version upgrade. Android is constantly making behavior changes in order to circumvent newly found threats. For example, to mitigate the logging information leakage problem, since Jelly Bean (Android 4.1), an app can only collect and view log messages originating from itself. However, on a rooted device (i.e., a device allows any app to run with administration permissions on Android)[32], a malicious app can, by executing a '*pm grant'* command, grant itself a READ_LOGS permission. This means it is still dangerous for an app to keep sensitive information in system logs. According to the Android platform distribution[33] collected in March, 2014, almost 40% of the overall Android devices are under the version of Jelly Bean. Due to a large number of Android device users and mHealth apps, it is lucrative for malicious parties to investigate ways to harvest sensitive personal healthcare information from mHealth apps.

User agreements. We observed that many apps may ask users to share their private health information by providing privacy policy agreed by users themselves. In our study, most of the apps do make privacy policies available to users either via an URL link in the app or shown when the app is launched for the first time. How health data is managed and transmitted is generally out of control or visibility of the users, but the apps should at least encrypt all data in transit and at rest. We believe that understanding the privacy policies of mHealth apps is an interesting future research topic. Users should know what they are agreeing to in order to use the app and how their data can be used.

6. Conclusion

A study of Android mHealth apps reveals common shortcomings in security and privacy when using communications and storage. Steps should be made to encourage mHealth app vendors to assure encrypted network links for communications and the use of third party storage only when adequate security and privacy guarantees are obtained.

Fostering Multilinguality in the UMLS: A Computational Approach to Terminology Expansion for Multiple Languages

Johannes Hellrich and Udo Hahn

Jena University Language & Information Engineering (JULIE) Lab
Friedrich-Schiller-Universität Jena, Jena, Germany

Abstract

We here report on efforts to computationally support the maintenance and extension of multilingual biomedical terminology ressources. Our main idea is to treat term acquisition as a classification problem guided by term alignment in parallel multilingual corpora, using termhood information coming from of a named entity recognition system as a novel feature. We report on experiments for Spanish, French, German and Dutch parts of a multilingual UMLS-derived biomedical terminology. These efforts yielded 19k, 18k, 23k and 12k new terms and synonyms, respectively, from which about half relate to concepts without a previously available term label for these non-English languages. Based on expert assessment of a novel German terminology sample, 80% of the newly acquired terms were judged as reasonable additions to the terminology.

Introduction

The life sciences are one of the most active areas for the development of terminological resources covering a large variety of special thematic fields such as human anatomy, cell structure, diseases, chemical substances, gene products, etc. These individual activities have already been bundled in several portals which combine up to some hundreds of these specialized terminologies and ontologies, such as the Unified Medical Language System (UMLS),[1] the Open Biological and Biomedical Ontologies (OBO),[2] and the NCBO BIOPORTAL.[3]

This stunning variety of terminological resources has grown over time primarily for the English language. Despite ambitious efforts by non-English language communities to provide translated "mirror" terminologies in their native languages the term translation gaps encountered here remain huge—even for prominent and usually well-resourced European languages, such as French, Spanish or German. The non-English counterparts of the UMLS for these languages lack between 65 to 94% of the coverage of the English UMLS (see Table 1), and there is an even much lower long tail for under-resourced languages, e.g. Greek or Hungarian. Missing terminological coverage not only decouples the English-speaking medical language community from the non-English ones but also hampers all sorts of meaningful international data exchange or data compilation (e.g. gathering reasonably sized cohorts for rare diseases).[4] Further multilingually rooted healthcare problems arise in the age of ever-increasing cross-border mobility of people due to world-wide tourism and for countries with a substantial proportion of immigrants lacking sufficient proficiency of the country's language which is not their primary language.[5]

Table 1. Number of UMLS terms and synonyms per selected language in a slightly pruned UMLS version (taken from the CLEF-ER challenge data),[6] term coverage relative to the English UMLS version, number of additional entries acquired through our terminology extraction system and lexical extension rate (increase relative to the number of previously available entries for the selected language). Data are based on classifier 7 (see Table 5).

Language	UMLS terms & synonyms	Coverage rate (w.r.t. English)	Additional entries	Lexical extension rate (w.r.t. selected language)
English	1,822k	100.0%	–	–
Spanish	644k	35.3%	18k	2.8%
French	137k	7.5%	19k	13.9%
German	120k	6.6%	23k	19.2%
Dutch	116k	6.4%	12k	10.3%

We here report on automatic efforts to partially close this gap by treating term acquisition as a classification problem, capitalizing on lexical and phrasal alignment techniques from the field of statistical machine translation (SMT) and named entity recognition (NER) techniques applied to selected parallel corpora. SMT uses statistical models to align and thus map expressions from a source language into expressions of a target language. Nowadays most SMT translation models are phrase-based, i.e. they use the probability of two text segments being translational equivalents of each other and the likelihood of a text segment existing in the target language to model translations.[7] SMT model building requires an ample amount of training material, usually *parallel* corpora. Such corpora are manually constructed, direct translations from a source into a target language text. In the meantime, open source SMT systems have been demonstrated to automatically generate translations of considerable quality for languages such as German, Spanish or French, even for specialized domains such as biomedicine.[8]

Since the availability of parallel corpora is so crucial for the operation and performance of SMT alignment systems, we assembled several corpora that are thematically rooted in the biomedical domain and took care as much as possible of such issues as linguistic variability and variance in text genres. For the purposes of this paper, we focus on two types of parallel corpora: MEDLINE, on the one hand, supplies English translations of titles from a wide range of non-English scientific journals (especially numerous for Spanish, French and German). On the other hand, the EMEA corpus provides patient information leaflets in 22 languages, among them about one million sentences each for Spanish, French, German and Dutch.[9] All these documents have carefully been crafted by the authors of journal articles or educated support staff such as editors or translators so that translation quality is generally high. Using parallel corpora for biomedical terminology extraction has already been proposed by Déjean et al.[10] and Deléger et al.,[11,12] with German and French as the respective target languages from English sources. Compared with today's standards for biomedical NLP system engineering this early work, however, suffers from limited scalability and generalizability and lacking transparency of the evaluation frameworks (for a more detailed discussion, see below).

Since parallel corpora are mostly rare (for some domains they are even unavailable) and limited in scope, researchers have been looking for reasonable alternatives such as *comparable* corpora. Just as parallel corpora they consist of texts from the same domain, but unlike parallel corpora no direct mapping between content-related sentences can be assumed for the different languages. Comparable corpora are easier to get and much larger in size and thematic diversity,[13] yet provide less accurate results due to the increased level of inherent noise. Therefore, they are sometimes used in combination with parallel corpora which leads to better results than employing each on its own.[10] Comparable corpora are typically accompanied by context-based projection methods, i.e. collecting context vectors for words in both languages and partially translating these with a seed terminology—words with similar vectors are thus likely to be translations of each other. A brief overview of the use of comparable corpora in SMT and the influence of different parameters is provided by Laroche & Langlais.[14] Skadia et al.[15] show how a subset can be extracted from a comparable corpus which can be treated as a parallel corpus.

Aker et al.[16] treat term extraction as a classification task as well. Yet they use single-word translation probabilities generated from parallel corpora to extract terms from comparable corpora rather than phrase probabilities generated and terms directly extracted from parallel corpora as in our approach.

Non-English terminology can also be harvested from documents in a mono-lingual fashion, without an *a priori* reference anchor in English; hence, no parallel corpora are needed. These approaches are primarily useful, if no initial multilingual terminology exists. After extraction, these terminologies need to be aligned, which can be done using purely statistical or linguistically motivated similarity criteria.[17,18]

Terminology extraction in the biomedical field is a tricky task because terms not only appear as single words (e.g. *'appendicitis'*) but much more as multi-word expressions (e.g. *'Alzheimer's disease'* or *'acquired immunodeficiency syndrome'*). Approaches towards finding these multi-word expressions can be classified as either pattern-based, using e.g. manually created part-of-speech (POS) patterns that signal termhood, or statistically motivated, e.g. utilizing phrase alignment techniques. Pattern-based approaches such as the ones described by Déjean et al.[10] or Bouamor et al.[19] are fairly common. The downside of these approaches is their need for term-indicative POS patterns that are often hand-crafted and may become increasingly cumbersome to read, write and maintain. Alternative approaches rely on statistical data, like the translation probabilities of the single words of a term (treated as a bag of words)[20] or phrases. Those phrases can be linguistically motivated, i.e. use POS information,[21] or be purely statistically informed, e.g. derived from the model produced by a phrase-based SMT system.

Also in terms of evaluation, a large diversity of approaches can be observed. Some groups report only precision data based on the number of correct translations produced by their system;[11] others issue F-scores based on the system's ability to reproduce a (sample) terminology.[10] In these studies, numbers for new and correct translations range

between 62% and 81%.[11,12] Unfortunately, these results are not only grounded in the systems' capabilities, but also strongly influenced by both the particular terminology and parallel corpora being used—thus, comparisons between systems are generally hampered by the lack of a common methodology and standards for evaluation.

An earlier state of our own work was decribed by Hellrich & Hahn.[22] This contribution supersedes that former version in numerous technical and methodological respects. In particular, it contains the following pieces of new information: We here evaluate the performance of the JCoRe named entity tagger (Table 3), provide an in-depth empirical analysis of the term re-invention performance of our approach under different experimental conditions (e.g. various choices of cut-offs and feature combinations, including phrasal translation probabilities, named entity termhood, as well as string length and string similarity criteria) by considering the UMLS as a gold standard (Table 5), and evaluate the term mining performance under two different conditions in a human assessment task. We also include a quantitative assessment of the relative frequency of UMLS terms of different lengths which is crucial for the length limitation of string similarity computations (Figure 1).

Methods

Methodologically speaking, our approach primarily combines reusable off-the-shelf components, namely the LingPipe[a] gazetteer for lexical processing, Giza++[23] and Moses[24] for generating phrasal alignments, the JCoRe[25] biomedical named entity recognizer (to indicate the degree of termhood of phrases) and Weka[26] as the machine learning repository from which we took a Maximum-Entropy classifier to combine NER and SMT information. We distinguish three steps in our approach: corpus set-up, term candidate generation and term candidate classification. Both the corpora and the UMLS version we used were taken from the CLEF-ER 2013 challenge material.[b,6]

1. Corpus Set-Up

We started by merging the MEDLINE and EMEA parallel corpora, resulting in one single corpus per language pair. These corpora contained 860k, 713k, 388k, and 195k parallel title phrases (from MEDLINE) and sentences (from EMEA) for the German, French, Spanish and Dutch language, respectively (see Table 2 for details), with English always acting as the reference language. Subsequently, a flat annotation for the common "Biomedical Entity" type was performed. For this task, we used a LingPipe-based gazetteer informed by the UMLS-derived terminology for all languages involved; this was used as gold data for training and evaluation. The gazetteer approach relies on only exact matching and cannot disambiguate terms (about 2.5% of them correspond to more than one concept), yet was chosen for its capability to work for any language.

Table 2. Overall corpus size, number of MEDLINE titles and EMEA sentences for each language pair. These numbers reflect the final version of the CLEF-ER data and are more recent than the original ones from the challenge website.

Language pair	Corpus size	MEDLINE titles	EMEA sentences
German-English	860k	719k	141k
French-English	713k	572k	141k
Spanish-English	388k	248k	141k
Dutch-English	195k	54k	141k

10% of each of the automatically annotated corpora were set aside and used to train language-specific JCoRe NER systems in order to find biomedical entities, in general, without any deeper distinction of more fine-grained semantic groups, such as Disease or Anatomy (common in the UMLS framework). Thus, the probabilities provided by the systems merely characterize domain-specific, in our case biomedical, termhood of a word sequence under scrutiny. Performance data for these systems can be found in Table 3. The remaining 90% of the corpora were used to generate phrasal alignments with Giza++ and Moses, the basis for term extraction. The gazetteer-based annotations were exploited for the training and evaluation of the term extraction system. The corpora were split to prevent NER re-classification effects from inflating term extraction performance.

Table 3. Performance of the language-specific JCoRe NER systems (10-fold cross-validation for each language).

Language	F_1 Score	Precision	Recall
German	0.78	0.88	0.70
French	0.77	0.83	0.72
Spanish	0.82	0.87	0.79
Dutch	0.58	0.92	0.43

2. Term Candidate Generation

The so-called phrase table generated by Moses contains alignment information in terms of phrase pairs, e.g. *'an indication of tubal cancer' :: 'als Hinweis auf ein Tubenkarzinom'* and translation probabilities for each such pair—conditional probabilities for a phrase in the target language *t* (either German, French, Spanish or Dutch) and a phrase in the source language *s* (English) being translations of each other. More specifically, we take into account the direct phrase translation probability $\phi(t|s)$, the inverse phrase translation probability $\phi(s|t)$, the direct lexical weighting lex(t|s), and the inverse lexical weighting lex(s|t). Term candidates for enriching the UMLS were produced by selecting those phrase pairs that translate a known English biomedical term into one of the target languages, as long as the term candidates were different from all synonyms in the target language with respect to all predecessors and sucessors of the concept in question.

3. Term Candidate Classification

A naïve baseline system enriches the terminology with all term candidates forming these pairs, yet most of them will presumably be wrong. Since the phrases in this system are statistically rather than linguistically motivated, a simple mapping from text segments onto other text segments is given. This may also lead to scruffy translations like *'cancer' :: 'Krebs zu'* ['cancer to'], which not only contain the relevant biomedical terms (*'cancer'* and *'Krebs'*) but also (sometimes multiple) text tokens merely adding noise (here, *'zu'* ['to']).

A first refinement step keeps only those term candidates that are the most probable ones according to the phrase table, as those will be both relatively frequent and specific. This can be achieved by introducing a cut-off which selects the *n* most likely target term candidates based on the direct phrase translation probability, $\phi(t|s)$, for each English biomedical source term. In our experiments, a cut-off of '5' led to recall statistics identical with the baseline while massively reducing the number of odd translations. Hence, this cut-off was taken for all subsequent filtering steps.

Additional filtering conditions became instrumental in a binary classifier for term candidates. We trained a Maximum-Entropy classifier from Weka, using the gazetteer-based annotations generated for the corpus set-up as positive training examples (all other potential term candidates were taken as negative examples, so that the system is biased towards proposing new terms) and tested combinations of the following features:

- *Translation probabilities* from the phrase table;
- Judgments on each term candidate's termhood based on its classification as a *biomedical named entity*. We generated this piece of evidence by running the NER system on all sentences containing the candidate. We then summed the probabilities for each candidate being a named entity and divided the sum by the total number of the sentences containing that candidate (using '0', if no match was found);
- A *scaled ratio belancing the length* of the term candidates against their putative translation equivalents (the rationale was to exclude overly length-biased and thus unlikely translation pairs);
- Five *string similarity criteria* based on cognate features (following Aker et al.[16]). Since our work is based on word sequences (see Figure 1 for an overview of the number of words per term in the UMLS) rather than single words, we tested several reordering variants that are likely to appear in the UMLS as well. Besides comparing the unmodified term candidate and its translational equivalent we also tested all permutations of the term candidate's constituent words (for terms up to length '5' only, due to computational constraints). This was done both for independent reordering, selecting the permutation yielding the highest value for each feature and with a single uniform reordering for all features, selecting the permutation leading to the maximal harmonic mean for all five cognate features. Collapsing these five features into their harmonic

mean as a single feature was pre-tested, yet led to slightly degraded performance. Overall, this feature turned out to be Janus-sided during the evaluation in the following sense: it inceased the performance for reconstructing UMLS fragments (i.e. known terms), whereas it decreased the recognition of acceptable new terms.

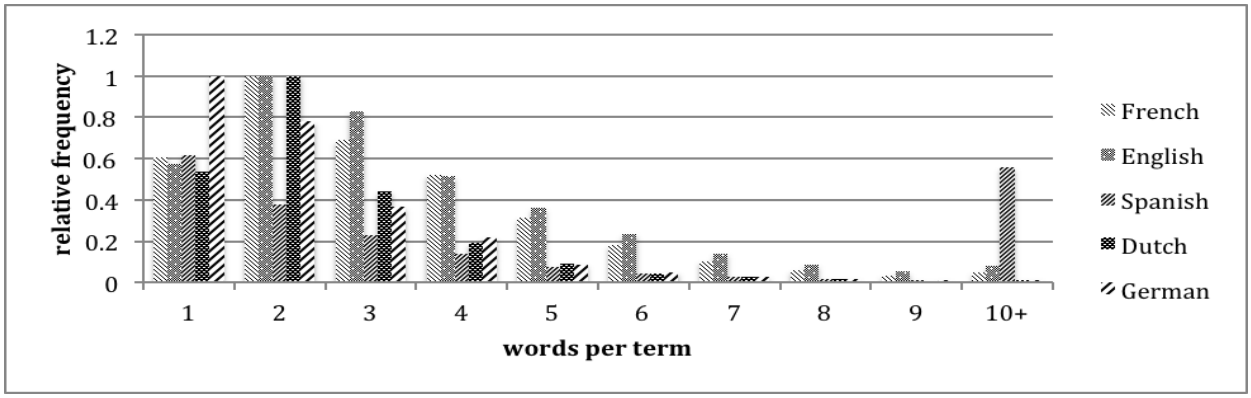

Figure 1. Relative frequency of UMLS terms with *n* words per language; normalized by dividing through the absolute frequency of the most frequent number of words per term for each language.

Results

In general, three types of translation equivalents can be found for the non-English terminologies using our approach: already *known terms*, *additional synonyms for concepts* already labeled in a terminology, as well as *entirely new terms for concepts* with no prior label in a terminology. In order to evaluate the validity of the extracted terms we conducted both an automatic evaluation procedure (for already known terms and additional synonyms) and elicited human expert assessments (for entirely new terms).

1. Automatic Evaluation: Matching Terminologies for Term Re-Invention

In the first setting, we actually measured the system's ability to *re-invent UMLS fragments*, using 10-fold cross-validation for the classifier-based systems. This evaluation was carried out concept-wise, i.e. a term being a synonym for multiple concepts, or a translation thereof, was examined multiple times depending on its ambiguity rate. A term was counted as being correct, if it was already contained in the set of synonyms in the considered language for the UMLS concept. False negatives (for recall calculation) were counted by using those concepts as an upper bound for which the gazetteer system had annotated terms in two aligned sentences (see Table 4 for an overview); we call such terms *traceable*. An obvious drawback of this approach is that additional synonyms and entirely new terms are erroneously counted as being incorrect, since they are not yet contained in the terminology. This may also hamper training, since valid additions are treated as negative examples during training. Any alternative avoiding these shortcomings would have required manual annotation.

Table 4. Number of traceable terms and synonyms, i.e. known terms and synonyms in parallel sentences, per language, used as an upper bound estimate to calculate recall.

Language	Traceable
Spanish	19,797
French	17,492
German	15,428
Dutch	2,017

The automatic analysis allows us to assess the influence of different approaches and feature combinations on term extraction for all four languages (results are listed in Table 5). A system without any candidate classification, i.e. merely enriching the terminology with all translations contained in the phrase table, is listed as a *naïve baseline* and trivially dominates recall. We also list a *cut-off based system* discarding all but the most probable *n* translations of an English term (*n*=1,3,5), an approach that achieves medium F_1 scores. These cut-off selection systems have recall values comparable to the baseline, indicating a strong capability of the aligment step to identify relevant phrases. Finally, we list the *classifier-based systems* considering different feature combinations. The versions with all features described in Section 3, i.e. incorporating translation probabilities, NER termhood, length scaling, and similarity measures, performed consistently best by F_1 scores. Especially for German, uniformly reordering words during similarity calculation improved recall and outperformed the F_1 score for other feature combinations. Classifier systems without translation probabilities as a feature (classifier 1) performed under par, whereas systems using only this information (classifier 2) performs close to the overall best systems, indicating again the high quality of the phrases generated by the SMT system.

Performance is comparable over all languages, with Dutch suffering from tremendous precision problems while achieving above-average recall—this could be caused by the low number of traceable Dutch terms (i.e. examples for classifier training; see Table 4) or the smaller corpus size (see Table 2). The former guess is more likely, since Spanish achieves the overall best F_1 scores and precision values despite a medium corpus size, yet has the highest number of traceable terms. The effect of the NER feature on the performance of classifiers 3 and 4 seems to be strongly language-dependent, yet there is no clear connection to the F_1 scores reported in Table 3, with Spanish and Dutch profiting equally little despite being the best and worst, respectively, in terms of NER performance.

Table 5. Evaluation of the re-invention performance by considering the UMLS as a gold standard, with F_1 score (F), Precision (P) and Recall (R) for all four languages. We list a naïve baseline (without candidate filtering), cut-off selection systems picking up the top *n* candidates (by direct phrase translation probability) for each term and classifier-based systems with different feature combinations.

Method	German			French			Spanish			Dutch

2. Manual Evaluation: Expert Judgment for Term Mining

We performed a manual evaluation for classifier 4 and 7 as terminology acquisition systems using phrase translation probabilities, NER termhood, string length scaling and, in case of classifier 7, string similarity based on uniformly reordered words as features. Both systems found a comparable number of entirely new terms and additional synonyms for each of the four languages. Classifier 7 (with string similarity) came up with 23k, 19k, 17k and 12k new terms for German, French, Spanish and Dutch, respectively, whereas classifier 4 (without string similarity) produced 23k, 18k, 19k and 12k new terms for these languages. Table 1 reveals the over-all lexical extension rate, Table 6 contains a detailed breakdown of the output of classifier 4. Results are similar for German and French, yet the much smaller size of the Dutch corpus leads to a higher number of entirely new terms while the inverse seems to be true for Spanish, probably due to the comparably larger *a priori* coverage of the Spanish UMLS.

In order to evaluate the terms and synonyms not yet contained in the UMLS we elicited judgments from two experts, both native speakers of German (with decent knowledge of the English biomedical terminology) and graduate students in the biomedical domain. They judged a random sample of 100 German terms each for classifier 4 and 7 according to the following three categories:

- Correct translation and perfectly suited as a terminology entry (including abbreviations and loan words);
- Correct translation, yet not directly suited as a terminology entry, e.g. due to vagueness or deviation from inflection norms (only nominative singular and plural terms are permitted);
- Incorrect translation.

Based on these samples 63% of the terms extracted by classifer 7 and 80% of those extracted by classifer 4 can be assumed to be both correct translations and suited as terminology entries. Thus, string similarity measures seem to be particularly apt for the reconstruction of the UMLS, yet they are not really helpful for the mining of novel terms.

A big chunk of the terms (49 items) produced by classifier 4 are spelled identically as an already known English term for the same concept, e.g. the name of the tuna species '*Thunnus thynnus*'. This is caused by a large number of entries marked as "English" in the UMLS, despite being used worldwide to denote the same concept. Furthermore, 8 terms are linguistically correct translations of an English term, although not yet suited as terminology entries, e.g. the inflected form '*linken Nebenniere*' (accusative) instead of '*linke Nebenniere*' ('*left adrenal gland*', nominative). Only a small portion of the errors of our system (6) raise serious concerns as mistranslations, e.g. caused by partial matches during phrasal alignment, such as with '*Flussmessung*' ('flow measurement') as a synonym for '*cardiac flow*'. The rate of serious errors for classifier 4 was comparable to that of classifier 7 (5 items); partial matches like *'intermittens'* as a synonym for *'claudication'/'limping'* due to their combined appearance in *'claudicatio intermittens'* ['temporary limping'] are again a main reason for errors. The 17-word gap between both classifiers was primarily caused by the judges' disagreement on the terminological validity of terms in 12 cases. Six of these were due to inconsistent use of annotation guidelines regarding inflected forms, e.g. the plural form '*Osteopenien*' ['bone losses'] was rejected by one judge, two were disagreements regarding the termhood of names, e.g. the protein nickname *'Harakiri'*, and four were caused by disagreement regarding abbreviations like *'CA2'*, a brain areal.

Table 6. Number of terms extracted by classifier 7 (see Table 5) with all features for all four languages. We distinguish three types of extracted items: "already known terms and synonyms" are already contained as a label for this concept and language (*term re-invention*), "additional synonyms" supplement terms/synonyms known for this concept and language by new ones (*term enrichment*), "entirely new terms" comprise really novel terms for a concept in that language, i.e. these concepts were previously unlabeled (*term mining*).

Language	Already known terms and synonyms	Additional synonyms	Entirely new terms
German	11k	11k	12k
French	11k	9k	10k
Spanish	18k	15k	3k
Dutch	4k	4k	8k

Discussion

The terminology acquisition system we developed for German, French, Spanish and Dutch parts of a UMLS-derived terminology yielded 23k, 19k, 18k and 12k additional synonyms (for terms already listed in the terminology) and entirely new terms (for concepts lacking any official label in this language), respectively. The extension rate for the corresponding languages relative to the already existing resources are 19.2%, 13.9%, 2.8%, and 10.3%, respectively.

About 80% of these new terms can be assumed to be correct and reasonable for this domain based on human judgments on a sample of 100 newly acquired German term candidates. We also showed that similarity features as proposed by Aker et al.[16] might be useful for reconstructing portions of the UMLS, yet they may be disadvantageous for the extraction of new biomedical terms.

For our experiments, we benefited a lot from the availability of parallel corpora. However, in order to further boost the rates for term mining we might have to enlarge our set of text corpora substantially. Using texts from other sources, like webpages[13] or Wikipedia[27], including the use of comparable corpora,[15,17] should be straightforward alternatives to improve our system and decouple it from its reliance on strictly parallel corpora. We also plan to incorporate alternative classifiers (such as CRFs or SVMs) with an enriched feature set, in particular, including "phrasal" types of features such as term collocations[28] and additional indicators of termhood such as term extraction metrics.[29]

Abstract

Electronic problem lists are essential to modern health record systems, with a primary goal to serve as the repository of a patient's current health issues. Additionally, coded problems can be used to drive downstream activities such as decision support, evidence-based medicine, billing, and cohort generation for research. Meaningful Use also requires use of a coded problem list. Over the course of three years, Intermountain Healthcare developed a problem management module (PMM) that provided innovative functionality to improve clinical workflow and boost problem list adoption, e.g. smart search, user customizable views, problem evolution, and problem timelines. In 23 months of clinical use, clinicians entered over 70,000 health issues, the percentage of free-text items dropped to 1.2%, completeness of problem list items increased by 14%, and more collaborative habits were initiated.

Background

A problem list is a fundamental component of an electronic health record (EHR), serving as a thumbnail view of ongoing diagnoses, findings, symptoms, and other health concerns that pertain to an individual patient [1]. When clinicians maintain an accurate problem list, patients generally receive better care [2], have less frequent omissions of care [3], and benefit from more frequent adherence to evidence-based care. Clinicians also benefit from using the problem list by receiving clinical decision support (CDS) alerts [4] that guide them to better outcomes, viewing detailed information about a disease via infobuttons [5], and more easily referring to a list of ongoing health issues, without searching through past notes. Furthermore, medical researchers benefit from an accurate problem list as they seek/mine for specific diseases in order to generate study cohorts and conduct comparative effectiveness research based on diagnoses and other patient health issues [6–9]. Effective use of a problem list is necessary for certification through Joint Commission [10], ONC HIT certification [11], and American Recovery and Reinvestment Act/Meaningful Use (ARRA/MU) [12], which can ultimately lead to incentive pay and/or avoidance of penalties.

Despite their many benefits, problem lists have been found to be sub-optimal, being inaccurate, incomplete, and out of date [13]. Studies have shown that even major health issues such as coronary artery disease and hypertension have a 49-51% probability of inclusion on a patient's problem list [2,14]. There is disagreement about what actually belongs on a problem list [15], and who owns the list, consequently leaving clinicians often unwilling to update a problem to its proper state [2] even if they know it to be inaccurate. Adding a duplicate problem to the list rather than updating an existing item adds clutter, which further reduces the value of the problem list. This behavior can be compounded by the fact that many organizations maintain multiple problem lists per patient - often segregated by discipline, care site, or acute/chronic state of the problem.

At Intermountain Healthcare (IH), an electronic problem list has been available for almost 20 years [16]. However, low utilization of the problem list, high prevalence of free-text problems, the need to replace an aging problem list system in the NICUs, and Meaningful Use (MU) requirements prompted the design of a new problem management module (PMM) that expanded the notion of the problem list to include a wider scope of health issues and workflow associated with them. When this project began in January 2011, only 47% of patients had any problems on their list. In fact, as a whole, IH averaged 8 problems per patient, with a median of just 1 problem per patient, 72.5% of which were coded. In the entire IH inpatient population, only 34% had an active, coded problem as required by MU.

Objective

The objective of this paper is to describe the PMM developed at IH and the functionality designed to overcome the following limitations of the prior system: underutilization, duplicate entry, out-of-date problems, free-text problems, missing attributes, inability to find the proper problem in a large list, cumbersome addition of new problems, an inability to tell the clinical story, and problem maintenance tension between care givers, resulting in incorrect

problem status. We present new and unique functional improvements incorporated into the PMM, and present quantitative results of pilot implementations at IH care locations.

Materials and Methods

Setting

The PMM was built at IH, in Salt Lake City, Utah, a not-for-profit integrated health care delivery network. IH operates 22 hospitals across Utah and southern Idaho and employs over 33,000 employees, 1,000 of whom are multispecialty clinicians working in 185 ambulatory clinics [17].

In order to meet the specific needs of the clinicians, and IH in general, a steering committee was formed, comprised of clinicians from different disciplines and care settings. This committee met every week, along with representatives from informatics, terminology, data modeling, knowledge management, clinical analysis, user interface design, and software engineering. Weekly meetings focused on forthcoming work, demonstration of the current state of the PMM, and resolution of issues that arose during the development process. Additionally, several structured user-acceptance testing sessions occurred with clinicians from many specialties. This iterative, user-centric, participatory approach culminated in the PMM tool that was initially released to a select, primarily inpatient audience at IH, including newborn and adult Intensive Care Units (ICU), acute care floors, and Tele-Health. The goal of the participatory design was to develop a common model that could be used across diverse care settings.

For quantitative results, we queried usage statistics for the PMM and legacy problem list application from our enterprise data warehouse and terminology logs for the period from the original pilot implementation on August 24, 2012, to the most recent data available on July 21, 2014. In some cases we compared data from before PMM implementation to post-implementation. Simple statistics were generated by the authors from these data. IRB approval was obtained prior to study initiation.

System Description

Master List

When opening the PMM, a longitudinal list of problems is presented, containing all problems from birth to death, whether active, inactive, acute, chronic, or historical (Figure 1). Viewing historical problems alongside active problems made it easier to ascertain a picture of a patient's overall health status. However, for the master list to be useful and not overwhelming, focus on data presentation and mechanisms for sorting, filtering, and grouping was needed.

One such mechanism aggregated multiple instances of the same problem, reducing overall length of the master list. Once aggregated, only the most recent instance of the problem was visible, with a superscript denoting the actual number of instances. Clicking the superscript opened a list of all prior occurrences with their detail.

Another mechanism for managing data was custom sorting. Each list column defined a custom sort order that tailored sorting of problems to an individual clinician's needs. When applied to body system, a clinician may choose to see cardiovascular-related problems first, respiratory-related problems second, and fluids/electrolytes-related problems last. Once set, data are automatically sorted according to the clinician's own preference.

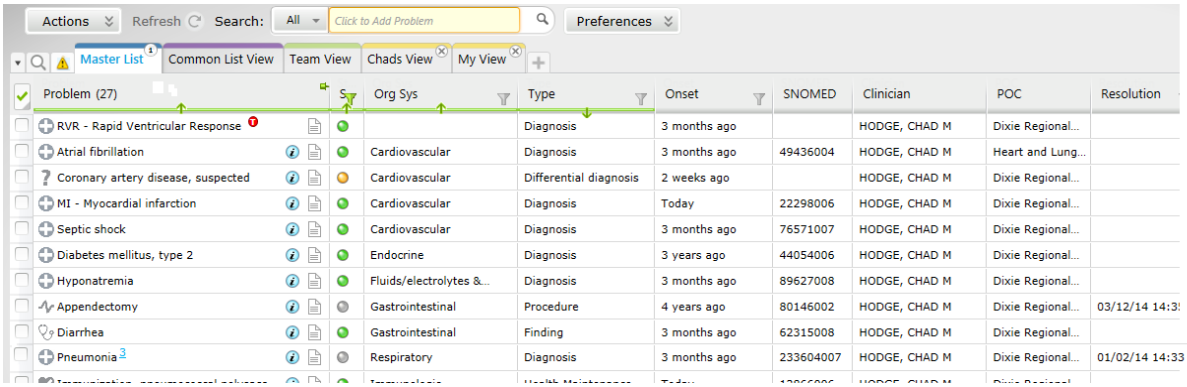

Figure 1 - Master problem list view within the PMM.

Smart Search

Scrolling through a long list of problems on the master list was a tedious task. IH created the Smart Search field to be the integral means by which clinicians searched for existing problems within the problem list, and as the sole means of adding new problems. Smart Search allowed clinicians to find a problem of interest by typing in a portion of the problem description. The description was used to find matches in three data sources: the patient's master list, the terminology database, and the clinician's common list. The results from searches against these three sources were then merged, ordered, and displayed as a single result set (Figure 2).

Searching the master list first allowed identification of the patient's existing problems. Presenting existing problems helps to keep the problem list uncluttered and up to date. An active instance of a problem cannot be added to the list until the current instance is resolved.

The second source searched is the terminology database. The search term is matched against a constrained domain of problem concepts that have been explicitly included based on identified needs and historical usage patterns. The matches are also translated into possible synonyms, so closely related terms and acronyms may be quickly found. For example, if a clinician enters 'heart', the search will return exact matches with the word 'heart', but also synonyms or acronyms, such as CHF, myocardial infarction, cardiomyopathy, etc. Search results are pre-coordinated so that body system, problem type, and status are automatically selected for the clinician [18]. The pre-coordinated attributes for each problem are available in an XML document residing in our knowledge repository [19].

The third source searched is the clinician's common list, consisting of a clinician's most commonly used problems. Matches against the common list are used to prioritize search results, so the clinician's preferred terms (typically specialty or setting specific) are shown at the top of the result set. This allows faster identification of higher-interest problems that a patient may have. The search results are limited to 40 items to avoid overwhelming clinicians. Clicking on one of the search results will add the pre-coordinated problem to the patient's problem list. Problems are mapped to SNOMED-CT terms where possible.

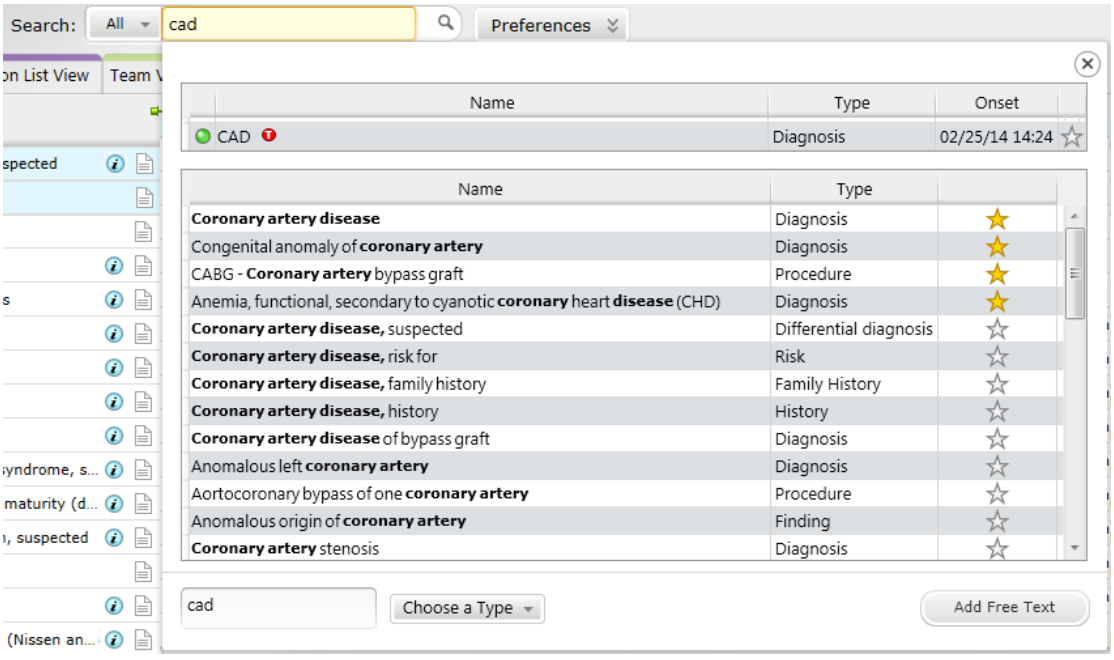

Figure 2 - Smart Search results. Existing problems are shown first, followed by matches from terminology, both results are ordered by common list preference

Feedback Mechanism

IH works with clinicians prior to implementation of vocabularies to define, pre-coordinate, and load only the concepts and representations that are clinically relevant, as evidenced by usage and clinician review. Post-implementation, clinicians require new content, and request synonyms for existing content that allow for efficient

searching. When terminology is incomplete, clinicians revert to adding patient data as free-text rather than as coded concepts. Current processes for handling terminology requests are ad-hoc and entail months of effort. This can leave clinicians disengaged from content governance, and patient data remain uncoded and thus unavailable for decision support. To address these issues, IH developed a new terminology feedback process to engage clinicians. Novel and efficient mechanisms were developed to identify gaps and allow clinicians to interactively review and approve recommended content in the context of patient care.

When clinicians added a free-text problem, a structured request was automatically routed to the terminology work queue. Clinical modeling engineers (CME) then inspected the free-text term, and searched for and evaluated matches for the term in the existing dictionary, to determine if the term was misspelled, an acronym, a synonym, or missing. CMEs then added the new content or created mappings between the synonym/acronym and root concept, ensuring future searches return proper results. CMEs then created a list of candidate substitutions for the clinician's free-text problem, and sent that list back to the application for review by the clinician.

The next time a clinician opened the same patient's problem list, the application presented the clinician with the substitution candidates for the free-text problem (Figure 3). When reviewing, the clinician viewed the original free-text alongside the list of candidates. The clinician could select a single choice to serve as the replacement for the free-text problem, or could choose to reject all provided choices with an accompanying reason. If rejected, the process was performed one more time, resulting in a new set of candidates. If the clinician chose to accept one of the newly provided terms, the free-text problem was automatically replaced by the coded concept.

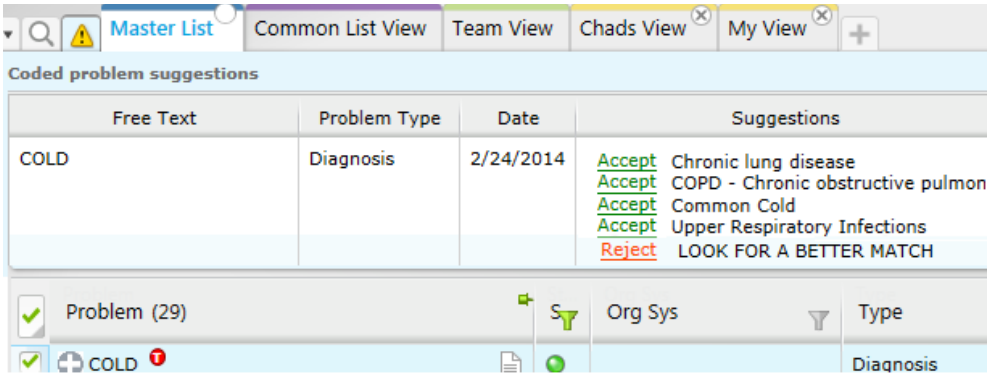

Figure 3 - Feedback Mechanism presenting a clinician with suitable substitutes for an entered free-text problem.

Problem Evolution

Problems tend to follow a predictable progression, or evolution. When treating a patient, clinicians begin creating a mental list of differential diagnoses, ruling out or confirming each one as data become available. Once confirmed, a differential diagnosis is evolved to a diagnosis, meriting treatment and monitoring. When a diagnosis is resolved, if a clinician decides that a reminder of the condition should be available to other caregivers, the diagnosis is evolved to a historical problem.

To support the evolution of problems, IH worked with a team of clinicians to enumerate 10 distinct problem types (Table 1). Through experience, IH clinicians felt that the problem list was the logical place to record and communicate these various types of health issues managed by their interdisciplinary teams. (*Health issue* is the more correct term for items on the PMM list, but we will interchangeably refer to them as *problems* throughout the paper for brevity.) A mapping between the types was created, defining the evolution pathway. For each coded concept in the problems terminology domain, a knowledge document was created that described how the specific problem may progress along the evolution pathway. Each of the 10 problem types was given a set of unique statuses that, when used, automatically triggered the progression of a problem along its evolution pathway.

The evolution document describes possible evolution pathways and the coded concepts that represent an evolved problem. When a clinician changes a problem's status to one defined in the document, evolution is triggered. For example, when a differential diagnosis is 'Confirmed' the problem automatically evolves to a diagnosis concept. The new diagnosis concept is added to the problem list and linked to the existing differential diagnosis. Only the most recent evolution for the problem is shown in the list, though all linked previous evolutionary states may be seen in the change history (Figure 4).

Once the diagnosis is resolved, a clinician may choose to evolve the problem to the terminal state of *historical* problem. Selecting the status of 'Resolved, Create History' will trigger a traversal of the evolution document one more time, locating the equivalent concept for the historical problem. That new concept is added to the list and linked to the end of the problem chain.

Having so many different statuses for each type of problem was confusing to the clinicians. Thus, a second knowledge document was created that mapped each problem status to one of four overarching meanings: active, proposed, inactive, or error (Table 2). This equivalency mapping was used to present a color-coded status indicator, agnostic of the actual status wording. For instance, a 'Recommended' health maintenance issue and a 'Scheduled' procedure both mapped to a yellow indicator, meaning both were in a *proposed* state. This allowed clinicians to focus on the meaning of the status, not the wording of the status.

Table 1 - Problem Types & Statuses.

Type	Description	Possible statuses
Finding	Observation about the patient that is less than a diagnosis occurring in relation to a physical exam. E.g., Abdominal pain.	Active, Inactive, Proposed, Resolved, Error, *Resolved, Create History <Evolve>*
Procedure	An action taken on a patient's body, typically diagnostic or treatment related. E.g., Lumbar puncture.	Active, Cancelled, Candidate, Resolved, Error, Unconfirmed, Ordered, Scheduled, *Resolved, Create History <Evolve>*
Differential Diagnosis	A possible diagnosis that has yet to be confirmed or ruled out. E.g. Sepsis, suspected.	Working Up, Ruled out, Error, *Confirmed <Evolve>*
Diagnosis	A confirmed health issue, describing the nature of a disease, injury, or congenital defect that requires monitoring or treatment. E.g. Carotid artery stenosis, or Trisomy 8 mosaic syndrome.	Active, Inactive, Proposed, Resolved, Error, *Working Up <Devolve>, Resolved, Create History <Evolve>*
Health Maintenance	Care steps taken to maintain good health, focused on early detection and prevention. E.g., Well child check-ups or vaccinations.	Due, Error, Recommended, Up-to-date, Resolved, *Create History <Evolve>*
Risk	An event with high probability of occurrence. E.g., Falls Risk.	Active, No Longer of Concern, Proposed, Resolved, Error
Event	A specific major occurrence. E.g., Automobile accident.	Active, No Longer of Concern, Proposed, Resolved, Error, *Resolved, Create History <Evolve>*
Device	An implantable device designed for a specific function. E.g., Pacemaker, or Port-a-cath.	Unconfirmed, Present, Removed, Error, Removed, *Create History <Evolve>*
History Of	Any medical and surgical item that has resolved, but continues to be pertinent to patient care. E.g., Breast cancer, or organ transplant.	Validated, Unknown, Proposed, Resolved, Error
Social History	Lifestyle choices. E.g., smoking, alcohol, or illicit drug use.	Active, Unknown, Proposed, Resolved, Error, *Resolved, Create History <Evolve>*
Family History	Major diseases which were/are present in the patient, but which are present in family members, potentially increasing the likelihood the patient will acquire the disease. E.g., cystic fibrosis.	Validated, Unknown, Proposed, Error

Table 2 - Status Equivalency

Status Equivalent	Description
Active (Green)	The problem is currently present in the patient, or is actively monitored and treated.
Proposed (Yellow)	The problem is potentially of concern, but more work is needed to confirm.
Resolved / Inactive (Grey)	The problem is resolved or no longer a concern.
Error (Red)	The problem was added in error, perhaps on the wrong patient.

History:

Description	Problem Type	Status	Org Sys	Onset Date	Resolutic
Sepsis, history	History	Validated	Infectious Disease	02/17/14 15:07	03/12/14
Sepsis	Diagnosis	Resolved, create history	Infectious Disease	02/17/14 15:07	03/12/14
Sepsis	Diagnosis	Active	Infectious Disease	02/15/14 15:07	
Sepsis	Diagnosis	Active	Infectious Disease	02/15/14 15:07	
Sepsis, suspected	Differential diagnosis	Confirmed	Infectious Disease	02/13/14 15:07	
Sepsis, suspected	Differential diagnosis	Working up	Infectious Disease	02/13/14 15:07	

Figure 4 - Change history of Sepsis showing evolution.

New Problem Indicator

When a clinician sees a patient and updates the problem list, there is a sense of ownership over what is in the problem list. However, when the same patient is seen later, the list may be significantly different because other clinicians have seen the patient and added and updated problems. When this occurred, the sense of ownership over the list was lost because it was too difficult to easily determine what specifically had changed, and a clinician may no longer be willing to maintain the list, even if they know it is inaccurate. To combat this, an indicator was created that alerts clinicians to changes in a patient's problem list.

Each time a clinician views a patient's problem list, a time-stamp is logged for that clinician-patient combination. On subsequent views, the time-stamp is retrieved and compared against the last edit time of the patient's problems. A running count is generated that tracks how many problems were added or updated since that date. This number appears directly on the master list tab (Figure 5). The clinician can click on the number to get more details about what has changed since last review. When clicked, a popup appears listing newly added or updated problems and relevant details. Selecting a problem from the list navigates the clinician directly to the problem in the master list.

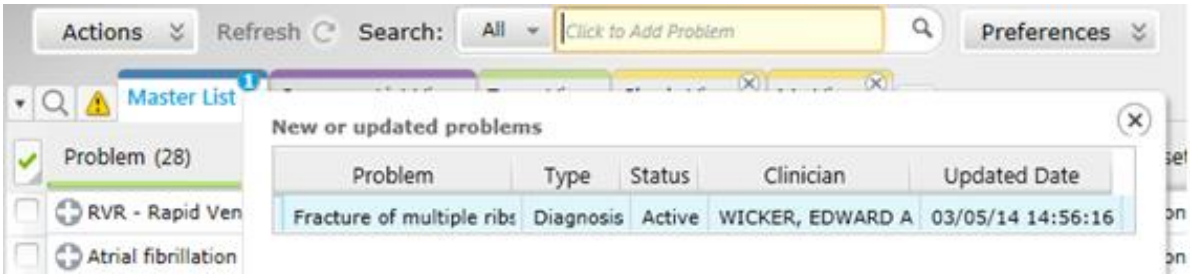

Figure 5 - New problem indicator. The superscript "1" on Master List tab indicates one new problem on the list.

Assessment and Plan

The prior version of the IH problem list application required clinicians to open a separate module to create the assessment and plan (A&P) for a problem. To find previous A&Ps written for a specific problem, one would have to review all recent clinical notes for any mention of the problem, which was a tedious task because previous A&Ps were sometimes copied forward without adding new information. IH clinicians expressed a desire to add and review A&P notes while reviewing a specific problem, using a single application.

To address this workflow issue, the PMM allowed an A&P to be created and stored for an individual problem. All A&Ps pertaining to a problem are listed in chronological order and are readily accessible from a note icon next to the problem. This makes it easier to determine progress towards treatment goals.

When an overarching clinical note needs to be created, such as a progress or discharge note, the latest A&P of each active problem was retrieved and automatically inserted into the note. This generated note contained much of the necessary detail of each problem, requiring only small changes before finalizing it.

No Known Problems

To meet MU requirements, functionality added to the PMM allowed attestation that a patient has "no known problems". If there are no MU-defined problems on a patient's list, the PMM displayed a link to a "no known problem" form (Figure 6). By using the form, the clinician affirms that the patient had no known problems. This attestation counted as a coded problem in the MU numerator. When attested to, the date and clinician name is shown. Once an actual problem was added to the problem list, the "no known problem" assertion was automatically

removed since it is mutually exclusive to coded problems on the problem list. If all problems were resolved, attestation would begin anew.

Patients may visit a clinician to address any of the health issue types shown in Table 1, allowing entry of a broader range of health issues than just diagnoses and medical history. For example, if the visit is for purely preventative reasons, a health maintenance problem can be added to the problem list. However, the numerator criteria set forth in MU guidelines do not recognize all 10 health issue types that PMM supports. In the case that none of the items on the patient's problem list meets the MU criteria for problems, the "no known problems" logic is initiated.

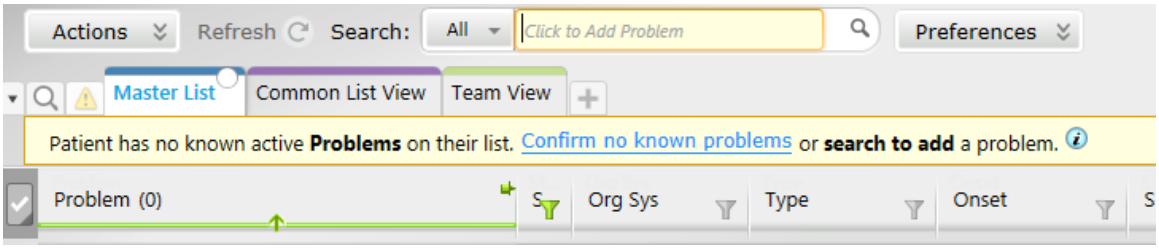

Figure 6 - No Known Problems indicator.

Timeline View

To improve the comprehension of complex problem lists, and to see patterns in a patient's health history, a timeline view of the problem list was created, similar to work reported by Plaisant et al. [20].The timeline view graphs health issues currently in view, in relation to time. The x-axis is time, starting at the patient's date of birth, minus 9 months, on the far left, until present day on the far right. The y-axis lists each distinct health issue visible on the patient's list, placing the earliest onset health issue on top, and the most recent onset health issue at the bottom. When multiple occurrences of the same health issue are present, they are mapped on the same line, and each occurrence is placed in the appropriate period on the x-axis. Each health issue is drawn as a rectangle with the onset of the health issue as the left edge, and the resolution date as the right edge of the rectangle, showing the lifespan of the issue. A patient's encounters/visits are overlaid on the graph to correlate them in time with health issues. Thin transparent bars represent a short visit to an outpatient provider, and a wider bar denotes a longer inpatient encounter (Figure 7).

The timeline view provides immediate detail about how many problems a patient has had, how long these problems lasted, what health issues occurred concurrently, if a caregiver was seen during that time, and when the most recent instance occurred. Long-standing problems will show prominently, prompting clinicians to inquire further. Additional patterns, such as problem overlaps, may emerge when viewing data on a lifetime scale that are otherwise not obvious.

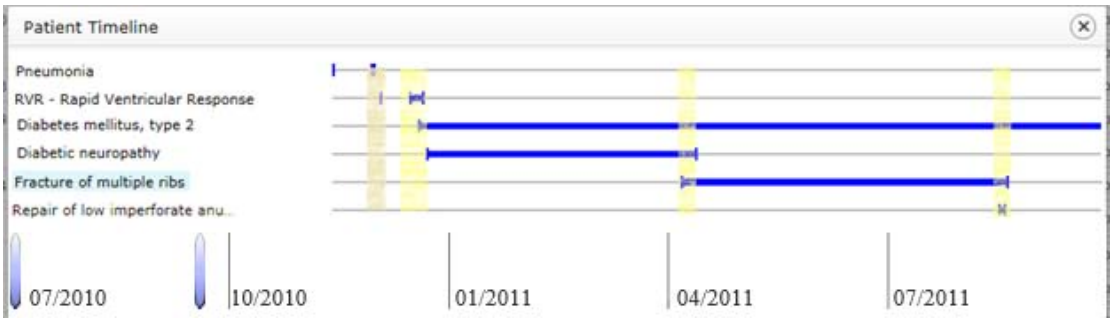

Figure 7 - Plotting problems in chronologic order for a holistic representation of the patient's problem history.

Views

During clinician testing of the PMM, it was observed that some clinicians occasionally became frustrated that there were problems on the list that did not specifically pertain to the patient's current visit. These frustrated clinicians chose to resolve all the problems on the list and then add problems specific to the current visit, rather than deal with the existing large problem list. This action is detrimental to the accuracy of the patient's problem list, and may

destroy years' worth of problem history. This phenomenon was termed *Tension*, because a clinician was acting as a force to deform the problem list, pushing it out of harmony with the patient's true health state.

To resolve the underlying cause of this behavior, *Views* were introduced (Figure 8). A View is simply a way for a clinician to separate problems from the large master list, narrowing to a focused problem list. A View references selected problems from the master list, allowing the clinician to choose only those problems that are of interest, imbuing the clinician with a sense of ownership over those few problems.

This concept reduced clinician's frustration with large lists; however, they became curious about what other clinicians' Views looked like for the same patient. To satisfy that curiosity, a search function was added that allowed discovery of other Views, and allowed them to be opened in read-only mode. The viewing of other clinician views was useful when dealing with referrals to a specialist.

Now that IH clinicians could create a list of problems for their own needs, they wanted to show the interrelatedness of those problems, to better express the clinical story. The PMM allowed clinicians to drag and drop one problem onto another, building a subsumption hierarchy in whatever manner best depicts the clinicians thought processes. When the PCP searched for the cardiologist's View, he or she would not only see the problems the specialist was concerned with, but also the relations between them. For example, the hierarchy might inform the PCP that the patient has underlying heart issues caused by poorly managed diabetes, prompting a discussion with the patient.

When presented with Views for individual clinicians, it was realized that an entire care team could also benefit from the Views concept. The Team View allows groups of clinicians in a specific care setting, such as an ICU or outpatient clinic, to define a set of problems with relationships. The Team View allows the entire care team to collaborate on what problems should be monitored and treated, giving all shifts and specialties a better understanding of the team's priorities. Just as personal views could be searched for and inspected in read-only mode, so too could Team Views. Using another team's view is useful when patients transfer from one team to another. The prior team's thoughts and work could be referred to before receiving the patient in a new unit so that preparations could be made, thereby improving handoffs.

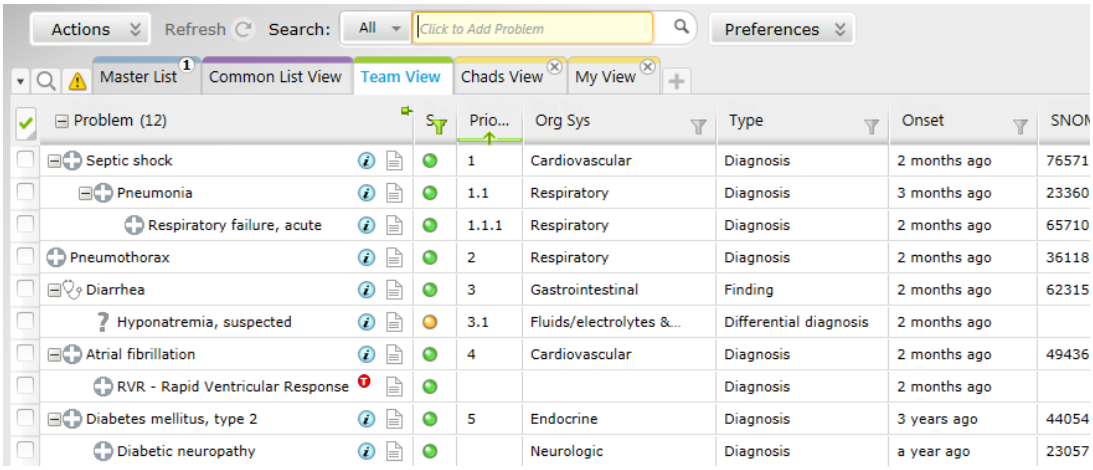

Figure 8 - A team view that depicts subsumed and prioritized problems for a care team.

Results

During the time period examined, 580 clinical users, including physicians, nurse practitioners, and physician assistants from 9 locations, have used the PMM. These users entered information on 5,557 patients, adding 71,838 total health issues. On average, 110 clinicians are entering or updating 3,900 health issues per month, with a peak of almost 200 clinicians entering over 4,700 issues during one month. Clinicians used the Assessment and Plan tool to attach over 997,000 A/P notes to problems on 5,079 patients.

Free-text problems entered using PMM were 1.2% of the total problems entered during the study period. During the same period, 11% of problems entered using the legacy problem list application were free-text. We also found that roughly half of the problem terms selected by users in the Smart Search tool contained pre-coordinated information.

The number of missing data elements has fallen from an average of 27.63 per 100 problems using the old problem list application, to 13.73 using the PMM, for fields such as body system, problem type, and status.

Not only are data more complete, problem evolution has added a new dimension of insight to the problem list. Using PMM, clinicians evolved 3,098 health issues, most commonly by changing a status to "Resolved, create history." But clinicians also evolved a differential diagnosis to a confirmed diagnosis 1314 times: The most frequently evolved differential diagnoses were *Jaundice due to preterm infant, suspected* (308), *Respiratory distress syndrome, suspected* (208), *Jaundice in a term infant, suspected* (175), and *Sepsis, suspected* (142).

Clinicians utilized views, subsumption hierarchies, and prioritization to organize problem lists in clinically-meaningful ways. Care-teams selected problems off the master list and built Team Views 9,352 times; individual clinicians created clinician-specific Views 116 times. Arbitrary segregation of problems into a View is one way of organizing problem data; an additional method is to subsume problems into a hierarchy of relatedness. The maximum depth any view subsumed a problem is 5 levels deep, with an average depth of 1.5 per view. When prioritizing problem data in a View, the largest number of problems prioritized was 18, with an average of 3. The most commonly prioritized problems were apnea, nasal cannula oxygen administration, hyperbilirubinemia, and septic shock.

Discussion

The large number of problems added per patient (average 12.9/patient) using the PMM can be explained in three ways. First, problem evolution results in many new problems being created automatically for a single issue as the original problem's status is changed to "resolved" and its newly evolved instance is created, which is not readily apparent to the clinical user. Second, most of the users of the PMM were in ICU settings, which average a much higher number of problems per patient than other care settings. Third, organizational incentives for clinicians to meet MU goals coincided with use of the PMM, possibly inflating results. Future studies will further compare use of the PMM with the legacy problem list application, which is still in use in certain locations (primarily outpatient clinics), to determine if the new features are the cause of a perceived improvement in problem management at IH. Workflow and clinician engagement improved as a result of the new problem terminology search and maintenance functionality. The large percentage of pre-coordinated terms selected in the Smart Search tool likely helped clinicians find appropriate terms and reduced free-text entry. The usefulness of the Feedback Mechanism was also evident and will be incorporated in other parts of our EHR.

Not only has the PMM created much more data than a typical problem list application, it has created entirely new types of data for study, such as how clinicians aggregate data in a view and evolve problems. It is evident from our usage statistics that clinicians in our currently ICU-centric pilot sites prefer to create team views rather than personal views. This is largely due to the fact that these clinicians use a team-oriented model for care in which information and treatment plans are shared. Future work will explore how clinicians and teams use Views, and the manner in which they impart order to the Views by subsuming problems into a hierarchy. Additional studies will investigate if Views lead to a more accurate problem list, and if they reduce tension between caregivers of the same patient.

The goal of the PMM project was to increase clinician adoption of the problem list by addressing issues associated with the use of problem lists in general. Each of the enhanced features described was designed to address one or more of these issues. Current usage statistics indicate that these interventions have been successful. However, a more formal study will be necessary in order to determine the exact impact of each of these enhancements on problem list usage and patient care, and their generalizability to more clinicians and settings. In the 23 months of use, feedback from clinicians has been extremely positive, affirming that the PMM provides more value, is easier to use, and offers innovative features that entice use of the system.

Acknowledgements

The envisioning and development of this application involved dozens of people over three years, spanning both technical and clinical domains. The authors would like to acknowledge the invaluable input of Jean Millar, Lisa Gleed-Thornton, Ed Wicker, Chris Wood, Larry D. Eggert, James Orme, Ning Zhuo, Annie Bigler, Harsha Puthalapattu, and Srinivasulu Reppale Venkat.

Reasoning Based Quality Assurance of Medical Ontologies: A Case Study

Matthew Horridge PhD[1], Bijan Parsia PhD[2], Natalya F. Noy[1] PhD, Mark A. Musen MD, PhD[1]
[1]Stanford University,CA, USA; [2]The University of Manchester, UK

Abstract

The World Health Organisation is using OWL as a key technology to develop ICD-11 – the next version of the well-known International Classification of Diseases. Besides providing better opportunities for data integration and linkages to other well-known ontologies such as SNOMED-CT, one of the main promises of using OWL is that it will enable various forms of automated error checking. In this paper we investigate how automated OWL reasoning, along with a Justification Finding Service can be used as a Quality Assurance technique for the development of large and complex ontologies such as ICD-11. Using the International Classification of Traditional Medicine (ICTM) – Chapter 24 of ICD-11 – as a case study, and an expert panel of knowledge engineers, we reveal the kinds of problems that can occur, how they can be detected, and how they can be fixed. Specifically, we found that a logically inconsistent version of the ICTM ontology could be repaired using justifications (minimal entailing subsets of an ontology). Although over 600 justifications for the inconsistency were initially computed, we found that there were three main manageable patterns or categories of justifications involving TBox and ABox axioms. These categories represented meaningful domain errors to an expert panel of ICTM project knowledge engineers, who were able to use them to successfully determine the axioms that needed to be revised in order to fix the problem. All members of the expert panel agreed that the approach was useful for debugging and ensuring the quality of ICTM.

Introduction

The World Health Organisation International Classification of Diseases (ICD)[1] is a large and widely used resource. The current version, ICD-10, which was published in 1990, is essentially a large hierarchical terminology that contains codes, titles, and textual descriptions of diseases. It is used in areas such as epidemiology in order to compile health statistics, for remuneration in various jurisdictions, to monitor health-related spending, and to guide health policy decisions. In 2007, the World Health Organization (WHO) initiated work on ICD-11. The development of ICD-11 is a large social/collaborative effort involving over 250 subject matter experts and is being carried out using the *iCAT* tool. iCAT, which stands for "ICD Collaborative Authoring Tool", is a highly customized version of WebProtégé[2] – part of the well known Protégé suite of tools – and allows users to simultaneously review, edit and extend ICD-11[†].

In contrast with all previous versions of ICD, it was decided by the WHO that ICD-11 would be represented in a well-structured, computable form, defined by a *Content Model*. The main motivation for this was the hope that it would make it possible for subject matter experts to view, edit and curate content in a variety of software tools. It was also hoped that it help to resolve ambiguities in terms of what information needed providing and would also allow some form of automated error checking and quality assurance to be implemented. Initially, the Content Model was a three layer UML model, which specified requirements such as "a term should have a title, a list of synonyms, a code etc.". However, the decision to re-implement the Content Model as an ontology was made, and the UML model was re-implemented using the widely used *Web Ontology Language* (OWL)[3]. The OWL *Content Model Ontology* essentially provides a "schema" for *data*, which corresponds to descriptions of diseases, to be entered. The entered data then forms the basis for ICD-11.

The main benefits of using ontologies, and in particular OWL, for the Content Model were stated to be that:

- Other ontologies and applications would be able to reuse ICD or portions of ICD more easily than if it was represented using some other language or semi-structured data format such as XML Schema. Thus, the chances of interoperability with other software systems is maximized;
- Expressive OWL constructs could be used to formalize the Content Model and could be used to generate the (form based) user interface for entering content;

[†] While iCAT is meant for ICD-11 content editors, end users of ICD-11 (and members of the public) may view nightly compilations at http://www.who.int/classifications/icd11

- OWL would be able to provide a path to future use of automated consistency checking and class hierarchy computation, which could, (a) be used for Quality Assurance purposes; (b) reduce hierarchy construction mistakes (placing something in the wrong place); and, (c) be useful for the purposes of migrating ICD from a pre-coordinated terminology to a post-coordinated terminology.

While the first two points have been proven to some extent[4], automated reasoning has not yet been used, either at Content Model Ontology design time, or at runtime when data is being entered into the system by subject matter experts. In this paper, we therefore explore how standard reasoning, in the form of consistency checking, and non-standard reasoning, in the form of justification finding, can be used to debug and explain inconsistencies that arise during the development of a Chapter of ICD. We look at the potential utility of such services and reflect on the current state of tool support. More specifically, we investigate the following: Are inconsistencies that arise during the development of real world complex medical ontologies indicators of meaningful errors in the ontologies? Is it possible to deal with a large number of errors? Are there regularities in the reasons for inconsistencies and if so can these regularities be exploited to triage the errors? Can off-the-shelf explanation tools provide pointers so that these errors can easily be corrected?

We focus our investigation on the development of Chapter-24 of ICD, which deals with the specification and description of Traditional (Chinese) Medicine and medical practices. This chapter was developed as part of the *ICTM* project, where a customized version of iCAT (iCAT-TM – herein simply referred to as iCAT) and a Content Model Ontology that extends the ICD Content Model Ontology were used to create it. The reasons for focusing on this Chapter are two-fold: (1) The chapter provides a smaller subset of ICD that is more convenient to experiment with compared to the complete ICD classification; (2) The development of the chapter uses the same underlying workflows, tooling and technologies that are being used to create other chapters of ICD-11. Thus, any results of experiments on this chapter should be generalizable to ICD as whole. Furthermore, while we use ICTM as a case study, the approach should be adaptable to any system that uses a logic based ontology as a schema for data entry.

Preliminaries – Ontologies, OWL, Reasoning and Justifications

Ontologies: Ontologies are machine processable artifacts that capture the important concepts, and the relationships that hold between them, in some domain of interest. Ontologies are used in many diverse domains, but they are heavily used and are important in the areas of medical-informatics. For example, SNOMED-CT[5] is a huge multilingual healthcare ontology. It provides a vocabulary for clinical findings, symptoms, diagnoses, procedures, and body organs amongst other medical domain knowledge.

OWL: The latest standard in ontology languages is The Web Ontology Language, OWL[3] (or to be more precise, OWL 2). The main units of currency in an OWL ontology are *axioms*. An axiom is basically a *statement* of truth. For example, Heart SubClassOf Organ is a subclass axiom, which states that every instance of Heart is also an instance of Organ. Axioms tie together *entities*, which are names for basic concepts and properties in the domain. An entity may be a *class*, *property*, or an *individual* (an individual may also be called an instance). In this paper we use the convention that, class names start with uppercase letters, and property and individual names start with lowercase letters. Furthermore, we write all entity names in a sans-serif font, and property names in particular in an *italic sans-serif font.* We can broadly categorize axioms into *TBox* axioms and *ABox* axioms. TBox axioms represent the "schema" part of an ontology – they are used to specify descriptions of classes. ABox axioms represent the "data" part of the ontology – they are used to specify descriptions of individuals.

Entailment: OWL is a *logic-based ontology language*, which means that the semantics of the language is precisely specified by a mapping to an underlying logic. This gives OWL axioms a well-defined, unambiguous meaning. It also allows the specification of a consequence, or rather *entailment*, relation. In OWL, it is possible to deterministically compute whether or not an axiom follows from, or is implied by, what has been stated in an ontology. For example, if an ontology states that, Heart SubClassOf Organ, Organ SubClassOf AnatomicalStructure. Then it is possible to determine that Heart SubClassOf AnatomicalStructure also follows from the ontology. If an axiom follows from an ontology we say that the axiom is *entailed* by that ontology. We also refer to an entailed axiom as an *entailment*.

Reasoning: OWL was designed with favorable computation properties in mind and it is possible to automate the computation of entailments using off-the-shelf tools called *reasoners*. Reasoners are software systems that can be used both at ontology design time and at application runtime. At design time, a reasoner can be used to check that certain desirable entailments follow from what has been stated, and, more typically, that certain undesirable entailments (logic bugs) do not follow from what has been stated. One of the most serious logic bugs that can occur

for an ontology is for it to be inconsistent[‡]. When an OWL ontology is inconsistent, it entails *anything*. In other words, any conclusion may be drawn from it and under classical semantics an inconsistent ontology is essentially meaningless.

Justifications (explanations): In this work we use a reasoning service that can generate explanations for inconsistent ontologies. These explanations are known as *justifications*. A justification is a minimal subset of an ontology that is sufficient for an entailment to hold. In the case of an inconsistent ontology, the axioms in a justification explain what has been stated that makes the ontology inconsistent. For example, the justification, J = {PatientC2 InstanceOf Man, PatientC2 InstanceOf Woman, DisjointWith(Man, Woman)} explains an inconsistency caused by the individual PatientC2 being an instance of the classes Man and Woman which also happen to be disjoint (disjoint classes cannot share any instances). There may be multiple justifications that explain why an ontology is inconsistent, reflecting the fact that there can be multiple reasons for a single inconsistency. Furthermore, these justifications may overlap with each other, that is, they may share axioms. Finally, justifications have emerged as the dominant form of explanation in the OWL world. This is because they are conceptually simple, there are off-the-shelf tools for computing them (which work with any OWL reasoner), and searching for the cause of logic bugs without some kind of pinpoint device like justifications is like looking for a needle in a haystack – that is, it is a wretched and error prone process.

Preliminaries – iCAT(-TM) and WebProtégé

The content for ICTM, which forms Chapter-24 of ICD-11, is created, edited and viewed with the *iCAT-TM* tool (ICTM Collaborative and Authoring Tool, herein simply referred to as iCAT). iCAT is a customization of WebProtégé, a Web-browser-based collaborative ontology development environment that can be used by geographically distributed users to simultaneously edit OWL ontologies.

Figure 1. A screenshot of an iCAT-TM form. Selecting the Disorder/Syndrome radio button at the top of the form causes property assertions to be added to the underlying ontology stating that the underlying individual, representing an ICD code has a type relationship to Disorder/Syndrome. The end user (an ICTM subject matter expert) does not need to know what an individual is, or what a property is, or what a property assertion axiom is. The grid at the bottom of the form shields the user from editing multiple complex expressions and axioms that define the given term.

A key feature of iCAT, and one that has been heavily used in the context of the ICTM project, is form based entity editing. Figure 1 shows an example of an iCAT form. Forms can consist of checkboxes, radio buttons, text fields, tables and the like. They provide a simple graphical way of editing OWL axioms under the hood. The advantage of this is that an end user of the system does not necessarily need to have any prior knowledge of OWL or ontologies to be able to contribute to the authoring of an ontology such as ICD or ICTM. In essence forms allow an ontology to be edited and extended "by stealth".

The forms that iCAT displays are declaratively specified using a custom markup language. This markup language specifies how form elements are rendered on the screen. It specifies the kind of widgets that should be used to display content, and also specifies how to translate specific input values of widgets into domain specific vocabulary and axioms in the underlying ontology. A key feature of the system is that it uses a loose, manually specified,

[‡] Note that if an ontology is inconsistent then we say that the whole ontology is inconsistent. That is, an ontology is either consistent or inconsistent. While there may be multiple subsets of an ontology that cause it to be inconsistent (that is, multiple reasons for the inconsistency), there is still only a single inconsistency.

coupling of forms to the underlying ontology. This provides a certain level of flexibility in translating the form inputs into ontology constructs.[§] Additionally, it makes it possible to provide tighter constraints on form entry values without having to over-constrain or pollute the ontology with baroque modeling choices that do not necessary sit well with languages like OWL. One drawback of the loose coupling is that the person who configures the forms has to take some care in ensuring that the forms do not allow data to be entered that could be *inconsistent* with axioms specified in the underlying ontology. For example, a form that allows multiple distinct values to be entered for a functional property (single valued property) in the ontology would result in an inconsistency.

Preliminaries – The ICTM Content Model Ontology

The *ICTM Content Model Ontology*, developed by the HiM-TAG, and herein simply referred to as the Content Model Ontology, is an expressive OWL ontology. The main purpose of the Content Model Ontology is to provide a formalization of a "schema" for the data that is entered into the system as ABox axioms via the iCAT forms. It is used by the internals to actually store data and, to some extent, it is used to design and guide the construction of the forms that are displayed to end users who author content.

While the Content Model Ontology was initially fairly simple, it has evolved considerably since the project began. New versions of the Content Model Ontology have been developed as modelers have used the iCAT tool and the requirements of what has to be captured have become clear. A Content Model Ontology update cycle typically starts by subject matter experts indicating that they cannot specify the necessary details for some type of entity. For example, they might say that they cannot specify the location for a disease. Next, a discussion ensues with the ICTM working group and engineers about how the required information would be best presented (on a form) in the system. Based on this, the Content Model Ontology is then extended and updated to capture what can be represented. Finally, the forms are altered to enable new data to be captured.

Using Reasoning and Justification Finding for Quality Assurance

Having introduced iCAT and discussed the relationship between the Content Model Ontology and the Forms Configuration used in iCAT, we now present an exploration of using off-the-shelf reasoning and explanation generation technology that we believe is useful for debugging and carrying out Quality Assurance checks on the combined Content Model Ontology, entered data and Forms Configurations in iCAT.

The investigation is split into two experiments. The first experiment (**EXPERIMENT-A**) involved computing, examining and categorizing justifications for an inconsistent version of the ICTM Content Model Ontology plus data. The goals of this experiment were to answer the questions: Are there a large number of justifications for the inconsistency? Do the justifications have any regularities or patterns that can be exploited in order to triage the problem? What is the makeup of the justifications – are axioms in them purely TBox axioms, or a mixture of TBox and ABox axioms? (Justifications that only contain TBox axioms are highly likely to indicate problems with the Content Model Ontology alone, while justifications that contain a mix of TBox and ABox axioms could indicate a problem with the Content Model Ontology, Data, or both). The second experiment (**EXPERIMENT-B**) involved semi-structured interviews of people on an expert panel that was made up from the team of researchers/engineers that work on the design and evolution of the Content Model Ontology and forms in iCAT. The purpose of the interview was to determine the nature of the problems that cause the inconsistencies (whether the problems lie in the Content Model Ontology, the Data or the Forms); to determine how they would go about fixing the inconsistencies; and, to ascertain whether they believe that the techniques used are generally useful and could fit into some future tool chain. The goals of this experiment were to answer the questions: Do the justifications for inconsistencies indicate meaningful errors to the Content Model Ontology engineers and Forms Configuration engineers? What is the nature of the errors? Can the justifications be used to easily correct or suggest a strategy for correcting the errors? What do the Content Model Ontology engineers and Forms Configuration engineers think about reasoning and justifications as a way of pinpointing errors?

EXPERIMENT-A - Materials: A revision of the ICTM Content Model Ontology plus entered content (data) from May 2013 was used in the experiments that follow. The revision (Content Model Ontology with data) was found to be

[§] It is worth noting that this is rather different to Protégé 3 (desktop) forms generation mechanism, where the forms are automatically directly-generated from the ontology. In Protégé 3, there is a tight coupling between the "schema level" of the underlying ontology and the forms used for data entry. In WebProtégé, the loose coupling it makes it possible to provide highly customized layouts and simple widgets for editing multiple complex constructs, which is either not easy or not possible with the Protégé 3.

inconsistent during examination with the HermiT reasoner (version 1.3.8)[**]. It should however be noted that the Content Model Ontology alone (separate from the entered content/data) was consistent. All experiments were performed on a 2.2 GHz Intel Core i7 MacBook Pro, running Java 1.6 with 3GB of RAM allocated to the virtual machine. For computing justifications we used the justification finding library that is distributed with the Explanation Workbench plugin in Protégé 4.3. The library essentially implements a black-box justification finding algorithm[6].

EXPERIMENT-A - Methods: We computed justifications for the inconsistent ICTM Content Model Ontology plus Data. Given that inconsistent ontologies can typically have large numbers of justifications, we imposed a 30-minute timeout on the justification finding run. We sorted the justifications that had been computed, by eye, into categories according to similarity patterns – justifications that appear in the same category are structurally similar to each other, meaning that they are either isomorphic to each other[7] or that they only differ by a subset of axioms that are used to entail the same intermediate entailment/step that is necessary in some other part of the justification. For example, an individual can be entailed to be an instance of a particular class by a direct assertion, or it can be entailed to be an instance of the class by being an instance of a subclass of the class.

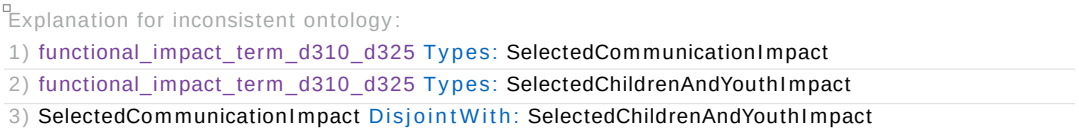

Figure 2(a) Justification-1. functional_impact_term_d310-d325 is an instance of SelectedCommunicationImpact (Axiom-1) and also an instance of SelectedChildrenAndYouthImpact (Axiom-2). However, these two classes are in fact disjoint with each other (Axiom 3), which makes the ontology inconsistent. Intuitively, an individual cannot be an instance of two disjoint classes.

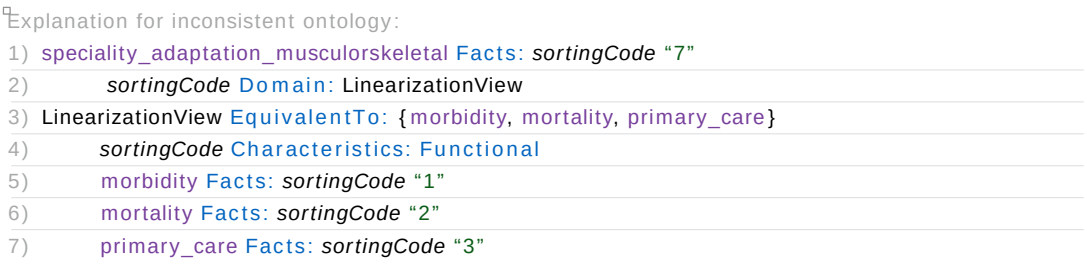

Figure 2(b) Justification-2. Recall that OWL does not have the Unique Name Assumption. That is, two individuals that have *different names* could denote the *same* object. In this justification, speciality_adaptation_muskuloskeletel is an instance of LinearizationView because it has a *sortingCode* (Axiom-1), and anything that has a *sortingCode* must be an instance of LinearizationView (Axiom-2). Furthermore, anything that is an instance of LinearizationView must be equal to one of morbidity, mortality, or primary_care (Axiom-3). Therefore, speciality_adaptation_muskuloskeletel must be equal to one of morbidity, mortality, or primary_care. However, speciality_adaptation_muskuloskeletel has a *sortingCode* value of "7". This means that it cannot be the same as any of these three individuals as any given individual can have at most one value for *sortingCode* (Axiom-4), and they each have a different value for *sortingCode* (Axioms 5-7). Intuitively, there are three possible values for LinearizationView, but other assertions contradict this and require a fourth distinct value (speciality_adaptation_muskuloskeletel). This makes the ontology inconsistent.

EXPERIMENT-A - Results: 621 justifications for the inconsistent ontology were computed within the 30-minute timeout (300 were computed within the first 5 minutes, with most being computed soon after, followed by a trickle of justifications in the remaining time). Browsing the 621 justifications (in the Protégé 4.3 Explanation Workbench) revealed that there were three main categories of justifications. The first category contains the single justification shown in Figure 2(a), the second category contains 531 justifications that are similar to the justification shown in Figure 2(b), and the final category contains 89 justifications that are similar to the justification shown in Figure 2(c).

EXPERIMENT-A – Analysis: A large number of justifications, 621, for the inconsistency were computed. Despite the large number, the justifications could be boiled down to *three distinct patterns*, indicating *three main kinds of*

[**] HermiT is an OWL reasoner that is bundled with Protégé. It is also available at http://hermit-reasoner.com. Note that we also used FaCT++ (https://code.google.com/p/factplusplus/) to double check that the inconsistency was a real inconsistency and not just due to a reasoner bug.

errors. It is worth noting at this point that some tool support for automating, or semi-automating, this process would have been extremely useful. However, after browsing the set of justifications for several minutes it became obvious that many of them followed common patterns. The main reasons for the large number of justifications in relation to the kinds of errors that can be observed are that (a) the Content Model is rather rich, meaning that there are many ways of entailing the same thing; and (b) the data (or entered content) is quite regular, meaning that the same patterns crop up over and over again, leading to many similar but distinct justifications. From Figure 2, it is noticeable that Justification-2 and Justification-3 are non-trivial and the ontology is inconsistent due to the interplay of many different kinds of axioms. The justifications *contain TBox axioms*, that are present in the Content Model Ontology, *and also ABox axioms*, that have been created via the iCAT tool (as data). Note that, although Justification-1 initially appears trivial, in the sense that it is straightforward to understand, it is highly unlikely that this could have been spotted by eyeballing the ontology. Finally, although it is possible to guess a repair for the inconsistent ontology from these justifications, in reality, some domain knowledge is required to understand where the problem really lies and to understand which axioms should be altered or removed.

Explanation for inconsistent ontology:

1) *factorBasedDiagnosis* Characteristics: Functional
2) influenza_A_H1N1 Facts: *exteriorOrInterior* exterior
3) *exteriorOrInterior* SubPropertyOf: *factorBasedDiagnosis*
4) influenza_A_H1N1 Facts: *yinOrYang* yang
5) diabetes_mellitus Facts: *yinOrYang* yang
6) *yinOrYang* SubPropertyOf: *factorBasedDiagnosis*
7) diabetes_mellitus Facts: *coldOrHeat* cold
8) *coldOrHeat* SubPropertyOf: *factorBasedDiagnosis*
9) *coldOrHeat* Range: ColdOrHeat
10) exterior Types: ExteriorOrInterior
11) ColdOrHeat DisjointWith: ExteriorOrInterior

Figure 2(c) Justification-3. influenza_A_H1N1 has a *factorBasedDiagnosis* value of exterior (Axioms 2 and 3), and a *factorBasedDiagnosis* value of yang (Axioms 4 and 6). Since any given individual can have at most one value for *factorBasedDiagnosis* (Axiom-1[††]). This means that exterior and yang is entailed to be the same individual. diabetes_mellitus has a *factorBasedDiagnosis* value of yang (Axioms 5 and 6) and a *factorBasedDiagnosis* value of cold (Axioms 7 and 8). Again, since any given individual must have at most one value for *factorBasedDiagnosis* (Axiom-1). This means that yang and cold must be the same individual. Since exterior is the same as yang and yang is the same as cold this means that exterior is the same as cold. Since cold must be an instance of ColdOrHeat (Axioms 7 and 9), exterior must also be an instance of ColdOrHeat. Since exterior must also be an instance of ExteriorOrInterior (Axiom-10), and ColdOrHeat is disjoint with ExteriorOrInterior (Axiom-11) this makes the ontology inconsistent.

Given the justifications computed in **EXPERIMENT-A**, three representative justifications, one from each category, were shown to the three members of the expert panel as part of a semi-structured interview in **EXPERIMENT-B**:

EXPERIMENT-B – Materials: A justification from each category was selected. The actual justifications are those shown in Figures 2(a) - (c). The set of guiding questions for the semi-structured interview is shown in Figure 3.

EXPERIMENT-B – Methods: A semi-structured interview based on the set of guiding questions presented in Figure 3 was conducted (by Horridge) with each participant on the expert panel. Each question in Figure 3 was asked with follow up questions where necessary to ensure the correctness in understanding of answers.

EXPERIMENT-B – Results: Three interviews lasted approximately 50 minutes, 40 minutes and 75 minutes. All participants described the ontology development process described earlier in this paper. None of the participants had used a reasoner during the evolution of the content ontology or for checking dumps of the Content Model Ontology plus data. *When asked to identify what would be a problem for the ontology, two out of the three suggested that logical errors, including inconsistency, would be problematic.* All of them suggested that incorrect classification of diseases etcetera would be problematic and that the long term goal is to eventually use reasoning to

[††] If a property is declared "Functional" this means that, for a given individual, it has at most one value. Multiple declared values will actually be entailed to be the same object. For example, in Figure 2(c), diabetes_mellitus essentially has two values, yang and cold, specified (via sub-properties) for the property factorBasedDiagnosis. Since factorBasedDiagnosis is functional, this means that yang and cold are entailed to be the same individual (same value). Note that OWL does not have the Unique Name Assumption hence, different names can refer to the same object.

assist the user in placing new terms into the class hierarchy. None of the participants had prior knowledge that the union of the Content Model Ontology plus the entered data was inconsistent. When presented with each justification, all of the participants were keen to understand what the problem was and all of them identified similar reasons for the problem. *All of the justifications indicated meaningful domain specific errors to the participants.*

For Justification-1 (Figure 2(a)), the participants identified either a possible problem with the modelling choices in the Content Model Ontology – in that the disjoint classes axiom should not be in the ontology – or some of them thought this might be due to a bug in the Form Configuration in iCAT. For Justification-2 (Figure 2(b)), all of the participants immediately identified the problem to be an issue with the Content Model Ontology. The EquivalentClasses axiom (Axiom-6) was introduced early on in the Content Model Ontology and was not updated as the Content Model Ontology evolved to represent more kinds of "linearization types" (instances of LinearizationView). Two participants said that the axiom should be updated and one said that it should either be updated or removed. Finally, for Justification-3 (Figure 2(c)), all participants spotted a problem with the Content Model Ontology, namely the functional property axiom (Axiom-1), which specifies that *factorBasedDiagnosis* is functional (single valued), should be deleted from the ontology. *All of the participants thought that the justifications were useful and the justifications identified significant errors in the Content Model Ontology*. For each justification all of the participants were able to suggest an initial possible repair to the Content Model Ontology or Forms.

General questions:
What was the methodology used for the development of the content model?
What was the measure of success for the content model ontology?
Did you use a reasoner (either during ontology construction or at runtime)?
What would be a problem for the content model ontology?
Would inconsistency or incoherence be problems for the content model ontology?
The ontology is inconsistent. Were you aware of this?

For each justification:
What do you think of it? What is your initial reaction?
Given the justification, can you explain what the nature of the problem is?
What kind of problem does it indicate?
How would you alter the ontology or data to fix the problem?
Would you change your modelling patterns as a result of this?

Finally:
Was this helpful as a QA exercise?
Would some kind of tool to assist help here?

Figure 3 – The guiding questions for the semi-structured interview.

EXPERIMENT-B – Analysis: Although one of the main goals of translating the Content Model to OWL and collecting the entered data as an OWL ontology was to have a more formal representation that could be automatically checked, this had not been carried out to date and was scheduled as part of future work in the project. None of the participants thought the Content Model Ontology would actually be inconsistent, and indeed, when taken in isolation, the Content Ontology Model is consistent. While some of the participants were initially surprised at this, when presented with the justifications they were able to quickly grasp what the problem was. In each case they were able to either immediately identify a way of fixing the problem themselves or they were able to identify a clear debugging/investigation strategy to be explored.

Two main categories of possible problems were identified: (1) *Problems with the content model* – the content model was deemed to be incorrect or buggy either because (a) it contained modelling slips, which had not been caught. In some cases the intended semantics were not the encoded semantics (for example the misuse of functional properties); or (b) because parts of it (in this case single axioms) were outdated with respect to an iteration in the evolution of the ontology. As stated previously, the Content Model Ontology evolves quite frequently and not all parts were updated to account for evolutions elsewhere in the ontology. (2) *Problems with the form configurations*. Ultimately, the forms accepted data that is inconsistent with respect to the Content Model Ontology (regardless or whether or not the Content Model Ontology is correct). In some cases for example, Justification-1, it was not immediately clear without further investigation whether the inconsistency was caused by a problem in the Content Model Ontology or by a problem in the Form Configuration in iCAT that allowed multiple choices for property values to be specified when only one choice should have been possible.

Finally, it was noticeable that all participants thought that having access to justifications was very useful (and interesting in itself – one of the participants would have liked to have gone through more justifications). They all

thought that this approach would prove quite valuable as a Quality Assurance procedure. All of the participants thought that some kind of tooling for use by Content Model Engineers and Form Configuration Engineers (as opposed to the subject matter experts who fill out details in iCAT) would be particularly useful.

Using Justifications to Repair the Content Model Ontology

For an inconsistency that can be traced back to problems in the Content Model Ontology, justifications for the inconsistency can be used to derive a repair plan for the ontology. A classic justification based repair requires all justifications for the problem in question: Given all justifications the simplest repair involves choosing one axiom from each justification and removing that axiom from the source ontology. Note that, this does not mean that for *n* justifications *n* axioms will need to be removed from the source ontology since justifications may overlap (share axioms) with each other. However, as mentioned previously, in **EXPERIMENT-A** not all justifications for the Content Model being inconsistent were computed. In this case it is necessary to perform an incremental repair – i.e. make changes to the ontology based on some axioms in *some* set justifications, next if the ontology is still inconsistent compute further justifications (which will not contain the justifications that were used for the repair), and repeat.

Given the descriptions of the problems provided by the expert panel we carried out a trial repair as follows. First, it was clear that the axiom LinerariztaionView EquivalentTo {morbidity, mortality, primary_care} was incorrect. We therefore removed this axiom from the Content Model Ontology (as suggested by one member of the expert panel) and recomputed the set of justifications. In this second round, 234 justifications were computed within a 30-minute timeout (with the majority being computed within 5 minutes). Most of these justifications were of the same form as the justification shown in Figure 2(c) and 233 of them contained the functional property axiom that makes *factorBasedDiagnosis* functional (single valued), which we chose to remove. We then recomputed the justifications again. This time, only 1 justification was computed – the justification shown in Figure 2(a), and we chose to remove the DisjointClasses axiom, which fixed the ontology so that it became consistent.

Discussion

The importance of detecting errors in ICD-11 and ICTM: The errors found in this case study were caused by errors with the ICTM Content Model Ontology, which the interview participants thought were genuine and significant. While ICTM and ICD have been under construction in iCAT for a period of time, it was a recent evolution of the Content Model Ontology where the inconsistency surfaced. Although the particular errors did not cause a specific problem with data entry via the iCAT forms at the time, it is arguable that maintaining a consistent Content Model Ontology is vital for the purposes of future proofing development and for preventing errors from creeping into Forms Configurations. Moreover, the success of the reusability of ICD-11 by other (OWL aware) software systems would be significantly impacted if the combination of the Content Model Ontology and data were inconsistent. Since one of the primary goals for ICD-11 is to achieve greater interoperability between software systems that use ICD-11, we consider a consistent Content Model Ontology and data to be of fundamental importance.

The importance of OWL reasoning and justification finding services for debugging ICTM: All of this work relies heavily on OWL reasoning and some kind of justification finding service. This was picked up by one of the interview participants who pointed out that it is highly unlikely, to impossible, that the errors would have been detected without using these technologies. Although they had not thought about using this kind of technology (particularly justification finding) for debugging and Quality Assuring ICD before, all of the participants thought that it was very useful for being able to identify and resolve these kinds of errors and saw genuine value in the technology going forward.

Using Justifications for Repair: The previous section describes a possible repair based on the computed justifications (i.e. which axioms to remove or edit in order to achieve consistency). While the decision of which axioms to alter or remove required the input from the expert panel – that is, people who are familiar with the domain, the use of justifications ultimately guided us in pinpointing the causes of the inconsistent Content Model and data, and also provided some guidance as to what a repair might be. Despite the very large number of justifications that were initially computed, it was not necessary to analyze them one by one in order to formulate a repair plan. Furthermore, it was not necessary to compute *all* justifications for the repair to be successful – an incremental repair was entirely satisfactory. It is worth noting that for this simple repair, we chose to modify the Content Model Ontology rather than the Forms Configuration – happily, this only required a few axioms to be touched. However, any ABox (instance assertions) axioms that appear in a justification could indicate problems with the Forms Configuration and provide a starting point of how to alter the Forms Configuration so that further data entry does not make things inconsistent.

Checking Form Configurations in advance: In our case study of ICTM, the Content Model Ontology by itself was consistent. It was only the combination of the Content Model Ontology and form data that was inconsistent (although the problems mainly originated from the Content Model Ontology). We only detected this inconsistency after "live data" had been entered into iCAT. Ideally, since forms should enforce consistency, it would be nice to have an *automated* testing tool that could detect any potential form configuration issues before forms "go live". While this could be tested by entering random data into the forms on some kind of staging platform and then inspecting the result, a smarter and more automatable strategy would be to generate an OWL ABox (instance assertion) representation of the forms and form data. These ABox statements could be generated automatically by examining the form structure, which could be obtained by parsing the form markup language. Since it is possible to map automatically generated ABox statements back to form widgets, any justifications for inconsistencies which contain these ABox statements could be directly used to highlight the parts of the form that cause the problems.

Taking the existing tools forward: The tools that we used in this work are essentially off-the-shelf OWL reasoning tools, which have been available in editors such as Protégé-4 for several years. While we foresee a situation where this tool chain will be used by expert administrators to debug the Content Model Ontology, it would be nice to have a single testing tool that integrates the tool chain into a single testing utility. Such a utility could provide a summary of the hundreds of justifications that get computed by using some kind of lemmatization strategy[8], or by using different notions of justification isomorphism[9]. Finally, a more advanced tool would have the ability to check forms prior to deployment and identify parts of forms that would cause a disparity (manifested as an inconsistency) between the entered data and the content model ontology. Such a tool could even suggest a variety of repair plans that the user might want to consider.

Generalizability and applicability to other medical ontologies: While we used ICD-11 Chapter-24 (traditional medicine) as a case study, it is likely that the techniques presented here should generalize to the complete development of ICD-11. In principle, the techniques used in this paper could also be generalized to the form-based editing of other medical ontologies where there is an underlying template (Content Model) ontology. While the content model is specific to a particular chapter of ICD-11, WebProtégé (on which iCAT is based) is a domain independent ontology editing environment. In terms of scaling the approach to much larger ontologies, such as the whole of ICD-11 (or other ontologies such as SNOMED-CT or the NCI thesaurus) there are three things to bear in mind: (1) In practice, the justification algorithm runtime performance does not directly depend on the size of the ontology[6] – It actually depends upon the number of justifications for a given entailment. While, in the theoretical worst case, the number of justifications is exponential in the size of the ontology, in practice, this is not the case and for most ontologies it is practical to compute all justifications for a given entailment; (2) Even if the *total* number of justifications is large, it is not necessary to compute *all* of them in order to carry out an interactive repair (simply seeing a handful of justifications was very informative in this case); and, (3) Even if the number of justifications computed is large, as was the case here, regularities, and the justificatory structure can be used to identify key patterns and problems and can be used to initiate a repair.

Related work: This project is not the first to use automated reasoning to assist in the construction of large medical ontologies. The ability to use reasoning as a kind of "complier" for medical ontologies was harnessed many years ago in the GALEN project. However, rather than being used as a debugging aid, the primary use of reasoning in GALEN was to compute an implied hierarchy and drive the end application Pen&Pad[10]. In work by Suntisrivaraporn[11] justification finding was used to explain subsumptions in the SNOMED-CT class hierarchy. The explanation tool in Suntisrivaraporn's work would theoretically be invoked by end users browsing SNOMED-CT who want to understand the reason for a particular subsumption (in a consistent version of SNOMED-CT). In contrast, we make use of the consistency checking during development to *directly flag errors*, indicated by inconsistencies, in the ontology plus data. We then compute the source of these errors using justification finding and use the computed justifications to point to whether the errors occur in the Content Model Ontology or the entered data. In recent years ontology quality assurance has become a hot topic, particularly in the area of bio-medical ontologies. Indeed, the Journal of Biomedical Informatics has devoted a special issue[12] to the problem. Rogers[13] presents a good overview of the quality assurance of medical ontologies.

Conclusion

Representing the ICTM (and ICD) Content Models in OWL was stated to have several benefits, one of which was that it would make it possible to use automated reasoning and error checkers to perform consistency checking and spot errors in the classification. In this paper we have successfully used automated OWL reasoning to detect inconsistencies in the union of the Content Model Ontology and the data entered into the ICTM authoring tool

iCAT-TM. We used an off-the-shelf reasoner to check consistency and used an off-the-shelf justification finding library to generate explanations for these inconsistencies. The justifications helped pinpoint and fix the causes of problems, which were identified as genuine problems by Content Model and Forms Configuration engineers. Whether the root of the problems lies in errors in the Content Model Ontology, or the Forms Configuration, the computed justifications make it possible to identify either a part of the Content Model Ontology that needed fixing, or narrow down the possible causes to a problem with interplay between the Content Model Ontology and the Forms Configuration. Without the use of automated reasoning, the inconsistency of Content Model Ontology plus data would not have been detected. Without the use of an explanation generation library to generate justifications, it would have been impossible to track down the reasons for the inconsistency.

All in all the use of OWL, automated reasoning, and non-standard reasoning services such as justification finding helped detect and debug errors in ICTM (and ultimately ICD-11). It seems promising that these tools could form part of a tool-chain that could be used to check Content Model Ontology and Form revisions before they are deployed in the runtime system. It also seems possible that such a tool chain could be used to regularly check for conflicts between the Content Model Ontology and data entered into the iCAT tool both as the Content Model Ontology evolve and the collected data grows.

Coordination of Care for Complex Pediatric Patients: Perspectives from Providers and Parents

Jan Horsky, PhD[1,4], Stephen J. Morgan, MD, FAAP[1,3,4], Harley Z. Ramelson, MD, MPH[1,2,4]

[1]Brigham & Women's Hospital, Boston, MA; [2]Partners HealthCare, Boston, MA; [3]Massachusetts General Hospital, Boston, MA; [4]Harvard Medical School, Boston, MA

Abstract

Coordinators help patients requiring complex chronic care manage frequent ambulatory visits and services received at home or from community-based agencies. EHRs directly support only a few of the required tasks as they do not allow access to all parties involved in care. Our goal was to examine how technology was used to coordinate efforts and to describe common barriers and facilitators. Insights may inform the design of tools that would effectively support identified goals. We conducted five hours of interviews with sixteen parents and six clinicians and characterized emergent themes from transcripts. Situational awareness, care and visit planning, document aggregation, abstraction and interpretation were tasks essential to coordination yet generally poorly supported by EHRs. Providers communicated primarily by email, telephone and by exchanging paper and scanned documents. A preliminary model of coordination that could be used in the planning and testing stages of a User Centered Design process is described.

Introduction

Inadequate coordination has been identified as a significant impediment to effective care,[1, 2] contributing to increases in costs and negatively affecting quality.[3-5] As specialist care is increasing and accounts for more than half of all ambulatory visits, teams consisting of several providers located at different institutions are common.[6] Patients with multiple chronic conditions may visit up to 16 physicians in a single year.[7] Each provider often needs to review results, findings, relevant patient history and other information gathered by the others in order to make care decisions. Exchange of information across technological and institutional boundaries, however, has been a time-consuming, complicated process fraught with care delays, duplication of effort and a source of frustration.

Most currently available electronic records systems (EHR) do not support coordination and collaboration among caregivers adequately.[8] A survey of clinicians using vendor EHRs found that the technology provided only limited support for many common coordination tasks.[9] For example, an accurate, updated list of care team members is not yet widely available.[10] The low prevalence of this resource in current systems is reflected in the modest requirement by the Office of National Coordinator (ONC) to maintain such lists for at least 10% of patients in order to receive Meaningful Use Stage 2 certification.[11] The referral process for specialty care is often described as a frustrating series of disjointed phone calls, faxes and mail that may result in delay, lapses and duplication of effort.[12]

Care for patients with chronic conditions, especially congenital and childhood-onset diseases, is highly complex, involves non-medical professionals and requires significant involvement of patients and their family members. Coordination, characterized as a flow of information between providers to ensure that they all act toward a common goal, encompasses health services such as ambulatory, hospital, post-acute and home care, and social support services from state, community and private organizations.[13-16] Vendors have so far not adequately addressed the limitations of EHRs in supporting coordination beyond institutional boundaries.[17] Professionals providing patient care and services therefore need to rely on other technologies to communicate[18] and often turn to web-based applications to improve the process.

We conducted a qualitative study to gather and analyze insights from clinicians, coordinators and parents of children with multiple chronic conditions to formulate a preliminary model of care coordination intended to inform the design of electronic support tools. It models information needs and flow between participants, describes common technical and organizational barriers and outlines the complexities of information exchange that advanced software tools will need to support. Studies of similar scale and purpose are usually performed in the initial phase of a User-Centered Design (UCD) process[19] as necessary precursors to functional and design specifications that are sensitive to appropriate fit to task and clinical context. UCD is established in software development as a robust, reliable process across many industries and has recently been required for HIT design under the 2014 Meaningful Use Act.[20, 21]

Methods

We interviewed twenty-two individuals at two institutions affiliated with a large urban healthcare delivery network in five sessions lasting an hour each. Two primary care physicians and one nurse practitioner were interviewed individually and a primary care physician, a social worker and a coordinator as a group. Sixteen parents of children with multiple chronic problems formed a focus group during their scheduled monthly meeting. The interviewer asked open-ended questions intended to elicit descriptive narratives about their routine tasks and activities in coordinating care for their children. Participants were encouraged to describe facilitators and barriers to effective care management, their most frequent modes of communication and to give examples of the types of documents they gather, receive, store or exchange with other parties, including patients and their families. The interview structure was gradually adapted over time to focus on salient themes emerging from preceding sessions and to follow up on specific topics. Interviewees were selected as a sample of convenience but attention was given to including providers from both hospital and community settings in order cover a broader set of personal perspectives.

All sessions were recorded, transcribed and analyzed using NVivo 10 software.[22] Codes were developed and refined in three iterations by one investigator in which statements representing discrete meaningful concepts were either aggregated into broader categories based on similarity or differentiated into more descriptive units (axial and selective coding).[23] The final structure was reviewed and refined in two consecutive sessions in collaboration with a second investigator.

We analyzed all transcripts by using a constant comparative method[24] that involves identifying ideas in discrete statements (units of observation) and aggregating them into sets. This method produces categories derived from the participants' expertise and language and those the researcher identifies as significant to the focus of inquiry (e.g., coordination, communication). The goal is to develop theoretical insights into processes that characterize the flow of information and construction of goals in a socio-technical system (STS).[25] The sociotechnical framework was used to interpret and analyze the findings as components of goal-oriented activity that encompasses humans, technology and artifacts.[26]

Interview analysis

We identified and coded statements about roles, communication and information technology and characterized actors, technological agents and artifacts. For example, we analyzed accounts of compiling, abstracting, and interpreting information from visit notes and other sources routinely done by physicians and administrative staff in order to update patients on the course of treatment and to plan future tests and visits. Analysis of the parent focus group followed themes that were unique to their experience and those that provided their perspective on processes and issues identified in interviews with providers.

Results

Descriptive and analytical results from the interviews are described below. We identified main participants in communication and information exchange (parents, families, care and assistance providers), technology (EHR, email, mail, phone, fax) and goals and activities characterizing coordination (aggregation, abstraction, interpretation, visit planning, situational awareness, care planning, medications and problems). We also describe how these findings would inform the design of software tools for coordination.

Patients and families

Families with children who had three or more chronic problems or disabilities requiring frequent treatment and continuous care were assisted by coordinators whose task was to manage most communications with the care team, interpret and clarify medical findings provided by specialists and advise parents on the progress of care and next steps. For example, one coordinator described the treatment complexity of most patients as "having four to five subspecialists who are seen regularly every few weeks to every few months; almost all having physical, occupational or speech therapy." Parents were regarded as the main source of information about previous care and as agents who maintained contacts to community-based assistance providers and mediated the forwarding and transferring documents between offices and agencies without direct formal affiliation. However, primary care providers and coordinators actively maintained communications and activities for those not able to carry out the tasks themselves.

Role	Description
Primary Care Physician	Located in large care centers or in patient's home community
Specialist Physician	Affiliated with hospital network or in independent clinics and offices
Nurse	Clinic, community, school, home care workers, visiting nurses
Therapists	Physical, occupational, speech, and specialized forms of therapy
Administrator	Supports PCPs and other clinicians in care management.
Coordinator	Services and care coordination at clinics, state and private agencies
Social Worker	Services and management at hospital centers and state agencies

Table 1 Roles of collaborating professionals

Parents described similar levels of care complexity as did clinicians and coordinators although individual experiences varied. Several parents reported receiving care regularly from about ten providers, "six of them out of the system," and worked extensively to maintain communication and timely updates. Their frequency of visits was typically "between six times a month to about five times every two months, with physical therapy sessions occurring several times per week." Collectively, they expressed the feeling of "being intermediaries, especially for episodic care like ED visits," or "being the clearinghouse for information," closely echoing the perceptions of clinicians.

Care and assistance providers

Medical care providers were either co-located in one physical setting (e.g., a hospital or a clinical center) or had private offices in other locations, sometimes in a patient's home community. A list of professional roles of care givers participating in coordination activities, as described in the interviews, is in **Table 1**. Those affiliated with the same care network shared an EHR system although some records such as emergency department visits, discharge summaries or specialty visit notes may have been stored on non-integrated systems and therefore available only to some clinicians. Primary care physicians (PCP) provided routine care and either communicated with a coordinator or assumed the responsibilities of a medical home. Nurses provided care at clinics, patient homes (visiting services) or at schools, therapy centers or other facilities and organizations. Providers not directly affiliated with the network generally maintained their own notes and gave occasional updates to a PCP. There were several coordinators of clinical care and of social services who worked at state agencies (e.g., Departments of Social Work, Early Intervention, Families and Children, etc.) or at community support centers, schools and other institutions. Their contact with PCPs and hospital-based care coordinators and social workers was primarily through email and telephone. Several parents noted that their PCP was not central to coordination and mostly "was there for your typical colds and well visits." However, this arrangement required them to do more information forwarding and updating as "all specialists refer you back to your PCP."

Communication and information technology

Coordinators and providers relied primarily on email, phone and mail to reach others across institutional boundaries. These forms of communication were often inadequate, laborious and time consuming, requiring extra and duplicative effort to manually update electronic records and private notes. For example, information circulated by mail was not always received or reviewed in time to effectively support face-to-face conversations and maintain situational awareness. As one coordinator explained, "if I have a question, I'll call the PCP and he says that we didn't receive a letter from you although I sent it the day after I saw the patient. They may be too busy to follow up with us." Specialists who did not have access to a shared EHR had difficulties forwarding information such as visit notes and records of prior care. They often scanned documents to a PDF and emailed them or used a fax or the mail.

Delays and other complications resulting from slow communication sometimes affected care decisions. Several parents whose children received immunizations, sick and other routine care from PCPs in their community and more extensive chronic and specialty care at hospital network centers decided to transfer all their care to the centers even if it entailed more travel and time. However, coordination and communication between the providers became less problematic as a result. A coordinator noted that "this may not be the case if we were able to communicate better."

All interviewed professionals expressed a strong preference for a common electronic platform that would accommodate automated updates of such basic information as contact records and also clinical and other personal data for the entire team, including patients and their families. According to one social worker, "just knowing who is

Technology	Limitations
EHR System	Limited to affiliated providers only. Duplicate sets of data need to be maintained separately by other parties.
Email	Bridges institutional boundaries but is often a poor workflow fit. Group conversations are difficult to maintain and security and privacy is a concern.
Mail	Substitutes for lack of interoperability. Extra work is needed to abstract data for coded entries into an EHR.
Telephone	Poor support for group decision making. Synchronous conversations do not often fit into workflows.
Fax, PDF	Documents are mostly not searchable and need to be abstracted for EHR use.

Table 2 Communication technology

on the team is a huge challenge for parents and also for the vast army of involved people, the folks that help the children at home, physical therapists, early intervention people, the school nurse, probably the teachers and others." This frustrating situation was described by a PCP who noted that "reaching out to the community side, agencies responsible for approving equipment the patient needs, finding out what letters need to go with that and recording it is enormously laborious." A list of the most frequently used communication technology and its limits for documentation exchange, as described in interviews, is in **Table 2**.

Direct access to selected information by patients and family members was considered essential for reducing their dependence on mediation by clinicians, coordinators and social workers. For minors, elderly patients and those without computer skills, "care planning still has to be done the old fashioned way, either in person or on the phone," according to one PCP. However, many others would benefit from direct access and could update or correct information and be more engaged in their own care.

Care coordination

Activities directly associated with care coordination that were discussed in the interviews were, a) *aggregation* of documents and information, b) *abstraction* of key events from charts for EHR entry, c) *interpretation* of medical findings and advice for patients, d) scheduling and tracking of referrals and *visits*, e) maintaining long-term *situational awareness*, f) development and updates of *care plans* and g) maintenance of medication, allergy and problem *lists*. The associated tasks and activities are summarized in **Table 3** and described in detail in the sections below**.**

Aggregation

Before the first visit of a new or a transfer patient, administrators, nurses and coordinators collected all available electronic, paper and scanned documents they were able to obtain from prior and current providers. Patients or their families were central to this process as they often provided names, contact information and key dates although missing information still had to be identified and added. Some PCPs were able to "off-load much of this information gathering" to staff but for very complex patients or those with cognitive impairments clinicians had to "figure out who in their life are key people who could help with information." However, this process was time consuming and incurred considerable delays as information arrived through the mail as paper documents or printouts of electronic notes from systems that were not interoperable. As one coordinator noted, "you may have seen the child a couple of times before the records arrive and that is incredibly frustrating for parents."

Abstraction

Physicians often had to abstract, compare and summarize from multiple records core health problems, patient history, prior treatment and procedures and to identify information that is missing or requires updates and more detailed description. This work had to be completed by clinicians (often the PCP) rather than support staff. As a coordinating physician noted, "it means that I have to hunt through hundreds of pages and find what's important although summaries may exist for some patients in a one or two page document that has all the key information in one spot." Direct phone conversation with identified referring physicians can sometimes clarify "what the key issues, hospitalizations and problems are" if the record is too extensive to review.

Patients receiving complex care had a large volume of records of which only a fraction – those generated by providers from the same care network – were electronic. Very frequently, documents were forwarded across settings in scanned PDF files that could be "hundreds of pages long" and from which "immunization record,

Activity	Description
Aggregation	Compile records generated by clinicians, professionals and family across all settings.
Abstraction	Identify and summarize key points from extensive records of prior care.
Interpretation	Collate and interpret visit notes for patients, clarify results, requirements and next steps in care.
Visit planning	Initiate and track appointments, test, consultations and referrals.
Situational Awareness	Maintain awareness of new events, care progress, upcoming and missed visits.
Care Plan	Individual course of interventions, monitored for situational awareness.
Medications, Problems	Reconciliation of lists at hospital and community locations.

Table 3 Activities associated with care coordination

operative, advanced directive and other things I will need to search for" had to be extracted and the information entered in a coded form into the EHR. PDF documents were mostly not searchable automatically. Paper charts, forms, documents and even printouts from systems that were not interoperable were routinely scanned and entered into EHRs as attachments to clinical note entries.

Abstraction and comparison of documents from multiple providers was also done to reduce redundant or conflicting recommendations. A physician noted that "I want to know what the social worker has done so that I'm not asking the same battery of questions and recommending the same services already put in place." As the notes were coming from many different sources "it took a long time to do our homework – there is no one place to read all of this."

Interpretation

Clinicians and coordinators compiled and interpreted for patients and their families important findings and instructions from numerous specialist and procedures that were not well understood during the visit, either for their complexity or the sheer volume of information. Coordinators typically talked to a patient after three or more medical visits have taken place (often on a single day), "collating who they saw and what that person wanted to happen next" and to "look at the big picture of who recommended what, and to synthesize information." This overview often generated further queries to the providers to confirm particular requirements or to get more detailed instructions. For example, a coordinator noted that "I can address any mismatches or ask questions – if the cardiologist said this patient needs to have a catheterization I can make sure that the patient understood it." Patients or parents often asked coordinators to follow up with questions they did not raise during visits for lack of opportunity or understanding. A coordinator noted that "it took a lot of emailing behind the scenes to get a sense. For example, if a kid was started on new epileptics, are they supposed to be seizure-free or are we hoping for a 50% decrease? What's the time period that you would expect this, what are the side effects and can he continue to go to school?"

Visit planning and referrals

Patients typically needed to schedule and keep regular appointments with four or more sub-specialists, therapists, social workers and other assistance providers. Coordinators helped patients navigate new environments such as large hospital and clinical centers so that they did not get "overwhelmed by the volume of information and moving parts" and called and emailed multiple providers to arrange visits so they to co-occurred on the same day in one location. In some cases, complex scheduling was arranged by a dedicated service center available at the hospital. When patients did not have access to a coordinator, their PCPs had fewer opportunities to call and schedule multiple visits, so often "the parents were pretty much on their own for making those appointments." Knowing which appointments needed to take place, what procedures or tests will need to be done and coordinating planned care was essential for avoiding redundant visits or missing some due to conflicts.

Tracking visits and their outcomes was difficult, required careful planning and active outreach to providers to find out whether an appointment did take place and what were the next follow-up steps. For example, a coordinator noted that "a large proportion of all referrals never actually get completed and without proactively keeping track I can't assume that they were done." The EHR was considered to be only marginally useful in displaying scheduled and missed appointments as many specialists did not share the same system. A physician described the task as "actively, manually tracking what are the specialties and clinics, who needs to follow up with them and when."

Reasons for missing appointments varied widely but coordinators felt that they could effectively intervene to prevent some of those if they were sufficiently informed of the situation. For example, a social worker noted that families needing transportation services from a state agency may "miss six appointments in a day if the required paperwork did not go through." A more effective, integrated communication system may allow coordinators to notice such gaps and contingencies and act in time to make sure that medical care can be provided or rescheduled.

Situational awareness

Awareness of activity and communication taking place in a socio-technical system is essential for understanding how events and actions of all agents – human and technological – affect current personal and common objectives and future plans. The design of most EHRs generally does not allow clinicians to maintain this level of activity awareness, especially across different institutions.[27]

A physician described updating others on the same care team about planned actions: "After a patient visit I usually talk to their various other providers to make sure we're all on the same page." There was no central place to "see the care team and when they want to see the patients next and what the active issues are." The physician had to recreate the sense of the current state of care from "looking at notes," a time-consuming task of aggregating and reading through electronic and paper records and emails. Coordination of tasks for very complex patients required in-person meetings and appointments with patients to "go through all of the specialty visits, answer questions, think ahead and troubleshoot any care deficits."

Workarounds were devised by coordinators to keep them informed about unscheduled events, underscoring the inadequate support for this task by their EHRs. For example, the IT department developed by request an email service to automatically generate an alert message when patients on a tracking list were admitted, discharged or seen at the emergency department or same-day surgical units. Events and visits taking place outside of the hospital network, however, could be tracked only if patients reported them. Another repurposing of email to remind about future events, as reported by a physician, was to set up messages to arrive on days of important follow-up appointments and to "call afterwards to make sure that they went." However, this strategy was not suitable for tracking a large number or frequent visits. The physician in such cases required patients to "come back and figure out if they've missed things – but I can't be calling." Sub-specialists would sometimes notify PCPs by email about missed care and then "somebody would reach out to the family."

Poor situation awareness and event tracking may contribute to adverse events resulting from missing or delayed care. A physician reported that "one of my patients didn't go to catheterization because they didn't understand the conversation with the cardiologist and I didn't know about it, then the patient got hospitalized." Tracking abnormal radiographs and tests was also seen as a recurring problem with many opportunities for omission.

The lack of reliable, integrated information sharing between medical and non-medical care providers confounded situation awareness for the entire team. Most communications took place through email, over the phone or by postal service, requiring secondary manual documentation and updates. Non-medical events with the potential to negatively affect care were difficult to discover in time to intervene. For example, a physician may learn about a change in a patient's social services or about serious incidents "only if the family informs me or if someone from DPH tries to contact me, but that hasn't really happened." In cases where children are "moved to a different home or foster parents" their local records may not be transferred with them. As one PCP noted, "when they come back in 2 or 3 years, I don't know what happened, did they get their vaccines, etc. It takes digging into records and talking to the social workers and getting all that information."

Coordinators or primary care physicians usually received information from social and community workers only "on demand" and in case of serious problems when "they will reach out to us to come up with a plan together." Several clinicians thought that "sometimes folks in the community feel very disconnected from teams at the hospital" and that better access to shared records would benefit all involved and allow them to make better decisions. Some questions from patients could be directly answered by the most appropriate person rather than being mediated by physicians. For example, families now approach their primary care providers for "community related things like they need to know how to get a wheelchair, ramp, accessible housing, transportation, a better day program and a host of other non-medical things. Finding out which case worker needs to know that a request for equipment was filed is very time consuming."

Communicating with patients is often done through secure email and then documented by "copying all the emails to the chart." Some physicians felt that it is currently difficult to extend or route these conversations to those who can provide the best answers such as "administrators, nurses, social workers and the other people on the team."

Parents noted that they often need to actively monitor their own care and recognize that certain events should take place which could be difficult for very complex treatment plans. An automated system of reminders about "appointments or blood draws that they have to do through email or something outside of their own scrap paper" was regarded as highly desirable.

Care plan

As the number of problems, providers, and sites increase, overall coordination of different provider-specific treatment plans, discipline-specific plans of care, and the production of a master care plan are needed.[28] Physicians providing primary and specialty care as well as therapists develop their own respective plans that need to be monitored for progress and completion of goals and adjusted if necessary. Core information from plans such as due dates, missed and achieved goals and new or unplanned events are important components of situational awareness. Coordinators needed to review and monitor this data periodically in order to take appropriate action. This function was approximated by reviewing notes to "figure out if they haven't seen some person, are due for something, or there are upcoming things involving patient care." The process had almost no support by information technology. A physician reported that "I can put one concrete piece of plan in a clinical message to my nurse and the nurse can call but if my plan is complex and evolves through a discussion then I need to do that myself." Email and phone communication, however, was ineffective for team discussions and real-time updates as "there are so many points where any little thing can slip up that will erode that communication and it can be disastrous sometimes."

Increased situational awareness may improve appointment scheduling, event prioritization and better responsiveness to emergent care needs. Such system, however, would need to bridge the existing electronic boundaries delineated by limited access to shared electronic information and replace the often poor workflow fit of email and phone communication with more appropriate forms. A parent noted that they felt as if long-term planning was not prioritized or well maintained by anyone. For example, "I don't feel that there is a management system for the long term things; critical care is well managed and followed up, but it's up to me to figure out what needs to be taken care of next and send emails so that it doesn't fall off the radar screen."

Medication and problem lists

Lists of currently active and prior medications and problems were usually maintained by the primary care physician on an EHR. Care providers in the community such as visiting and school nurses administered the medications and kept their own records. Although dosing changes and substitutions need to be approved by a physician, central updates and reconciliation of lists was usually done at intervals coinciding with visits that sometimes substantially lagged behind actual events. As reported, many reconciliations took up patient visit time that would be otherwise focused on care issues. For example, patients may have a medication list from visiting and community nurses and the primary care physician "hopes that when they come in, it matches mine, but most of the time it doesn't so the majority of the visit is spent reconciling medications." Reconciling over the phone may "take 20 minutes or so" and fax communication may never close the confirmation loop if not returned in time.

Parents acknowledged that from their experience, reconciliation was a laborious and often imprecise process. For example, one parent reported that "it's painful; they ask you to verify it and I see the same things that we told them the last time to take off the list. Something was prescribed two years ago by a specialist and then it just sits there on the list of your standard medications."

Differences in separately maintained lists could be substantial if a primary care physician sees a patient once every 2-3 months. Updates accumulated over time between home, school and hospital discharge lists may take several hours to complete, especially with patients who may be taking 40 or more medications. A more efficient way to update lists electronically and to propagate changes to all when they occur was a common request by all interviewed coordinators and physicians.

Care coordination model

A web-based tool would need to support, at minimum, the following tasks and activities: increased situation awareness by allowing plan, visit and event tracking, allowing medication and problem list updates via secure email

and embedded links, provide a two-way patient-facing portal for care instructions and requests and integrating updated information such as medication changes with the primary EHR after a reconciliation and confirmation process. We hypothesized that while it was unreasonable to expect that all participants would be willing to change their preferred workflows to navigate to a common website in order to communicate with others or update shared lists, they would likely respond to email prompts with one-click links to give and receive information updates that would be valuable for their own work.

Figure 1 Model of possible integration with existing technology

A model of possible integration of a coordination tool with EHRs at separate institutions and with direct access from patients is in **Figure 1**. EHRs at hospitals and clinics can implement basic interoperability of medication, problem and contact updates through email links, state agencies may exchange electronic forms, community and visiting nurses can update medications through email automation and patients can review care instructions and educational materials online. Participants may copy emails to others on a shared server and update their contact information. Electronic forms can support semi-automated entry of coded information through text processing and confirmation.

Discussion

The core themes about barriers to effective care coordination that emerged from the interviews showed that lack of integration and system interoperability within and primarily across institutions and professions adds considerable effort to the work of most clinicians and providers of services. Real-time situation awareness that is indispensable for the coordination of actions and reduction of duplicative effort is difficult to derive from existing fragmented and mixed use of electronic and paper documentation. Compiling, tracking and following up on events across the medical-social services boundary was the most challenging part of coordination as the EHR – virtually the only shared electronic resource – does not extend outside of a network of affiliated clinics and offices.

Clinicians and assistance services managers disproportionately relied on paper or scanned documents when information had to be sent to others on the care team. However, it seems that many transactions (e.g., requests for

standard social services or medical equipment approvals) used paper forms and collected fairly structured information that could be easily replicated in electronic form. We also noted that some tasks described as having no electronic support could in fact be accomplished with existing systems although some clinicians were not aware of the possibility.

Our results correspond with previous reports about inadequate EHR support for team-based chronic care management and that monitoring, plan feedback and assurance that plan components were completed are core requirements for effective coordination.[29] Our model, however, outlines the necessity to integrate non-medical professionals with the care team more closely. We also propose that improvement of EHR design alone can benefit only those clinicians who have access and that bridging communication gaps to care and service providers outside the network may require innovative approaches that integrate several technologies such as web and email-based forms and include interoperable connections between different EHR systems.

We formulated design advice and proposed a model primarily to support the work of care coordinators serving as liaisons between patients requiring complex care and the care team. Primary care physicians with responsibilities to maintain a medical home may also benefit from a similar system that is tightly integrated (e.g., as a module) with their EHR. They often take care of young adults who have transitioned from specialized pediatric care centers but may require as much coordination as before without adequate staff support.

Limitations

This study was conducted on a scale that may not be sufficiently large for generalization or validation of the coordination model as a comprehensive and predictive construct. It was intended, however, to give adequate understanding of the needs of patients, clinical and other professionals involved in the process of chronic care as a pre-requisite for the design of an advanced electronic coordination tool. Studies of similar size are commonly done in the first, planning stage of a user-centered design process and give informaticians and designers insights into unmet needs, communication and information flow complexities and requirements that the software will need to support and accommodate. Our methods and results should serve as valid reference and a comparison points to investigators and developers engaged in the design of similar electronic tools and looking for guidance.

Acknowledgment

This work was supported by a grant from Partners-Siemens Research Council. We thank the clinicians, coordinators and parents who shared their expertise and experiences with us and generously gave us their time to be interviewed.

Abstract

As the obese population is increasing rapidly worldwide, there is more interest to study the different aspects of obesity and its impact especially on healthcare outcomes and health related issues. Targeting non-surgical times in the operating room (OR), this study focuses on the effect of obesity along with clinical factors on pre-incision times in OR. Specifically, both the individual and combined effect of clinical factors with obesity on pre-incision times is studied. Results show that with the confidence of 95%, pre-incision time in the OR of obese patients is significantly higher than those for non-obese patients by approximately five percent. Findings also show that more complex cases do not exhibit significant differences between these patient subgroups.

1. Introduction

The International Obesity Task Force estimated that 300 million people worldwide are obese and 750 million more are overweight. Thirty percent of adults in the United States are obese (Source: CDC National Center for Health Statistics), and 20.6% of U.S. healthcare expenditures are coming from additional medical spending as a result of obesity[1]. These expenditures account only for the direct costs of medical spending as a result of medical visits, and prescription drugs. The indirect and hidden costs that obesity imposes on healthcare systems need to be further analyzed and investigated. The operating room (OR) is considered to be the most expensive resource to keep open and the most profitable resource in hospitals; mainly related to the expensive staffing of these resources. Studies reveal that duration of surgery and length of stay of obese patients is longer when compared to non-obese patients ([2], [3]). However, there is less research focusing on effect of obesity on non-surgical times in the OR.

It is important to better understand the effect of obesity on non-surgical times in the OR as this helps to (re)design workflow in the OR and to accurately predict OR times for surgical scheduling. Extensive amounts of time stamp data and clinical factors are collected in the OR which provides the opportunity for understanding trends and patterns. Using this data, this research focuses on the duration of pre-incision times in the OR, and the impact of obesity along with other clinical factors on these times. Difficulties with the positioning of obese patients as well as difficulties with anesthesia process for these patients are some of the problems reported for obese patients [4],[5] by OR staff during pre-incision times. However, it is not clear whether these difficulties make a difference in the duration of pre-incision times in OR. For instance, spine surgery involves extensive amount of tasks around patient positioning. Further, the Agency for Healthcare Research and Quality reported spine surgery as the most costly operating room procedure performed in U.S. hospitals. They also ranked spine surgery sixth in terms of frequency of the surgeries that are performed in the U.S. [6]**.** For these reasons and to ensure a homogenous group of surgeries, this paper will focus on pre-incision times of spine surgeries. Specifically, this research will address two questions: 1) how does obesity impact pre-incision times in OR for spine surgery? and 2) how do clinical factors combined with obesity influence pre-incision times of spine surgery?

The answer to these questions allows better understating of the impact of clinical factors on workflow, and help OR managers better plan staffing and surgical scheduling, thereby reducing delayed surgical starts and overtime. This also addresses some of the indirect costs that obesity may levy on healthcare. The reason for denominating the costs of obesity is not to stigmatize obese population, rather to inform clinicians and administrators to better plan for such patients and reduce unsafe surgeries, delays and excessive cost of overtime.

The rest of the paper follows with a background section with a brief review of the literature, description of workflow during pre-incision time, and methods and results sections. Next, a discussion and conclusion follows with future research direction.

2. Background

The prevalence of the obesity epidemic is increasing worldwide along with the health problems associated with obesity. A BMI higher than 30 kg/m^2 is generally regarded as obese [7]. There have been several causative factors associated with obesity such as lack of exercise, genetics, poor lifestyle choices, and poor diet [8]. Obesity is associated with several adverse clinical conditions including cardiac disease, diabetes, arrhythmias, increased all-cause mortality, high stress levels, lack of sleep, and increased cancer incidence [8]. Additionally, obese women who have early-stage breast cancer have been shown to have worse survival rates than their non-obese counterparts [9]. Complications[10], mortality[11], outcomes[12], readmissions[13], duration of surgery[14], levels of infection[14], and financial costs[13] have all been shown to be higher in obese populations undergoing surgery.

The impact of obesity on certain aspects of spine surgery has been studied. Bederman et al., [10] studied social structure, demographics, personal, health beliefs, medical need, and community resource factors impacting rates of knee, hip, and spine surgery, and found that obese patients had higher levels of surgical complications. Kalanithi et. al., [11] studied obese patients undergoing spinal fusion and discovered that obese patients had higher rates of mortality. Fang et. al., [12] studied obese patients who had undergone spinal procedures which had become infected after surgery and identified risk factors. Fang et. al., [12] found obese patients to have worse outcomes than their non-obese counterparts. Silber et. al., [13] examined obese patients and specifically studied financial and medical outcomes that are associated with surgery and found that obese patients have higher numbers of readmission and greater financial costs than their non-obese counterparts. Mehta et. al., [14] studied the role of weight in post-operative infections and found that obese patients have longer surgical durations and higher levels of infection than non-obese patients. There are also reports for higher chance of adverse events on obese patients [8].

Obesity is becoming more prevalent among patients who are considering orthopedic surgery and spine surgery [7]. However, there is still some controversy regarding obesity's association with failed reconstructions, complications, and reoperations after spine surgery is performed [7]. Also the relationship between obesity and the duration of non-operative times in the OR is unknown. The aim of this study is to examine how obesity and certain clinical factors specifically affect preparation times that occur within the OR. Next, a brief background on the workflow of various activities in the OR along with a description of clinical factors for spine surgeries is provided.

2.1. Clinical Workflow during Pre-incision times

Surgery related activities on the day of surgery consist of two major set of tasks. The first set of tasks occur outside of the OR, and the second set of tasks is performed inside the OR. The OR-related times (from the time the patient enters the OR to the time the patient exits the OR) is divided into three common time periods: time to incision (TtI), skin to skin (StS), and closure to exit (CtE) (Figure 1). As the names imply, TtI is from the time the patient enters the OR until the time the incision starts; StS time is from the incision start to closure; and finally CtE is the time after closure to the time the patient is taken out of the OR. The focus of this study is on TtI in spine surgeries. There are several events that take place during TtI, some of which depend on the type of surgery and the institution where the surgery is performed (Figure 2). The order of these events however may vary based on the approach taken for the surgery (anterior or posterior or staged, to be discussed shortly) and the anatomic location of incision. As the patient is moved to the OR on the cart, the staff verifies patient's information, discuss the procedure with the patient and answer last minute questions. The patient is then prepared for intubation. After intubation, IV (intravenous) lines, other lines (e.g. central venous catheter or CVC) are placed as needed for intraoperative administration of fluids, medications and anesthesia, as well as to draw blood. Then the patient is positioned on the OR bed for the approach of surgery to be performed (anterior, posterior, combination of anterior and posterior which is called staged) dependent upon the type of surgery and targeted levels of the spine. The most commonly used positions in spine surgery are supine, prone, and sitting. In a supine position, the patient is slid from the cart to the OR table and remains face up. This position allows the surgeon adequate access to the anterior aspects of the chest, abdomen and pelvic region. In this position, staff should ensure that the head and cervical spine are aligned along the midline. There are also guidelines for protection of the heels, elbows, and upper arms with soft padding to prevent pressure ulcers from long surgeries. The prone position is usually achieved by intubation on the patient's stretcher and movement after anesthesia onto the patient's abdomen by either manually logrolling or using a specifically made bed

which rotates the patient on a table that supports the head, upper chest, hip area and legs, to leave the center of the chest without pressure. Care must be given to avoid excessive pressure on the eyes, ears, nose, breasts, and male genitalia [15]. In addition special attention must be given to the knees and ankles, head and to the arm position to avoid injury. Less commonly used position in spine surgery is the seated position. Positioning of the patient can require several members of the OR team, and require a long time to perform, contributing to high variability in TtI time.

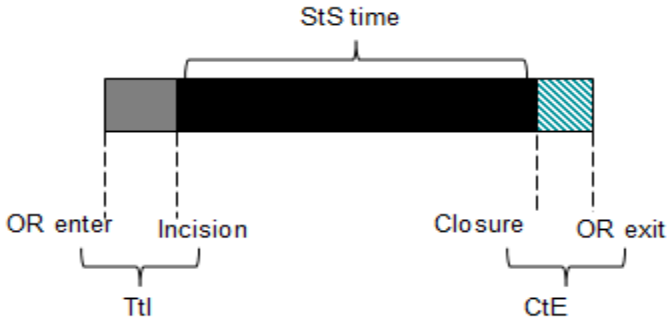

Figure 1. Time durations in the operating room

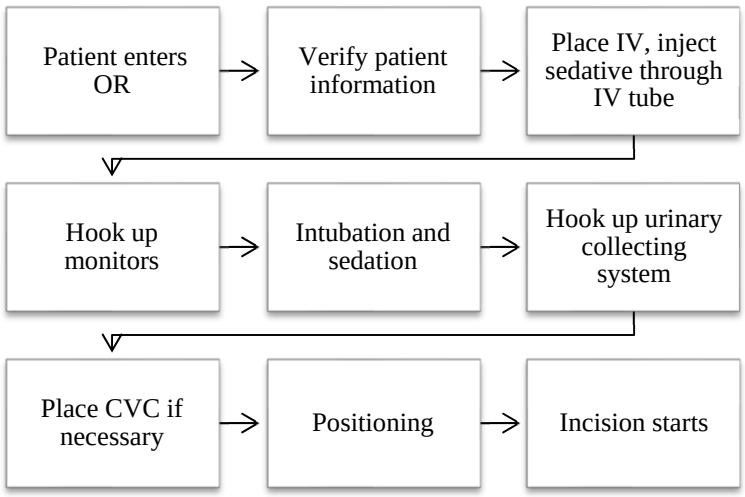

Figure 2. Pre-incision time workflow

3. Methods

3.1. Sample and Assumptions

This study is based on records of 3,677 adult patients aged 30 years or older (gathered from Surgical Information Recording System, SIRS) which had planned spine surgeries in a large tertiary academic medical center in the mid-west, from the start of 2010 through the end of the 2012 (3 years). This data includes a total of 2,611 procedures performed by neurosurgeons and 1,066 performed by orthopedic surgeons. Outliers were excluded where TtI was greater than 2.3 hours which was the highest one percent of the distributed times.

3.2. Measures

The primary outcome variable studied is time to incision (TtI) which is measured in minutes, and one of the independent variables is obesity measured as body mass index (BMI). The other independent variables include ASA category, number of spine levels, approach and fusion, and from here forward, these four will be referred to as clinical factors. Table 1 shows the data spread for spine patients over the four BMI categories defined by Centers for Disease Control & Prevention. As could be seen, the majority of spine surgery patients are overweight or obese.

Table 1. Patients in BMI categories

	Underweight	Normal	Overweight	Obese
% of Total	0.8%	19.4%	36.1%	42.8%
N	31	713	1329	1574

Since the primary focus was on obese patients, and the underweight patients accounted for less than one percent, these underweight patients were dropped from further analyses. Further, with significance of 95% there was no difference in TtI between the normal and overweight patients based on statistical hypothesis testing (difference of less than a minute on average), hence, they were lumped together under non-obese patients and compared against obese patients. In the final sample, 43% of the patients were obese and the rest were normal or overweight.

The American Society of Anesthesiologists (ASA) adopted a five-category physical status classification system; a sixth category was later added. These are:

1. Healthy person.
2. Mild systemic disease.
3. Severe systemic disease.
4. Severe systemic disease that is a constant threat to life.
5. A moribund person who is not expected to survive without the operation.
6. A declared brain-dead person whose organs are being removed for donor purposes.

The ASA physical status classification is used for assessing the clinical condition of patients before surgery. Only patients from ASA categories one through four were present in the sample.

The number of levels as the name implies refers to the number of spine levels in the procedure. Level 0 is used to represent cases where no spines are worked on, rather the procedure involves just a washout. As the number of levels of spine increases from one through five, TtI increases rapidly. Then for levels six through eight, TtI flattens and again starts to increase slowly for levels greater than nine through 19. However, these cases are very rare. Specifically, there are only 57 cases with spine levels greater than eight. Based on these facts, the sample includes levels 0 through five, 6-8 and 9+, thus a total of seven groups.

Spine surgeries are performed using three different approaches, anterior, posterior, and staged. Anterior approach is applied when spine is accessed from an anterior position whereas in posterior approach, spine is accessed from a posterior position. Staged approach is the combination of anterior and posterior where both of these approaches are used in one surgery and with separate incisions. The patient is usually positioned supine for anterior approach and prone or rarely seated for posterior approach. In staged approach, the positioning is done based on the order in which anterior and posterior approaches are used, and the patient is repositioned after the first incision is closed. Thus the variable approach can be one of anterior, posterior or staged.

The spinal column is made of individual vertebrae separated by discs. Fusion surgery removes much or the entire disc, replacing it with bone grafts or hardware (screws and rods). Hardware keeps the spine stabilized while the bones grow together or fuse. This variable is binary in nature representing the presence or absence of fusion.

3.3. Analysis

Two types of analyses were conducted, 1) regression analysis to study the effect of the five factors on TtI, and 2) t-tests to study the combined effect of the factors (obesity and ASA category, obesity and spine levels, obesity and approach, and obesity and fusion). TtI is normally distributed, and hence the student t-test was selected. We also studied the individual effect of each of the factors on TtI. The results of this analysis are described in the next section.

4. Results

4.1. Regression and Individual Effects

Based on the regression analysis, all five factors have highly significant effect on TtI. This could be seen in Table 2.

Table 2. Regression analysis test results

Factor	Sum of Squares	F Ratio	P-Value
Obesity	6578.75	11.1679	<.0001
ASA category	22996.32	26.0253	<.0001
Number of levels	105712.6	21.1123	<.0001
Approach	12426.1	21.0942	<.0001
Fusion	96427.46	327.3851	<.0001

When TtI is compared for obese and non-obese patients, the time is significantly different (slightly higher for obese patients by three minutes on average). Among cases with ASA categories of one through four, as the ASA category increases, TtI also increases. Figure 3 shows how TtI is changing for different ASA categories. As for approach, staged surgeries have on average the longest TtI among the three approaches, taking 3.5 minutes longer than those surgeries with an anterior approach, which in turn takes on average 15 minutes longer than those with posterior approach. The sample includes 80% of cases with posterior approach, 12% anterior, and only 8% of cases with staged approach. With the fusion, the sample includes 47% of spine cases with fusion. Cases with fusion have TtI which on average is 20 minutes longer than cases without fusion.

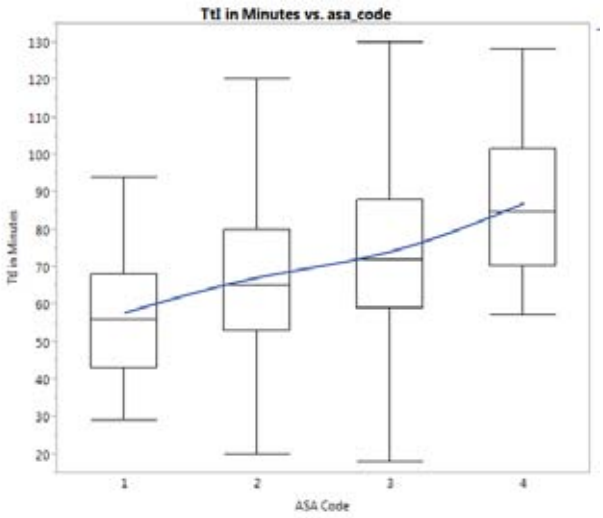

Figure 3. ASA categories and time to incision

4.2. Combined effect

When the combined effect of obesity and the clinical factors were studied, some of the factors were significant. Table 3 shows the results of the statistical results from ANOVA for effect of four clinical factors combined with obesity on TtI. These results indicate that TtI of obese and non-obese patients for any given ASA category is not statistically different. As for the effect of spine levels combined with obesity on TtI, surgeries done on one or two levels of spine, there is a significant difference between TtI of obese and non-obese patients (that is for 68% of cases). For single spine level surgery, TtI of obese patients is on average four minutes longer than non-obese patients. For two levels, this difference is three minutes on average. For higher number of levels of spine, the difference between obese and non-obese patients is not significant. The comparison of averages of TtI for obese and non-obese patients with different number of levels of spine are shown in Figure 4.

Table 3. ANOVA results for combinational effect of factors with obesity

Factor	Factor Value	P-Value
ASA category	1	0.3647
	2	0.3362
	3	0.0781
	4	0.2465
Spine levels	0	0.8095
	1	<0.0001
	2	0.0183
	3	0.4752
	4	0.3819
	5	0.4567
	6-8	0.7371
	9+	0.8456
Approach	Posterior	<0.0001
	Anterior	0.0271
	Staged	0.3985
Fusion	Yes	<0.0001
	No	<0.0001

The statistical results show that TtI for obese patients with posterior and anterior approach is significantly different from TtI for non-obese patients for the same type of approach. With the staged approach however, there is no significant difference between TtI of the two groups of obese and non-obese patients. Our analysis indicates that TtI of obese patients within each approach takes few minutes longer than non-obese patients (four minutes for posterior and anterior approaches, and three minutes for staged approach). Based on the results of ANOVA shown in Table 3, fusion has a significant effect on TtI of obese and non-obese patients. Obese patients with fusion have on average TtI which is two minutes longer than TtI on non-obese patients. This difference for patients without fusion tends to be five minutes on average.

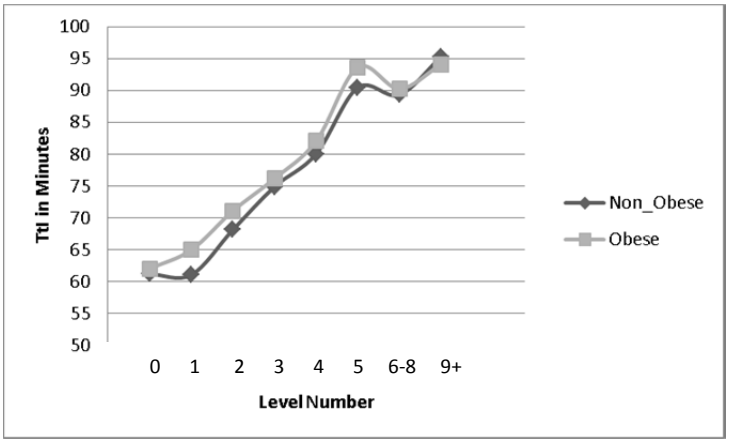

Figure 4. Average time to incision by level

5. Discussion

Obesity is considered as a factor that influences tasks that take place during TtI. The primary goal was to study the individual and combined effect of obesity and clinical factors on TtI. As for individual effect, all five clinical factors are significant. Obesity makes for a low difference of just three minutes, however the clinical factors account for much higher differences (19 minutes for approach, 20 minutes for fusion and up to 30 minutes for ASA category). This increase might be because patients with higher ASA category need more prep time in the OR. This is partly due to the complexity added as a result of the existing condition of the patient which may require additional equipment to be attached to the patient. With patients having higher ASA categorie**s**, there also may be difficulties with patient positioning due to increased frailty caused by illness. Results show that surgeries using an anterior approach have an average TtI which is 15 minutes longer than that for the posterior approach, despite the prone and seated positioning used in the posterior approach typically being more complex and taking longer time. Input from the OR team suggests that increased time is not patient-related, but OR staffing related; for the surgery done using anterior positioning (in lower levels of spine), the presence of a non-orthopedic surgeon (usually a vascular surgeon) is often required for incision to start. This is mainly due to the fact that accessing spine from anterior position requires a second surgeon to prepare the abdomen for the greatest access as possible to the front of the spine while keeping the large vessels safe, leading to extra preparation time. Also, since the presence of a second surgeon is required, the orthopedic team may need to wait until the second surgeon arrives from their primary surgery or other tasks. This factor seems to be the main reason for TtI of anterior cases to be significantly longer than posterior cases. However, it is noted that posterior approach is more common among the spine surgeries in our data. The effect of obesity could be explained due to the difficulty with intubation and positioning of obese patients. Obesity and some other factors such as limited neck mobility and poor mouth opening accounts for two thirds of all contributing factors for difficulty in intubation [16]. Obesity is also related to other contributing factors for difficult intubation such as short and fleshy necks. Obesity may also be related to difficulty in line placement, due to difficulty palpating landmarks for central lines, or peripheral lines [17]. Other difficulties as a result of patient obesity during preoperative tasks in the OR include problems with positioning of obese patients including difficulty lifting the patient, size of the bed and ensuring patient safety by requiring extra personnel. These difficulties are often assumed to require extra time to get resolved.

As for the combined effect, there is a significant difference for surgeries with one or two levels, but not for higher levels. When effect of approach is combined with obesity, for approaches anterior and posterior, there is a significant difference between obese and non-obese patients in terms of TtI, but for staged approach the difference is not significant. Overall, obesity is shown to be a significant factor affecting TtI. However, when the cases are more complex, obesity does not make a significant difference in TtI of patients. For instance, surgeries, with higher ASA category, higher number of spine levels, staged-approach, do not exhibit significant differences between obese and non-obese groups of patients. This might be due to the fact these complex surgeries are uncommon and the sample size is extremely small. To increase sample size, multi-year surgery data can be combined to better study multivariate effect of factors. Such an approach also poses the problem of changes in culture, practice and technology over time. Hence, multi-institution data need to be warehoused in registries to address this lack of sufficient sample size for more complex cases.

6. Conclusion and Future Work

This study focused on the effect of obesity and clinical factors on TtI of spine surgery. Both, individual effects and combined effects (of clinical factors with obesity) were studied. Obesity shows to be significantly affecting TtI as an individual factor and in combination with the factors such as fusion, number of levels and approach. With more common surgeries such as one or two levels of spine, and anterior or posterior approaches, and for both fusion and non-fusion cases, obese patients have longer TtI. For less common cases such as those with higher ASA categories, higher levels of spine, and a staged approach, there is no significant difference between obese and non-obese patients. However, complex cases need to be further studied. As for obesity, our study was based on BMI and does not focus on extremely tall patients. Height is also a factor that affects positioning of patients, including challenges with instruments, bed size, etc. The next phase is to focus on including height and weight as separate factors and study the effect on TtI.

Enabling Locally-Developed Content For Access Through the Infobutton By Means of Automated Concept Annotation

Nathan C. Hulse, PhD[1,2], Jie Long, PhD[1], Xiaomin Xu, MS[1] Cui Tao, PhD[3]

Abstract

Infobuttons have proven to be an increasingly important resource in providing a standardized approach to integrating useful educational materials at the point of care in electronic health records (EHRs). They provide a simple, uniform pathway for both patients and providers to receive pertinent education materials in a quick fashion from within EHRs and Personalized Health Records (PHRs). In recent years, the international standards organization Health Level Seven has balloted and approved a standards-based pathway for requesting and receiving data for infobuttons, simplifying some of the barriers for their adoption in electronic medical records and amongst content providers. Local content, developed by the hosting organization themselves, still needs to be indexed and annotated with appropriate metadata and terminologies in order to be fully accessible via the infobutton. In this manuscript we present an approach for automating the annotation of internally-developed patient education sheets with standardized terminologies and compare and contrast the approach with manual approaches used previously. We anticipate that a combination of system-generated and human reviewed annotations will provide the most comprehensive and effective indexing strategy, thereby allowing best access to internally-created content via the infobutton.

Introduction

Information needs and infobuttons

Information gaps at the point-of-care have been well documented in the medical literature, and they pose a real risk in ensuring that current best practice is reflected the care that patients receive[1,2]. Several approaches to addressing these information needs have been presented in the informatics literature[3,4]. One of the more notable means for addressing this issue is the infobutton, a context-aware linking resources that points users to relevant clinical reference materials at the point of care, typically accessed in clinical workflows while users are engaged with routine tasks in electronic health records[5,6]. The profile of the infobutton has been elevated in recent years through the development and refinement of international standards and implementation guides in Health Level Seven (HL7) as well as its inclusion in the Meaningful Use criteria, as part of the United States government incentive program for broadening the uptake and usage of key features within electronic health records[7].

Figure 1 illustrates the flow of information within a typical infobutton exchange, as prescribed by the HL7 standard. In this type of exchange, a request is manifest from the electronic health record (EHR), passing several key parameters including 1) the primary (and secondary if applicable) concept of interest, the age and sex of the patient, the role of the intended recipient, the care setting, and even the user's current task in the EHR. As information moves to the infobutton manager, key tasks including logging, selection rule logic, translation of internal codes to reference terminologies (like SNOMED, LOINC, ICD-9, etc), conversion to appropriate URLs to request further information take place. As these requests propagate outward to content repositories, including externally licensed and internally developed content, each repository is tasked with identifying relevant content and responding with metadata that can allow the users at the point of care to access that relevant content. Most content providers do so by building upon a combination of intelligent text parsing and indexing materials with relevant concepts from standardized terminologies. The approach and challenges faced by content providers in dealing with these terminology issues and aligning their content and services with these systems have been well-documented by Strasberg et al[8].

Although the infobutton standard allows for flexibility by enabling requests to pass free text in the place of coded concepts, anecdotal evidence has consistently shown that infobutton performance improves greatly when content providers index their materials appropriately using relevant terminologies, instead of just relying fully upon free text queries. This poses some unique challenges for content providers in that they must index content using appropriate terminologies and granularity, as well as deal with the important issue of 'rank' among results that come back from these queries. It also poses a unique challenge for institutions who have infobuttons, but also want to implement access to local content repositories from the infobutton. These organizations must address the infrastructure necessary

for centralizing, searching, and providing standards-based responses against their own content in order to enable this type of access from the infobutton. Open-source efforts like the Infobutton Responder within the OpenInfobutton open-source project are reflective of this need[9]. Local content owners need the ability to centralize their content, assign appropriate metadata, and include keywords indices from relevant reference terminologies in order to make their local content visible from these frameworks.

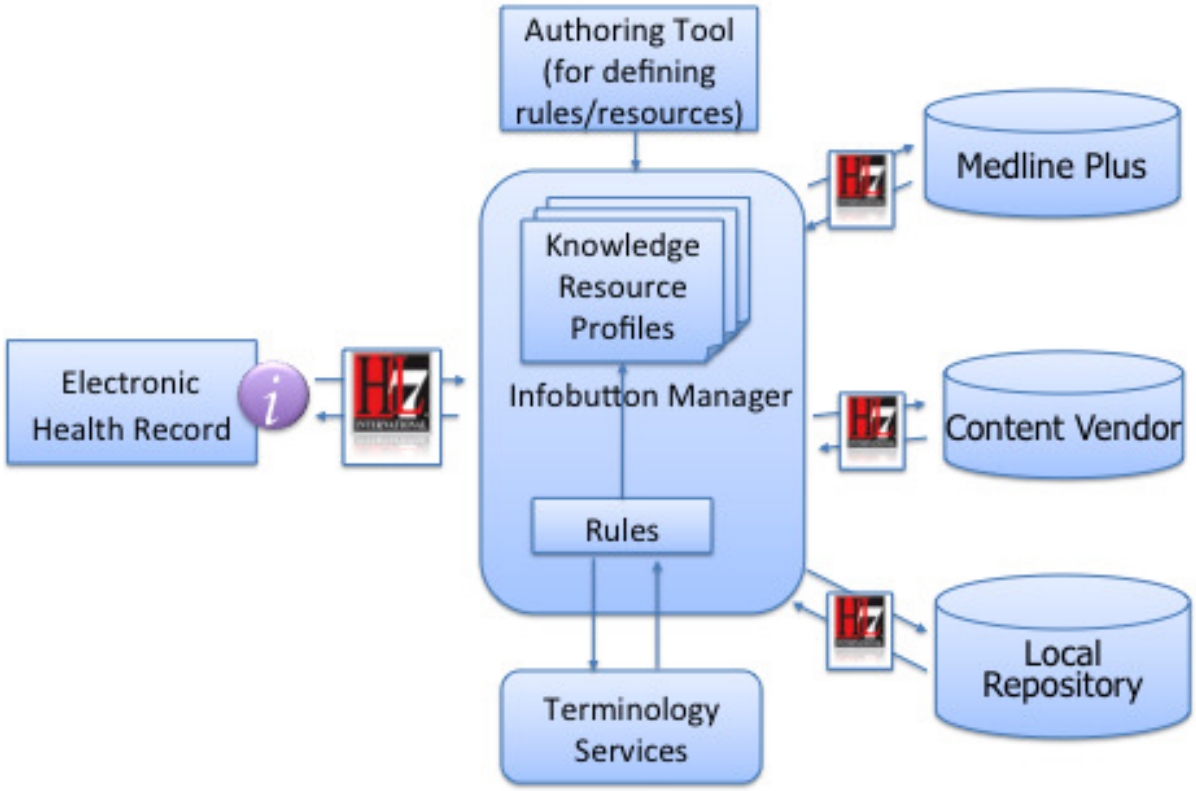

Figure 1- Flow showing data exchange and processing through infobutton manager. Request is passed from EHR to infobutton manager, where matching, code translation, and request output send queries to content providers. Content providers receive requests, process them using standardized parameters, and return best results by means of search algorithms and indices using standardized terminologies.

Background

Infobutton use at Intermountain Healthcare

Intermountain Healthcare is a not-for-profit integrated healthcare delivery system based in Salt Lake City, Utah. It provides healthcare for the entire state of Utah and parts of southeastern Idaho. Intermountain maintains 22 inpatient hospitals (including a children's hospital, an obstetrical facility and a dedicated orthopedic hospital), more than 185 outpatient clinics, and 18 community clinics serving uninsured and low-income patients. Intermountain provides primary and specialty care for approximately half of the residents of the state of Utah. Its clinical information systems are internally built and maintained, dating back several decades. They include inpatient and outpatient EHRs, a decision support framework, an infobutton manager platform, and a patient portal. They have been widely-regarded as 'state-of-the-art' and are well recognized in the literature for supporting best care practice with clinical decision support interventions[10]. Intermountain's infobutton manager (a key component of this effort) is used regularly and its development and uptake have been detailed previously[11-13].

Infobuttons have been in use at Intermountain Healthcare for over 14 years. They have been integrated in two separate clinical systems, including usage from 4 major modules within these systems including medication ordering, lab result review, problem list, and microbiology. Usage has steadily increased over the years, with over 1,700 unique monthly

users, accounting for over 18,000 infobutton sessions per month. They have also recently been made available for patient use from our patient portal in the same modules. At present, we are transitioning our production infobutton manager environment from a legacy, internally-built system over to a local implementation of the OpenInfobutton initiative.

At Intermountain Healthcare, we have maintained an enterprise clinical knowledge repository designed for centralizing, versioning, and distributing internally-developed clinical content for the past 15 years[14]. In the past, a very limited subset of these materials have been made available through our infobutton manager, but the process involved to do so was fairly arduous. Terminology engineers, knowledge engineers, and content experts had to work in concert with one another to assign specific terminology concepts to the metadata for these documents in our knowledge repository, as well as in corresponding domains in our healthcare data dictionary. The tasks involved were such that a content expert would be ill-equipped to index and maintain content without substantial technical help. Furthermore, the content authors who create and maintain many of these content resources may or may not be well-versed in the relevant terminology standards for indexing that content, and as such, may not be best suited for that type of task. As a result, only small portions of Intermountain's internal content library have been accessible via the infobutton.

Current needs and strategic directions

As part of a broader effort at Intermountain to make internally-developed content more accessible to users through channels like the infobutton, we have recently engaged with a group of content authors who maintain a library of patient education materials. The collection includes over 1,600 locally-authored patient education handouts, worksheets, forms, and we are exploring means for automating the annotation process described above. In current processes, content authors can and do assign free-text keywords to their content to facilitate local search, but have never had need to index the content using standardized terminologies. We envision an environment in which automated content analysis and suggested codes for annotation accompany the normal content publication and versioning processes typical in knowledge management. As such, we hope to draw upon the unique strengths of both computer-based and human annotators in indexing our local content libraries with relevant, appropriate metadata.

Methods

Terminology selection

We prefer to use an annotation approach that is as generalizable as possible, and be capable of producing ICD-9 and SNOMED-CT codes. Our previous efforts at annotating and exposing content through our infobutton manager have been based on our local terminology, the Healthcare Data Dictionary. This terminology, however, is not intended to be an independent reference standard. Our contracts with external providers have shown that these are the two terminologies that have the most support among content providers who index their content accordingly. Since our content of choice was most applicable for requests from the problems domain, we deemed that these were appropriate choices for the effort.

Tools and Services

We analyzed several annotation engines for possible inclusion in our effort, including Metamap and the NCBO BioPortal Annotator. Although both have their strengths, we opted to use the BioPortal Annotator, which is based on the Mgrep concept recognizer[15]. It has been shown to have high precision in a study that used it for recognizing disease terms in descriptions of clinical trials (87%) and has been characterized as a lightweight concept recognizer that can provide fast, good-enough concept recognition in clinical texts[16-17]. It also already contains lexicons for both SNOMED and ICD-9, an important feature in the overall effort we were pursuing.

We selected a convenience sample of 59 documents (from a subcollection of the library) to test our approach. In our content repository, all documents consist of two artifacts, a standardized XML header containing uniform metadata about each document, as well as the document body itself. For the annotation effort itself, we decided to focus strictly on the body of the document. Although the metadata in the document header could be useful for indexing, we felt that annotating the corpus of the knowledge itself would be a more generalizable approach, with fewer dependencies on the local approach to metadata management.

All of the 59 documents were stored in PDF format. In order to extract and preserve the content of these documents for analysis and annotation, we used the open-source Apache Tika software, a toolkit that detects and extracts metadata and structured text content from various documents using parser libraries[18]. After processing these documents through Tika, the resultant text streams files were stored to memory and streamed into a local instance of the NCBO Annotator.

The annotation engine produces XML files for each document analyzed, containing a rank-ordered list of identified concepts, links back to the NCBO website for more detailed views about each concept, character mappings for each concept identified and match types associated with each reference. Figure 2 illustrates the flow of information from the documents, through TIKA, the NCBO Annotator and the resultant output. After processing each file and creating an XML file with the annotations data, we extracted the relevant concept terminologies, identifiers, and text representations and consolidated them into a text file for analysis. All 59 documents were able to successfully be processed and annotated. The NCBO Annotator found one or more matching concepts for all of the documents in either SNOMED-CT or ICD-9.

Figure 2- Illustration depicting flow of information from PDF files through Tika software, the resultant text stream feeding through the NCBO annotator, and the outputted XML annotations files

Separately, we extracted all of the human-derived keywords for each document from our clinical knowledge repository. As mentioned earlier, each document has a corresponding header document which contains metadata about the document, including a keywords section that accommodates both free text and coded keywords. Although most of the keywords were free text, a subset of these were ICD-9 codes. For purposes of comparison, we normalized all the concepts to free text and organized them for analysis.

Results

Keyword Overloading by authors in manual keyword entry

One of the early results of our analysis is that our authors have found ways of 'overloading' or misusing the existing metadata fields in the header. They have developed an internal identification pattern and have used the keyword field as if they served as an 'alternate ID' field. Presumably, they have done so in ways that allow them to search and retrieve content using these identifiers. For example, a document about depression would contain expected keywords like "clinical depression", "mental health", "major depression" but also internal codes such as "CPM019". This did prove problematic in the analysis of the data, so we removed these data points from consideration.

Dealing with 'noise' concepts in the annotation space

One of the interesting results of processing the document set through the NCBO toolset was that raw processing of the documents against a concept space like ICD-9 or SNOMED resulted in large concept sets. Collectively, annotating the 59 documents against ICD-9 resulted in over 1138 ICD-9 codes (roughly 19 per document) and over 35,000 SNOMED-CT codes (338 per document). Some of the ICD-9 codes were deemed to be irrelevant in the context of concepts relevant to the problem list (the proposed point of integration via infobutton for this content). Concepts such as 'process', 'hospital facility' and 'time' were clearly concepts found in the document, but were deemed as less relevant in the context of the specific task of indexing content for linking from the problem list. This number was cut somewhat by further processing the data to remove category or 'container' concepts in ICD-9 (e.g. T052, or 'Activity').

One of the reason for which there were a surprisingly large number of concepts in the SNOMED-CT annotation space is that the annotator included retired concepts in the output. We were able to consolidate this list by programmatically reducing the search space by collapsing identical 'concept term' entries. We also leveraged an existing mapping table to our local terminology space to identify active SNOMED terms. This reduced the overall SNOMED-CT concept space by more than 50%.

Given that the practicalities of annotating content have shown that assigning that many identifiers to the content is not useful in making search results precise, we employed other methods to further narrow the concept space. We

preprocessed the documents by first annotating the content using a MedLine Plus ontology available in the NCBO annotator, and then subsequently annotated that concept space using the ICD-9 and SNOMED-CT lexicons. This was particularly useful in that it focused the output concept space to be relevant to concepts in the MedLine Plus ontology, one that is more tightly focused on diseases and conditions. This further reduced the concept space of the SNOMED-CT codes by almost 80%.

Collectively, after accounting for retired concepts in SNOMED-CT, removing some of the less-relevant categorical ICD-9 codes and pre-processing the annotation space against the MedLine Plus ontology, we derived a unique concept set of 117 ICD-9 concepts and 741 SNOMED-CT concepts, some of which that were identified in multiple documents in the set we tested.

Similarity between human-identified keywords and annotated concepts

The analysis of similarity between the two concept spaces (human-identified keywords and machine-derived codes) made for a somewhat difficult process. Automatic transformation of free-text entries to coded elements resulted in poor translation and very scant results overall. Translating codes back to text representations at least allowed for each identified concept to have a representation, but made the comparison between concept spaces somewhat difficult, due to the inherent nature of free text. The differences in the overall number of concepts identified per document between the human and computer raters, combined with the non-categorical data made kappa analysis not a good option. In the end, we opted to convert coded entries to free text and present some metrics of similarity based off some computed and some human-analyzed metrics.

For purposes of illustration, we present our analysis of a random sample document that we reviewed manually, aligning and matching computer-derived and human-derived concepts to compare and contrast the concepts identified by each respective sets. This document focused on the management of low back pain, including assessment, treatment options and goals. Table 1 contains keywords identified by the content authors, ICD-9 and SNOMED-CT. Although we present data specific to this particular document, the observations hold true across multiple documents in the set.

Human coded keywords

Free-text captured keywords often have special characters. It is often hard for machine to analyze and match to terms. The data not normalized and standardization of capitalization, and the approach to using nouns vs. adjectives is often haphazard. As noted earlier, most of the documents had keyword entries that serve as internal identifiers, such as CMP009d. Human assigned identifiers include no rank of relevance and appear in apparently random order.

Another interesting observation is the inclusion of concepts derived from knowledge outside the space of the concept domain. The content authors referenced a "start back protocol" while annotation engine missed the term completely. The referenced concept is the Keele STarT back tool that was developed by the Primary Care Centre at Keele University, with funding from Arthritis Research UK. It is well validated for low back pain, but is also being used widely for other spinal pains. Other documents contained similar examples, including references to instruments like the PHQ-9 for mental health.

Coded concepts

The ICD9 code list provided a much smaller concept space. In an extreme example, the ICD-9 annotation provided 20 concepts while the SNOMED-CT annotation gave 2087. The ICD-9 annotations often don't have as much detail as the SNOMED-CT codes, in part due to the granularity of the terminologies. The ICD-9 codes sometimes included concepts from unexpected domains, (including activities like 'yoga' that were found) but the tools allowed us the flexibility to include or restrict those as we saw fit. The pre-annotation against the MedLine Plus ontology helped significantly with the large numbers of concepts we derived when using SNOMED-CT. We opted not to index the content directly against the MedLine Plus ontology because these codes aren't typically used as reference terminologies in infobutton implementations.

In all three sets of concepts, the overarching concepts of 'pain' and 'chronic pain' are present in all three, but the SNOMED-CT matching offered more specificity by listing 'low back pain' as its top concept. The ICD-9 annotation found 'cauda equina syndrome' which was not found in the SNOMED-CT set, but was present in the

human keyword space. Overall the major, expected concepts were present in most annotation sets.

Table 1- Human derived keywords, and computer-derived ICD-9 and SNOMED-CT codes for a patient education sheet dealing with low back pain.

Human Keywords	ICD9CM	ICD9 text	SNOMEDCT	SNOMEDCT text
lumbar	338-338.99	PAIN	279039007	LOW BACK PAIN
radiculopathy	338.2	CHRONIC PAIN	62482003	LOW

Discussion

Feasibility and performance

One of the key points we established early in the effort is that we were not interested in implementing a full-fledged natural language processing environment. In order to index the content of these documents, we wanted a system that was 1) capable of identifying key concepts, 2) able to detect and present overall concept relevance in ranked order, and 3) able to connect these concepts with identifiers in relevant reference terminologies. We believe that we have succeeded in these objectives. The system was able to perform these annotations quickly, giving us some hope that this type of analysis might be feasible at runtime, when a user is publishing a new document or updated version of existing content. If this proves to be the case, we may be able to leverage this system while the users are updating other required portions of metadata, giving them a chance at the end of that session to review, and accept or reject the proposed coded concepts that may be deemed relevant in the document by the NCBO Annotator. An approach like this would still allow human review of the concepts, but would push much of the burden of identifying and embedding relevant terminology codes in the metadata.

We have not yet conducted an analysis of determining whether the machine-identified concepts are acceptable for use from our clinical partners. Our limited matching analyses presented above suggest that while there is significant overlap in the human and computer-derived concept spaces, there are key differences as well. We plan to present our findings to our clinical education partners (the owners of the content set that is desired to be 'infobutton friendly'. Assuming that our clinical domain experts agree with the approach, we anticipate that we should be able to scale the process up quickly to index the full set of 1600+ patient education sheets. For each document, we would add the coded concepts from SNOMED and/or ICD-9 to the header metadata document in the knowledge repository. With this information in place, we could configure infobuttons to point to these resources in relatively quick fashion, provided a brief update to the enabled profiles in our infobutton manager configuration center.

Limitations

We have not accounted for negation (e.g. through a NegEx type of implementation) in the early phases of our project[19]. While this is not likely to play as important of a role in concept identification for educational materials as it does in understanding the meaning behind clinical notes (where negative findings and 'rule-outs' are common) we anticipate that implementing its inclusion would likely enhance the performance of the system. We intend to explore this in subsequent phases of our implementation

We have not been able to calculate and share Kappa statistics, since the computer and the users annotated content in different ways (coded elements vs. free text). We anticipate that we could further analyze similarity using ontology-based similarity tools that match and assign probabilistic similarity metrics to concepts under comparison. We expect that as we do so we will continue to find some overlap, but also areas where both the human and computer codes differ from each other, due to their different approaches in annotating content. The differences between tacit and explicit knowledge will likely be exhibited in the differences that analysis would show.

Even with coded concepts in place for all the documents in the collection, our approach doesn't yet provide a satisfactory way of addressing the important issue of presenting 'rank' and overall relevance back to infobutton users. It is highly likely that indexing all 1600 documents in this collection will result in some significant overlap in terms of multiple documents that are indexed with common concepts like 'diabetes' and 'obesity'. While the NCBO toolset does output a rank-ordered list of concepts in rendering its output, our current approach for storing metadata for coded concepts does not allow for capturing 'relative relevance scores' or the like. We anticipate that in providing a service that is capable of presenting multiple results back to an infobutton, ranked by relevance, we will need to further capture this detail either in the metadata, a separate index file, or through other search engine types of techniques to apply weights to the various results.

Another limitation to our approach is that at present, we are not indexing the content with relevant terminologies in other domains like medications and lab orders. Often, the document owners would insert text-based keywords like amoxicillin, doxycycline and others, indicative of treatment patterns for the condition being discussed. We can look to perform similar indexing using these types of terminologies in future efforts.

Our approach to annotation also does not account for materials which are written in Spanish. This will be less of a problem going forward in our local knowledge repository, since English and Spanish versions of the same document are semantically linked in our database. As such, annotating these concepts in the English narrative could be used to

encode concepts in the corresponding Spanish documents as well. In other document repositories where these types of linkages don't exist, the alternate language documents may not be able to be processed and annotated automatically.

Conclusion

We have demonstrated the feasibility of using existing annotators in the biomedical informatics research domain to identify key concepts of patient education materials, using ICD-9 and SNOMED-CT as reference standards. Our system was able to extract and analyze concepts for all documents we analyzed in the set of 59 patient education sheets sampled. In a parsimonious effort to do so, we were able to identify more than 117 ICD-9 codes and 741 SNOMED-CT codes to index the starter set of content analyzed. When projected back to the complete set of more than 1600 documents, we anticipate that we will be able to present this content from hundreds of relevant entries in the problem list, expanding the reach of this content without the need of extensive, time-intensive human-based annotation. We expect that combining the strengths of computer-based annotation and human review will allow for the best approach for combining strengths and saving time in annotating knowledge content for better access from tools like the infobutton.

Abstract

Electronic medical records (EMR) contain a longitudinal collection of laboratory data that contains valuable phenotypic information on disease progression of a large collection of patients. These data can be potentially used in medical research or patient care; finding disease progression subtypes is a particularly important application. There are, however, two significant difficulties in utilizing this data for statistical analysis: (a) a large proportion of data is missing and (b) patients are in very different stages of disease progression and there are no well-defined start points of the time series. We present a Bayesian machine learning model that overcomes these difficulties. The method can use highly incomplete time-series measurement of varying lengths, it aligns together similar trajectories in different phases and is capable of finding consistent disease progression subtypes. We demonstrate the method on finding chronic kidney disease progression subtypes.

Introduction

Electronic medical records (EMR) increasingly provide comprehensive clinical data collected during routine clinical care encounters. EMR has a collection of longitudinal phenotypic data that potentially offer valuable information for discovering clinical population subtypes and using them further in association studies in medical research and even in prediction of outcomes in patient care. A number of clinical parameters and laboratory tests are collected as part of routine clinical care and their results are stored in the EMR or in data warehouses. The data warehouse represents a general patient population and the data can be used for statistical analyses. The common examples of routinely collected variables are systolic blood pressure (SBP), low-density lipoproteins (LDL), high-density lipoproteins (HDL), triglycerides, hemoglobin A1C (marker for diabetes and diabetes (blood glucose) control), and estimated glomerular filtration rate (eGFR; a marker of kidney function).

There is obvious interest towards discovering groups of similar patients with similar disease progression patterns in metabolic syndrome that involves varying accumulation of obesity, hypertension, hyperlipidemia, Type 2 diabetes, coronary artery disease and chronic kidney disease (CKD). Previous research has suggested[1] that using population subtypes in association studies instead of broad disease definitions can lead to superior results. Separating differential progression patters in the phenotypic variables can potentially discover these subpopulations. Especially with chronic and progressive diseases, the crucial difference between subtypes of a disease is often differential rates of progression, and any model attempting to find subtypes in progressive diseases must be able to account for this.

We use CKD as a case study in this paper. The prevalence of CKD ranges from 10% to 15% in the United States, Europe and Asia[2]. CKD is associated with increased mortality, decreased quality of life, and increased health care expenditure. CKD is defined in most cases clinically by loss of kidney function as estimated by a glomerular filtration rate (eGFR) below a threshold of 60 ml/min/1.72kg^2 (normal eGFR range 90 to 120 ml/min/1.73kg^2) and/or persistent increased urinary albumin excretion lasting more than 90 days[3]. Untreated CKD can result in end-stage renal disease (ESRD) and necessitate dialysis or kidney transplantation in 2% of cases. CKD is also a major independent risk factor for cardiovascular disease, all-cause mortality including cardiovascular mortality[6,7]. Approximately two thirds of CKD are attributable to diabetes (40% of CKD cases) and hypertension (28% of cases) [3]. However, CKD is also characterized by variable rates of progression with a significant proportion of patients having stable kidney function over time while some patients have rapid progression. These differential rates of progression[9] lead to clinically relevant, interesting subtypes among patient populations.

We aim to develop an unsupervised machine learning approach that takes longitudinal data of one variable from all patients and clusters them to population subtypes of which some are healthy and some turn out to be disease subtypes. The aim is to be able to include as many of the samples as possible in the analysis. Using the population subtypes as disease labels in association studies may be superior to the standard approaches of assigning disease labels from EMR data. We also hypothesize that using population subtypes and their temporal progression patterns may lead to improved performance in risk prediction. Most existing disease risk prediction models are coarse case/control models (do not account for subtypes) and use only snapshots of data without considering the temporal

patterns. Examples are Framingham risk score or the kidney disease progression model [4]. Even most of the advanced time-series models remain case/control models and do not attempt to discover population subtypes.

Electronic medical records are a messy, observational data source, as opposed to randomized controlled trials used in designed disease or drug studies. In the latter, data is collected at regular intervals under tight control of the investigators and disease onset times (first time points) are clearly recorded. In statistical analysis of EMR data, however, there are two major challenges: (a) Sparse data (large proportion of missing data) and (b) Unaligned nature of the longitudinal data. For instance, the Mount Sinai BioMe Biobank program has a longitudinal data collection from a period of 11 years and our aim is to use quarterly (every three months) median values of the laboratory measurements to reach a clinically relevant resolution. However, the number of years from which there are data from an individual patient varies greatly and only a minority of patients have a full coverage of data from 11 years; extremely few when quarterly values are sought (see Figure 1). When a large portion of the data is missing, imputation or removing samples or rows with missing data are not sensible options since we would end with a very small number of samples available. An even more difficult problem in modeling longitudinal EMR data is that there is no clear initial time point (t=0). Since patients have their first visit to a certain hospital at highly varying phases of progression of a disease, the first hospital visit with recorded data cannot be used as the initial time point. We have also concluded that using diagnostic criteria (such as the first eGFR<60 measurement in CKD) to fix the initial time point does not give adequate results in subtype modelling [data not shown]. Furthermore, many patients do not yet even have any major disease but it is desirable to include all patients in the analysis. Without the start point, standard clustering algorithms cannot be used since time points do not match between patients. Consequently, most studies in EMR are restricted to using only a single snapshot from the longitudinal data: usually the first or last time point.

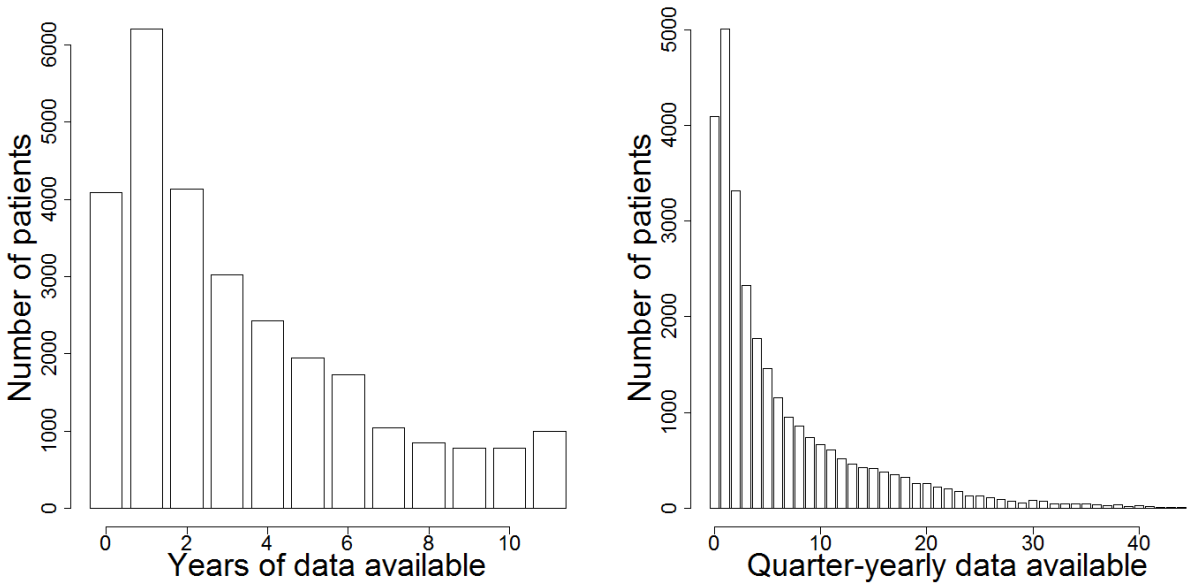

Figure 1. (Left) Most of the 27985 patients enrolled in Mount Sinai BioMe biobank have eGFR data available only from a small number of years out of a total of 11 years. The histogram shows from how many years patients have eGFR data available. (Right) Very few patients have a full coverage of 44 quarterly measurement of eGFR available. The histogram shows from how many quarterly time-points patients have eGFR data available. Multiple measurements from the same quarter-year have been converted into one median value.

In this paper, we present a Bayesian clustering and alignment model that is capable of identifying subpopulations of patients from a longitudinal dataset and overcoming the main challenges of sparse and unaligned data. The method aligns together time-series profiles in different phases of their disease progression in order to find clusters of similar progression patterns. Our generative latent variable formulation enables constructing a model that can use also samples with a large proportion of their time points missing. As a result, we can use a large proportion of the patients in the database in our modelling. A latent variable model is also a good approach for clustering short time-series, since different rates of progression can be separated easily.

One obvious purpose of clustering the longitudinal data collection in an EMR database is to visualize the progression patterns present in the entire patient population. Another application is using the cluster labels as traits in association studies with e.g. ICD9 codes, laboratory, medication or genomic data. We demonstrate that our method finds meaningful CKD progression subtypes and validate our model by showing that certain CKD-related ICD9 codes are much more common in certain disease clusters than in the rest of the patient population.

Data

The Mount Sinai BioMe Biobank Program has a collection of DNA and blood plasma from over 28000 patients linked to their full medical histories in the Mount Sinai electronic medical records database. In this paper, we use a collection of sparse longitudinal eGFR measurements from 2003-2013 from 27985 patients. We simplify the longitudinal dataset by binning each variable to quarter-yearly median values, which results in 44 time points. The eGFR has been estimated from measured serum creatinine. Though proteinuria is included in the KDIGO definition of CKD; in real-world practice, it is rarely collected and there is significant variability in the measurement tools. Also there are recent data indicating that neither microalbuminuria nor proteinuria is a significant predictor of decline in kidney function[5].

We have transformed the collection of all ICD9 diagnosis codes into a binary matrix that indicates whether patient has had a certain diagnosis code observed. Furthermore, an ICD9 is also considered observed if any more specific ICD9 code in the hierarchy has been observed (For example, 250 is considered observed if 250.1 or 250.03 has been observed. 250.1 is considered observed if 250.11 has been observed).

Methods

Clustering and alignment model

We have constructed a Bayesian generative model for the task of clustering and alignment of a longitudinal dataset. In this paper, we concentrate on one variable only. The combination of clustering and alignment of longitudinal data is an active machine learning research topic with many application areas[8]; here we consider the case of a large proportion of missing values and apply it to EMR disease progression data.

Clustering is a standard statistical method that partitions observations (patients) to sets of similar observations (clusters). This is accomplished by iterating between assigning the observations to clusters and updating the cluster centers. The number of clusters to be sought is defined *a priori* as a model parameter, but there are procedures for determining the optimal number of clusters. Clustering time-series data is a well-studied problem in the case where clear start points are known. As there are no well-defined start points in EMR data (first visit to the hospital is not a valid start point), we have to learn the start points (iteratively) from the data as well. Aligning the start point of each patient's trajectory in the cluster trajectory (cluster center) is an extra step in the iterative model. The start point parameter does not have an exact interpretation (such as disease onset), but it enables the alignment of the unaligned time-series so that coherent progression patterns can be found (Figure 2).

Each patient i ($i = 1{:}I$) comes with a data vector x_i of T time points so that the first element is the first visit to the clinic, and in general most elements are missing (Figure 1). In this paper, $T = 44$, $I = 10539$. The clustering model is essentially a multivariate mixture of Gaussians with two modifications. Firstly, as the data have missing values, cluster assignments of the samples (patients) are sampled such that the likelihood of the sparse time-series with respect to the corresponding cluster center trajectory is evaluated using only the time points with non-missing data. Secondly, the longitudinal data vectors need to be temporally aligned and we allow M different starting points in each cluster; as a result, each cluster center is of length $(T + M - 1)$, using $M = 20$. The alignment is done jointly with clustering by additionally evaluating the likelihood of the time-series in each possible start point in each cluster. The reason why we use a Bayesian generative model to tackle our problem is that when sampling the cluster assignments and alignments of time-series of varying lengths and with many missing time points, some of the time points of the cluster trajectories may not have any data currently assigned to them. In that case, priors determine the values of those cluster trajectory points.

By following the Bayesian formalism, we assume a generative model that has generated the observed data. The model can then be used to learn the model parameters from the data; the relevant model parameters here are cluster assignments k and learned start points m for each patients and the cluster trajectories (centers) θ_{kt} that can be viewed as average progression patterns.

The generative model is

$$x_{it} = N(\theta_{k(t+m-1)}, \sigma),$$
$$k \sim multinomial(\pi),$$
$$m \sim multinomial(\beta),$$
$$\pi \sim Dirichlet(\alpha),$$
$$\theta_{kt} \sim N(H, \sigma_2).$$

We thus assume that the observed data has been generated by the following mechanism: patient i comes from cluster k that is randomly chosen from a multinomial distribution of cluster weights π and the patient has the first visit to a hospital at phase m in the cluster trajectory, randomly chosen from a multinomial distribution of prior weights β. The data points in the time-series x_{it} are generated from a Gaussian distribution, where the cluster trajectory point $\theta_{k(t+m-1)}$ is the mean and σ is the standard deviation. Cluster weights π are determined by a Dirichlet distribution with a base measure α. The cluster centers θ_{kt} come from a Gaussian distribution with hyperpriors H and σ_2.

The σ is here a fixed parameter set to a tight value $\sigma = 1$ to get coherent clusters. We set H as the average of all eGFR measurements in the dataset. The $\sigma_2 = 30$ is set as a loose value to enable the modelling of a wide range of cluster trajectories, $\alpha = 1$. We set the first five and last five values of the prior weights of the alignments β to a low value and all the middle values to a uniform high value in order to improve the mixing in the sampling of the model (that trajectories would not get stuck in the beginning or end).

When a clustering configuration has been reached, the cluster assignments can be used for making inference of the data. The progression patterns can be visualized by plotting the data divided into clusters together with the alignments (Figure 2). Gibbs sampling was used for approximate inference (iteratively). It is straightforward to derive the Gibbs sampling equations from the generative model (see [19]). The method was implemented using the R statistical software. The analysis took 20 hours using a single Intel Core i7-2600 3.40GHz processor, but the computation can be made significantly faster by parallelization.

Validation of clusters by association studies

The population subtypes (cluster labels) are used in an association study where we ask whether a certain ICD9 disease diagnosis code is more common in a certain population subtype compared to the rest of the patients. We use Fisher's exact test and we run the association test between all disease subtype - ICD9 code pairs. When the association tests are run over 10000 ICD9 codes and 9 clusters, the Bonferroni multiple correction rate is $p = 10^{-7}$. Ordering the obtained p-value matrix by rows and columns gives information on what are the most distinctive subtypes and what are the most interesting disease diagnoses enriched in these subtypes. The maximum enrichment of selected relevant ICD9 codes can be used as a criterion for determining the optimal number of clusters. With $K = 9$, a 100% enrichment of ICD9 code 585 (Chronic kidney disease) was found in one cluster. The same statistical testing procedure is used to study the enrichment of males and self-reported ethnicities in the clusters.

Patient selection criterion

As patients have different numbers of data points available (Figure 1), we need a criterion for deciding which patients to include in the clustering analysis. It is clear that patients with zero or one eGFR measurements are not useful in finding longitudinal trajectories; patients with two or three measurements contain some information on the progression, but the measurements may be noisy and a large number of very short time-series may result in less coherent progression patterns. On the other hand, we aim to include as large a proportion of the available patients as possible in the analysis and the more stringent the selection criterion, the fewer patients fulfill it. We will compare the progression trajectories obtained by different selection criteria. The quantity to compare is the number of years from which patients have at least one data point available. The years do not need to be consecutive.

We construct a metric to evaluate the goodness of the learned trajectories. As differentiating disease progression rates between clusters is an important aspect of our modeling, we evaluate the difference of the eGFR slopes of individual trajectories compared to the slope of the cluster trajectory they have been assigned to. The slopes are calculated simply by fitting a regression line. Furthermore, as it turns out that some trajectories are non-linear (see Results section) and patients may have their available data from different parts of the non-linear trajectory, fitting a linear curve to a non-linear trajectory is not an optimal solution. We alleviate this problem by fitting a “local slope”, i.e. fitting the curve only to the part of the cluster trajectory from which the patient has data available and has been aligned to, and compare the individual slope to the local slope.

Results

We demonstrate our method on finding CKD progression subtypes from eGFR measurements. As can be seen in (Figure 1), only a small fraction of the total 27985 Biobank patients have eGFR data from the full period of 11 years and very few have a full coverage of 44 quarter-yearly measurements that would correspond to fully observed dataset (no missing values). As explained in the Introduction, even such full coverage data would not be readily usable since patients are in highly different phases of their disease progression and there are no clear start points. By using our Bayesian clustering and alignment approach, we can, however, use a significant portion of this heavily incomplete dataset.

Patient data criteria and evaluation

We now evaluate how many eGFR measurements are required for patients to be included in the clustering as a tradeoff between patient attrition and model accuracy. In (Table 1) we compare the criteria from how many years the patients need to have at least one measurement available (each year has been divided into four quarters). The number of available patients decreases with tighter criterion, with the benefit of better model accuracy. The slope error is the difference of the slope of an individual trajectory compared to the slope of the cluster trajectory. Please refer to the methods section for the definition of the accuracy of the model.

Table 1. Sample size and median error for different number of years

Selection criterion (Years)	2	3	4	5
Number of patients with data available	17672	13558	10539	8117
Median slope error	1.66	1.35	1.24	1.18

As can be seen from (Table 1), the number of patients with a sufficient amount of data available to meet the inclusion criterion drops rapidly when tightening the criterion. In the same time, the accuracy of the model increases, as there are a smaller number of short, potentially inaccurate time-series worsening the clustering result. We choose to include patients with eGFR measurement from at least 4 different years. Using this selection, we get very coherent progression subtypes yet have a large number of patients (10539) available.

We show in (Figure 2) the eGFR progression patterns for 9 clusters, representing the entire BioMe Biobank subcohort with at least 4 years of eGFR data. We have chosen 9 as the number of clusters as we have empirically observed it to be the minimum number that finds all the clinically meaningful main progression patterns and at least one cluster (C8, lowest eGFR values) with 100% enrichment of the ICD9 code 585 (Chronic kidney disease). As can be seen from the images, there is considerable noise in the data since eGFR measurements are inherently noisy and the trajectories from 10539 patients have been forced to 9 clusters. This noise could be reduced by using yearly medians instead of quarterly medians (with the cost of clinically important time resolution); even more coherent clusters could be sought by increasing the number of clusters.

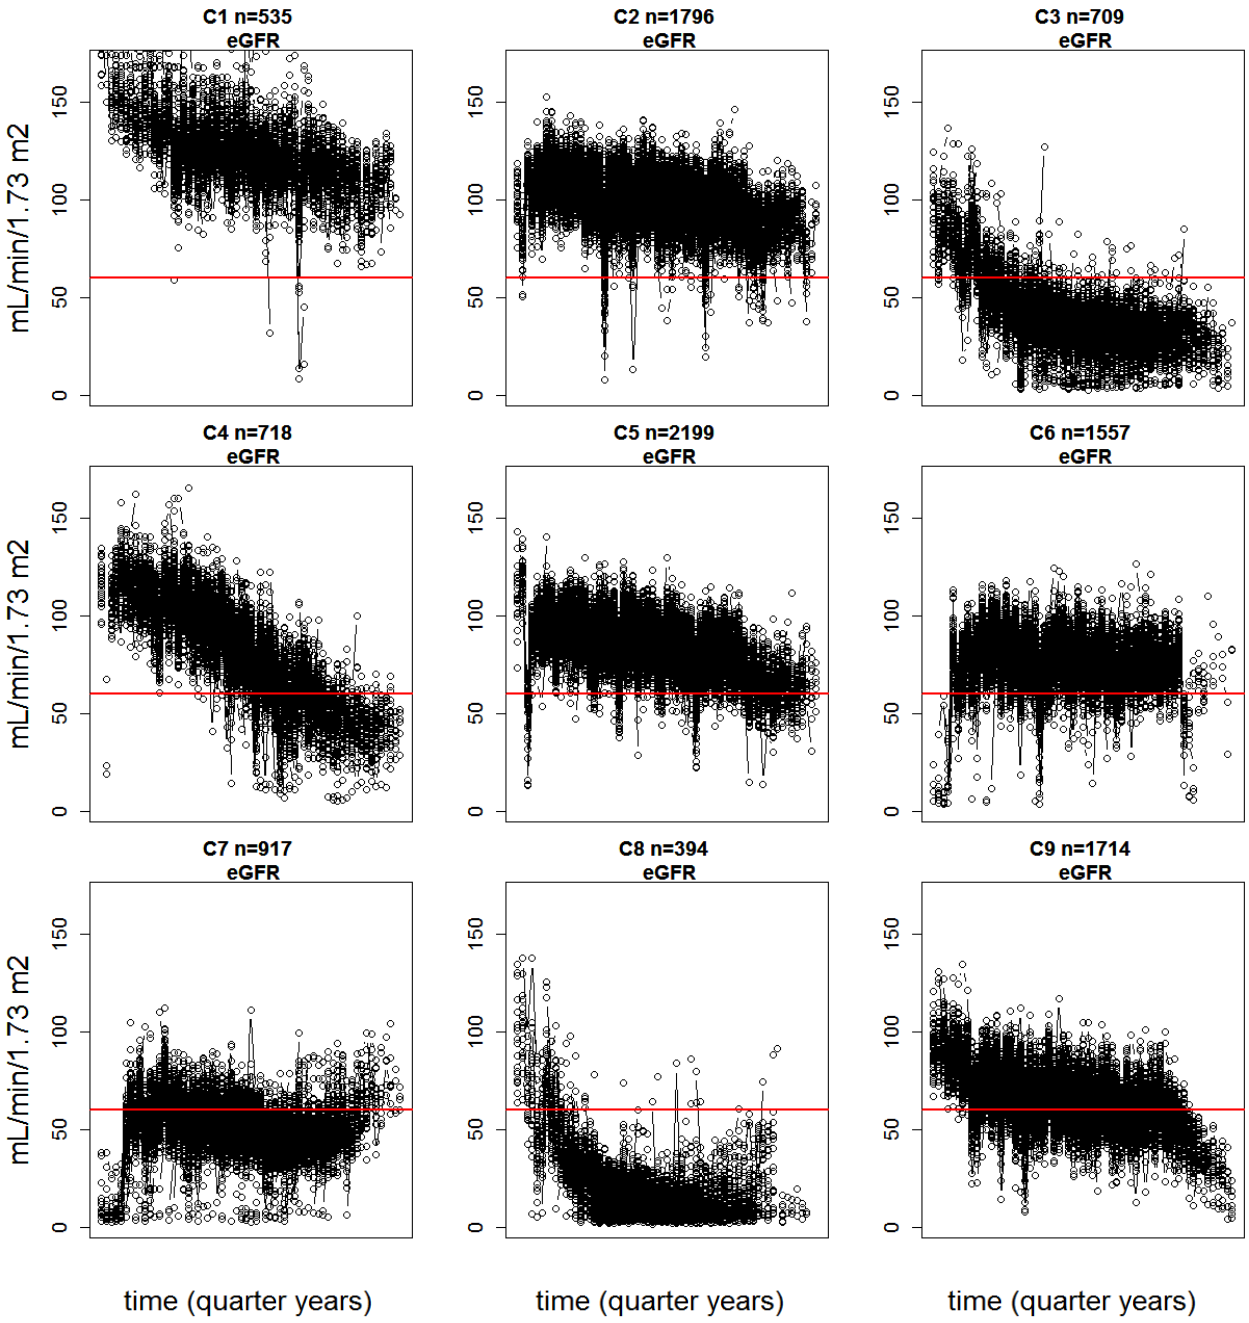

Figure 2. Many distinct coherent eGFR progression patterns can be found from the 10539 patients that represent the entire hospital cohort. The figure shows clustering and alignment results for eGFR using 9 clusters; each cluster in the figure consists of eGFR trajectories of all the patients in that cluster that have been aligned together. These trajectories have highly varying lengths (see Figure 1 and Table 2) and varying numbers of missing values. The time span corresponds to 16 years; each patient has data from 4-11 years (up to 44 quarter-yearly time points) and 20 possible start points are allowed. The n indicates the number of patients in each cluster; C indicates the cluster index.

In (Table 2) we demonstrate the median and interquartile range of the first and last time points of the eGFR of patients in each cluster, the mean duration (years) of data available, and the average slope of progression. Columns 4-7 show the values of the first and last points of the cluster trajectories (cluster centers) and the slope that has been fitted to the cluster trajectories. The values are in accordance with one another and with (Figure 2). Note that the median of the first values of the individual trajectories is different from the first point of the cluster trajectory since the patients in a cluster have their first time point (first visit to the clinic) at varying stages of the cluster trajectory (this also applies to the last time points). The accordance of the slopes of individual trajectories in a cluster with cluster trajectories is further visualized in (Figure 3).

Table 2. Summary of the eGFR progression patterns

	Mean (S.d.) years eGFR data	Median first eGFR [IQR]	Median last eGFR [IQR]	Average ΔeGFR per year	Cluster center first eGFR	Cluster center last eGFR	Cluster center ΔeGFR per year
C1	7.5(2.3)	127.6[18.1]	120.3[17.1]	-1.6	142.9	86.9	-2.9
C2	7.6(2.4)	105.7[13.4]	98.7[14.8]	-0.9	105.9	91.2	-1.7
C3	6.9 (2.5)	50.3[28.1]	33.2[15.7]	-3.4	78.1	31.4	-3.4
C4	6.4(2.6)	108.0[18.0]	76.9[38.3]	-5.2	118.2	43.2	-7
C5	6.9(2.6)	93.8[12.4]	83.9[15.6]	-1.5	94.5	63.7	-2
C6	6.5(2.6)	80.9[14.4]	77.5[12.6]	-0.6	79.6	73.4	-0.7
C7	6.9(2.7)	58.2[15.8]	50.3[12.4]	-0.8	50.5	47.8	-1.4

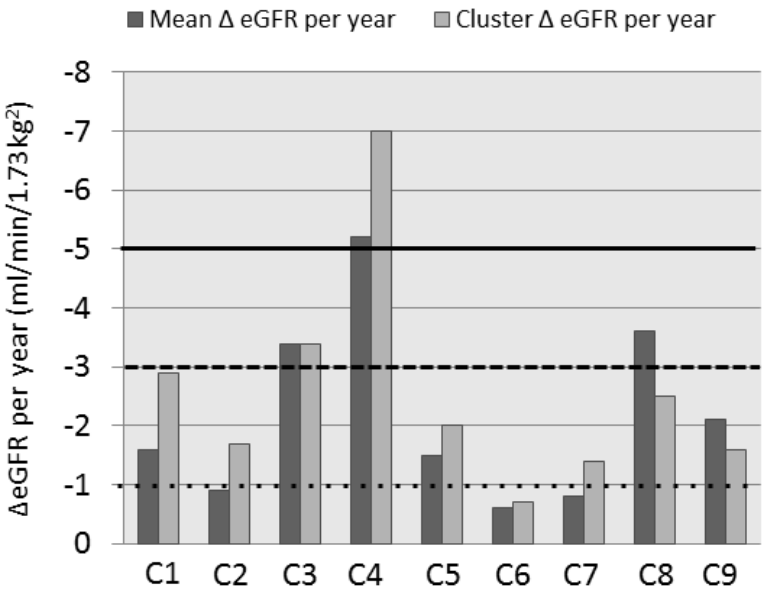

Figure 3. Bar graph of mean of eGFR change (ΔeGFR) per year (dark grey) and cluster center ΔeGFR (light grey) for patients in clusters C1 to C9. Lines indicate usual thresholds for nonprogression (dotted line), moderate progression (dashed line), and rapid progression (solid line).

In order to assess the clinical applicability and relevance of this clustering method, we hypothesized that demographic and disease patterns that were seen in longitudinal studies with similar patterns of eGFR progression would replicate independently in these clusters. In (Table 3) we show the mean and standard deviation of age, percentage of males and self-reported ethnicities (European ancestry (EA), African ancestry (AA), Hispanic/Latino (HL), Others) in each cluster. The star denotes clusters were the enrichment of a certain ancestry or gender was statistically significantly higher than for all the other patients using Fisher's exact test (Bonferroni rate $p = 10^{-7}$).

Each cluster had a statistically significantly different mean age compared to the patients in the other clusters using t-tests.

Table 3. Demographic characteristics of clusters, of all the patients in the analysis and all the patients in the biobank

	Age [Sd]	Males (%)	EA (%)	AA (%)	HL (%)	Other (%)
C1	36.9[10.7]*	32	5.5	59.3*	32.1	3.1
C2	50.1[10.6]*	36	13.1	34.3*	46	6.6
C3	71.7[12.2]*	40	24.4	28	42	5.6

These demographics and ICD9 codes present an independent clinical validation of the relevance and applicability for the clustering patterns. For example; cluster 1 represents a group of patients that start at a high eGFR with the median eGFR being more than 120 ml/min/1.73m^2. Clinically, this represents a group of patients who have glomerular hyperfiltration (a precursor to developing kidney injury with elevated eGFR above 120 ml/min/1.73m^2) which usually happens in younger patients who are usually African-American and occurs in the very early stages of diabetes mellitus and hypertension and thus might not have a confirmed diagnosis of them[10,11,12]. As demonstrated in (Table 3 and 4); patients in cluster 1 are significantly younger than those in other clusters with a mean age of 36.9 years and have a lower prevalence of diabetes mellitus and hypertension as compared to the other clusters.

Clusters 3 and 8 provide more evidence for this validation. As shown in (Figure 2), these are clusters where patients starting from a CKD stage 3/4 with a mean eGFR of 50 and 27 ml/min/1.73m^2 progress rapidly to a low eGFR (mean eGFR of 33 and 10 ml/min/1.73m^2 respectively). These clusters have the highest prevalence of an ICD9 code for acute kidney injury (AKI), heart failure and anemia amongst the clusters. As shown in multiple studies, AKI[13,14], heart failure and anemia[15] are very significant risk factors for both CKD progression and end stage renal disease (ESRD) development. This is further validated within these clusters since cluster 8 that has a higher prevalence of acute kidney injury, heart failure and anemia compared to cluster 3, also has a higher proportion of ESRD and dialysis and a lower final eGFR. Cluster 2 is an example of healthy patients with normal eGFR and they do not have many CKD diagnoses.

Thus we demonstrate that this automated machine learning approach organizes sparse and non-aligned data into coherent and clinically meaningful subtypes based on disease progression and this finds further independent validation after comparing demographics and ICD9 code enrichment.

Conclusions

We have demonstrated the use of clustering and alignment modelling for finding disease progression subtypes from highly incomplete EMR laboratory data. We have shown that using this type of modelling, we can use a large portion of a longitudinal dataset that has irregular time series of varying lengths and a high proportion of missing data. In particular, we have shown how to deal with the fact that there are no clear initial time points in the time-series; the solution is to align similar trajectories together. Our method was successful in finding from the data meaningful CKD progression patterns that correspond to known disease subtypes and stages.

The generative Bayesian modelling formalism is a flexible approach that allows for the construction of models that take into account all the necessary aspects of the modelling problem. In our case, clustering longitudinal data, alignment and dealing with missing data could all be done within a single unified model. We also successfully validated our clusters by association studies between the clusters, demographics and ICD9 diagnosis codes.

There are many potential applications for this approach. For instance, although novel genetic associations with eGFR have been reported, there are other potential genetic associations that explain the differential rates of CKD in different ethnic populations[16,17]. However most genetic association studies are cross-sectional in nature and longitudinal studies require the resources of clinical cohorts. This clustering approach could be applied to evaluating genetic associations with longitudinal disease progression especially in institutions which have EMR linked biobanks. This is of special importance with national consortia such as the Electronic Medical Records and Genomics (eMERGE) Network, a NHGRI funded consortium tasked with developing methods and best-practices for the utilization of the Electronic Medical Record (EMR) as a tool for genomic research[18]. Also, since this approach can be deployed at multiple sites with EMR, a large number of patients can be used for modeling purposes that would not be possible in conventional longitudinal cohort studies.

In this paper, we considered the clustering of only one longitudinal variable, however, our model can be directly used for multiple variables. One can, for instance, cluster and align longitudinal eGFR, SBP and hemoglobin AIC data together in order to find clusters with similar progression in multiple variables. Adding more variables and increasing the number of clusters in the analysis can lead to discovering ever more specific clinical subtypes, critical in the future direction of personalized treatment decision support. Finally, though we used CKD as an example the opportunities for examining distinct disease progression subtypes and making innovative discoveries are endless in any disease area depending on available data in the EMR

Abstract

Use of deceased subject Electronic Health Records can be an important piloting platform for informatics or biomedical research. Existing legal framework allows such research under less strict de-identification criteria; however, privacy of non-decedent must be protected. We report on creation of the decease subject Integrated Data Repository (dsIDR) at National Institutes of Health, Clinical Center and a pilot methodology to remove secondary protected health information or identifiable information (secondary PxI; information about persons other than the primary patient). We characterize available structured coded data in dsIDR and report the estimated frequencies of secondary PxI, ranging from 12.9% (sensitive token presence) to 1.1% (using stricter criteria). Federating decedent EHR data from multiple institutions can address sample size limitations and our pilot study provides lessons learned and methodology that can be adopted by other institutions.

Introduction

The use of electronic health records (EHR) for research is becoming commonplace. Patient privacy and ethical oversight by institutional review boards (IRBs) present practical and administrative challenges for scientists who need to access Big Data.[1] De-identification (elimination of the protected sections of health information) can allow EHR records to be considered "not human research subject data", thus reducing regulation.[2] Another approach is to restrict research to the use of deceased patients' records.[3] Although data analyses that use only deceased patient records may have inadequate power due to small sample size, they can provide pilot results whether particular EHR-based data extraction or analysis is feasible. Data analyses in multi centric clinical studies that use data inputs from varying EHR software vendors or varying user groups may benefit from an administratively simpler pilot experiment first. Such a pilot study on deceased subjects' records can prevent situations in which an investigator tediously obtains IRB approval for a multi-site study that uses more complete record sets (such as de-identified or even identified data) only to discover that the records lack the data necessary for the study.

In a previous perspective paper,[3] we outlined several challenges to establishing a *deceased subject integrated data repository* (dsIDR), such as proving death status, involvement of next of kin (surviving spouse or children), possible deletion of deceased patient data by the organization (to limit the data warehouse size after the minimum record-keeping period expired), and patients' perceptions of the value of dsIDRs. Creation of dsIDRs using only terminology-coded information, such as structured medication, laboratory results and diagnostic or procedural data that do not require de-identification is relatively easy to accomplish. However, additional challenges are encountered when a dsIDR contains narrative text clinical documents. In such a repository, personal identifiers defined in the Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule (Safe Harbor Method) as well as "personally identifiable information" (PII) defined in the Privacy Act must be detected and redacted properly.

One particular challenge with narrative text document inclusion in the dsIDR, identified in our prior analysis, was handling the PHI of people other than the patient. Because research use of private health data of living and deceased is regulated differently, we need to distinguish two types of PHI/PII: *primary* (about the primary patient in question) and *secondary* (about individuals other than the primary patient, such as relatives or caregivers). We use the term *secondary PxI* to refer to both secondary PHI and secondary PII. We also use the term PHI to denote removal of the 18 specified identifiers (e.g., primary or secondary phone number), rather than removal of health data. The regulatory provisions for decedent EHR research do not mandate specific de-identification method (as opposed to the clear definition of 18 PHI identifiers in the Safe Harbor Method). The relaxed approach to de-identification in a dsIDR does not extend, however, to secondary PxI of living relatives, which must be entirely removed. This removal may be more difficult since the typical approach of using the primary patient's name may not be helpful in identifying secondary names. The process is further complicated because primary PHI that would ordinarily be allowed in a dsIDR must be removed if it helps reveal identity of secondary persons mentioned in the record (e.g., if a primary patient last name remains in the record, it may also provide a last name for a living relative identified in

the EHR only by a first name). Based on our own legal analysis, we hypothesize that mention of dates and locations (e.g., city or town) that would have to be scrubbed in traditional de-identification for whole population IDR, may stay in dsIDR.

In this paper, we report on efforts to establish a dsIDR at the National Institutes of Health's Clinical Center (NIH CC) and our investigation of the rate of secondary PxI in deceased patients' EHR.

Background

Institutional context

The NIH Clinical Center is a 240-bed hospital dedicated to research. Since 2008, it has established an integrated data repository called the Biomedical Translational Research Information System (BTRIS). BTRIS contains data on over 500,000 research subjects seen at the NIH CC since 1976. BTRIS contains data from the current EHR (Sunrise Clinical Manager v5.5, Allscripts, Chicago, IL), a prior EHR (Medical Information System, Technicon Data Systems, Tarrytown, NY) and several ancillary clinical and research systems.[4] BTRIS offers two modes of data export: identified data extracts available to study investigators and de-identified data extracts available to any NIH investigator. Currently, de-identified data exports are limited to structured coded data and a limited number of narrative text documents (e.g., pathology reports).

Design Principles of NIH CC dsIDR (dsBTRIS)

With our dsIDR dataset and framework, we hope to offer interested researchers yet another platform for generating hypotheses and piloting informatics methods. We also hope to learn important lessons about dsIDR design and actual use from creating a single institution dsIDR. These findings can inform development of a federated dsIDR of deceased patient EHR data from multiple institutions. The design principles for our dsIDR include the following elements:

- Access is limited to researchers who obtain approval (with exemption from IRB review) from the NIH Office of Human Subject Research Protection (OHSRP)
- Researchers must certify that they will not try to identify deceased subjects or other persons in the provided data
- The EHR of deceased patients undergoes the following transformations
    - Structured data: direct patient identifiers (e.g., structured name, address or employer field) are removed since they have none or very limited value to research
    - Unstructured data: The current dsIDR implementation pilot does not contain any unstructured data; selection of the best de-identification approach is one of the goals of this study; we plan to remove primary patient name from narrative text documents (e.g., progress note and laboratory text comments); dates and locations (e.g., "Suburban Hospital") would remain in the documents; secondary PxI would also be removed

Legal framework for deceased subject research

A legal framework for use of EHR data post mortem has been explored in greater detail in our earlier perspective paper.[3] The most important legal factor is that deceased subject research does not require traditional consent and full IRB review. Decedent research is listed in Title 45 of the Code of Federal Regulation under section §164.512, titled "Uses and disclosures for which an authorization or opportunity to agree or object is not required" [45 CFR 164.512(i)(1)(iii)].[5] The enabling statue for this regulation is the Health Insurance Portability and Accountability Act (HIPAA; Public Law 104-191).

The regulation allows disclosure of PHI of decedents without the need to seek full IRB approval and has to adhere to the following conditions:[6]

(1) use is sought solely for research on the PHI of decedents;
(2) the researcher can provide, on request, documentation of the death for individuals used in the study; and
(3) the PHI is necessary for the research.

Throughout this article, we refer to this HIPAA provision as "decedent research clause".

When information is private

Of note is also the fact that health related information may become secondary PHI only after it is combined with a clear designation of a secondary person (such as full name or phone number). If a record contains the sentence "Her mother and daughter both have symptoms of multiple sclerosis", it only becomes secondary PHI when associated with a *living* person's full name. How unique and identifying is the context information provided about the

secondary person is of significance (quasi-identifiers). This masking phenomenon is well described by the concept of k-anonymity (each dataset record is indistinguishable from at least k-1 other records given a group of identifying attributes) and the concept of l-diversity (each group of identifying attributes is immune to probabilistic inference attack and has at least l well represented value).[7] There is no clear established boundary; however, the HIPAA ZIP code rules offer one potential precedence: HIPAA zip code rule (45 CFR 164.514) permits revealing 3-digit ZIP codes as long as the 3-digit ZIP code covers an area populated by more than 20,000 people, as this is considered to be sufficient "masking" of the individual. The masking principle is important in redacting or preserving a sentence, such as, "Patient has a 9-year-old daughter" in a document that otherwise contains unmodified dates and locations, but does not contain the primary patient name.

Fall back policy

In addition to the dsIDR use policy that forbids subject re-identification, NIH CC has a general institutional policy for situations when identifiers are discovered in a dataset that has been thought to be de-identified. The existing NIH CC process generating de-identified data starts with production of an *initial de-identified data set*. An NIH employee not affiliated with the research (an "honest broker") reviews any BTRIS-derived dataset and determines whether it is free of PHI. If the initial data set is certified as sufficient, it is provided to the researcher. If PHI is found, the honest broker creates additional rules and data transformations to produce a *revised de-identified data set*. Ultimately, the researcher receives the initial or revised de-identified data. If the researcher encounters PHI that were missed by the honest broker, NIH OHSRP policy requires him to discontinue the use of the data and obtain IRB approval (typically, with waiver of consent) in order to continue the research. This process has two weak points. First, the review by the honest broker is lengthy, labor intensive, and has to be repeated for each project. Second, the researcher runs the risk of project interruptions and the requirement for additional review if PHI is discovered during the data analysis. The goal of the dsIDR is to produce a resource that does would not require additional human review and could be re-used for multiple projects.

Methods

Establishing the dsIDR

We used existing BTRIS death status data to establish the size of the dsIDR and explored the proportion of structured and narrative-text data available on deceased subjects. We looked at how many data rows are excluded by existing PHI filters (developed for the purpose of current de-identified BTRIS exports). We compared the size of the dsIDR with the full BTRIS repository in terms of number of patients, laboratory results, medication data, diagnoses and clinical documents.

Analysis of narrative text clinical documents

We used National Library of Medicine's (NLM) Scrubber software to parse dsIDR narrative documents.[8] Due to data size, requirements for computing time, and focus on recent and active documents, we limited our analysis to documents authored between October 1st, 2011 and October 1st, 2013). We also limited the analysis to the most frequent documents that accounted for 99% of all documents, ignoring rarely used document types. We obtained ethical approval for our deceased records research from NIH OHSRP office.

In order to correctly detect and remove sensitive patient information, we define the term *a priori PHI* as patient identifiers that have limited or no research value, that are known prior to the initiation of the PHI scrubbing process, and that definitely have be removed from clinical documents. In other words, our term "a priori PHI" refers to primary patient identifiers that are known from patient demographic data entered in structured form within an EHR. A priori PHI elements in our study were first, middle and last name and medical records number (MRN) of the primary patient. Of note is that patient identifiers do not equate Protected Health Information. Patient identifiers are Personally Identifiable Information, which meet the definition of PHI for living patients but not technically PHI for deceased patients.

Our work also relies on the assumption that any document containing secondary private information must indicate by at least one token who that person is (e.g., husband). We refer to this as the "token presence assumption". We defined a set of secondary person tokens that may indicate presence of secondary PxI. We used a regular expression search with the following word elements (including plural versions, combinations with applicable prefixes and suffixes, and other variations): mother, father, spouse, parent, wife, husband, daughter, son, sister, brother, children, child, mom, mommy, mama, dad, daddy, papa, sibling, aunt, uncle, "grand-*", "*-in-law", "in[-]law", friend, supervisor, employer, employee, girlfriend, boyfriend, roommate, partner, boss, collaborator. We sought to discover the frequency of secondary person tokens in clinical documents.

In addition to general occurrence, we used the document type (e.g., discharge summary vs. pathology report) as the key document parameter to investigate the occurrence of secondary PxI. We assumed that patterns of secondary PxI occurrence would be similar within a given document type; hence, our analysis is structured by document type. However, we also understand that this assumption may not be fully relied upon, as users may differ in their choice of document type and may differ in how they use those types. For each document type, we measured the frequency of occurrence (in dsIDR), and the frequency with which they contained a priori PHI, any personal name or a secondary person token.

We used NLM Scrubber to detect human names, alphanumeric identifiers (IDs) and addresses. Personal names are detected by multiple methods with the most discriminative method being the computation of the likelihood ratio of name to non-name of a given word. To identify sensitive alphanumeric identifiers, NLM Scrubber uses a two phase process where it first tries to identify laboratory values (that should be preserved) based on a set of hard coded patterns and in the subsequent second phase marks the remaining alphanumeric strings as sensitive tokens. Addresses are recognized mostly via "shapes" component of a specialized part-of-speech tagger (called dTagger) that looks for address-like patterns. For each analyzed document, NLM Scrubber outputs a set of tagged tokens classified by the identified type (e.g., address or personal name) appended to the end of the document or stored within a database. Marked up documents can also be browsed and edited in an associated editor called Visual Tagging Tool (VTT). Because of our focus on secondary PxI, we did not use other features of NLM Scrubber such as de-identification of ages (over age 89) and dates. On the other hand, we added new features, such as the ability to detect a set of secondary person tokens and the ability to analyze sensitive tokens that are in proximity to a secondary person token (e.g., address near "daughter"). We used NLM Scrubber's token-level output to detect frequency of various identifiers by tag. A full description of NLM Scrubber is available in a prior published study on name detection[8] and in an internal NLM report (non-name tokens).[9]

Manual review of secondary PxI instances

In addition to software-assisted analysis, we employed manual review of a subset of clinical documents to improve our understanding of different types of secondary PxI, to improve our definition of a true positive secondary PxI, and to inform our final scrubbing methodology. Due to a large volume of documents, we picked a single frequent secondary person token and a single frequent document type. We then reviewed all those document instances in a single calendar year (2013) and classified the secondary PxI into classes that could be later used in PxI removal efforts.

Table 1: Size of structured EHR data (full and decease subject repository)

Parameter	Full repository (BTRIS)	Deceased subject repository (dsBTRIS)
# patients (with laboratory data)	264,885	23,962 (9.1%)
# laboratory tests results	213.3 M	52.0 M (24.4%)
# medication administrations	16.5 M	5.2 M (31.5%)
# diagnoses	1.9 M	0.3M (15.8%)
# clinical documents	21.3M	5.6 M (26.3%)

Results

Our analysis resulted in the creation of a pilot deceased subject data repository. NIH researchers interested in using the dsIDR can seek ethics approval using an NIH OHSRP form that has pre-filled elements applicable to dsIDR research projects. This form (with pre-filled elements indicating the use of dsIDR platform) is available as an online appendix A at http://dx.doi.org/10.6084/m9.figshare.924793). This form is relatively short and dsIDR projects require less detailed description compared to a full IRB submission.

Size of dsIDR dataset

As of March 2014, the NIH BTRIS data repository contained coded data on 23 962 deceased patients. Table 1 shows side by side comparison of the full BTRIS repository versus deceased subject subset (numbers reflect laboratory test results and medication administrations, not orders). In comparing the number of patients (first row in table 1), we only considered patients with at least one laboratory result due to a significant number of patients that are administratively entered but lack a critical number of clinical diagnostic or treatment data (e.g., trial screening or patient's relatives). Existing BTRIS de-identification filters excluded 1.4M laboratory test results and 45 644 medication records where associated comments include PHI (patient name or MRN).

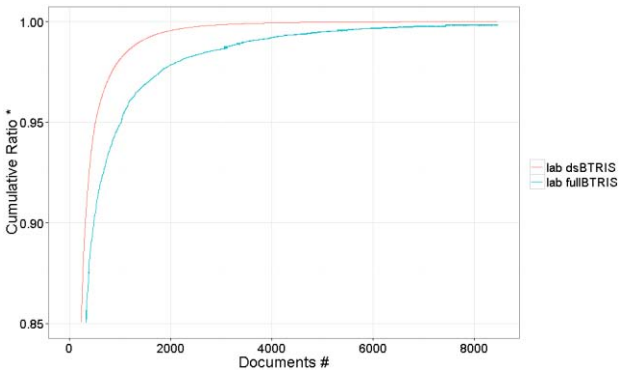

Figure 1: Pareto chart of lab tests for BTRIS and the dsBTRIS. # 8470 dsBTRIS laboratory types; 5000 full BTRIS test types (0.14% of all test instances) are not shown. * Cumulative portion of the respective repository that is accounted for by the test terms on the horizontal axis; the fullBTRIS line stops at 99.86% of all tests covered by all 8470 dsBTRIS tests).

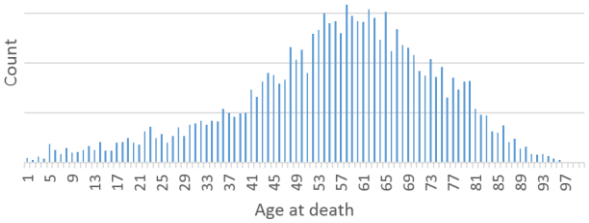

Figure 2: Patient distribution by Age at death (years 2009-2013)

(vertical axis legend (count) is not shown to mask exact counts)

A sub-analysis of laboratory data showed that whereas BTRIS contains 13,470 distinct laboratory test types (e.g., plasma folic acid level), dsBTRIS has 8,470 types. However, looking at the most frequent tests[10], we found that dsIDR contained 99.85% (1997 test types) of the 2000 most frequent test types (see Figure 1 for cumulative percentage graph).

To help researchers seeking recent data within a particular age group, we produced histograms of age of death for different time periods. An example, for deaths occurring during 2009-2013, is shown in Figure 2.

Analysis of narrative text clinical documents (by document type)

Within the documents from the last 2 years, we identified over 379 thousand clinical documents in deceased patients that were of 391 distinct document types. Excluding 1% of rare documents, the number of distinct document types reduced to 177 document types (376 051 documents). Each analyzed document type in the final set had at least 80 instances. A small number of document types capture the majority of the data. We found that 28 document types accounted for 80% of all documents and 59 document types accounted for 90% of all documents. An overview of all document types is available as appendix B at http://dx.doi.org/10.6084/m9.figshare.924793.

NLM Scrubber took 105 hours running in 4 parallel processes on a Linux workstation (8 CPU, 16GB RAM) with most computing time spent on part-of-speech tagging. Results were stored in a MySQL database to allow subanalysis by document type, tag or token. NLM Scrubber parsed 112 million tokens overall and marked 1.9 million as sensitive, with 53.4% being tagged as alphanumeric ID, 42.6% as personal name, 2.3% as address, and the remaining 1.7% as a combination of multiple tags. On average, a document contained 5.3 tagged tokens (ranging from 0 to 324) with 5.3% of documents containing no sensitive tokens. No list of local provider names was provided to NLM Scrubber.

Presence of a priori PHI: The presence of a priori PHI discovered by the NLM Scrubber varied widely by document type, from 0% to 100%. Table 2 presents document types that contain a priori PHI in more than 50% of document instances. Six document types (e.g., Speech Language Pathology Document) contain a priori PHI in more than 75% of all instances. The table shows that a priori PHI occurrence also differs by user group (e.g., National Institute of Allergy and Infectious Disease [NIAID] Intramural Research Program). A priori PHI presence data on all document types are available in the online appendix B.

On the other hand, we found 17 document types (9748 documents in total) that neither contained a priori PHI nor secondary person tokens. Analysis by document type revealed that 9 of these 17 document types always contain the same text telling the clinician to refer to a second document. For example, "Ophthalmology Consult (National Eye Institute)" document type consisted of 350 documents with the text: "NEI Clinical Documentation - Please click the camera icon in the bottom left corner of the window to see this document". Six document types were very brief forms related to admission, blood transfusion or anesthesia (e.g., Pre-Operative Anesthesia Record, Anesthesia Perioperative Record, and Post Anesthesia Care Unit Record), and often consisted of administrative content. Such "medium value" documents often repeated patient data such as research protocol assignment or patient gender. Only one document type ("Point of Care Testing Document") contained more variable clinician-entered data, such as glucose bed side test results.

Table 2: Document types that frequently contain a priori PHI

Document Type	Total Count	% of instances with a priori PHI	% of instances with secondary person token
NIAID Progress Note - Study Coordinator Document (CC, CRIS)	154	100%	15%
Speech Language Pathology Document (CC, CRIS)	98	99%	53%
Transfusion Medicine Note Document (CC, CRIS)	88	89%	27%
Dermatology Consult (CC, CRIS)	237	86%	39%
SOAP Progress Note Document (CC, CRIS)	1052	83%	28%
Genitourinary (GU) Oncology Free Text (CC, CRIS)	230	80%	24%
Bereavement Intake Progress Note (CC, CRIS)	121	79%	99%
Radiation Oncology HPE Document (CC, CRIS)	123	78%	96%
Radiation Therapy Summary Document (CC, CRIS)	112	75%	21%

Pooling all documents (regardless of the document type), we found that 4.61% of clinical documents (17 340 out of 376 051) contained a priori PHI.

Presence of a secondary person tokens: Table 3 presents the frequency of secondary person tokens across all documents identified by NLM Scrubber. The most frequent secondary person tokens were: mother, spouse, parent, wife and father. Secondary tokens with less than 0.5% relative occurrence were collapsed into two bottom items "other-family" and "other-non-family" to reduce the size of the table. Data on all tokens are available in a separate sheet of online appendix B.

When analyzed by document type, occurrence of secondary person tokens ranges from 0% to 99%. For example, in "Bereavement Intake Progress Note" the occurrence was 99%, while the occurrence in "Tumor Measurements and Response Document" was 0%. Again, online Appendix B also contains data on secondary person token presence for all 177 analyzed document types and Table 2 includes secondary person token column for selected documents.

To produce a conservative estimate and assuming that every document with a secondary person token includes secondary PxI, then NIH CC's IDR incidence of secondary PxI is 12.94% (48,679 out of 376,051 documents). Using a two-fold condition of simultaneous presence of secondary person token and presence of a priori PHI (primary patient name or MRN), we found that 1.14% of all documents (4,276 out of 376,051) satisfy this stricter condition.

Table 3: Absolute and relative occurrences of individual secondary person tokens across all document instances.

Secondary Person Token	Occurrence	% of All Occurrences	Secondary Person Token	Occurrence	% of All Occurrences
MOTHER	17,979	14.21%	PARENTS	3,196	2.53%
SPOUSE	16,942	13.39%	MOM	2,695	2.13%
PARENT	13,825	10.93%	SIBLING	2,583	2.04%
WIFE	11,858	9.37%	FRIENDS	2,540	2.01%
FATHER	8,959	7.08%	FRIEND	2,528	2.00%
DAUGHTER	6,460	5.11%	CHILD	1,872	1.48%
HUSBAND	6,124	4.84%	SIBLINGS	898	0.71%
SISTER	5,359	4.24%	DAUGHTERS	754	0.60%
BROTHER	5,313	4.20%	DAD	743	0.59%
SON	3,867	3.06%	OTHER (FAMILY)	6,477	5.12%
CHILDREN	3,742	2.96%	OTHER (NON-FAMILY)	1,780	1.41%

Regarding the detection of personal names, we found that a majority of document types include the names of the authoring clinicians (complete data available in Appendix B). Without prior knowledge about local clinician names or document structure clearly tagging electronic signatures, the detection of personal names was not an optimal signal for detecting instances of secondary PxI due to too many false positives.. However, proximity search

measures (personal name near a secondary person token) could potentially result in improved detection of true instances of secondary PxI.

Manual review

For manual review, we selected the "daughter" secondary person token since this was the most frequent secondary person token belonging to an offspring which, in turn, is the generation that is likely to be surviving the primary patient. For the reviewed document type, we selected the highly variable document type "Progress Note – Free Text Document", authored by physicians (rather than nursing staff). This selected document contained a secondary person tokens in 16% of instances. A pilot study of two other pairs of secondary person token and document type did not yield significant findings.

Based on review of all sentences containing the selected token, we classified the secondary PxI instances into three categories listed in Table 4 together with de-identified examples. We found:

1. *Health related secondary information:* e.g., secondary person diagnosis. Note that such information technically constitutes *protected* (in HIPAA sense) health information only if it is explicitly or implicitly combined with a secondary person first name (most often), full name or other identifier in addition to the secondary person token presence. Otherwise, it can be considered de-identified (meets criteria for the Safe Harbor Method).
2. *Non-health secondary information with an identifier (secondary PII)* (e.g., secondary name, secondary phone number or secondary age)
3. *Non-health secondary information without a secondary identifier* (e.g., description of care situations involving a family member)

Table 4: Classification of secondary PxI and examples identified during manual review

Class	Information Domain	Example
Health related secondary information	Diagnosis	Her *mother* and *daughter* both have symptoms of *multiple sclerosis*.
		Patient started on antibiotic post exposure prophylaxis for *pertusis* (daughter tested positive)
Non-health secondary information with an identifier (secondary PII)	Name	I had a frank 2 hour discussion with Ms Doe and her husband and her daughter *Alice*.
		She was accompanied in our meeting by her husband and her daughter *Alice*
	location	His daughter lives in Richmond.
	phone	Mrs. Doe daughter *Alice Carol Smith (123-123-1234)* contacted research nurse Alice Jones, R.N., and requested that I call her.
		I attempted to reach *Mrs. Smith (cell 123-123-1234)* this morning to convey our condolences on Mr. Smith passing earlier this morning.
	age	He is married and has a 9-year-old daughter.
	combination	Mr. Doe young adult daughters (*ages 18 and 23*) as well as his sister and sister-in-law are anticipated to arrive this evening from *Cleveland* around 8:30pm.
		SH: ... Happily married. One son lives in *Annandale – active duty Army*. *Daughter* in *Pennsylvania*. *3 grandkids*.
		Mrs. Doe was accompanied by her daughters *Alice* and *Carol* who drove her from *Pennsylvania* for the procedure.
Non-health secondary information without a secondary identifier	n/a	Pt did ROM exercises in bed with her *daughter*.
		We discussed in detail with patient, *spouse* and *daughter* the progression of disease based on radiographic findings and worsening symptoms
		The *daughter-in-law* will be returning with Ms Smith between 10am - 12pm tomorrow for dressing change, supplies, and d/c instructions. (data note: Smith is the primary patient)
		She stated that his *daughters* did arrive to the hospital but the *sons* had not made it.

Discussion

This study is the first to report on an informatics repository and platform created specifically around deceased subjects. The dsIDR contains a smaller number of patients and observations compared with the full IDR; however, the most frequent items are well represented. For example, 99.9% of the top 2000 the full IDR laboratory tests are also present in the dsIDR. Table 1 shows that while the dsIDR consisted of only 9% of patients (24 000 out of all 265 000 IDR patients with any laboratory data), it accounted for 24% of all laboratory tests and 32% of all medication records. This can be explained by the disproportional care provided to older or sicker patients[11] and also by the NIH Clinical Center casemix bias due to its research hospital status. In building the dsIDR, we were able to

re-use existing processes for structured coded data (e.g., laboratory results) that remove results where comments contain patient name or medical record number. However, due to costs and available resources, robust de-identification techniques for unstructured data (narrative clinical documents) are only now being developed.

Narrative text clinical documents

Since valuable clinical information is often stored in unstructured narrative text clinical documents and the dsIDR's purpose is to serve as a pilot platform, inclusion of narrative-text clinical documents within the dsIDR is highly desirable. In order to protect the identity of secondary persons, removal of primary patient name is highly advisable. For example, if a record mentions the diagnosis and the first name of a family relative, the presence of the primary patient last name helps reveal the full name of the relative. Although the Privacy Act does not apply to dead people, for non-research use, HIPAA protects health records of decedents for the period of 50 years after death as if they were living.

In our effort to remove a priori PHI (more specifically, primary patient identifiers), we found that their presence in documents differs widely (from 0% to 100%). For document types where all or almost all instances contain primary patient name and medical record number the reason may be due to data integration processes for external ancillary system. If an external system is used, re-entering patient IDs ensures proper data integration of data authored in the external system to the primary system or common data viewing platform. Although some document types do contain with high frequency a priori PHI identifiers (Table 2), the overall rate across all documents is only 4.61%. This implies that in majority of narrative clinical documents, the patient identity is not repeated within the text. Therefore, if a document mentions a family relative by relationship (e.g., daughter), 95% of documents will not provide the context of primary patient full name to identify the secondary person. This is also demonstrated by the considerably lower estimate (1.14%) that uses the two-fold criterion as opposed to mere secondary token presence (12.94%).

The review of alphanumeric identifiers found by NLM Scrubber also showed that date of birth is frequently used as safety check within EHR forms and could potentially be another a priori PHI element type. However, including date of birth in this set (together with name and MRN) may be meaningless because dsIDR already contains structured data on date of birth.

Study limitations

Our pilot exploration of secondary PxI in a deceased subject repository has several limitations. Our goal was not to arrive at a final method capable of removing all secondary PxI. Our set of secondary person tokens, although designed to be broad, may not contain all keywords of importance at other institutions. For example, the presented results reflect an older version of this token set that did not contain the keyword "fiancé". Also, we have only used a single de-identification tool and data from a single institution.

Our work relies heavily on the secondary person token presence assumption. It was out of scope of this pilot study to formally evaluate and measure, most likely by manual validation, the percentage of excluded documents (based on explicit presence of a secondary person token) truly contain secondary PxI (true positive vs. false positive). Similarly, we did not validate that included narrative documents, lacking secondary person token, are truly free of any implicit secondary PxI (false negative). This evaluation would improve our estimate of secondary PxI presence which should be interpreted as a machine-based upper bound approximation rather than an exact determination.

Lessons learned and future work

During our pilot creation of the dsIDR we found that removing secondary PxI differs significantly from general de-identification tasks that focus on the 18 identifiers specified by the HIPAA Safe Harbor method. While the Safe Harbor research route is well characterized in the regulation, the regulatory guidance for decedent clause research is less precise. We can apply the Safe Harbor Method guidance on any secondary PxI, but it is less clear on how aggressive the scrubbing must be for the primary deceased patient. The classification shown in table 4 (manual review of secondary PxI instances) shows several examples of varying level of sensitive context ranging from family phone number to a simple age fact). In our interpretation, we assumed that all primary patient information can stay, unless it provides context to reveal secondary PxI of a living person. For example, whereas traditional de-identification within a whole population IDR would require removal of locations and dates, they are permitted to stay in the dsIDR (unless related to a secondary person, which is much less frequent). It is also important to note that the recent regulatory change in decedent PHI protection (shortening to 50 years instead of indefinitely) does not apply to the research context; the decent research clause provides research access to decedents' records immediately after death.

Another useful lesson was about importance of empty (un-filled) EHR forms. We found that many documents are semi-structured and clinicians enter only short entries into this pre-populated structure (e.g., anesthesia type). Some

of those semi-structured document fields are even pre-populated by software (e.g., protocol number, gender) and never edited by the user. Documenting this as metadata at the document level (list of all document questions/sections, software field pre-population, editability) provides useful prior knowledge for scrubbing. In our future revisions, we may consider measuring Levenshtein distance, which is a string metric for measuring the difference between two text sequences as number of single-character edits (empty EHR form vs. complete document). Such an approach is suitable for documents with minimal clinician-entered content (e.g., Post Anesthesia Care Unit Record).

Alternatively, for a limited set of non-dictated documents authored within the modern EHR form paradigm, the optimal dsIDR unit of information is a clinical document section or question rather than the full document. In a separate study,[12] we analyzed problem list sections in dsIDR as well as full IDR. Due to the OHSRP requirement for de-identification, we performed a manual review to verify that truly only problem list information is entered into the problem list document section. We found that clinicians may occasionally forget to hit <tab> or otherwise advance to the next form field and enter social history or family history into the problem list section resulting in PHI being present in the dataset. Another observed problem related to the issue of empty forms and form structure was the presence of a false positive secondary person token (e.g., children) in the form questions or pre-populated entry (e.g., clinical trial title "Continuing Treatment for *Children* and Adults in the Center for Cancer Research; clinicaltrials.gov: NCT00001295).

Regarding the detection of phone numbers as the most frequent alphanumeric identifiers, we found that local hotels, local pharmacies and internal department pagers were often detected as false positive secondary PxI identifiers. Scrubbing software could take advantage of a prior list of permissible phone numbers. Detecting the nature of the phone number by an Internet search engine is another strategy that can distinguish publicly known phone number from phone numbers intentionally kept private. If an EHR contains a structured and well used field that provides primary patient's phone number, it can be used as a priori PHI element to improve the scrubbing accuracy. Similarly, names of investigative drugs could be extracted from clinical trial descriptions and white-listed as allowed alphanumeric identifiers.

Table 5: Summary of lessons learned

- Lack of clear regulatory guidance for de-identification of decedent records for research use (in contrast to the Safe Harbor Method for general de-identification within a whole population IDR)
- Need for metadata on document structure (empty EHR forms; pre-populated fields, secondary person tokens as part of the form question; plain free-text vs. structured provider e-signatures)
- Phone number as the most sensitive secondary ID and possible disambiguation methods for phone numbers (local hotel or pharmacy vs. secondary person private number)
- Provision of prior information to scrubber about local provider names or permitted alphanumeric IDs, such as experimental drug names.
- Importance of accurate deceased status using local institutional data or external data from State Vital Statistics Administration (research context only) or federal death index data

We plan to incorporate some of the above mentioned issues (see Table 5 for summary) in the future versions of our overall processing pipeline and NLM Scrubber feature set. Our pilot study and presented experience offer some guidance to other institutions interested in establishing their own dsIDR in terms of how to characterize the size of the dsIDR, narrative document lessons learned and the value of collecting and verifying death status data. NLM Scrubber is planned to be released freely prior to the AMIA Annual Symposium in November 2014 and could provide to interested institutions as a no-cost software tool with potentially additional experimental features for detecting secondary person tokens. Federation of multiple dsIDRs can address the sample size limitations of any single repository. Central Intelligence Agency Factbook estimates that each month about 221 thousand deaths occur in the USA and 66.5% of those deaths occur outside the home (in hospitals, nursing homes or other facilities; according to a 2009 Medicare study).[13] Internal records and first-hand primary death data are important because national death registries, such as the Social Security Death Master File contained 0.03% false positive deaths and since 2011 omits records from several US states.[3,14]

Conclusions

The HIPAA decedent clause represents an important and often overlooked alternative to using de-identified EHR records. Use of deceased subject records does not require full IRB review or patient consent. The 18 patient identifiers listed in the HIPAA Safe Harbor Method do not have to be removed in dsIDR; however, in order to protect the privacy of secondary living persons, we argue for removal of those that have limited research value. Removal of only secondary PxI results in less distorted research data compared with general de-identification used in whole population IDR. Our study is the first to suggest a basic method for de-identification of decedent records and provides the first estimate of the rate of secondary PxI in EHR data (12.9% using only the secondary person token presence criterion and 1.1% using stricter criteria). With potential increased use of decedent EHR data, clearer guidelines addressing the issue of secondary PxI and what constitutes acceptable proof of death could facilitate such research. We also recommend modifications of existing de-identification programs (such as NLM-NS) to offer a dsIDR scrubbing mode in addition to existing modes where all 18 PHI identifiers are being targeted. In our exploration of secondary PxI, we found secondary person phone numbers to be most frequent and most sensitive secondary person identifiers. Federated dsIDRs can address the issue of limited sample size and make them even primary research platform for certain hypotheses.

Abstract

Observational research using data from electronic health records (EHR) is a rapidly growing area, which promises both increased sample size and data richness - therefore unprecedented study power. However, in many medical domains, large amounts of potentially valuable data are contained within the free text clinical narrative. Manually reviewing free text to obtain desired information is an inefficient use of researcher time and skill. Previous work has demonstrated the feasibility of applying Natural Language Processing (NLP) to extract information. However, in real world research environments, the demand for NLP skills outweighs supply, creating a bottleneck in the secondary exploitation of the EHR. To address this, we present TextHunter, a tool for the creation of training data, construction of concept extraction machine learning models and their application to documents. Using confidence thresholds to ensure high precision (>90%), we achieved recall measurements as high as 99% in real world use cases.

Introduction

The increasing use of electronic health records (EHR) provides potentially transformative opportunities for clinical research in the breadth and depth of data contained within them. However, unstructured clinical notes are often the most valuable source of phenotypic/contextual information because of limitations in the scope and acceptability of structured fields. In response to this challenge, Natural Language Processing (NLP) has been employed to extract appropriate assertions in a structured format amenable to the needs of researchers[1]. While significant success has been achieved in many areas, the demand for ever more variables to be extracted from the clinical narrative is currently bottlenecked by the limited supply of technical skills[2]. For example, rule based approaches to novel problems are often effective, but require a certain degree of technical knowledge and experience, which can be too time-consuming and thus expensive to produce in high volume. Proposed solutions include ontological or dictionary mapping techniques, which are appropriate where there are well-constructed resources; however, the standards imposed by these may not be easy to adapt to real world clinical sub-languages[3], or where there is controversy about the appropriate use of clinical language[4]. Machine Learning (ML) approaches are an increasingly popular means of circumventing rule based systems, but require even more technical expertise and are limited by the availability and ease of creating appropriate training data[5,6]. Finally, although progress has been made in the development of publicly available corpora for evaluating different clinical NLP methodologies[7], these offer no guarantee that the performance obtained by models trained on such data will provide a generalizable solution (for example, for work on EHRs in different medical domains, dialects, languages, or work cultures)[8].

These issues form barriers to progress for groups who have access to unstructured clinical data, but do not have sufficient technical capabilities to trial the wealth of information extraction techniques on offer. In recent years this has prompted the development of tools such as Arc[9] to democratize access to generic information extraction capabilities. However, there are currently no free tools available that offer a full end-to-end solution for concept level extraction, including the principle tasks of:

1) Extracting instances of concepts from a database or large collection of documents

2) Creating sufficient training data specific to a concept to enable a machine learning approach

3) The configuration and testing of an (ML) algorithm for the given concept

4) The application of the model to the entire document set of interest, and the subsequent export of results into a familiar format

In order to make concept extraction technologies accessible to groups without informatics support, we have developed the TextHunter tool to address these tasks.

Methods

Data: The South London and Maudsley mental health case register

The South London and Maudsley NHS Trust (SLAM) is the largest mental health organization in Europe, and is a virtual monopoly provider of mental health services to 1.2 million individuals within its geographical catchment area (Lambeth, Southwark, Lewisham and Croydon boroughs in South London). In 2007-08, funding from the British National Institute for Health Research supported the development of the Clinical Record Interactive Search (CRIS) database. CRIS operates as a pseudonymized version of SLAM's EHR system, accessible for researchers via its distinctive, patient-led information governance model[10]. CRIS houses more than 230,000 de-identified patient records, which in turn represent over 20 million free text documents. The CRIS system continues to grow at a rate of approximately 170,000 free text documents per month. Clinical information documented in unstructured text is of particular value in mental health research where there is an increasing emphasis on using dimensional symptom scales to define mental illness rather than discrete diagnostic categories[11–14]. While CRIS also has large amounts of data contained within structured fields, the development of TextHunter was precipitated by the needs of many disparate groups of researchers who require access to the wealth of additional information contained within the clinical narrative.

TextHunter System Description

TextHunter is a program that guides a user through all of the required processes to create and apply a concept extraction model for a selection of documents from start to finish. It performs six important tasks, the end result of which delivers a structured representation of a concept. Its intended use case is typically phenotype cohort identification, although it can be employed for more generic purposes. The program is built from open source libraries, and uses the GATE library as its core NLP engine[15]. The ML element uses the Support Vector Machine (SVM) based 'Batch Learning' plugin supplied with GATE[16]. In consideration of the rigorous information governance requirements of clinical data, TextHunter is designed to operate as a standalone 'offline' program on desktop hardware, although its multithreaded design enables its deployment on more powerful workstations/virtual machines to handle larger datasets. It is capable of connecting to commercial database environments such Microsoft SQL Server to process massive datasets, but for succinctness, only its standalone operation mode is described here.

The underlying principle of TextHunter is 'Find, Annotate, Build, Apply' - respectively addressing the four key problems described above. The integration of these concepts into a single system creates the possibility of providing lay users with access to more advanced ML techniques, such as active learning. Each phase of the TextHunter pipeline is described below:

1. Search Phase

This phase addresses task 1). The first stage of the TextHunter pipeline requires a user to define a list of keywords, regular expressions and/or phrases to describe their concept of interest. The user then directs the program to a directory holding the text files of interest. Upon executing the 'search' phase, each document is scanned for mentions of the user's expressions. When a mention is identified, a short section of text consisting of multiple sentences, including the sentence where the concept mention was found, and up to two sentences either side of the sentence of interest is extracted. This is stored in an embedded file based database, along with a copy of the underlying document. Deconstructing documents in this way facilitates the downstream management of text instances for annotation and classification.

2. Annotation Phase

This phase addresses task 2). The user is directed to TextHunter's annotation interface, which has been specifically designed for the rapid annotation of concept instances. We define an instance as a group of one to five sentences centered on a concept keyword, and its classification as defined below:

i) Positive – the example is a relevant hit and is an appropriate positive example of the user's concept

ii) Negative - the example is a relevant hit and is an appropriate negated example of the user's concept

iii) Unknown - the example is a relevant hit but the user is unable to ascertain the correct classification, or the example is irrelevant

In this phase, the user is required to produce a 'test' corpus for model validation (typically of 100-300 instances), which are randomly selected from all instances in the document set. This is followed by the production of a 'seed' corpus to be used in training models. This also numbers about 100-300 instances, but is enriched by ensuring no identical instances are present. In real world clinical datasets, the required semantic context that enables the classification of a concept instance may cross sentence boundaries. To ensure appropriate features are available for training, the user can specify the required 'context' (up to two sentences before and two sentences after) needed to make the classification, centered on the sentence containing the concept keyword. These boundaries are arbitrarily chosen by the GATE sentence splitter module, although we expect that only in very rare cases will more than five sentences be required to express medical concepts as they are normally found in EHRs.

3. Feature selection/Model Building Phase

This phase addresses task 3). Here, TextHunter builds and evaluates a range of models against the task, using different features and SVM parameters each time. The default feature vector used by TextHunter is a classic bag of words using part-of-speech tags and token stems from the user specified context around a concept. When applying a model to unseen data, TextHunter creates feature vectors from up to six different combinations of sentences around the sentence containing the concept term. The classification resulting from the feature vector producing the highest overall confidence is chosen as the result. In addition, TextHunter has a modular design that allows developments from the clinical NLP community to be integrated into its core pipeline via GATE creole plugins. Currently, TextHunter takes features of the GATE implementation of the ConText algorithm[17], which uses hand crafted rules to determine whether a concept is negated, temporally irrelevant or refers to a subject other than the patient. Stop word removal is also explored during feature selection.

Cross validation of the training data is used to mitigate the dangers of overfitting the model to a small amount of data. The model producing the best F1 score is taken forward for testing against the human labeled 'test' corpus, which is never used in model training. A range of easy to interpret output files are produced, containing estimates of 'real world' performance the user might expect.

4. Application Phase

This phase addresses task 4). This phase allows the user to apply the best performing model to all instances of text in their dataset, as captured in the search phase. As with the model building phase, combinations of sentences are tested around the concept. The classification that results from the combination with the highest confidence is chosen as the final result. Once this stage is complete, the user may export the output into several formats.

5. Active Learning Phase (optional)

Conceptually, active learning is an iterative process whereby an ML algorithm selects instances that it has difficulty classifying and presents them to a human annotator for labeling. These are then fed back into the model, with the intention that the new model arising will be better at classifying similar, difficult examples. TextHunter supports a 'simple margin' inspired method of active learning[18]. A seed model is constructed from randomly selected instances of text, as described above. This model is then applied to a large sample of the entire population of relevant text instances. For each classification the model makes, it also assigns a level of certainty, between -1 and +1. Theoretically, highly positive scores are representative of easy to classify 'positive' instances, whereas highly negative scores are representative of easy to classify 'negative' or 'unknown' instances. Instances with a certainty score close to 0 are thus 'difficult', and presented to the user for labeling in order to retrain the classifier.

Use cases

To evaluate the performance of TextHunter, we defined three real world use cases of concept extraction. Examples of search expressions and typical instances for each use case are detailed in Table 1:

Case Study 1: Cannabis Smoking

Cannabis use has been indicated as a potentially aggravating factor in patients suffering from mental illness[19]. Through the vast amount of electronic documentation generated in the course of patient care, we attempted to identify a patient's cannabis smoking status based upon reports by mental health professionals. The CRIS database contains intra-profession clinical correspondence style documents and clinical notes resulting from patient contact. Each type of document may contain references to cannabis usage by the patient. In this study, our objective was to use TextHunter to build a classifier to identify current or historical cannabis usage. We conducted a review of the most common nouns and slang terms used to describe cannabis in SLAM, to produce a list of expressions which formed the basis for finding instances to classify. A psychiatrist then produced multiple sets of annotations using the standard TextHunter procedure, making use of the active learning functionality. Although it was not possible to double annotate the training data, we adopted a restrictive manual coding strategy in order to allow as little subjectivity as possible (for example, by classifying mentions pertaining to future events, or tangential/circumstantial references into our predefined 'unknown' class).

Case Study 2: Psychosis Symptomatology

Patients suffering from psychosis can exhibit a wide range of symptoms, which in turn inform the nature of their treatment plan. Common tools to quantify symptomatology in psychosis include such instruments as the Positive and Negative Symptom Scale and the Clinical Assessment Interview for Negative Symptoms[12,13]. These depend on an assessment of the patient's presentation in regard to a wide range of possible symptoms. Our previous work to capture some of these from clinical notes with ML approaches has been described[20,21]. In this case study, we used TextHunter to capture two additional symptoms: delusional symptoms and evidence of hallucinations, using the standard TextHunter workflow. The annotated data for 'delusions' were generated by a clinical informatician, with a random sample checked for accuracy and consistency by a psychiatrist. In the case of 'hallucinations', all annotations were generated by a public health physician. In both cases, the restrictive coding strategy as described above was employed.

Table 1: Search expressions and examples of instances. Theoretical patient identifiers masked by ZZZZZ.

Case Study	**Examples of subword patterns (case insensitive) for search phase**	**Fictitious examples of instances (Parentheses indicates typical labeling by human annotator)**
Cannabis smoking	cannab hash weed pot	ZZZZZ told me that he continues to smoke cannabis only no other illicit drugs. **(positive)** ZZZZZ has no history of amphetamine or cannabis use. **(negative)**
Psychosis symptomatology	delusio hallucina	She is continuing to experience hallucinations and is becoming increasingly distressed by these. **(positive)** Staff observed him to rambling and delusional, repeating himself and his gait was abnormal and more pronounced. **(positive)**

Case Study 3: Ethnicity

Ethnicity is a key variable in many epidemiological and clinical studies. Although ethnicity can theoretically be captured via the structured elements in SLAM's EHR system, in reality, it is often not recorded in the course of routine clinical practice. However, as with many other variables, ethnicity is often referenced in clinical free text. The purpose of this case study was therefore to classify instances of text describing a patient's ethnicity, into one of 17 ethnic groups. A range of terms was selected in association with each ethnic group, and a 'positive' classification was made if the context for the term was suggestive of the patient belonging to that group. A single researcher produced the annotated dataset for training/testing, using a similarly restrictive coding strategy.

In each case study, a sample of the evaluation instances were double annotated by an individual in a related profession to generate inter-annotator agreement statistics.

Results

In all case studies, we used 10 fold cross validation for the model building phase, which took approximately one hour on a desktop computer with a Core 2 Duo E7500 processor.

In the cannabis smoking study, we used 13 terms to capture cannabis mentions. The CRIS database yielded 663,979 mentions of cannabis. For the psychosis symptomatology study, the search phase found 603,818 mentions of delusions, and 703,996 mentions of hallucinations. Each symptom was represented by a single term in the search phase. Finally, there were 3,444,435 mentions of concepts potentially related to ethnicity, resulting from 277 terms commonly used to define our 17 ethnic identities.

Traditionally, the performances of information extraction algorithms in NLP are described in terms of precision, recall and the F1 statistic. However, the high level of noise commonly associated with EHR based observational research necessitates the capture of high quality data in order to generate clearly defined cohorts. This data quality requirement restricts the use of automated concept extraction techniques to those that can be shown to have a high true positive rate, relative to the inherent predictive value of a mention of a concept. For example, a mention of a cannabis synonym will refer to a patient's current or past use 70% of the time, whereas a mention of a term denoting ethnicity will refer to a patient's actual ethnicity only 20% of the time (Table 1). A further consideration of the real world viability of a given model is the longitudinal nature of the electronic health record. A patient may have numerous contacts with a health service over a number of years, creating multiple instances of time independent concepts. For example, a patient may have multiple references to their cannabis consumption habits, especially if it is identified as a factor in their illness. Similarly, a patient's ethnicity may be described in service referral letters generated during the course of their care. Only one positive instance needs to be captured precisely for a high quality output to be achieved. However, spurious data points are more problematic. Given these factors, it is more practical to develop information extraction tools that favor precision over recall in most use cases. For this reason, in Table 2 we describe the recall statistic at two arbitrarily defined levels of precision (90% and 95%), which are identified by filtering the classified instances in the test set via the classification confidence threshold. We present Receiver-Operator Characteristic (ROC) plots for each case study in Figure 1. For brevity, we only report the highest F1 achieved without any confidence filtering (note, this is not necessarily the same model that achieves the highest recall at the 90%/95% precision threshold).

The best performance was seen in the hallucinations case study, with over 97 % recall obtained at the 95% precision threshold. The worst performance was observed in the ethnicity study, where recall reached only 9% at 90% precision, and declined with further training.

Different problems required different features in order to obtain the best overall result. In Table 3, we present the types of features that were found to be most useful in each case study.

The rate of training data production varied moderately between the studies, the slowest recorded at approximately 100 instances labeled per hour, and the fastest at roughly 230 instances per hour. Since different individuals annotated each study, further comparisons were not possible. Anecdotal reports from the annotators suggested that the process of annotating instances selected via active learning was slower than the randomly selected instances in the seed set.

Table 2: Performance statistics for TextHunter 'positive' instances ('unknown' and 'negative' instances are grouped together). [1]Observed Agreement and Cohen's Kappa. [2]Baseline precision assumes presence of keyword is a 'positive' instance (by definition, recall is 100%), and provides a measure of how predictive a mention is of a concept without any processing applied. P = precision, R = recall, F1 = harmonic mean of precision and recall. [3]Parentheses indicate count of training instances in the model building phase (subsequent active learning iterations increase the number of training instances available). [4]Recall measured at precision levels of 90% and 95%, attained by confidence filtering.

Case Study	Inter annotator agreement [1,3]	Test Instances	Baseline precision[2]	Seed data base performance[3]	Seed data Recall[3,4]		Active learning iteration 1 recall[3,4]		Active learning iteration 2 recall[3,4]		Approximate total annotator time spent creating training data
					90	95	90	95	90	95	
Cannabis smoking	88% 0.76 (211)	233	75%	P = 81% R = 95% F1 = 0.87 (478)	45	38	68	52	72	53	~10 hours
					(478)		(1 329)		(1 835)		
Delusions	95% 0.91 (110)	206	68%	P = 89%/ R = 99%/ F1 = 0.93 (708)	95	87	N/A		N/A		~4 hours
					(708)						
Hallucinations	89% 0.78 (117)	131	70%	P = 93% R = 99% F1 = 0.96 (150)	99	97	99	97	N/A		~7 hours
					(150)		(914)				
Ethnicity	97% 0.94 (201)	650	20%	P = 82% R = 75% F1 = 0.78 (396)	9	9	3	3	N/A		~3 hours
					(396)		(805)				

Table 3: Additional features used in best performing model delivering >90% precision

Case Study	Best Model ID	ConText used?	Stop words removed?	SVM Cost	SVM kernel type
Cannabis Smoking	128	No	No	0.6	polynomial
Delusions	136	No	No	0.6	polynomial
Hallucinations	88	Yes	No	0.5	polynomial
Ethnicity	24	Yes	Yes	0.7	polynomial

Discussion:

In our analysis, we used TextHunter to extract a diverse set of concepts that are typically in demand in clinical research environments. We arbitrarily set two desired precision standards, and adopted strategies to try to maximize the recall given this requirement. Three of the four test cases reached over 70% recall at the lower precision cut-off of 90%. We do not attempt to tackle the question of what constitutes acceptable performance for research applications here. Nevertheless, we have confidence that the range of case studies investigated here establishes a

proof of concept in enabling end users to create and deliver information extraction solutions independently of significant NLP expertise.

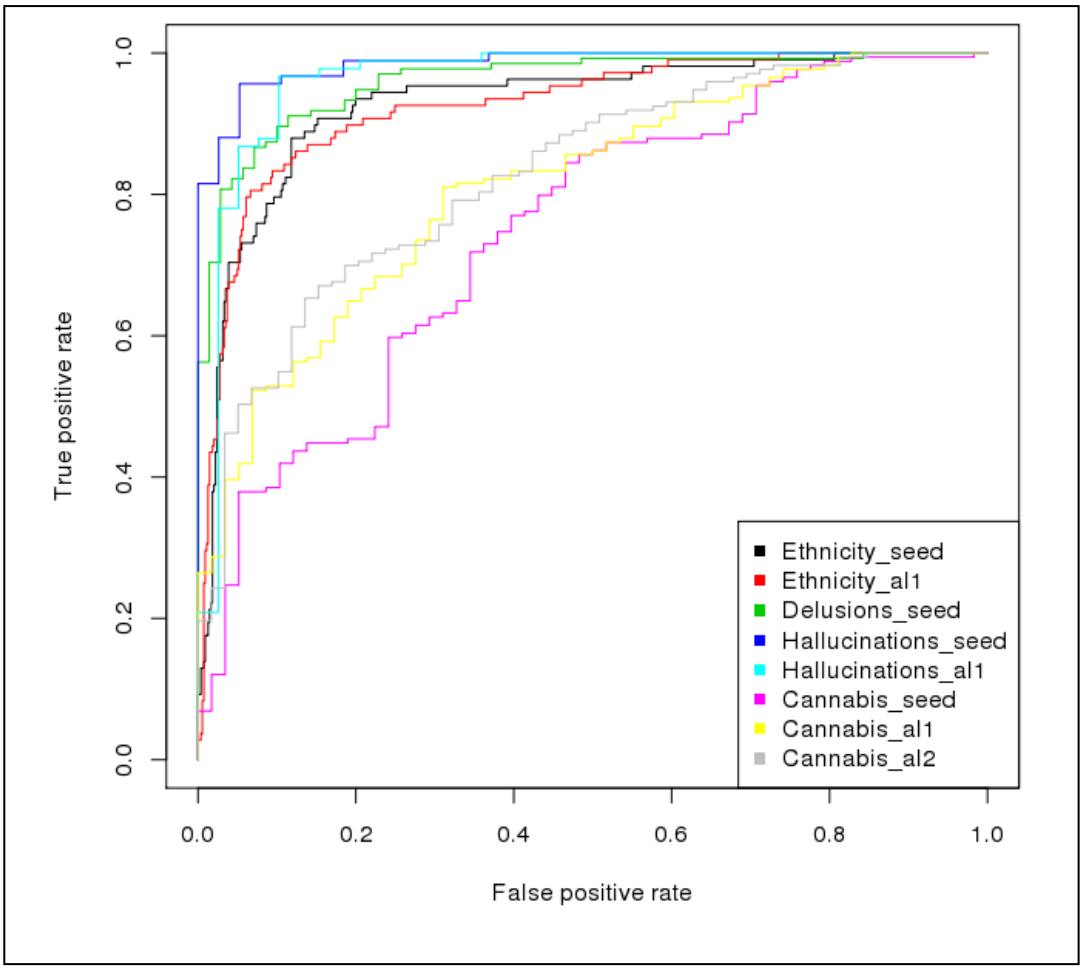

Figure 1: Receiver Operator Characteristic for TextHunter models on 'test' data, generated with SVM confidence thresholds.

Given our limited range of test cases, the SVM parameters and additional features used varied greatly, even between the two conceptually similar problems explored in psychosis symptomatology. This substantiates our approach of testing a range of models to find the best solution for a given problem. However, a predominant factor in the algorithms' ability to reach higher levels of recall is the predictive value that a simple mention of a concept produces (i.e. how likely a human annotator is to label a randomly selected mention of a concept as 'positive'). For instance, the ROC curve produced for the ethnicity study compares favorably with that of the cannabis study, and we achieved a substantial performance benefit over the baseline precision for our list of ethnicity terms. However, because of our self-imposed requirement of a minimum 90% precision, the recall for ethnicity falls very quickly as this threshold is approached. Intuitively, in high noise datasets where 'positive' mentions of a concept are rarer, the concept extraction problem is significantly more challenging. In addition, the low predictive value of ethnicity terms means the 'positive' class will be less represented than the 'negative' or 'unknown' classes in the model. Currently, TextHunter makes no adjustment for unbalanced classes, and future work could investigate mitigation strategies for this, such as using uneven margins [22]. It should also be noted that we were required to use many more terms to capture mentions of ethnicity, which may be indicative of the inherent difficulty of defining concepts that are largely social constructs.

In the case of the cannabis study, we were able to improve the model substantially by providing additional training data through active learning. We did not try to quantify the added benefit of adopting an active learning

methodology over randomly selecting new instances. However, others have previously demonstrated that active learning can accelerate the development of machine learning models in clinical NLP[18,23,24]. Active learning did not produce an additional benefit in the hallucinations case study, although the model resulting from the seed data had already produced a very high F1 statistic. Here, our application of confidence filters was not required, as the performance of the model generated from the seed annotations surpassed our precision requirement of 95%. In the case of ethnicity, adopting an active learning approach noticeably depreciated the quality of the model. To investigate, we conducted a subjective review of the instances that active learning retrieved. This revealed that many were incoherent strings of text, seemingly resulting from jumbled emails, faxes and other malformed documents. Since these were not representative of natural language, their inclusion in training the model possibly introduced more noise than benefit. Previous reports have highlighted the difficulties of applying general NLP tools on clinical text[8,25], and we suspect that this scenario is not uncommon in real world EHR systems. One possible mitigation strategy would be to employ document classification methods to filter out malformed documents and/or a more sophisticated active learning methodology, such that new training data are more representative of the instances of interest. Nevertheless, an SVM approach as implemented in TextHunter appears to be valid for simple concepts that tend be succinctly expressed - for example, if it can be defined with a relatively short list of keywords, is not over-complicated by frequent ungrammatical usage (such as in lists or questionnaire text) and has a baseline precision of at least 60%.

It was not practical to double annotate our training data fully, so we are only able to provide inter-annotator agreement (IAA) statistics for a subset of the total test set in each case study. Despite our limited set, our data suggest relatively high levels of agreement, highlighting a high degree of objectivity in the expression of concepts in clinical text. However, clinical constructs in mental illness are often subtle. Initial reports from annotators in each case study suggested that the annotation process itself influenced their own views on the interpretation of notes created by others. Specifically, the exposure to a wide range of writing styles from other clinicians may introduce unforeseeable subjectivity into the annotation process. Regardless, methods that place subject matter experts (rather than NLP specialists) in the role of defining a concept are likely to be less subjective, as any subjectivity introduced by the annotation process will likely be compounded by attempting to convey the subtleties to a non-expert third party. Any clinical subjectivity may then be mitigated by a process of iterative discussion and re-annotation to produce well defined annotation guidelines. A potentially useful future development of TextHunter may be to incorporate a model of clinical data, such as the Clinical Element Model[26]. This would encourage the re-use of standard definitions of concepts, thus promoting greater interoperability with NLP tools.

A notable shortcoming of the TextHunter methodology was the ethnicity case study, which had the highest Kappa statistic but the lowest F1 score from the seed data. This highlights the divide between human and machine interpretation, and the need for more complex reasoning systems to resolve more difficult problems.

Conclusion

The requirement to develop this software was driven by an imbalance between the demand for concept extraction and the supply of skilled individuals capable of delivering solutions to the needs of researchers. We have shown that it is feasible to package an appropriate suite of tools into a simple interface, and that this enables researchers to produce concept extraction models without input from NLP specialists. TextHunter uses a flexible SVM based algorithm as a generic, user friendly information extraction capability. We have validated the methodology with a variety of typical problems, and produced high precision and relatively high recall models. Although it is not suitable for all tasks, we argue that the ‘solve small problems quickly’ approach to information extraction is appropriate for many types of variable likely to be of interest to researchers, and offers the attractive advantage of rapidly generating models that have been trained on data sourced from the intended target. Finally, the simple annotation interface enables a rapid annotation process, with labeled data stored in a standard, reusable format. The pipeline style operation of GATE and the open source licence of TextHunter should encourage the future development of additional features to improve performance and expedite its use on more complex NLP problems.

Analysis of Online Information Searching for Cardiovascular Diseases on a Consumer Health Information Portal

Ashutosh Jadhav, MS[*1], Amit Sheth, PhD[1], Jyotishman Pathak, PhD[2]
[1]Knoesis Center, Wright State University, Dayton, OH; [2]Mayo Clinic, Rochester, MN

ABSTRACT

Since the early 2000's, Internet usage for health information searching has increased significantly. Studying search queries can help us to understand users "information need" and how do they formulate search queries ("expression of information need"). Although cardiovascular diseases (CVD) affect a large percentage of the population, few studies have investigated how and what users search for CVD. We address this knowledge gap in the community by analyzing a large corpus of 10 million CVD related search queries from MayoClinic.com. Using UMLS MetaMap and UMLS semantic types/concepts, we developed a rule-based approach to categorize the queries into 14 health categories. We analyzed structural properties, types (keyword-based/Wh-questions/Yes-No questions) and linguistic structure of the queries. Our results show that the most searched health categories are 'Diseases/Conditions', 'Vital-Sings', 'Symptoms' and 'Living-with'. CVD queries are longer and are predominantly keyword-based. This study extends our knowledge about online health information searching and provides useful insights for Web search engines and health websites.

INTRODUCTION

Since the last decade, Internet literacy and the number of Internet users have increased exponentially. With the growing availability of online health resources, consumers are increasingly using the Internet to seek health related information[1,2]. Online health resources are easily accessible and provide information about most of the health topics. These resources can help non-experts to make more informed decisions and play a vital role in improving health literacy. According to the Center for Disease Control and Prevention (CDC) in the United States, CVD is one of the most common chronic diseases and the leading cause of death (1 in every 4 deaths) for both men and women[3]. CVD is common across all socioeconomic groups and demographics including age groups, genders, and ethnicities. Most of the CVDs require lifelong care and the patient is in charge of managing the disease through self-care (such as diet, exercise, and other health lifestyle choices)[4]. Prior studies[4,5] have shown that online resources are a "significant information supplement" for the patients with chronic conditions. As the percentage of people suffering from CVD is very high, the number of people using the Internet to search and learn about CVD is also large[4,5].

One of the most common ways to seek online health information is via Web search engines such as Google, Bing, Yahoo!, etc. According to the Pew Survey[1], approximately 8 in 10 online health inquiries start from a Web search engine. Therefore, studying CVD related search logs can help us to understand what health topics Online Health Information Seekers (OHIS) search for ("information need") and how do they formulate search queries ("expression of information need"). Such knowledge can be applied to improve the health search experience as well as to develop more advanced next-generation knowledge and content delivery systems. Although chronic diseases affect a large population, very few prior studies have investigated online health information searching exclusively for chronic diseases and especially for CVD. In this study, we address this knowledge gap in the community by performing a comprehensive analysis on a significantly large corpus of 10 million CVD related search queries. These queries are submitted from Web search engines and directed OHISs to the Mayo Clinic's consumer health information portal[6].

One of the contributions of this paper is the demonstration of the effectiveness of UMLS MetaMap[7,] as well as UMLS semantic types and concepts for customized categorization. We implemented a rule based categorization approach (with Precision: 0.8842, Recall: 0.8607 and F1 Score: 0.8723) based on the UMLS semantic types and UMLS concepts. Using our approach, we categorized 92% of the 10 million CVD related search queries into 14 "consumer oriented" health categories. Additionally, we analyzed the structural properties of the queries (length of the search queries, usage of search query operators and special characters in the search queries), types of search queries (keyword-based, Wh-questions, Yes/No questions), and misspellings in the search queries. As the linguistic structure of the search queries has implications on information retrieval using Web search engines[8], we have also analyzed basic linguistic characteristics of the CVD search queries.

[*] This work was done during author's internship at Mayo Clinic, Rochester, MN, United States.

As per our analysis, the top searched health categories for CVD are 'Diseases and Conditions', 'Vital Sings', 'Symptoms' and 'Living with'. CVD search queries are longer and are predominantly keyword based. CVD queries have few search query operators, special characters, and spelling mistakes. This study provides useful and interesting insights for online health information seeking in chronic diseases and particularly in CVD. Such knowledge gives us better understanding about how OHIS search for CVD information and their information needs, which can be utilized to improve the health information search process.

Related work

Many previous studies have investigated online health information searching behavior, primarily using focus group studies, user surveys, and by analyzing health-related Web search query logs. In the studies[9-11] based on focus group and user surveys, researchers have analyzed online health searching characteristics such as how people use the Internet for health information searching, their demographic information (age, gender, education level, etc.), devices/Web search engines used for the searching, online health searching in the case of specific health conditions, and age-groups. Although these studies provided important insights, their main limitation was the inclusion of a limited number of participants (ranging from 100 to 2000 people), which may not cover population-level diversity and represent all socioeconomic groups. Researchers have analyzed web search logs from the health domain with diverse objectives, such as health/epidemic surveillance[12], PubMed usage[13], and online health information searching[14-19]. The studies focusing on online health information searching, have studied a variety of aspects of health query logs, such as health query length, changes in the health behavior with type of disease[17], effect of device used for health information searching[18] and changes in online health search patterns with disease escalation from symptoms to serious illness[19].

Previous studies in chronic diseases have looked at different facets of the diseases such as how education, income, and occupation contribute to risk factors for cardiovascular diseases[20]; use of information technology to improve the management of chronic diseases which includes home monitoring of vital signs for patients with chronic diseases[21]. Ayer et al.[4] studied the relationship between chronic illness, use of the Internet for health information, and change in health behavior. The study suggests that the use of the Internet empowers patients' in the management of their chronic conditions resulting in an increased ability to make informed decisions about their health. Lorig et al.[22] indicated the effectiveness of Internet based chronic disease self-management. Although chronic diseases affect a large population and prior studies have highlighted the usefulness of the online health resources for patients with chronic diseases, very few studies[4] have investigated how and what OHIS search for chronic diseases and especially for CVD. A focused study on chronic diseases, such as the CVD use-case presented in this paper, helps us to study details about online health searching for chronic diseases that may not be revealed through analyzing online health searching in general. Such knowledge can be applied to improve online health information systems, to promote health literacy and to accomplish a more balanced approach to wellness and prevention of the chronic diseases.

MATERIALS AND METHODS

Data Source: In this study, we have collected CVD-related search queries originating from Web search engines (such as Google and Bing) that direct OHISs to Mayo Clinic's consumer health information portal[6] (MayoClinic.com), which is one of the top online health information portals within the United States. The MayoClinic.com portal provides up-to-date, high-quality online health information produced by professional writers and editors. Our recent Web analytics statistics indicate that the MayoClinic.com portal is on average visited by millions of unique visitors every day and around 90% of the incoming traffic is originated from Web search engines. This significant traffic to the portal provides us with an excellent platform to conduct our study.

Dataset Creation: The MayoClinic.com Web Analytics tool (IBM Netinsight on Demand) keeps detailed information about Web traffic such as input search query, time of visit, and landing page. MayoClinic.com has several CVD-related webpages that are organized by health topics and disease types. Using the Web Analytics tool, we obtained 10 million CVD-related anonymized search queries originating from Web search engines that "land on" CVD webpages within MayoClinic.com and are related to CVD. These queries are in English language and are collected between September 2011-August 2013. Our final analysis dataset consists of 10,408,921 CVD related search queries, which is a significantly large dataset for a single class of diseases.

Data Analysis: We performed the following analysis on the CVD related search queries: 1) Top search queries associated with CVD; 2) Semantic analysis: categorization of the queries into health categories using UMLS MetaMap; 3) Structural analysis: length of the search queries in number of words and number of characters, usage of search query operators (such as 'and' and 'or') and special characters in the search queries; and 4) Textual analysis:

types of search queries (keyword based, Wh-questions, Yes/No questions), misspellings in the queries, and linguistic structure of the search queries (part-of-speech analysis).

1. Top CVD search queries: We selected the 20 most frequently searched queries from the analysis dataset.

2. Categorization of the queries into health categories using UMLS MetaMap

2.1. Selection of health categories: There are many possible health categories of interest. In this work, we selected 14 health categories **(Table. 1)** that are "consumer oriented" as well as can reveal details about what OHISs generally search for in the context of CVD. Here, we define "consumer oriented" health categories as categories that are easily understandable for a non-expert, lay population. While selecting the health categories, we studied the health categories on popular health websites (e.g., Mayo Clinic, WebMD, etc.) and the types of information frequently mentioned along with CVD search queries, e.g. vital signs (blood pressure, heart rate), age groups (infants, adult, elder), etc. Note that there can be possible overlaps between some of the health categories, for example 'Drugs and Medications' can be considered as a part of 'Treatment', but in our analysis we considered both as a separate health categories in order to study search traffic for each category separately. These categories and the categorization scheme **(Table. 1)** is reviewed and verified by the Mayo Clinic clinicians and domain experts.

Table 1. List of health categories and their description with examples

Categories	Description and Examples
Symptoms	Search queries related signs and symptoms, e.g. Stroke symptoms, heart palpitations with headache, home remedies for heart murmur, heartburn vs heart attack symptoms
Causes	Search queries related to cause/reasons for various CVD conditions, symptoms, e.g. causes of an elevated heart rate, heart failure reasons, morning hypertension causes
Risks and Complication	Search queries related to risk and complications, e.g. risks of pacemaker, risk factors to hypertension, complications of bypass surgery, heart ablation surgery risks
Drugs and Medications	Search queries related to drugs and medications, e.g. dextromethorphan blood pressure, medications pulmonary hypertension, tylenol raise blood pressure, ibuprofen heart rate
Treatments	Search queries related to treatments, e.g. exercise for reducing hypertension, cardiac arrest treatments, dilated cardiomyopathy treatment, bypass surgery, cardiac rehabilitation
Tests and Diagnosis	Search queries related to tests and diagnosis, e.g. heart echocardiogram, diagnosis of vascular disease, ct scan for heart, test for cardiomyopathy, urinalysis in hypertension
Food and Diet	Search queries related to food and diet, e.g. what is cardiac diet, what foods lower blood pressure and cholesterol, red wine heart disease, alcohol and hypertension
Living with	Search queries related to control, management, cure and living with CVD, e.g. exercises to lower high blood pressure, controlling blood pressure naturally, cure for postural hypotension, lifestyle changes to lower hypertension, living with pacemaker, how to control cholesterol
Prevention	Search queries related to prevention, e.g. ways to prevent heart attack, preventing stroke, foods to avoid heart diseases, aspirin for prevention of stroke, foods that lower risk of heart disease
Side effects	Search queries related to side effects, e.g. blood pressure pills side effects, side effects of beta blockers for hypertension, coq10 bp side effects, side effects of pulmonary hypertension
Medical devices	Search queries related to medical device references, e.g. living with a pacemaker, using blood pressure cuff, pump for pulmonary hypertension, blood pressure monitor
Diseases and conditions	Search queries related to diseases and conditions, e.g. medications pulmonary hypertension, born with holes in heart, stroke tia symptoms, hypotension, heart attack in pregnancy
Age-group References	Search queries with references to age groups, e.g. cardiac defects in children, average heart rate for an adult, heart murmur in adult, hypertension in adolescents, heart murmurs in infants
Vital signs	Search queries with references to blood pressure, heart rate, pulse rate, temperature, heart beat (without high/low blood pressure as we considered them under 'Diseases and Conditions'), e.g. blood pressure 125/90, normal resting heart rate, can tylenol raise blood pressure, healthy heart rate chart, sleep and blood pressure

2.2. Mapping CVD search queries to UMLS semantic types and concepts: We performed semantic analysis on the CVD search queries by mapping all the search queries from the dataset to UMLS concepts and semantic types using UMLS MetaMap[7]. MetaMap is a tool for recognizing UMLS concepts in the text. For a given search query, MetaMap identifies one or more UMLS concepts, their semantic types, Concept Unique Identifiers (CUIs), and other details. UMLS incorporates variety of medical vocabularies and concepts, and maps each concept to semantic types. Thus using UMLS, we can understand 'semantics' or 'meaning' of the words and phrases. For example: in

search query 'heart attack red wine' semantics is used to understand that the query is about two separate phrases 'heart attack' and 'red wine' and not about 4 separate words 'heart', 'attack', 'red' and 'wine'. Moreover using semantics facilitated by UMLS, we can understand "heart attack" is a disease or syndrome (DSYN) and "red wine" is a "Food item" (FOOD). Refer to Table 2 for semantic type abbreviations used in this paper.

Table 2. List of health categories and their respective UMLS semantic types/concepts used categorization. **Abbreviations**: SOSY-Signs and Symptoms, ORCH-Organic Chemical, PHSU- Pharmacologic Substance, CLND-Clinical Drug, TOPP- Therapeutic or Preventive Procedure, FTCN-Functional Concept, CNCE-Conceptual Entity, DIAP- Diagnostic Procedure, LBPR-Laboratory Procedure, LBTR- Laboratory Test Result, FOOD-Food, MEDD-Medical Device, DSYN-Disease or Syndrome, AGGP-Age Group

Health Categories	UMLS Semantic Types (**ST**), UMLS Concepts (**CC**) and Keywords (**KW**)
Symptoms	**ST**: SOSY **CC:** symptoms, signs, heart murmur
Causes	**CC**: cause, reason
Risks & Complications	**CC**: risk, complications
Drugs and Medications	**ST**: ORCH|PHSU, CLND, PHSU **CC**: medication, medicine, drugs, dose, dosage, tablet, pill **KW**: meds (without CC: alcohol, caffeine, fruit, prevent)
Treatments	**ST**: TOPP, FTCN (treatment, surgery), CNCE (treatment), **CC**: remedy, remediate (without CC: prevention and 'Drugs and Medication' queries)
Tests and Diagnosis	**ST**: DIAP, LBPR, LBTR **CC**: Test, diagnosis (without ST: DIAP| TOPP, CC: alcohol, blood caffeine)
Food and Diet	**ST**: FOOD **CC:** caffeine, recipe, meal, menu, diet, eat, breakfast, lunch, dinner, alcohol, drink
Living with	**CC:** control, manage, reduce, lower, coping, cure, recover **KW:** living with, bring down, low down
Prevention	**CC:** prevent, avoidance, low risk
Side effects	**CC:** side effect **KW:** side effect
Medical devices	**ST**: MEDD
Diseases and conditions	**ST**: DSYN **CC:** arrhythmia, avascular necrosis, enlarged heart, hypotension, blood pressure low **KW**: heart damage
Age-group References	**ST**: AGGP
Vital signs	**CC:** blood pressure, heart rate, pulse rate, temperature, Heart beat (without high/low blood pressure as we considered them under 'Diseases and Conditions')

2.3. Categorization Approach (**Table 2**): We categorized the search queries into 14 health categories as following:

1) UMLS has 140 semantic types and some of them are directly mapped to health categories that we selected; for example, 'AGGP' (Age-group) semantic type is directly mapped to the 'Age group' category. In this case, we categorized all the search queries with semantic type 'AGGP' into the 'Age group' category.
2) For a few health categories (e.g., 'Test and Diagnosis') we utilized multiple semantic types ('DIAP', 'LBPR', 'LBTR'). In this case, we categorized all the queries with at least one semantic type ('DIAP', 'LBPR', 'LBTR') into the 'Test & Diagnosis' category.
3) For a few health categories (e.g., 'Food and Diet'), there are certain concepts that are closely associated with the health category are not mapped to the selected semantic type. In such cases, we utilized both semantic types and well as semantic concepts for the categorization. For example, 'FOOD' semantic type does not include concepts such as 'meal', 'menu', 'diet', 'recipe' and 'lunch' as they are not actually food items. We categorized all the search queries that have 'FOOD' semantic type or at least one concept from (meal', 'menu', 'diet', etc.) into the 'Food and Diet' category.
4) For a few health categories (e.g., 'Cause') there is no directly associated semantic type. In such cases, we utilized semantic concepts for the categorization. For example, we categorized all the search queries which have either 'Cause' or 'Reason' semantic concepts into the 'Cause' category.
5) For a few health categories (e.g., 'Living with'), apart from semantic concepts, we also considered the presence of keywords ('Living with') within the search query as 'Living with' is not a concept in the UMLS.
6) Few semantic types include some undesired concepts (in the context of our customized categorization, not in the terms of UMLS concept hierarchy). For example, semantic types 'ORCH\| PHSU' and 'PHSU' are associated with the 'Drugs and Medication' category. These semantic types include some concepts that are not considered as drugs to a consumer/lay population: caffeine, fruit, prevent, etc. In such cases, we do not categorize the search

queries with semantic types 'ORCH/PHSU' or 'PHSU' and with semantic concepts caffeine, fruit, prevent, etc. into the 'Drugs and Medication' category.

7) We also considered lexical variants, as well as partial matches, of some concepts for example: diagnose, diagnosis, test, testing, etc. A search query can be categorized into zero, one or more than one health category depending on the mapping of the query to UMLS concepts and semantic types. We empirically evaluated queries in each category and performed several iterations to evaluate the semantic type/concepts for each category then defined the categorization scheme **(Table 2)**.

2.4. Categorization Evaluation: We evaluated the performance of the categorization approach as following:

1) Gold standard dataset creation: We randomly selected 1000 search queries from the analysis dataset. Two domain experts manually annotated 1000 search queries by labeling one search query with zero, one, or more than one health category. The annotators first discussed and agreed upon the annotation scheme. To reduce the probability of human errors and subjectivity, the two annotators discussed together and annotated each query and created a gold standard dataset with 1000 search queries.
2) Precision-Recall calculation: We categorized 1000 search queries from the gold standard dataset using the categorization approach as discussed in Section 2.3 and evaluated the categorization approach with respect to the gold standard dataset. Since we categorized search queries into 14 health categories, we also calculated Micro average Precision and Recall. Based on the evaluation, our categorization approach has very good Precision: 0.8842, Recall: 0.8642 and F-Score: 0.8723.
3) We also performed Precision and Recall analysis for each health category independently (Table 3) to check the performance of the categorization approach for individual health categories. The categorization approach works well for most of the categories while for a few categories the approach shows above average Precision/Recall. One observed reason that affected the Precision/Recall is multiple interpretations of the concepts that sometime may not be contextually correct, e.g. for the search query 'nuts good for your heart', MetaMap annotated 'nuts' as 'FOOD' as well as 'MEDD' (Nut - Medical Device Component or Accessory).

Table 3. List of health categories and their respective Precision and Recall

No	Categories	Precision	Recall	F1 Score	No.	Categories	Precision	Recall	F1 Score
1	Symptoms	0.9274	0.8042	0.8614	8	Living with	0.8659	0.9342	0.8988
2	Causes	0.8861	0.9859	0.9333	9	Prevention	0.8333	1.0000	0.9091
3	Risks and Complication	1.0000	1.0000	1.0000	10	Side effects	1.0000	1.0000	1.0000
4	Drugs and Medications	0.8582	0.9350	0.8950	11	Medical devices	0.8077	0.7500	0.7778
5	Treatments	0.7083	0.9444	0.8095	12	Diseases	0.9291	0.7751	0.8451
6	Tests and Diagnosis	0.6389	1.0	0.7797	13	Age-group References	1.0000	0.8889	0.9412
7	Food & Diet	0.9391	0.9558	0.9474	14	Vital signs	0.8872	0.8669	0.8769
Overall Micro Average **Precision (0.8842), Recall (0.8607)** and **F1 Score (0.8723)**									

3. Health query length: We calculated search query length by computing the number of words (separated by white space) and the number of characters (excluding white space) in the search queries.

4. Usage of query operators and special characters: In search queries, query operators ('and', 'or', 'not', etc.) are used to formulate complex queries. In this study, we have considered following operators: AND, OR, +, &, other (NOT, AND NOT, OR NOT, & NOT). Special characters are the characters apart from letters (a-z) and digits (0-9). The significance of special characters in health search query depends upon the usage of special characters in the medical domain. For example, OHISs may mention values in different formats, e.g., 2.3 ml, 40%, 17-19, 125/90 (for blood pressure) or $200 (for the cost of a drug or procedure). We analyzed the usage of search query operators and special characters in the CVD search queries based on their usage frequency in the search queries.

5. Misspellings in health queries: OHISs occasionally make spelling mistakes while searching for health information. To analyze the frequency of such errors, we used a dictionary-based approach. We first generated a dictionary of words using the Zyzzyva wordlist[23], the Hunspell dictionary[24], and its medical version (OpenMedSpell[25]), comprising a total of 275,270 unique words. We used this dictionary to check misspellings in the CVD search queries.

6. Type of Search queries: OHISs express their health information need by formulating search queries on Web search engines. OHISs can express their information need either by formulating search queries using keywords or asking questions (Wh-questions and Yes/No questions). For this analysis, we have considered the following Wh-questions (lexicon): 'What', 'How', '?', 'When', 'Why' and others ('Who' 'Where', 'Which'). Note that, although '?' does not come under Wh-questions category, we have included it for the simplicity. Yes/No questions are usually used to check some factual information, for example, whether coffee is bad for the heart. In this analysis, we have considered Yes/No questions that start with 'Can', 'Is', 'Does', 'Do', 'Are', and others ('Could' 'Should', 'Will', 'Would'). Using the lexicon for Wh-questions and Yes/No questions, we performed text analysis on the search queries to count the number of queries with Wh-questions and Yes/No Questions. Search queries that do not contain any questions (Wh- or Yes/No) are classified as Keyword-based. Additionally, for different Wh-questions and Yes/No questions, we computed their usage frequency in the search queries.

7. Linguistic analysis of health queries: Linguistic structure of the search queries has implications on information retrieval using Web search engines[8]. Thus we analyzed basic linguistic characteristics of the CVD search queries. We performed part-of-speech analysis on the search queries using Stanford's POS tagger[26]. For this analysis, we considered nouns, verbs, adjectives and adverbs. We mapped all the subtypes in part-of-speech (e.g. proper nouns, common nouns, compound nouns) to the main part-of-speech types (e.g. nouns). We analyzed usage of different part-of-speech types in the CVD queries based on their usage frequency in the search queries.

RESULTS

1. Top health queries: Most of the top search queries are related to major CVD diseases and conditions. At the same time, questions about blood pressure (high/low) and heart rate were also searched frequently (Table 4).

Table 4. Top search queries related to CVD

Top 1-5 Queries	Top 6-10 Queries	Top 11-15 Queries	Top 16-20 Queries
heart attack symptom	congestive heart failure	cardiomyopathy	echocardiogram
blood pressure chart	low blood pressure	heart palpitations	heart disease
how to lower blood pressure	stroke symptoms	blood pressure medication	orthostatic hypotension
heart rate	normal blood pressure	symptoms of stroke	heart healthy recipes
broken heart syndrome	high blood pressure symptoms	heat stroke	heart arrhythmia

2. Health categories: Based on **Table 5**, the most popular health categories while searching for CVD information are 'Diseases and Conditions' and 'Vital signs'. One in every two searches is related to either 'Diseases and Conditions' or 'Vital signs'. Due to close association of vital sings (such as blood pressure and heart rate) with CVD, OHIS might be searching it frequently. Other popular health categories that users search for includes 'Symptoms', 'Living with', 'Treatments', 'Food and Diet' and 'Causes'. Mostly due to the chronic nature of the CVD and as the patients are in charge of managing the disease with day-to-day care, many CVD patients might be searching for 'Living with' related search queries. As diet has a significant impact on the CVD, we observed large search traffic for 'Food and Diet' category. Many OHISs are also interested in learning about CVD 'Treatments', 'Medical Devices' (e.g. pacemaker), 'Drugs and Medication', and 'Cause'. Although CVD can be prevented with some lifestyle and diet changes, interestingly very few OHISs search for CVD 'Prevention'.

Table 5. Categorization of CVD search queries into 14 health categories

No	Health categories	Total Queries	Percentage Distribution	No	Health categories	Total Queries	Percentage Distribution
1	Diseases	4,232,398	28.66	8	Drugs and Medications	603,905	4.09
2	Vital signs	3,455,809	23.40	9	Causes	599,895	4.06
3	Symptoms	1,422,826	9.64	10	Tests & Diagnosis	344,747	2.33
4	Living with	1,178,756	7.98	11	Risks and Complication	277,294	1.88
5	Treatments	955,701	6.47	12	Prevention	136,428	0.92
6	Food and Diet	779,949	5.28	13	Age-group References	87,929	0.60
7	Med Devices	665,484	4.51	14	Side effects	25,655	0.17
					Total	14,766,776	100

Using our categorization approach, we categorized 92% of the 10 million CVD related queries into at least one health category (**Table 6**). Most of the queries (around 88%) are categorized into either one or two categories (Table 6). Very few CVD queries (4.28%) are categorized into 3 or more categories. Our approach did not categorize 8.13% of the queries into any health categories. After studying the uncategorized search queries, we found that there are few queries that do not fit into any of the selected 14 categories such as cardiac surgeon, cardiology mayo, video on cardiovascular, pediatric cardiology, and orthostatic.

Table 6. A search query can be categorized into zero, one, or more health categories. The table shows the distribution of search queries by number of health categories in which they are categorized.

Number of health Categories	Number of search queries	Percentage Distribution
0	845,744	8.13%
1	4,967,337	47.72%
2	4,149,803	39.87%
3	420,622	4.04%
4 and 5	25,415	0.24%
Total	10,408,921	100.00%

3. Health query length: Average search query length (**Figure 2**) for CVD is 3.88 words and 22.22 characters. Around 80% of the CVD search queries have 3 or more words. The analysis implies that, CVD search queries are longer than previously reported non-medical, as well as medical queries, as the average length for both of them is around 2.35 words[15,27]. This potentially indicates that OHISs describe their CVD information needs in more detail by adding relevant health context to the search query. Longer search queries also denote OHIS' interest in more specific information about the disease; subsequently OHISs use more words to narrow down to a particular health topic. Another possible reason for longer CVD search queries might be that even simple CVD related search queries have multiple words (Table 1, Table 4).

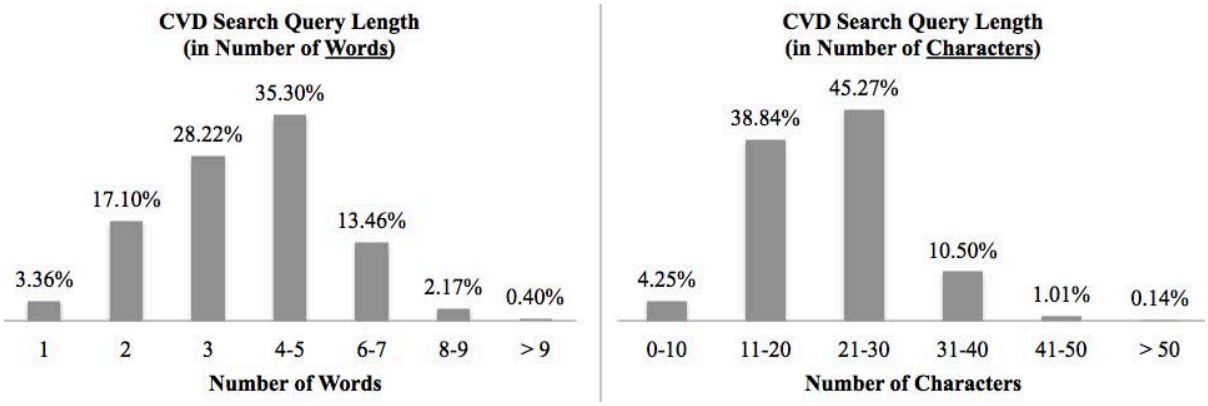

Figure 2. Distribution of length of search queries by number of words and number of characters

Table 7. Search query operators usage, special characters usage, and misspellings in the CVD search queries

Structural Analysis	Usage Frequency	Total Queries	Percentage Distribution
Number of Query Operators	0	10,011,257	96.18%
	>0	397,664	3.82%
Query Operators Usage	AND	366,117	92.07%
	+	7,115	1.79%
	OR	16,063	4.04%
	&	4,159	1.05%
	Other	4,210	1.06%
Special Characters	0	10,288,916	98.85%
	>0	120,005	1.15%
Spelling Mistake	0	10,075,665	96.80%
	>0	333,256	3.20%

4. Query operators usage, special characters usage, and misspellings in the CVD search queries (Table 7): Around 4% of CVD search queries use at least one query operator. 'AND' is the most popular operator (92%), followed by 'OR' (4%) and '+' (1.7%). Overall variations of 'and' (AND, &, +) operators comprise around 95% of operator usage in the search queries. OHISs formulate very few (1%) CVD search queries with special characters. In CVD search queries, 3.2% of the queries have at least one spelling mistake. Web search engine's "auto-completion" as well as "spelling correction" functionalities might be one reason to lower misspellings in the search queries.

5. Type of Search queries: As indicated by the analysis in **Figure 3**, OHISs predominantly formulate search queries using keywords (80%), though queries with Wh-Questions are also significant. Few queries (2.5%) are formulated as Yes/No type questions. In Wh-questions, OHISs mostly use "How" and "What" in the search queries and both of them generally signify that more descriptive information is needed. In Yes/No Questions, OHISs more often start the search queries with "does" "can" and "is".

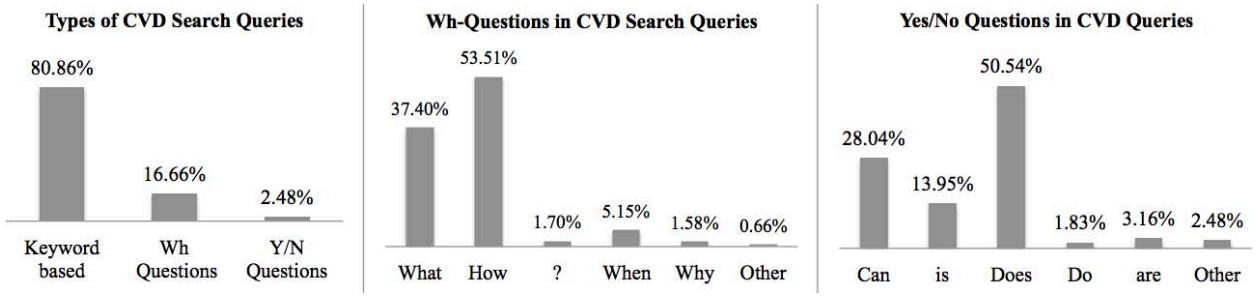

Figure 3. Types of search queries (how health information need is expressed) and distribution of Wh-Questions and Yes/No Questions based on frequency of their usage in the CVD search queries.

6. Linguistic analysis (Table 8): In health search queries, nouns typically denote entities like disease names, health categories, etc. Almost all the CVD search queries have at least one noun and most of the search queries (81.5%) have 2 or 3 nouns. A verb conveys an action or an occurrence, for example "how to control (verb) hypertension (noun)". Approximately 26% of the search queries have at least one verb. Adverbs are the words that modify a verb, an adjective and another adverb, while an adjective is a 'describing' word, giving more information about the object signified, for example "extremely (adverb) bad (adjective) heart (noun) pain (noun)." Very few search queries have at least one adverb and 47% of the queries have at least one adjective.

Table 8. Linguistic analysis (part-of-speech) on CVD search queries

Part-of-Speech	Usage Frequency	Total Queries	Percentage Distribution
Nouns	**0**	6,279	0.06%
	1	1,075,467	10.33%
	2	4,964,074	47.69%
	3	3,523,204	33.85%
	>3	839,897	8.07%
Verb	**0**	7,722,752	74.19%
	>0	2,686,169	25.81%
Adverb	**0**	10,151,641	97.53%
	>0	257,280	2.47%
Adjective	**0**	5,519,489	53.03%
	>0	4,889,432	46.97%

DISCUSSION

In this study, we analyzed a significantly large dataset of 10 million CVD related search queries in order to understand online health information searching for CVD. We implemented a rule based categorization approach (with Precision: 0.8842, Recall: 0.8607and F1 Score: 0.8723) using UMLS concepts/semantic types and categorized 92% of the 10 million CVD related search queries into 14 "consumer oriented" health categories. As per our analysis, the top searched health categories ("information needs") for CVD are 'Diseases and Conditions', 'Vital Sings', 'Symptoms', and 'Living with'. Other frequently searched CVD health categories are 'Treatments', 'Food

and Diet', and 'Causes'. Most of the queries (around 88%) are categorized into either one or two health categories. Even though CVD can be prevented with some lifestyle and diet changes, very few OHIS search for preventive health information. We found that use of MetaMap and UMLS concepts/semantic type to be a very good approach for categorization of the health related search queries as UMLS incorporates variety of medical vocabularies and concepts, and mapping of each concept to semantic types. However for customized categorization, we have to carefully select/eliminate UMLS semantic types and concepts considering the alignment of their scope with desired categories.

Our study reveals some interesting insights about structural and syntactic properties of CVD search queries. The average length of CVD search queries is longer than that of previously reported general search queries as well as medical search queries[15,27]. Our study implies OHISs may be interested in more specific information. Only 3.2% of the search queries contain at least one spelling mistake. The search engine's "auto-completion" feature, and spelling correction/suggestion functionality might be contributing to reduce misspelled words in search queries. Very few OHISs use search query operators and variations of 'and' (AND, &, +) operators comprise around 95% of operator usage in the search queries. OHISs formulate search queries primarily using keywords (around 80%), followed by Wh-Questions, and Yes/No Questions. In Wh-questions, OHISs mostly use 'What' and 'How' in the search queries, and both of them generally signify a need for more descriptive information, while search queries in the form of Yes/No questions indicate interest in factual information. Almost all the search queries have one noun. OHISs also use adjectives and verbs frequently in the search queries to add context to the topic of interest.

Following are some of the limitations of this study. The results of this study are derived from the analysis limited to CVD search queries from Web search engines that led users to MayoClinic.com. Even though Mayo Clinic web pages often ranked high in Web search engines, not all health information seekers visit MayoClinic.com. The focus of this study is limited to analysis of the search query log and we have not analyzed associated socioeconomic factors due to the anonymized nature of the data. To the best of our knowledge, there is not much research on understanding online health information searching for chronic diseases and especially for CVD. This study addresses this knowledge gap and extends our knowledge about online health information search behavior. The study provides interesting and valuable insights that can further be leveraged in multiple ways, such as:

1. Web search engines: to understand details about structural and linguistic characteristics of health search queries, search query complexity, and popular health categories in order to improve health information retrieval systems;
2. Websites that provide health information: to better understand an OHIS's health information need, and do a better organization of health information content;
3. Healthcare providers: to better understand their patients and their health information interest;
4. Healthcare-centric application developers: to better understand what and how OHISs search for and to build applications around consumer health information needs and priorities;
5. OHISs: we anticipate that this work will help empower OHISs in their quest for health information, and facilitate their health information search efforts by enabling the development of smarter and more sophisticated consumer health information delivery mechanisms.

In the future, we plan to leverage insights from this work to facilitate a better health search experience by developing more advanced next-generation knowledge and content delivery systems. Also, we plan to perform comparative analysis of major diseases to learn similarities and differences between them in online health information searching.

Conclusion

We presented a comprehensive analysis on CVD related search queries in order to understand what users search for ("information need") and how they formulate search queries ("expression of information need"). We found that using MetaMap and UMLS concepts/semantic type is a very good approach for categorization of health related search queries into health categories. The categorization approach can be reused for different set of health categories by defining new association rules**.** Distribution of the CVD queries by health categories indicates that, OHISs have most information needs for CVD related 'Diseases and Conditions', 'Vital Signs' 'Symptoms' and post CVD information ('Living with', 'Diet', 'Treatments, Drugs'). OHISs predominantly formulate search queries using keywords followed by Wh-Questions and Yes/No Questions. Almost all CVD search queries have at least one noun. A greater understanding of OHIS's needs may help us to accomplish the changes that will lead to improvement in online health information searching and a more balanced approach for health information intervention. This study extends our knowledge about online health information searching, and provides useful insights for Web search

engines, health-centric websites and application developers. Finally, we anticipate that this work will help empower OHISs in their quest for health information, and facilitate their health information search efforts by enabling the development of more advanced next-generation knowledge and content delivery systems.

Characterization of a Handoff Documentation Tool Through Usage Log Data

Silis Y. Jiang[1], Alexandrea Murphy[1] MPH, David Vawdrey[1] PhD, R. Stanley Hum[2] MD, Lena Mamykina[1] PhD

[2]Department of Pediatrics, Columbia University

Abstract

Handoffs are a critical component of coordinated patient care; however, poor handoffs have been associated with near misses and adverse events. To address this, national agencies have recommended standardizing handoffs, for example through the use of handoff documentation tools. Recent research suggests that handoff tools, typically designed for physicians, are often used by non-physician providers as information sources. In this study, we investigated patterns of edits of an electronic handoff tool in a large teaching hospital through examination of its usage log data. Qualitative interviews with clinicians were used to triangulate log data findings. The analysis showed that despite its primary focus on facilitating transitions of care, information in the handoff documentation tool was updated throughout the day. Interviews with residents confirmed that they purposefully updated information to make it available for other members of their patient care teams. This further reiterates the view of electronic handoff tools as facilitators of team communication and coordination. However, the study also showed considerable variability in the frequency of updates between different units and across different patients. Further research is required to understand what factors drive such diversity in the use of electronic handoff tool and whether this diversity can be used to make inferences about patients' conditions.

Introduction

Handoffs are a critical aspect of providing continuous care for patients in inpatient services[1]. Due to recent changes towards more restrictive resident work hours, handoffs have become commonplace in the hospital[2]. However, poor handoffs have been associated with near misses and adverse events[3,4]. Institutions such as the Joint Commission and the Accreditation Counsel of Graduate Medical Education (ACGME) have made recommendations towards improving handoffs[5] and require hospitals to ensure resident competency in handoffs[6]. These identified limitations of the current handoff practices suggest the need for new tools for facilitating handoff. With few nationally published or commercially available handoff tools, many healthcare institutions developed and optimized handoff tools to their own needs and workflows[7]. While many of these tools are paper based, there is a growing trend towards developing electronic and often EHR-integrated handoff documentation systems[8-10]. There is emerging evidence that interventions that include handoff documentation tools reduce errors in patient care and improve the quality and structure of handoffs[11].

Previous research on handoff tools has primarily focused on the impact of these tools on handoff standardization or patient care[12]. Furthermore, these previous studies usually adopted a singular user perspective, typically focusing on physicians[12,13]. At the same time, an emerging theme from recent handoff tool research suggests that electronic resident handoff documentation tools are adopted beyond their original user group. For example, Vawdrey et al. showed that non-physician clinicians (nurses, pharmacists, social workers, etc.) accounted for 60% of active users in a resident handoff documentation tool[7]. Similarly, Schuster et al. reported that the physician handoff tool was integrated into the daily workflow of non-physicians[14]. However, these studies have focused on handoff tools from a user viewing or information retrieval perspective. The process of creating or updating handoff documents is much less understood.

This study focuses on investigating patterns of use of a resident oriented handoff documentation tool, with a particular attention to creation of the handoff document, including edits and updates. The study was conducted at Columbia University Medical Center, where clinicians use a handoff documentation tool known as Handoff Tab. The tool's interface includes a series of labeled free-text boxes that can be directly edited by authorized users. Additionally, clinicians have the option to print the user-contributed data along with recent structured data, such as lab values and medication list. The tool is primarily edited by residents but available to all clinicians to view. This study sought to identify: 1) whether there are any systematic temporal patterns in the edits to the different fields of

the Handoff Tab; 2) whether there are any differences in the frequency and patterns of updates between different clinical units; and 3) whether there were any differences in how frequently Handoff Tab was updates across different patients.

Materials and Methods

Handoff Tab

Handoff Tab is a custom-designed module included in the commercial EHR system (Sunrise Eclypsis). It has 9 free-text boxes: Active Issues, Consult Notes, Contact Info, Coverage To Do List, Discharge Planning, Hospital Course, Notes and Comments, Patient Summary, and Primary To Do List. The tool also provided the functionality to produce a printable report that included structured data, such as labs and medication. Furthermore, users could choose to print a cover sheet that summarized select patients.

Dataset

To analyze patterns in Handoff Tab documentation, we used the document-editing event logs for all of October 2013 at the Columbia University Medical Center campuses of New York Presbyterian Hospital. The date and time of each edit event, which free-text box was edited, patient medical record number, patient bed location, clinician user ID, and care provider role were extracted from the audit log. All analyses on the unit level were normalized based on the number of unique patients in that unit. It is important to note, however, that not all patients in a unit may have Handoff Tab documents associated with them. Therefore, there may actually be more patients in the unit at a given time than can be estimated by the dataset. Analyses on the patient level were normalized based on the number of handoff days. The number of handoff days was calculated based on the first and last day a clinician edited the Handoff Tab document of each patient.

Additionally, four interviews were conducted with the medical staff in the pediatric intensive care unit at Columbia University Medical Center (CUMC). Three residents and one attending were interviewed. The interviewees were selected by convenience. The three residents were in their final year of residency, while the attending physician had previously used a handoff documentation tool during the final year of critical care fellowship training.

Quantitative Analysis

To identify editing patterns throughout the workday, all edit events were aggregated into a single 24-hour period and visualized, regardless of the day of the month.

To understand the influence of unit practices on editing patterns, the dataset was divided by units and then clustered. First, the total number of edits and the number of edits per Handoff Tab Field was calculated for each unit. These values were then normalized based on the patient count for individual units. Euclidean distance was used to measure the difference of each unit based on the edit frequency of individual fields. Hierarchical clustering based on the complete method was then used to group the units. A *k*-value was selected based on the outcome. This *k*-value was then applied to a *k*-means clustering algorithm (Hartigan and Wong method) of each analysis dataset.

To understand the influence of patients on editing patterns, the dataset was split by unique patients and then clustered. A similar method similar to the unit cluster analysis was used. Briefly, edits per Handoff Tab field was calculated on a patient basis and then normalized based on the handoff days. A distance matrix was used to calculate the Euclidean distance between each patient in the dataset. Hierarchical clustering based on the complete method was used to group the patients based on that matrix. A *k*-value was extracted from the hierarchical clustering analysis and applied to the k-means clustering algorithm (Hartigan and Wong method).

The statistical tool R was used for cluster data analysis and visualization. All clustering related methods were performed using the *stats* package, and all visualizations were created using the *ggplot2* package. All statistics are presented as means along with the standard error of the mean.

Qualitative Analysis

To supplement the quantitative data, interviews with physicians were conducted to provide insight and reasoning for unit differences in documentation behaviors. Four interviews were conducted with the medical staff in the pediatric intensive care unit at Columbia University Medical Center (CUMC). Three residents and one attending were interviewed. The interviewees were selected by convenience. The clinicians were consented prior to the start of the interview. The interviews were recorded and transcribed for analysis. Transcripts were reviewed for common themes.

This study was approved by the Columbia University Institutional Review Board.

Results

Temporal Distribution of Handoff Tab Updates

On average, each unit updated the Handoff Tab 13.67 times per patient during the study period with a standard error of the mean (SEM) score of 0.21 edits. The patients in this dataset had an average stay of 5.12 days (SEM = 0.007 days) and an average of 22.42 edits to their handoff document during their stay (SEM = 0.003 edits).

Table 1. Dataset Characteristics

Characteristic	**Sample size**
Total Number of Edit Entries During Study Period	145,872
Total Number of Units	132
Total Number of Patients	6515

After aggregating the dataset into a single 24-hour time frame, the data showed that Handoff Tab was updated throughout the day (Figure 1). However, not all fields were utilized equally. In general, the field “Consult Notes” were updated the least and the “Primary To Do List” field was updated the most. Updates were most frequently made during two timeframes corresponding to the periods right before handoff. However, the data also shows that Handoff Tab was updated throughout the workday.

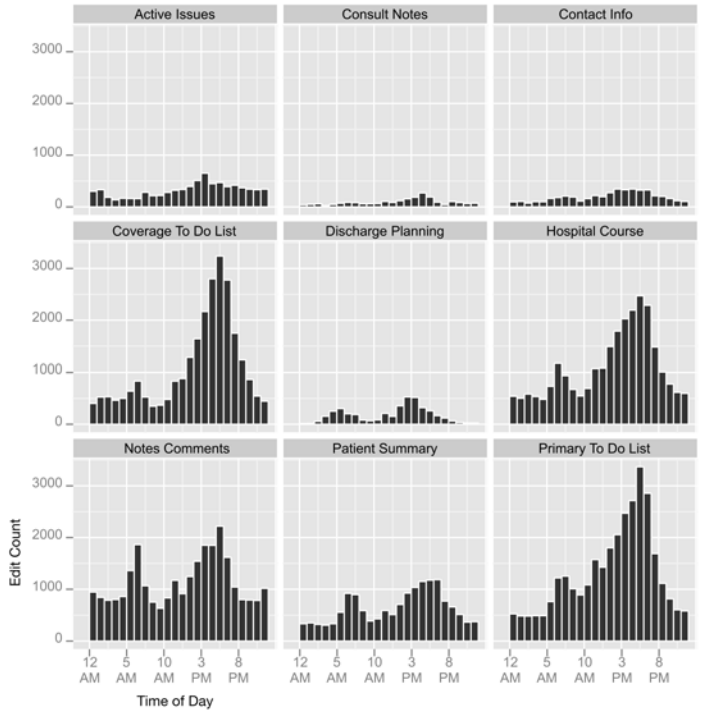

Figure 1. Hourly distributions of edit frequencies per Handoff Tab field

During interviews clinicians expressed awareness of other clinicians utilizing the tool and their notes as information sources. For this reason, residents reported updating the Handoff Tab up to three or four times per shift to make sure the information remain up to date.

> *"If we have down time and I have time to update during the day, I do that as well just so it is up to date for any one who refers to it and sometimes I know our nurses refer to it and the attendings refer to it." – Resident 1*
>
> *"Yeah. I'm usually – I usually keep track of things on my paper printout but then probably like three or four times a day I would do that [updating Handoff Tab throughout the day]." – Resident 3*

In these examples, the residents indicate a conscious effort to regularly maintain the information found in Handoff Tab. The desire to maintain an up-to-date handoff document provides one explanation for continuous updates throughout the day.

Unit Cluster Analysis

To understand the update pattern of the different units, a cluster analysis was performed based on individual unit update frequencies. Hierarchical clustering was used to identify possible cluster numbers for *k*-means clustering. In this case, a *k*-value of 5 was selected based on the hierarchical clustering (Figure 2A and 2B). The units in each cluster are differentiated by two factors: update frequency magnitude and field update distribution. Cluster 1 is characterized by having well above median update frequency magnitude. Cluster 1 has a unique distribution in its frequency peak for the "Notes and Comments" field, but the distribution also shows the "Patient Summary" field being edited more frequently than the "Hospital Course" field. Cluster 2 has well below median update frequency magnitude. Units in this cluster made less than 0.5 updates per patient in all of the fields. Furthermore, the distribution of updates per patient is relatively flat. Cluster 3 has the median frequency magnitude. For this cluster, the distribution of edits is appears to be roughly equal between the "Hospital Course", "Notes and Comments", and "Primary To Do List" fields. Cluster 4 has below median magnitude and roughly equal distributions between the "Coverage To Do List", "Hospital Course", and "Primary To Do List" fields. Cluster 5 has above median update frequency magnitude. The update distribution for this cluster is primarily focused on the "Notes and Comments" section and higher update frequency for ""Hospital Course" compared to "Patient Summary" (the opposite trend from cluster 1).

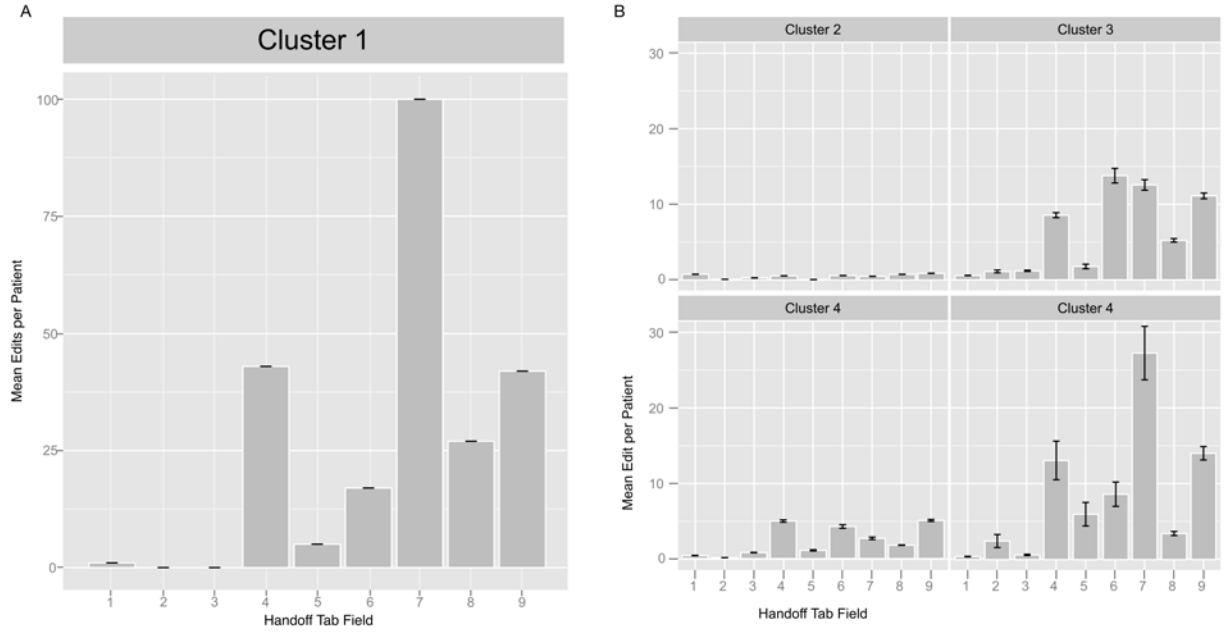

Figure 2A and 2B. Mean and standard error of the mean (SEM) of field frequencies per unit clustering. 1 = Active Issues, 2 = Consult Notes, 3 = Contact Info, 4 = Coverage To Do List, 5 = Discharge Planning, 6 = Hospital Course, 7 = Notes and Comments, 8 = Patient Summary, 9 = Primary To Do List

To test whether clusters could characterize unit properties, the patient count of each cluster was compared. Analysis comparing patient counts in each cluster showed no difference between clusters. Some units that had many patients during the study period update the handoff tab very frequently for each patient, while others with similar patient counts did not. Conversely, some units that did not have very many patients updated the Handoff Tab very frequently. Therefore, considering only the patient count was not predictive of that unit's cluster membership.

Patient Cluster Analysis

To identify whether different patients had differences in the update pattern of their associated handoff document, clustering was used to group patients. A hierarchical cluster analysis showed that a *k*-value of 8 was optimal for a *k*-means cluster analysis. Based on Figure 3, each cluster of patients has a different distribution of update frequencies per Handoff Tab field.

Unlike the unit cluster analysis, each cluster of the patient cluster analysis is differentiated by the distribution of updates between the Handoff Tab fields. For the majority of the clusters (clusters 1 to 6), the magnitude of update frequencies is roughly equal. The distinctive feature of patients in cluster 1 is the low update frequency in the "Consult Notes" field compared to other fields. Cluster 2 patients have relatively more "Consult Notes" and "Discharge Planning" edits compared to the other fields. Cluster 3 patients have a roughly equal number of edits in each field. While cluster 4 patients are similar to those in cluster 3, the edit frequency to "Patient Summary" and "Primary To Do List" appear to be slightly more relative to other fields in cluster 4. Cluster 5 patients have a distinctly high edit frequency in the "Active Issues" field. Cluster 6 patients have relative edit frequency troughs in three fields. Patients in cluster 7 have very distinct peaks in edit frequency in the "Active Issues" and "Contact Information" fields. The final cluster is characterized by having a very low edit frequency in every field, with the exception of the "Patient Summary" field.

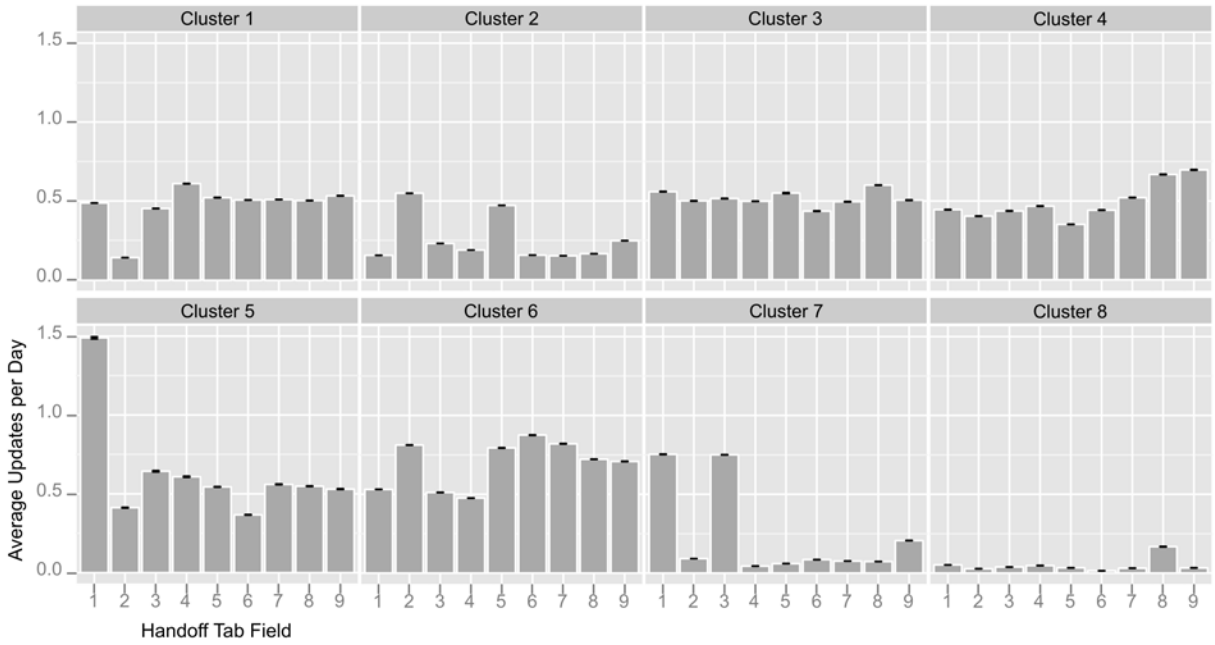

Figure 3. Mean and standard error of the mean (SEM) of field frequencies per patient cluster. 1 = Active Issues, 2 = Consult Notes, 3 = Contact Info, 4 = Coverage To Do List, 5 = Discharge Planning, 6 = Hospital Course, 7 = Notes and Comments, 8 = Patient Summary, 9 = Primary To Do List

Following cluster analysis, a comparison of the handoff days for each cluster was made. Based on Table 2, the mean handoff days for each cluster is similar. This suggests that handoff days is not a good indicator for predicting cluster membership. However, it may be possible for more complex patient characteristics, such as patient severity score, to be indicative of being a member of a certain cluster.

Table 2. Means and deviations of patient handoff days (Days) by patient clusters

Cluster	Patient Count	Mean Stays	Stay Standard Deviation	Stay Standard Error of the Mean
1	821	4.790499	6.513398	0.007933
2	2025	5.568395	6.99678	0.003455

8	278	5.309353	6.192868	0.022277

Discussion

There is a considerable body of research suggesting that communication is a key component of teamwork and team coordination[15-18]. Particularly in inpatient settings, where care is provided by patient care teams, communication, both verbal and non-verbal, is a crucial part of a team's ability to coordinate their efforts[15]. Due to common delays in written documentation, clinicians continue to rely on verbal communication to stay up to date[19]. At the same time, there is a growing awareness that verbal communication can be disruptive for work, requires both parties to be available simultaneously, and leaves no record[20]. Computer-mediated communication among members of patient care team can provide an alternative or complementary channel, less disruptive to the flow of clinical work. Yet, the patterns of communication through EHRs are not well understood[21].

Recently, handoff documentation tools were shown to be useful as a source of information for many user groups, beyond physicians[14]. The results of our study suggest that residents, who are primarily responsible for editing information in the Handoff Tab, purposefully use it as an improvised team communication tool, rather than strictly resident handoff tool. The analysis of the temporal patterns of Handoff Tool updates show that residents enter new information throughout the day, not only in preparation for transitions of care. Our interviews with residents further confirmed that often they updated the information to make it available to other members of their teams. Moreover, the residents indicated that Handoff Tab can be used as a collaborative writing platform, with other members of their teams suggesting updates and changes, even if they do not edit the fields directly.

At the same time, the results of our cluster analysis suggested that Handoff Tool is used differently by different departments, and even for different patients. Previous evaluations of handoff tools that included multiple departments were generally taken from a homogenous perspective[12,13]. In contrast to these studies, our analysis found substantial differences in the frequency of updates to Handoff Tool between different departments. Some of these differences are easy to account for. For example, departments with more critically ill patients, such as Intensive Care Units, had a higher frequency of updates than many other hospital units. Yet other differences are not as straightforward. For example, we found that neither the number of patients in the unit nor the average lengths of stay were indicative of the frequency of Handoff Tool updates in that unit. Moreover, interviews with residents suggested that different units developed varying practices in regards to what information is captured in different text boxes. Further research is needed to further explicate local practices in handoff tool use and the different factors that lead to the diversity in its adoption.

Finally, the analysis of differences in frequencies between different patients suggests that the use of Handoff Tab may reflect differences in patients' conditions and care. For example, patients with complex conditions who require ongoing care from different clinical specialties may have more updates in their Consult Notes and Contact Info fields. In contrast, patients with rapidly changing conditions might have more updates in the Active Issues list. Finally, patients who are nearing their discharge from the hospital may have more updates in the Discharge Planning area. While our dataset did not allow us to examine these relationships in greater detail, our interviews with the residents confirmed these intuitions. Recently, nursing documentation patterns were shown to be predictive of patients who experience a cardiac arrest or death[22]. Our study further suggests that there is great utility in understanding the documentation patterns of individual units and patients. For instance deviations in established handoff update frequency patterns for patients in a cardiology ward could prove to be indicative of future complications or deteriorations, such as cardiac arrest.

Limitations

A key limitation of the dataset is that it only provides the fields clinicians edited but not the information that was input. Since Handoff Tab consists of free-text fields, clinicians are free to write information unrelated to that field in the text box. This limitation partially hinders the ability to draw conclusions about what the cluster membership means for either units or patients. In other words, while cluster 1 in the unit clustering analysis suggests that the "Notes and Comments" field is edited frequently, it is impossible to determine what content the edits were focused on. Another limitation regards the correlation between handoff days and length of stay for patients in this dataset. Patients may have been admitted to the hospital before a Handoff Tab document was created or discharged to a unit that did not incorporate Handoff Tab into the unit workflow. Therefore the length of stay may be longer than estimated by handoff days. Furthermore approximately 1.5% of the patient population had length of stays that equaled or exceeded the study period. Additionally, this dataset provided little information characterizing either the unit or the patient. It was impossible to determine the service (cardiology, nephrology, surgical intensive care, etc.) that patient was being treated by. The dataset contained little information about patient severity or any patient outcomes. This limited the abilities to draw conclusions about the patients in each cluster. Lastly, it should be recognized that this dataset represents a small time slice within one academic medical center. With handoff workflows constantly changing, it must be acknowledged these findings may not capture all variations currently in clinical practice.

Conclusion

Handoff Tab was frequently edited throughout the day. This suggests that handoff documentation tools may be a valuable source of up to date information. Furthermore, clusters analysis indicates that different update patterns exist based on units and patients.

Abstract

Point of care access to knowledge from full text journal articles supports decision-making and decreases medical errors. However, it is an overwhelming task to search through full text journal articles and find quality information needed by clinicians. We developed a method to rate journals for a given clinical topic, Congestive Heart Failure (CHF). Our method enables filtering of journals and ranking of journal articles based on source journal in relation to CHF. We also obtained a journal priority score, which automatically rates any journal based on its importance to CHF. Comparing our ranking with data gathered by surveying 169 cardiologists, who publish on CHF, our best Multiple Linear Regression model showed a correlation of 0.880, based on five-fold cross validation. Our ranking system can be extended to other clinical topics.

Introduction

Since medical errors have become a leading cause of death[1,2] and the healthcare costs and complexity of the diseases have increased, Clinical Decision Support (CDS) shifted its focus from an auxiliary technology to a practical necessity.[3] Due to the sheer amount of information available on clinical topics and the limited time of the user, it is important to deliver context-specific natural language answers. Manual approaches to CDS is cumbersome for content maintainers. Therefore, an automated approach, like text mining, would be desirable.

Our previous research has demonstrated the feasibility of automatically extracting relevant sentences from MEDLINE® abstracts[4] to aid clinicians in finding relevant information quickly. But, much of the relevant information is in the full text article, not the abstract. Taking two randomly selected articles from UpToDate®[5] (a clinical knowledge system) titled "Overview of the Therapy of Heart Failure Due to Systolic Dysfunction" and "Clinically Isolated Syndromes Suggestive of Multiple Sclerosis", we can illustrate the shortcomings of abstract only processing. By counting the number of citations in the abstract and the full-text, we found that only 49.55% (56 out of 113) of the references in the Heart Failure related article and 68.11% (47 out of 69) of the citations in the Multiple Sclerosis related article refer to information in abstract text. Combining the two, only 56.59% (103 out of 182) of references in clinical articles refer to abstracts, suggesting the importance of processing full-text for providing clinical decision support.

Today, there are over 2500 journals that have at least one article indexed in Medline with the Major MeSH® Term – "Congestive Heart Failure". Therefore, it is important to prioritize the journals not only to assign a manageable task for text mining, but also to give confidence to clinicians by providing content from the journals they trust. In addition, journal ranking can be used as a feature in article prioritization task where systems rank[6] or classify[7] articles. There has been research focused on prioritizing individual articles based on quality, specifically for clinical decision support[8], but few focused on prioritizing journals first. Prioritizing journals first aids the clinical knowledge system's decision on the number of full-text articles to process. In addition, directly measuring an article's relevance to a topic is a manageable task using standard text categorization and machine learning techniques[6,7]; however, obtaining the full-texts of the articles for all the 2500 journals and processing each article is not.

Abridged Index Medicus (AIM)[9], also known as core clinical journal titles, is an existing resource that ranks top journals, which has been available since 1970.[10] However, this list is not suitable for identifying the journals from which articles about a specific topic or even a branch of medicine could be extracted. For example, the list misses cardiology journals such as *Circulation: Heart Failure, JACC: Heart Failure* and *European Heart Journal* that are perceived to be important by cardiologists. The McMaster Plus project[11] collaborates with the BMJ Group to provide citations, rated for quality by hand, from over 120 top journals. However, this list of top journals also

misses journals important for a specific topic such as heart failure (example: *Circulation: Heart Failure, JACC: Heart Failure* and *Journal of Heart Failure*).

In this study, we identified the top journals for "Congestive Heart Failure" and the factors that favored their positive perception among cardiologists. We then developed a regression model to prioritize automatically journals for any topic.

Methods

A. Survey Procedure

All the Medline abstracts indexed with the MeSH Major Topic – "Congestive Heart Failure" were downloaded in XML format using the PubMed® interface.[12] The email addresses of the corresponding authors and the countries of their affiliation were extracted using a set of rules and regular expressions.[13] To decrease the variability of the survey participants, we limited them to US organizations.

To reduce outliers and selection bias, we took into consideration that cardiologists are busy and an individual follows only a few journals. Therefore, we first ranked the journals by the number of their articles indexed in Medline by the MeSH Major Topic – "Congestive Heart Failure". The top-100 journals presented in random order were rated by eight cardiologists locally on a 1-5 scale based on their value for clinical decision-making (same criterion as actual survey). Sixty journals that are above a threshold agreed after looking at the distribution of the ratings were considered for the final survey. Based on our experience with the Mayo Clinic cardiologists, we asked the survey participants to rank at least 20 journals among these. The survey was sent to all the participants on March 8, 2013. They were reminded to participate on March 15, 2013 and finally again on March 22, 2013.

Informed consent was obtained for each participant by asking at the beginning:

We want to extract automatically sentences from journals that are relevant to clinician information needs. For the sake of building a prototype, we are asking cardiologists to provide a subjective opinion by rating few journals (presented in random order) in relation to congestive heart failure. By clicking the next button, please confirm that you are consenting to take part in the survey and that you are very familiar with cardiology and congestive heart failure in particular.

If they provided informed consent, we asked them the mandatory questions listed below:

- For how many years have you been practicing medicine?
- How many publications do you have in cardiology?
- How many journals related to congestive heart failure do you follow regularly?
- Choose all your current roles.
- Please rate how valuable information in each journal is to your clinical decision making.

Once they finished the mandatory questions, we asked them two optional questions:

- When choosing a rating for the journal, what are the factors important to you?
- Any comments about the survey?

B. Metric Analysis

With the help of a librarian, we searched existing medical literature to know what factors of a journal such as impact factors, aims & scope and download counts are important in determining whether clinicians follow that journal or use the information at point of care. The metrics mentioned in the articles[14-28] were used as choices in the optional questions.

In addition, the journal-related numeric metrics were compared to the rating average of the corresponding journal using Multiple Linear Regression[29] algorithm:

1. Impact Factor (IF)
2. H-Index
3. SCImago Journal Ranking (SJR)
4. Number of articles (Total Docs)
5. Number of references in the articles (Total Refs)

6. Number of articles for 3 years (3yr Docs)
7. Number of citations to articles for 3 years (3yr Cites)
8. Number of cited-articles for 3 years (3yr Cited)
9. Number of references per article (Ref/Doc)
10. Number of CHF-indexed Medline abstracts (CHF count)
11. Broad Journal Heading – cardiology (0/1) (BJH)
12. Core clinical journal (0/1) (AIM)

The metrics 1-9 are freely available every year from the online resource for journal ranking provided by SCImago Journal & Country Rank[30] from Scopus. The metrics 10-12 are also available freely from the NLM.

The impact factor (IF) of a journal is the number of times that articles published in the past two years are cited by indexed journals during current year, divided by the total number of articles published by that journal in those two years.[31] H-Index of a journal, similar to that of a scientist, is defined to be the maximum possible h such that h number of articles in the journal have at least h citations.[32] SJR is an adaptation of the PageRank metric[33] used by Google©, where the nodes are the individual journals and the edges have weights corresponding to the amount to the citations between the journals representing the nodes. Metrics 4-9 are self-explanatory.

The "Number of CHF-indexed Medline abstracts" is obtained from PubMed interface by limiting the search to the name of the journal AND the MeSH Major Topic – "Congestive Heart Failure". The "Broad Journal Heading" is extracted from the journal descriptions[34] provided by NLM®. For example, "American journal of cardiovascular drugs: drugs, devices and other interventions" has the following broad journal headings: Cardiology, Drug Therapy and Vascular Diseases. When one of the headings is Cardiology, we assign a score of '1'; otherwise, the score is '0'.

Cardiologists' survey rating averages were used as the response variable (Y) and the 12 journal metrics were used as random independent variables (X) for Multiple Linear Regression. We tried all the combinations of the independent variables ($\sum_{k=1}^{12}\binom{12}{k} = 4095$). Variables 11 and 12, which are ordinal, were also compared with the rating averages using the non-parametric (rating averages unlikely to be normal in distribution and the journals in at least one group is anticipated to be less than 25) Wilcoxon's Rank Sum Test.[35]

Results

A. Survey Output

Among all the Medline abstracts with the MeSH Major Topic – "Congestive Heart Failure", there were 32,702 abstracts with an affiliation sentence. Parsing them revealed 14,525 affiliation sentences with at least one email address and these are from multiple countries. Among them, 5,584 sentences correspond to the USA. In these affiliation sentences, we found 3,443 unique email addresses. Among these, 1,088 addresses expired or the recipient is out of office. Of the successful recipients, 169 accepted the eligibility criteria with informed consent and 161 finished the survey. Of these, 19 participants had 0-5 years of experience. For comparing the rating average of journals with the journal metrics, we considered the 142 participants with six or more years of experience.

Table 1 describes the characteristics of the participants. The majority of them have been in practice for over 15 years and published more than 20 cardiology articles.

We presented to them 60 randomly ordered journals preselected by the eight Mayo Clinic cardiologists, with an average score of at least 1.5. They were asked to rate these journals by their value in information about CHF in a 1-5 scale (1=least value, 5=most value). The rating averages of the 142 participants with at least 6 years of experience are right-skewed with a median of 2.17 (25% quartile =1.87 and 75% quartile = 2.54). Figure 1(a) shows the Stem and Leaf plot for the distribution of rating averages. It illustrates how a majority of journals got an average rating of 1.5-2.5. Figure 1(b) shows the Stem and Leaf plot for the distribution of response counts. It illustrates that each journal is rated by at least 96 participants.

Table 1. Characteristics of survey participants.

Participant characteristic (N=161)	No. (%) of respondents
Experience (years)	

0-5 6-10 11-15 16-25 >25	19 (11.8%) 20(17.4%) 22(13.7%) 45(28.0%) 47(29.2%)
Cardiology publications 0-5 6-20 21-50 51-100 >100	 24(14.9%) 41(25.5%) 31(19.3%) 23(14.3%) 42(26.1%)
CHF related journals following 0-5 6-10 11-15 16-25 >25	 118(73.3%) 35(21.7%) 7(4.3%) 0(0.0%) 1(0.6%)
All current roles Clinician Researcher Instructor	 130(80.7%) 132(82.0%) 98(60.9%)

The top-10 journals with their rating averages are in Table 2. The highest rating average is 4.35 (The New England Journal of Medicine) and the lowest rating average is 1.58 (Basic research in cardiology). Table 2 lists the rating averages with the number of responses for 10 journals with highest rating averages. The journal titles in **bold** are those that are NOT indexed in AIM (core-clinical journal list).

Journal of cardiac failure	3.04	117

Figure 2(a) shows the correlation coefficients of the first 10 variables, which are continuous along with the respective p-values. The rows with p-values in bold indicate that the correlation of the variable with ranking average is statistically significant (alpha=0.05). It should be noted from Table 3 and Figure 2(a) that although the topic-specific metrics (CHF count, BJH and AIM) are itself less predictive than other features, they provide complementary information that improves the overall predictive power significantly in combination with top-metrics such as SJR.

Table 3. Top-10 accurate multiple linear regression combinations (numbers rounded to 3 decimal places).

IF	H-Index	SJR	Total Docs	Total Refs	3yr Docs	3yr Cites	3yr Cited	Ref/ Doc	CHF count	BJH	AIM	Correlation

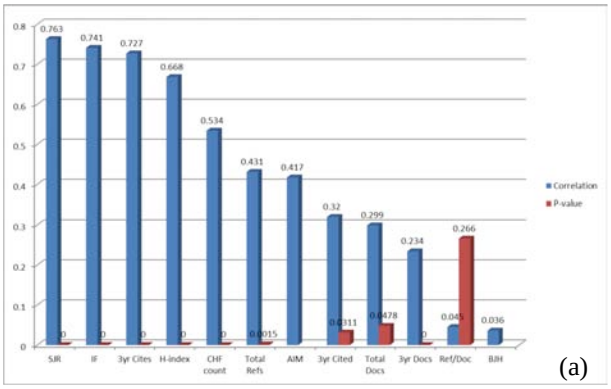

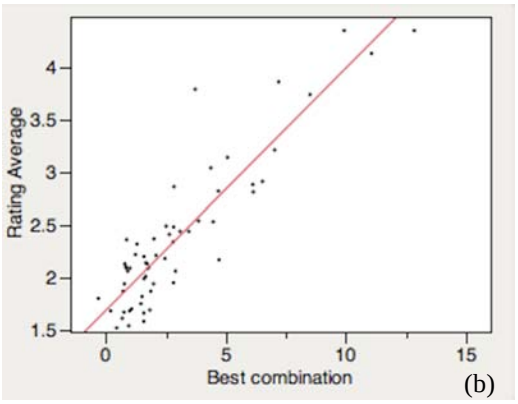

Figure 2. (a) Correlation of the continuous variables with rating averages (b) Linear bivariate fit of rating average by weighted combination of best model

B. Metric Analysis

The 60 rated journals by 142 cardiologists and twelve variables were used to create a Multiple Linear Regression model for rating average. Table 3 lists the top-10 combinations (among the 4095 combinations tested) of metrics and their coefficients. The best model has a correlation of 0.880. The correlation was calculated from the 5-fold cross validation and the final coefficients were obtained from the sixth run combining all the 60 journals. The only variable that is present in all the top-10 models is CHF count (Number of CHF-indexed Medline abstracts). In fact, the best 1,388 models employ the CHF count variable. Without employing this variable, the best correlation obtained is .806 (8.4% lesser). The other variables derived from NLM's sources – BJH (Broad Journal Heading) and AIM (core clinical journals) respectively take into account whether the journal is related to cardiology or is a top medical journal. Using none of these three metrics, the best correlation is only 0.792 (10.0% lesser).

We obtained the below formula to automatically rate the journals.

Formula 1: Journal rating metrics and coefficients

Journal priority score =

(0.82640 * SJR) -
(0.00377 * Total Docs) +
(0.00258 * 3yr Docs) -
(0.00190 * 3yr Cited) -
(0.01846 * Ref/Doc) +
(0.00295 * CHF count) +
(0.62864 * BJH) -
(0.32753 * AIM))

The two groups – core clinical journals (AIM) and the rest have statistically significant difference in means of rating averages ($p=0.0003<0.05$, Rank sums test). The respective means are, however, close – 2.9 vs. 2.1. The groups – cardiology journals and non-cardiology journals (based on BJH) do not have statistically significant difference in means of rating averages ($p=0.1888>0.05$, Rank sums test). Surprisingly, the non-cardiology journals have a slightly higher rating average mean (2.5) than cardiology journals (2.3). This is because the non-cardiology journals with higher impact factor, h-index or SJR such as NEJM and JAMA have a high acceptance even among cardiologists.

In addition, the participants (159 participants answered this question) rated the factors mentioned in literature and suggested by local cardiologists as shown below:

1. Clinical relevance: 108 (76.6%)
2. Impact factor: 93 (66.0%)
3. Type of articles – Human Vs. Animal Research: 66 (46.8%)
4. Electronic Access: 61 (43.3%)
5. Study design of the articles: 61 (43.3%)
6. Quantity of topic-related articles: 53 (37.6%)
7. Aims and scope: 50 (35.5%)
8. Proportion of topic-related articles: 49 (34.8%)
9. Open-access: 28 (19.9%)
10. Readership composition: 26 (18.4%)
11. Editorial board composition: 26 (18.4%)

Discussion

A. Selection Bias

Such a survey conducted at a single institution might be influenced by selection bias (sample being not representative of population). In our case, we invited participants from across the United States. This study is part of a 4-year project funded by the NLM (USA) intending to help cardiologists in the USA in areas such as CHF. The cardiologists invited are affiliated with organizations from all the 50 states of USA and Puerto Rico and over 500 different cities of USA.

Table 4. Distribution of citations to journal names

B. Number of Participants vs. Number of Journals (Nonparticipation Bias)

More participants will minimize a journal getting a significantly higher or lower rank than its true mean (central limit theorem). A higher number of journals allows for more statistical power in the calculations of association between the metrics and rating averages. However, we observed a tradeoff between the number of participants and number of journals they rate while testing the survey at Mayo Clinic. Several cardiologists recommended reducing the journals significantly. Therefore, we chose 60 journals instead of 100 and imposed a constraint in the survey so that the participants rated at least 20 (33%) journals. Despite these, we observed statistically significant differences for all metrics except Ref/Doc (Number of references per article) and BJH (Broad Journal Heading). On average, each participant rated 45.0 journals (out of 60 maximum) and each journal received 120.75 ratings (out of 161 maximum).

To further verify this, a replication survey was conducted at Mayo clinic in which 18 cardiology fellows participated. This step is also useful for comparing results of the previous survey where the participants are established clinicians or researchers and with this survey with a different population. The demographic characteristics of the participants are presented in Table 5. In Table 6, rating averages with the number of responses for the 10 journals with highest rating averages are presented. The highest rating average is 4.71 (The New England Journal of Medicine) and the lowest rating average is 1.50. The ranking of the journals show a large overlap.

Table 5. Characteristics of survey participants of 18 respondents

Participant characteristic (N=18)	No. (%) of respondents
Experience (years)	
0-5	7 (38.9%)
6-10	8(44.4%)
>11	3(16.7%)

The American journal of cardiology (11)	3.38	13
JACC. Cardiovascular imaging (19)	3.36	11

C. Generalizability

The best Multiple Linear Regression model has a correlation as high as 0.880. Figure 2(b) shows the regression fit with the weighted combination in the X-axis. We will also be able to update the list with new journals related to CHF or automatically update the scores for existing journals with time. The focus of our project was to help cardiologists with the topics – CHF and atrial fibrillation (afib). The survey we conducted locally solicited cardiologists to rate the journals for both CHF and afib. The correlation between the ratings is 89.16%. Therefore, it is likely that the list might be repurposed for other cardiology topics with expert editing.

To check the generalizability of Formula 1 for non-cardiology topics, we used the same two articles from UpToDate to assess how the rank of a journal obtained using the formula is related to the number of references from the journal. Table 4 shows all the journal names in the respective articles sorted by the journal priority score calculated using Formula 1.

It should be noted that the ranks of the journals obtained using the formula are similar to the rankings obtained from survey ratings. The top 15 journals as per the journal priority score calculated by Formula 1 for Heart Failure domain cover 94.69% (107 out of 113) of references. Using the same formula for the MS related article (with mesh counts calculated using “multiple sclerosis”), almost the same coverage is obtained (94.20% (65 out of 69)). In comparison, if the 119 AIM journals are used, 82.30% (93 out of 113) and 71.01% (49 out of 69) of references are covered in Heart Failure and Multiple Sclerosis topics respectively – a 14% less coverage on average. For building a topic-specific clinical decision support system using knowledge in literature, we might achieve a higher coverage even using lesser number of journals (about 15) than using all the AIM journals. When building a generic decision support system, one might expand the AIM journals for the key topics using the journal priority score formula.

Although this simple analysis suggests the formula might be generalizable on non-CHF related articles (94.20% coverage on MS topic), increasing the size of the corpus by conducting multiple surveys and training the system with more than one topic will increase the accuracy (measured by correlation) of the formula.

D. Choice of Algorithm

This was determined by the fact that this is not a classification problem (where algorithms such as Naïve Bayes are used) or a clustering problem (where algorithms such as K-means are used), but a regression problem. Since the individual metrics are linearly correlated, Linear Regression is more appropriate than other regression algorithms such as Logistic Regression. Here we chose Multiple Linear Regression algorithm since it accounts for all possible combinations of the metrics.

Conclusion

With the help of cardiologists across the United States, we rated and ranked journals related to CHF. A replication survey with cardiology fellows was done to verify that the ratings are generalizable to other demographics. While these ratings will help us move forward in CHF, we have also obtained a formula to automate the process for other topics such as Multiple Sclerosis. The Multiple Linear Regression model achieves a correlation of 0.880 (five-fold cross-validation). We demonstrated that general journal metrics such as impact factor, h-index and number of articles per year provide better results when used in combination with topic-specific metrics such as number of abstracts indexed with a MeSH term. Our participants ranked these and other factors in this order: clinical relevance (77%), impact factor (66%), human vs. animal research (47%), etc. All these factors need to be taken in consideration for further improving and generalizing this work.

Acknowledgement

We thank Mayo Clinic's cardiologists for helpful comments and discussion. We are also thankful to UpToDate© for allowing us to use their data for research purposes. This paper would not have been possible without the anonymous participation of cardiologists across USA. This publication was made possible by the NLM K99/R00 grant LM011389.

Abstract

Introduction: *The Privacy Rule of Health Insurance Portability and Accountability Act requires that clinical documents be stripped of personally identifying information before they can be released to researchers and others. We have been developing a software application, NLM Scrubber, to de-identify narrative clinical reports.* ***Methods****: We compared NLM Scrubber with MIT's and MITRE's de-identification systems on 3,093 clinical reports about 1,636 patients. The performance of each system was analyzed on address, date, and alphanumeric identifier recognition separately. Their overall performance on de-identification and on conservation of the remaining clinical text was analyzed as well.* ***Results****: NLM Scrubber's sensitivity on de-identifying these identifiers was 99%. It's specificity on conserving the text with no personal identifiers was 99% as well.* ***Conclusion****: The current version of the system recognizes and redacts patient names, alphanumeric identifiers, addresses and dates. We plan to make the system available prior to the AMIA Annual Symposium in 2014.*

1. Introduction

Electronic health records are treasure troves for clinical scientists because with the availability of high volumes of electronic reports, clinicians are no longer limited to a cohort of their patients and can easily test their hypotheses on much larger samples. Access to those records, however, is not easy and involves overcoming a number of institutional barriers. These barriers have been raised purposefully to ensure that only the right person could access the private information of the patient. While these barriers had been the primary means to protect patient privacy, the requirements were so difficult to attain that they also became a barrier to scientific progress. Having seen both sides of the issue, the U.S. Congress enacted Health Insurance Portability and Accountability Act (HIPAA) in 1991, which tasked the U.S. Department of Health and Human Services (HHS) with regulating access to health records while protecting the health information of individuals.

The Privacy Rule of HIPAA requires that clinical documents be stripped of personally identifying information before they can be released to researchers and others. There have been several attempts to de-identify clinical text data automatically via software with an upward trend of performance, yet the clinical research community still considers human verification and validation necessary prior to the release of any automatically de-identified clinical data.

We have been developing a software system to automatically de-identify clinical records, which we have named NLM Scrubber. The current version of the system recognizes and redacts patient names, alphanumeric identifiers, addresses, and dates. The primary goal in clinical text de-identification is to raise the sensitivity performance of the system to an acceptable level so that de-identified data can be used with no need of human verification. We designed NLM Scrubber with that goal in mind and this study is a new step forward to reach that goal.

2. Background

As defined by HHS, Protected Health Information (PHI) comprises a subset of the health information of an individual who is the subject of the health record *and* personally identifiable information[*] (PII), including demographic information, collected from the same individual to be used by the health care provider, health plan, employer or health clearinghouse. PII is any information that distinguishes or traces an individual's identity such as

[*] The text of CFR 45 § 164.514 uses the term *individually* identifiable information instead of *personally* identifiable information. One possible reason is that the meaning of the legal term *person* also includes entities other than natural person (human) such as trust, estate, partnership, corporation, and professional association among others. Since personally identifiable information and its acronym PII are more widely known terms, we used them here instead.

name, social security number, date of birth or biometric records and any other information such as medical, financial and employment information that is linkable to an individual.[2 3]

Table 1. Per HIPAA Privacy Rule, the following identifiers must be deleted from PHI to fully de-identify health information. (*) As of 2010, there were 18 sets of zip codes with distinct initial three digits whose corresponding population sizes were less than or equal to 20,000.[1]

1. Names
2. All geographic subdivisions smaller than a state, except the first two digits of the zip code of the postal address. The third digit of the zip code can also be left intact, only if the size of the population in the area of the censored two digits is greater than 20,000 according to the most recent census data.(*)
3. All elements of dates (except year) for dates directly related to an individual, including birth date, admission date, discharge date, date of death; and all ages over 89 and all elements of dates (including year) indicative of such age, except that such ages and elements may be aggregated into a single category of age 90 or older.
4. Telephone numbers.
5. Fax numbers.
6. Electronic mail addresses.
7. Social security numbers.
8. Medical record numbers.
9. Health plan beneficiary numbers.
10. Account numbers.
11. Certificate/license numbers.
12. Vehicle identifiers and serial numbers, including license plate numbers.
13. Device identifiers and serial numbers.
14. Web universal resource locators (URLs).
15. Internet Protocol (IP) address numbers.
16. Biometric identifiers, including fingerprints and voiceprints.
17. Full-face photographic images and any comparable images.
18. Any other unique identifying number, characteristic, or code, except the ones that may be generated by the covered entity for re-identification.

HHS developed the Privacy Rule, defining certain identifiers as part of PHI, which should be de-identified before health records are accessed for research purposes (see Table 1). Note that the health information dissociated from those identifiers of the individual is not considered PHI. According to the Privacy Rule the identifiers in Table 1 that belong to the individual or relatives, employers or household members of the individual, should not be present in any de-identified health records.[4]

2.1 Current Clinical Text De-identification Systems

De-identification of structured data is a fairly straightforward process, where the content of fields defined as containing PHI (e.g., name and birth date fields) be removed and made inaccessible to researchers. De-identification of unstructured data or free text, on the other hand, is a challenge. Because of the idiosyncrasies of any natural language, including English, the utterances of information are not always predictable and we have to devise intelligent tools to recognize those words and phrases containing PHI.

A thorough review of 18 clinical text de-identification systems has been published recently.[5] Since then only four additional systems have appeared in major journals.[6-9] These 22 systems can be categorized in two groups based on their target documents: general purpose vs. niche (specialized) de-identifiers. They can also be classified in terms of their underlying methodologies, which use either symbolic or machine learning approaches. Symbolic approaches mainly rely on rules, regular expressions, and lookup tables (also referred to as dictionaries or gazetteers). The availability of a de-identification system is another important characteristic; some are freely available, some are commercial products, and others have not been made available.

Currently, there are only five freely available systems, three of which were specialized to de-identify surgical pathology reports only.[10-12] The other two systems are general purpose de-identification systems developed by researchers at MIT and MITRE. MIT's system took a symbolic approach; whereas, MITRE's is a machine learning system using conditional random fields.

The name of MIT's system was not mentioned in their publication[13] but the filename of the code was *deid.pl*. Since there is another (commercial) system with the same name, De-ID, to prevent any confusion, we here call MIT's system "MITdeid". MITdeid provides various features that are closely tuned to clinical setting, such as accepting a list of provider names of the institute and the full name of the patient per report.

MITRE's system, MIST, was developed to demonstrate how an existing conditional random field program designed for generic use could be repurposed quickly as a successful clinical text de-identification system.[14] MIST has proven itself as one of the most successful systems in the i2b2 competition in 2006.[15] As a machine learning system, MIST requires a training dataset. The current version of the system does not store the constructed model and has to be re-trained before each testing session.

As part of Clinical Text De-identification Project at NLM, we studied personal name recognition in great depth. Since we previously reported the results of the name scrubbing performance of our system elsewhere, we do not repeat them here.[16]

2.2 Contribution of NLM Scrubber

There have been several attempts to de-identify clinical text data automatically via software, but all those systems that are freely available had failed to scrub some identifiers; showing the need for improvement. As part of HHS, NLM started the clinical text de-identification project to respond to this need and promote scientific progress by enabling the research community to access large amount of health information that does not contain personal identifiers. NLM Scrubber will be freely available at the time of this publication. The goal of NLM Scrubber is to facilitate the production of de-identified clinical text data, and minimize (if not eliminate) the burden of manual de-identification for the clinical research community.

3. Methods

In this section, we present (1) how we select and process the clinical text data from a large corpus of clinical reports in order to reliably study and develop robust de-identification methods; (2) the methods and components of our de-identification tool; and (3) our evaluation methods.

3.1 Data Selection

A hospital information system may retain many copies of a given report (e.g., the initial report, the report with addenda or corrections) and HL7 messages logs that we used do the same. A sample with duplicate reports may inflate the magnitude of events observed in the study. Duplicate reports in a de-identification test set would distort the analysis of tests and the success of a de-identifying program.

To ensure the reliability of the study results, we devised a random sampling method to exclude any redundant reports. For each randomly selected patient, we collected all reports generated during a particular visit of the patient, grouped them by report types, sorted each group by report filing time, and took only the most recent, presumably the most developed report in that group.

Our sampling method relies on the assumption that each visit is associated with a unique visit number and reports of the same type in two different visits are sufficiently dissimilar. Note that this assumption may not always hold. After performing the sampling, we sorted reports of each patient by word counts. The manual comparison of the reports that were similar in size helped us discover partially duplicate records from distinct visits of the same patients. We eliminated the earlier reports from these sets. This approach may inadvertently eliminate some non-duplicate reports, but in the final analysis, it yields an unbiased, large spectrum of reports per visit with distinct report types.

In this study, we used 3093 distinct clinical reports about 1636 distinct patients of the Clinical Center at NIH. The maximum number of reports per patient was 20.

We developed NLM Scrubber using a training set of 1140 clinical reports from the same institution. Unlike the study test data, retrieval of the training data was done in several iterations over a long period of time in an ad hoc and not truly randomized manner. The patient cohorts in the training and test data were mutually exclusive.

3.2 PII Recognition Methods

We collapse 18 types of identifiers defined by HIPAA into four distinct categories: 1) names, 2) addresses, 3) dates (incl. ages), and 4) alphanumeric identifiers (e.g., medical record numbers, report identifiers, telephone numbers). We reported our results with the first category, names, previously [16]. Here we report our results with the other three categories.

3.3 Alphanumeric identifier recognition

We define an alphanumeric string as a string of characters containing at least one or more digits. It may or may not contain other characters. Alphanumeric Identifier Recognizer (AIR) has a two-prong approach: It detects patterns that correspond to alphanumeric strings such as phone and social security numbers that need to be labeled as alphanumeric-Id, but it also detects patterns of known clinical entities such as lab values that need to be preserved. AIR also attempts to distinguish alphanumeric strings from date-like patterns so that dates would not be mislabeled.

If a token of alphanumeric string contains only a single digit, AIR ignores it completely; otherwise, it analyzes the content of token t and its context. If t is preceded by a token containing certain strings such as number, protocol, or # sign, it labels t as an alphanumeric identifier. If an alphanumeric token containing a sequence of two or more upper case letters is followed by certain tokens such as "protocol", it is labeled as alphanumeric identifier. A 9–10 digit number pattern with or without delimiters in between is also defined as alphanumeric identifiers (i.e., phone or social security numbers).

AIR also checks numerous conditions (e.g., a number followed by a unit of measure) that may indicate that token t be a valid piece of clinical data to be conserved and marks most other alphanumeric strings as alphanumeric identifiers.

3.4 Date and age recognition

Algorithms for identifying dates and ages are based on a set of regular expressions to detect the corresponding patterns. Some date patterns are listed in Table 2. For example, string 07-08-2012 would be identified using the pattern DD*MM*YYYY, where "*" is a delimiter and D, M, Y are digits such that YYYY should be greater than 1900 and less than the current year, $1 \leq \text{DD} \leq 31$ and $1 \leq \text{MM} \leq 12$.

Table 2. Date Patterns: D, M, Y, h, and m are date, month, year, hour and minute digits; * is a delimiter; MONTH, HOLIDAY are literal values of month and holiday incl. their abbreviations; X? denotes that X is optional; | indicates distinct disjunctive patterns

Pattern	Example	Pattern	Example
YYYY*MM*DD	2012-08-07	**DD*MM?**	07-08, 07-8
DD*MM*YYYY	07-08-2012	**YYYYMMDD**	20120708
MM*DD*YYYY	08-07-2012	**YYYYMMDDhhmm**	201207081215
MM*DD*YY	08-07-12	**YYYY**	2012
M*DD*YY	8-07-12	**DD?*?MONTH**	7-August, 7August, 7 Aug
YYYY*YYYY	2011-2012	**MONTH*YY(YY)?**	August.2012, August'12
DD*MM*YY	07-08-12	**(early|mid|late)*YYYY**	Mid-2012
M*D*YY	8-7-12	**YYYY*?MONTH**	2012/August, 2012Aug
M*DD*YY	8-07-12	**'YY*?MONTH**	'12-August, '12Aug
MM*YYYY	08-2012	**DD?MONTH*YY**	7August'12
DD*MM*DD*MM	07-08/08-08	**MONTH*DD?**	Aug7, August 7
MM?*DD	08-07, 8-07	**MONTH**	Aug, August
DD?*MM	07-08, 7-08	**HOLIDAY**	Christmas, Easter
MM*DD?	08-07, 08-8		

Unlike date patterns, age patterns are more involved. For example, age patterns may be required to catch phrases like "on his **ninety-third** birthday" or "in his late **90s**".We classified alphanumeric age expressions and labeled them with specific names (see Table 3). The corresponding patterns are recognized through regular expressions.

Whenever a date (age) regular expression is matched with the tokens in the text, those tokens are labeled as date (age).

Table 3. Alphanumeric Age Expression Classes

Expression Classes	Examples
AGE-WITH-SUCCEEDING-MARKER	he was [93 years-old]
AGE-WITH-PRECEDING-MARKER	at the [age of 93],
AGE-WITH-APPENDED-UOM	his father, [93yo], has
AGE-FRACTION-EXPR	he is [5-years and 3-months] old
AGE-FROM-PHRASE-CONTEXT	she [was nearly 93].
AGE-BIRTHDAY-CONTEXT	on his [ninety-third birthday]
AGE-DECADE-CONTEXT	in his late [90s]
AGE-SIMPLE-CATCH-ALL	(as 93)
AGE-COMPOUND-CATCH-ALL	(93 and 90)

3.5 Address identifier recognition

Addresses are recognized mostly via the "shapes" component of dTagger, a specialized part-of-speech tagger extended with limited pattern tagging abilities for entities, such as addresses.[17] The dTagger searches address terms in various lexicons, which contain city and states names as well as street types and their abbreviations (e.g., Avenue, Alley, Blvd, and Circle). In its current format, the recognizer is difficult to maintain and will be revised before the release of the software package; therefore, we do not provide any further specifications of the soon-outgoing recognizer in this report.

3.6 Redaction

The redactor removes the PHI content in a post-processing step, where it replaces the removed text with a corresponding standard PHI label. For example, John would be replaced with [NAME]. If two distinct recognizers (e.g., both date and alphanumeric-Id recognizers) tag the same token as PHI, the redactor labels the content as [PHI] instead of choosing one tag over another.

3.7 Evaluation Methods

We evaluated the NLM Scrubber on a test set of 3,093 dictated narrative reports generated at the NIH Clinical Center. The set was annotated by two experts, a linguist and a registered nurse, producing the gold standard for the test data. Following NLM Scrubber's run on the study data, we compared the resulting tags against the gold standard and evaluated them in terms of sensitivity, specificity, precision, and F_2 measures. We also evaluated the privacy risks due to the revealed PHI tokens.

We tested the scrubbing performance of two of the most prominent and freely available de-identification systems, MIST and MITdeid against the same data and used the same evaluation approach for all of them.

Since MIST is a machine learning system, it requires training before testing. We used our held-out set of 1,140 annotated reports as training data for MIST. After testing MIST extensively on the training dataset using various parameterizations and based on consultations with its developers, we decided to run it with a bias of –4, which greatly favors sensitivity over precision but not to the extent that the results become unreliable. We appreciate the generous assistance we received from many members of the MIST developer team at different phases of our study.

3.8 Evaluation of differently tokenized results

Most de-identification systems come with their own tokenizers producing different sets of incompatible results. In order to compare the results and to report token misalignment errors, evaluators devised terminology such as colliding tokens, boundary detection failure and partially tagged tokens. For example, Deleger et al. reported that partially tagged PHIs due to boundary detection errors were 13% of all tagging errors.[7] Some researchers in the NLP community also use complex alignment schemas to remedy the problem.[18] When tokens produced by different systems do not match, the evaluation gets complicated and the differences between results become obscured. The situation gets more complicated as the number of systems to be compared increases. In the literature, we have not seen any proposed solution to the problem for robust evaluation of de-identification systems.

In this study, we align all outputs to be compared to the tokens of the gold standard. This method simplifies the evaluation without introducing any bias favoring one system over another: (1) We re-tokenize all outputs using the

same tokenization scheme that the gold standard annotation has adopted. (2) When a token t in a system output does not correspond one-to-one to a gold standard token t_G, one of the following three scenarios is observed: (a) t may be a proper substring of t_G; (b) t_G may be a proper substring of t; or (c) t and t_G may overlap partially. After re-tokenization, the string of characters in t is distributed into a sequence of one or more tokens. We tag the resulting sequence of tokens with the original tag of t. (3) If t was tagged with a set of multiple tags originally, we apply them simultaneously to all tokens in the resulting sequence.

3.9 Evaluation of system's labeling of single tokens

Accurately distinguishing patient identifiers (e.g., telephone numbers and addresses) from provider identifiers is too difficult to attain for any text de-identification system. Recall that provider identifiers are not PHI. By design, NLM Scrubber (as well as most other clinical text de-identification systems) attempts to de-identify all personal identifiers regardless of whom they belong to. Throwing such a wide net does not degrade the quality of the de-identified text, since provider identifiers usually have no information value for clinical scientists.

Although this approach simplifies our task of catching *all* patient identifiers, it also complicates the evaluation process significantly. How should we evaluate labels of tokens related to providers? For example, if the system labels the physician's phone number as an alphanumeric identifier, should we count this label as true positive (TP)? Conversely, if the system misses a provider's phone number, should we count the instance as false negative (FN)?

When the aim is to protect patient privacy, the performance of a de-identification system should indicate the level of protection it provides. Inflating the TP count with the inclusion of de-identified non-PHI tokens would distort the actual performance. Note that in clinical reports, physician phone numbers are mentioned very frequently but patient phone numbers are extremely rare. Consider the case where a system de-identifies *all* physician phone numbers but misses a few, rarely-occurring patient phone numbers. Had we counted physician phone numbers as TPs, they would totally wash out the system's failure vis-à-vis the missed patient phone numbers. The resulting statistics would give a false diminutive impression on the system's failure on protecting patient privacy.

When we create the gold standard, should we then avoid labeling provider identifiers as PII? In that scenario, whenever a de-identification system recognizes a provider identifier as PII, we would have to count it as false positive (FP) and when it misses the provider identifier, we would have to count it as true negative (TN). Note, the design of our system requires de-identifying all personal identifiers. It would be incongruous to reward the system with a TN count when it misses a provider identifier or to penalize it with a FP count when it finds a provider identifier by following its design requirement faithfully. De-identifying a provider token (or keeping it intact in the text) has no effect on the actual performance of privacy protection or clinical information preservation; thus, we excluded provider tokens from performance evaluation.

The main purpose of our false positive rate analysis is to obtain an indirect measure about the level of preservation of scientific information present in clinical reports from de-identification. Most clinical information of any scientific value is represented in tokens that are not labeled in our gold standard annotation. The only exception to this rule is tokens representing non-PHI age (i.e., age < 90). The rate of preservation of non-labeled tokens and non-PHI age tokens is an indicator for the rate of preservation of clinical information.

If a system assigns a PII label to a token that actually is a patient identifier, we consider the decision as TP. If the system fails to label a patient identifier as PII, we call it as FN. A PII label would be FP if the token has no label in the gold standard (i.e., it is not PII) or if it denotes a non-PHI patient's age, because consequently the token would be redacted and the information would not be available to clinical scientists. If a non-labeled token or a non-PHI age token is labeled as non-PII, we consider it as TN.

3.10 Nonparametric analytic methods

Confidence intervals are staples of biostatics where samples usually come from a well-known parametric distribution and observations are random variables distributed independently and identically, which are not applicable to words in our dataset.

To estimate confidence intervals (CIs) in this study, we adopted a nonparametric bootstrap method,[19] bias-corrected, accelerated (BC_a) percentile intervals as implemented in package *boot* in R.[20] Through a bootstrap resampling strategy, we could truly simulate our initial sampling method. For each bootstrap sample, we randomly selected a patient and then included all reports (hence all associated token sequences) of the patient into the sample. We repeated this process until reaching the same number of patients in our original test data.

We computed statistical significance for the scores where CIs were overlapping, based on Wilcoxon paired signed test with Pratt's adjustments,[21] using the package *coin* in R.[22] This method is more suitable than bootstrap based *p* value estimation because it can successfully take into account that two sets of compared results are paired datasets.

These methods can be used in a wide-range of computational linguistic studies and provide a strong analytic footing for comparisons of different study results. We previously used them to compare and analyze information extraction performances of various systems.[23]

4. Results

In Table 4 on Alphanumeric-Id, Address, and Date rows, we reported each identifier recognition performance separately. For example, on the first row, the alphanumeric identifier recognition performance of NLM-S was isolated from the effects of date and address recognizers of NLM-S on the TP and FN counts. On the PHI rows, however, we reported the total effect of all three recognizers of each system.

Note that for any given system, neither TP nor FN counts on the PHI row are direct sum of the other three rows. For example, the total FN count of NLM-S (excluding PHI row) was 2 + 48 + 311 = 361, but the total missed PHI token count was 201, because some of the missed tokens by one recognizer (e.g., by Date recognizer) were caught by others (e.g., by Alphanumeric identifier recognizer). While we analyze each recognizer in isolation (before evaluating overall de-identification performance), it is important not to lose sight from the overall picture.

4.1 Alphanumeric Identifiers

In alphanumeric identifiers, NLM Scrubber (NLM-S) performance was clearly superior to others. It missed only two tokens, one of which was "406," a 3-digit area code of a telephone number, which should be considered non-PII since the area it covers is the entire state of Montana.[24] The other missed token was a protocol number, which is considered a low risk to privacy as the necessary information to re-identify the patient is not publicly available and such information is usually given to the patient's health care providers only.[25] MITdeid did not produce a viable alphanumeric de-identification on this dataset.

4.2 Addresses and Dates

In both addresses and dates, MIST results yield the best sensitivity scores, but on addresses, the sensitivity score difference between NLM-S and MIST was not statistically significant. After reviewing the false negative cases of NLM-S, we observed that most of the NLM-S's "missed address tokens" were actually non-PHI tokens such as geographical direction (e.g., Northern), state name abbreviation (e.g., VA), large city names in other countries (e.g., Beijing) and country names (e.g., England). None of the missed address tokens revealed a street address, but three of the revealed address tokens may cause some privacy concerns. They were Falls Church (Falls Church, VA: pop. 12,751) and Takoma (Takoma Park, MD: pop. 17,021).

Table 4. De-identification Sensitivity Results of NLM Scrubber (NLM-S), MIT's de-identification system (MITdeid), and MIST: Bold fonts denote the best results among the three, which are also statistically significant if their confidence intervals are written in bold fonts.

Identifier	Gold	System	TP	FN	Sensitivity
Alpha-Numeric-Id	4165	**NLM-S**	4163	2	**1.000 (0.998,1.000)**
		MITdeid	1444	2721	0.347 (0.334,0.359)
		MIST	4091	74	0.982 (0.977,0.986)
Address	292	NLM-S	244	48	0.836 (0.769,0.888)
		MITdeid	129	163	0.442 (0.371,0.510)
		MIST	250	42	**0.856** (0.791,0.905)
Date	29134	NLM-S	28823	311	0.989 (0.984,0.992)
		MITdeid	27595	1539	0.947 (0.942,0.951)
		MIST	28906	228	**0.992 (0.988,0.994)**
PHI	33591	**NLM-S**	33390	201	**0.994 (0.992,0.995)**
		MITdeid	29347	4244	0.874 (0.868,0.879)
		MIST	33310	281	0.992 (0.988,0.994)

In dates, MIST missed fewer date tokens than the other two systems and the differences were statistically significant. The sensitivity performance difference between MIST and NLM-S was 0.003, which however was statistically significant. NLM-S requires further sensitivity improvement on dates. None of the dates by NLM-S was tagged as PHI-Age (i.e., age > 89) in the gold standard.

Although trailing behind the other two systems, MITdeid showed strong sensitivity performance on dates (0.947), but not on addresses (0.442).

4.3 Overall Performance

It is not uncommon that a system tags a PHI token (e.g., a date) with a wrong label (e.g., an alphanumeric identifier). In such cases, there is neither a leakage of PHI nor a loss of clinical information. The PHI row in Table 4 indicates that there were a total of 33,591 PHI alphanumeric, address, and date tokens, of which NLM-S missed only 201, MIST 281 (40% more than NLM-S), and MITdeid 4,244 (21 times as many as NLM-S). NLM-S was clearly superior in overall sensitivity.

The decomposition of the revealed PHI tokens by PII types is displayed in Table 5. Note that the superiority of MIST on date and address de-identification that we observed in Table 4 is not present when we focus only on missed PHI instead of the accuracy of the classification into specific categories.

Table 5. Decompositions of Revealed PHI tokens by System

Tag	PII Type	Gold	NLM-S	MIST	MITdeid
AlphaNumericId	**AlphaNumeric-Id**	3502	0	24	1885
	Protocol-Id	660	1	3	659
	Telecom	3	1	0	0
Address	**Address**	292	48	40	163
Date	**Date**	29124	151	207	1532
	Age 90+	10	0	7	5
All		**33591**	**201**	**281**	**4244**

Although we do not have direct information about the inadvertent loss of clinical information due to over-de-identification, measures such as specificity, precision and F_2 may be used instead as indirect indicators (see Table 6).

Table 6. False Positive (FP), specificity, precision, and F_2 measures of the de-identification systems

System	FP	Specificity	Precision	F_2
NLM-S	5370	0.9950 (0.9947,0.9953)	0.861 (0.853,0.869)	0.964 (0.962,0.967)
MITdeid	2143	**0.9980 (0.9978,0.9982)**	**0.932 (0.926,0.938)**	0.885 (0.880,0.890)
MIST	3143	0.9971 (0.9967,0.9974)	0.914 (0.903,0.922)	**0.975 (0.971,0.978)**

MITdeid was superior in specificity and precision. Due to its low sensitivity score, however, its F_2 measure was not on par with others. In terms of F_2 measure, MIST did better than the other systems and NLM-S was a close second with a 0.011 difference.

5. Discussion

NLM-S revealed much fewer personal identifier tokens than the other two systems (see Table 5) and none of those revealed tokens were informative enough to disclose the identity of any patient. Our primary goal and our main criterion for success are to eliminate all patient related PII tokens when possible. As seen in results, NLM-S incurred a substantial number of false positives in order to catch the maximum number of identifiers, but the specificity penalty it incurred as a result was not higher than 0.005, which means that out of 1000 words only 5 of them were inadvertently deleted. This level of specificity does not have any significant adverse effect on the preservation of

clinical information and on the readability of the resulting text. For keeping the trust of the U.S. Public to the research community, we have to continue working on improving the sensitivity of NLM-S especially on dates and addresses even if it costs us more false positives to achieve that. On the other hand, we are also cognizant of the needs of the research community and have to pay great attention to false positive rates and to the effective conservation of clinical information in the upcoming versions of NLM-S.

In our study data, NLM-S has recognized more PHI tokens than MIST and MITdeid have, which are the only freely available, general-purpose clinical text de-identification systems at the time of this study. Our risk analysis indicates that the revealed tokens would not cause any substantial risk to the patient privacy. Only three instances of address identifiers revealed the home city of three distinct patients, where the population sizes were less than 20,000 but greater than 12,500. Population size 20,000 was devised by the Privacy Rule as a threshold for further censoring zip codes (see Table 1).

MIST was clearly the second best performing system of this study. Due to their underlying methodological power, probabilistic machine learning systems do very well in this domain. Given that we devised our system based on the characteristics of the clinical corpus in our hand, we should not be surprised if MIST outperforms NLM-S in another clinical dataset with different characteristics.

As we indicated in one of our earlier studies,[23] probabilistic machine learning and symbolic linguistic methods are not an either-or proposition, a good NLP system should incorporate methods of both paradigms and reap the benefits of both worlds. We plan to develop a robust machine learning component to our scrubber so that it could perform well on a variety of reports from different origins.

Acknowledgements

We are grateful to the Scientific Counselors of LHNCBC and Dr. Olivier Bodenreider, Chief of Cognitive Science Branch at LHNCBC for their generous inputs and contributions to the project and to an earlier, extended version of this text. We are grateful to Dr. Jon McKeeby, CIO, Clinical Center at NIH and his staff for their help in obtaining and interpreting the clinical data. We thank Guy Divita, Dr. Yanna Kang, Selcuk Ozturk, and Shuang Cai for their contributions to the project. We also thank Drs. Lynette Hirschman, Samuel Bayer and Ben Wellner as well as John Aberdeen of MITRE, for their generous help and offers to test MIST on our study data.

Funding

This work was supported by the Intramural Research Program of the National Institutes of Health, National Library of Medicine.

Competing Interests

The first author receives royalties from University of Pittsburgh for his contribution to a de-identification project. NLM's Ethics Office reviewed and approved his appointment.

Abstract

Individuals with chronic conditions face challenges with maintaining lifelong adherence to self-management activities. Although reminders can help support the cognitive demands of managing daily and future health tasks, we understand little of how they fit into people's daily lives. Utilizing a maximum variation sampling method, we interviewed and compared the experiences of 20 older adults with diabetes and 19 mothers of children with asthma to understand reminder use for at-home chronic disease management. Based on our participants' experiences, we contend that many self-management failures should be viewed as systems failures, rather than individual failures and non-compliance. Furthermore, we identify key principles from reliability engineering that both explain current behavior and suggest strategies to improve patient reminder systems.

Introduction

People with chronic conditions, or those who care for others with chronic conditions, are expected to manage complex medical regimens. For many, the demands are monthly, weekly, or even daily. For example, patients with well-controlled hypertension, diabetes, and hyperlipidemia must perform more than 3,000 health-management activities a year to be adherent to recommended self-care guidelines[1]. These activities include making changes to their diet, requesting medication refills, adhering to a medication regimen, monitoring critical health indicators (e.g. blood pressure), getting lab tests done, attending appointments, getting annual screenings and immunizations, and managing symptoms[2]. As a result of these challenges, many patients are not able to meet their goals for daily self-care activities successfully. In fact, half of individuals diagnosed with a chronic condition—such as asthma, hypertension, and diabetes—do not adequately adhere to their prescribed medication regimens[3] and miss as many as 21-34% of their scheduled appointments[4]. These failures in chronic disease management can lead to adverse patient outcomes, increased care costs, and create challenges to the patient-provider relationship[5–7].

To support patients managing a chronic disease, health care systems increasingly send reminders for appointments and chronic and preventive care activities. Successful reminder systems can alert people to scheduled medical visits and screenings, improve adherence, and enhance communication between patients and their provider team[8,9]. Moreover, many patients already utilize personal reminder systems to remember everyday tasks. The following scenarios help illustrate how people incorporate explicit and implicit reminders into their daily routines:

> *Bob is a 60-year-old diabetic. His typical morning routine is to wake up, walk into his bathroom to take his medication that he keeps out on the counter, then have breakfast. As he walks into the kitchen, he sees his blood glucose meter sitting on the kitchen table and remembers that he needs to check and record his blood sugar. He then starts up his coffee machine, and glances at his wall calendar to see what is happening that week. While eating breakfast, he receives a call from his clinic reminding him about an appointment the next day. Later on, his wife, who is out of town, calls him to check-in. Realizing he forgot to check his blood sugar while making coffee, he walks back to the kitchen to get his glucose meter.*

> *Cindy is a 34-year-old mother of a 9-year old child with persistent asthma. When she wakes up, she always glances at her smartphone's calendar to see her agenda for the day. She also takes a minute to enter in a to-do list. Among other things, her son needs his allergy shot at the clinic and she needs to send off her sister's birthday package. Before heading out, Cindy notices and grabs her son's inhaler by the door to make sure it gets into his backpack for school that day. In the rush to get her son to school from the appointment, she forgets to stop by the post office. But on her way home later that day, Cindy passes a mailbox that reminds her to send off the package and she makes a turn to the nearest post office.*

These vignettes, based on activities and experiences described by our study participants, demonstrate how people rely on a variety of tools and subtle triggers to help remember to perform future actions. In the first scenario, Bob relies mostly on environmental cues that are part of his morning routine. However, his wife will frequently check-in with him, which serves as a backup in case he does forget to do something. In contrast, Cindy makes heavy use of her

mobile phone to track what she needs to do for the day. She also makes deliberate use of visual cues like placing the inhaler by the door to make sure her son takes his inhaler. Yet, in both situations, the two people still experienced minor failures in achieving their intended tasks.

In this paper, we examine how individuals responsible for managing their own or others' chronic conditions integrate reminders and notification systems into their daily routines. By understanding these diverse individual experiences, we hope to gain insight into the optimal design characteristics for future patient reminder and support systems. We further contend that many self-care management failures may be accurately viewed as system failures, as opposed to failures of individuals[10]. Our work highlights the complex ecosystem of interactions, tasks, and reminders between the clinic and home environment for a person managing a chronic illness. Finally, we apply key principles from reliability engineering to help explain participants' self-management behavior and offer suggestions for strategies to further improve patient reminder systems in the future.

Background and Related Work

This work draws on several divergent literatures: prospective memory as a basis for task planning and recall, clinical and personal reminder systems, and systems reliability engineering to frame patient self-care tasks and failures.

Prospective Memory as a Basis for Task Planning and Recall

Remembering to perform all the tasks expected for proper self-management requires effective recall of what has already happened and a continuous scan of what needs to happen in the near future. The process of remembering is frequently framed as either of two types: (1) retrospective memory that is concerned with the retrieval of past memories of people, events, and words, or (2) prospective memory that is concerned with remembering to perform a planned action or intention in the future[11]. The latter process includes short-term intentions—such as daily intake of a medication—as well as delayed actions—such as going to an annual checkup appointment—that could occur weeks or months in the future. Outlined in Figure 1, the process for realizing a delayed intention begins with encoding the future action, retaining the intention, and then retrieving the intention at the appropriate time to complete the action. This can occur through either an explicit reminder system or through spontaneous retrieval. Actions such as remembering to take medication at breakfast often rely on spontaneous retrieval of the intention that is triggered through environmental and physiological cues linked to daily routines. However, intermittent actions further out in time often involve a more explicit signaling cue—such as creating an alarm on a phone—to retrieve and execute the action at the right time[12]. In the case of an individual managing a chronic condition, the capacity to reliably shape and direct future behavior is critical to successfully managing the disease. The role of both explicit and implicit reminder systems within this memory process is the focus of this paper.

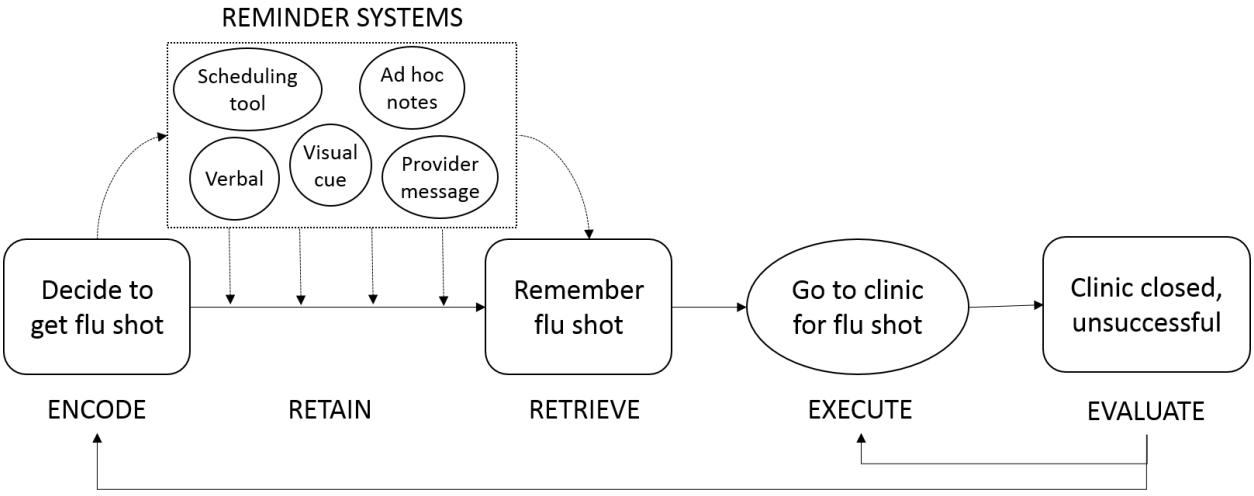

Figure 1. Model for establishing and realizing delayed intentions. Adapted from Ellis, 1996 [13]. When a person decides to get an annual flu shot (encoding), they need to maintain that intention over a delayed period (retention). At some point the person receives a signal to remember the flu shot (retrieval) and then goes to the clinic (execution). If successful (evaluation), the task is complete. Otherwise, the person attempts the activity again or re-plans the intention. In this model reminder systems provide a way for individuals to externalize the retention process as well as establish a way to cue retrieval of the delayed intention.

Clinic and Personal Reminder Systems to Support Recall

Reminders can be useful mechanisms to support the execution of delayed intentions described by prospective memory. James Reason describes the value of reminders in mitigating errors of omission that can lead to failures in planning and intention formation (encoding), intention storage (retention), action execution, and monitoring[14]. Research into reminders for health has typically evaluated clinic use of reminder systems. For example, health care organizations use postal mail or telephone calls to help prevent missed appointments and thereby reduce costs associated with disruptions to clinic workflow[15]. More recent articles have started to explore mobile phone-based strategies, such as text messaging and other types of electronic reminders[8,16]. Vervloet's review of electronic reminder systems initiated by providers showed short-term effectiveness of these systems in supporting medication adherence but suggested more investigation of reminder content and timing[8]. In a cross-sectional survey of patient preferences, Finkelstein et al. found that personalizing the delivery mechanism improved patients' responsiveness to reminders[4]. The research into clinic-initiated reminder systems indicates that they support improvements in patient adherence, are effective across diverse technologies, and are more likely to be successful through the personalization of message content based on patient preferences.

Outside of a clinic setting, individuals leverage a variety of tools for personal reminder systems. Grimes and Brush interviewed working parents and identified a number of challenges that they experienced in coordinating and interacting across their personal and professional schedules[17]. In a separate study, Brush highlighted the value of triggers in the workplace that are created from a mixture of explicit self-reminder systems, tacit "breadcrumbs" from recent activities, or based solely on memory to recall specific tasks[18]. However, there has been limited research into how these types of personal systems support patients' multiple chronic and preventive health care needs. For example, a review by Kapur et al. focused on the use of memory aids for neurological rehabilitation of individuals with severe memory impairments due to injury or a disorder[19]. While reminder systems are prevalent in a variety of contexts, there is an opportunity to explore how personal systems are used for chronic disease management, and importantly, how these tools integrate with clinic reminder activities and the home environment.

Systems Reliability Engineering to Understand Errors and Failures

Within this paper, we frame chronic disease management as a complex system of technical, organizational, economic, environmental, and human components that interact for a common purpose—the maintenance and coordination of an individual's health. This type of system highlights a growing trend in health care of utilizing human factors and ergonomics (HFE) concepts for designing patient-centered care. The National Research Council conducted a HFE evaluation of home health care that stressed systems engineering for designing technology interventions that facilitate interactions between the complex elements and tasks in the home environment[20]. Furthermore, Holden, Carayon, and colleagues introduced a popular framework for HFE thinking and reliability in health care with the Systems Engineering Initiative for Patient Safety (SEIPS) model[21]. The latest version of this model discusses the importance of a person-centered approach to work systems that include organizations, tools & technology, people, tasks, and the internal and external environments where the work takes place. In the context of reminders, the activity of remembering and executing self-management tasks at home involves the interplay between the patient, clinic, home environment, and devices and tools used to coordinate and execute care activities.

Building on HFE concepts, we are concerned with the reliability of the system to support individuals' ability to use reminders to perform their care coordination tasks successfully. The principles of reliability science and engineering help to describe design strategies for mitigating and responding to failures in complex systems. Reliability refers to the probability that a system will meet its minimum performance requirements, without failure, for a given period of time[22]. Three activities in particular—engineered redundancy, diverse and independent design, and regular monitoring—can enhance the reliability of a system[23]. **Redundancy** describes systems where duplicate processes or components are used to increase availability in case of a single point of failure. For example, many cars are designed with twin hydraulic brake circuits to ensure that the vehicle can still stop if one circuit fails. However, redundant systems do not increase reliability in situations where they are vulnerable to the same defect—referred to as common cause failure. To mitigate this vulnerability, engineers incorporate **diversity** into their design so that a system uses two or more different, independent techniques or processes for the same functional purpose[24]. For example, when backing up a car, a driver can visually assess their environment with the car mirrors as well as listen to the beeping sounds produced by proximity sensors built into many modern vehicles. Finally, reliable systems can use **monitoring** to actively audit the system and mitigate the impact of a breakdown through early detection of failures. Modern automotive anti-lock systems actively monitor wheel deceleration and distance from other objects to adjust the brake speed and prevent uncontrolled skidding. Although researchers have used reliability engineering to frame inpatient safety[25], none have used this framework to examine patient adherence to chronic disease management activities.

Study Overview

We conducted a series of semi-structured, in-depth interviews with patients diagnosed with Type 2 diabetes (n = 20) and mothers of children receiving treatment for asthma (n = 19). The choice of the two populations maximized the variation in the perspectives and experiences of individuals managing a chronic disease. Our sampling of parents of children with asthma focused on mothers, rather than fathers, since women in this age group also have a large number of prevention and maintenance activities and are typically the primary health information managers within the household[26]. The semi-structured interviews focused on reminder tools and systems that patients used for maintenance and care coordination activities such as appointment scheduling, medication adherence, and communication with their providers outside of the clinic. In addition to the interviews, the authors (LK, JE) toured the participants' homes in order to directly observe the systems and tools used in this context. This study was reviewed and approved by our institution's human subjects review board.

Sampling

We used purposeful sampling to identify participants that were representative of the general population in the Northwest United States based on gender, ethnicity, technology use (with recorded use of a patient portal as a proxy) and education. All participants were enrollees of an integrated healthcare delivery system that covers more than 300,000 members. Based on the sampling criteria, we contacted 586 individuals identified as either persons with diabetes or parents of a child with asthma. Of these, 402 could not be reached, refused to participate, or were lost to follow-up, and 118 were deemed ineligible based on follow-up screening. Of the remaining 66, we enrolled 39 participants, aged 27 to 88 (median=61). The diabetes cohort was older on average than the mothers of children with asthma and were less likely to use technology such as a patient portal for their health. Other details on our participant population are in Table 1. Each participant received a gratuity of $50 for completing the interview.

Analysis

The interviews lasted from 40 to 90 minutes. The audio recordings from each interview were transcribed and reviewed using Atlas.ti 7 and identified as "A##" and "D##" for the asthma and diabetes cohorts, respectively. To maintain confidentiality, we removed all information that could identify the patient from the transcripts. During the data collection process, the authors periodically reviewed transcripts to identify emerging themes and to assess topic saturation. Using an open coding technique and an affinity diagramming process[27], the authors clustered related terms and organized preliminary themes into higher-level categories. A subset of the authors then iterated on the codes through several rounds of transcript review to solidify the coding schema used for this article. One author used this schema to code each interview using Atlas.ti.

Results

Through this content analysis, we focused on two areas. First, we highlighted the reasons for failures in self-management routines as identified by participants during the interviews. Second, we characterized three strategies used by participants to improve the reliability of their reminder systems and overall management of their health. These strategies are summarized in Table 2.

Sources of Reminder Errors and Task Failures

Throughout the study, the participants provided examples of breakdowns in their self-management routines that included failures in memory, missed environmental signals, and failures in capturing tasks within a reminder system.

Memory failures were a common reason for failure as well as a rationale for using explicit reminder systems. Based on the prospective memory process in Figure 1, these types of errors can be described as retention and retrieval failures. For example, participants described how easy it was to forget because of their hectic schedules. A07 expresses the challenges representative of many busy mothers. *"If I don't have anything immediately reminding me of it, it's out of my head because I have so much going on. We have kids to pick up, drop off. We have cleaning house, I've got selling things, I've got to meet people." [A07]*. D02 and many elderly participants with diabetes described concerns with growing memory deficits as they aged. They expressed interest in updating their reminder systems as their memory started to become less reliable. Despite this interest, participants often relied on informal, tacit signals in the environment. For example, it was only after scheduling a separate appointment for herself that A08 remembered her child's annual well-child visit was overdue. Similarly, other participants remembered to go in for screenings and tests only after scheduling a visit for a separate health need. Reliance on environmental cues was particularly common for medication management. One participant described managing her child's inhaler by paying attention to when "*the propellant in it doesn't expel quite as well and so he doesn't feel like he's getting or receiving the medication as well and so he'll tell us that he needs a new one" [A11]*. Without having an explicit visual cue or timely notification from her child, she relies on trying to remember how much time has passed since the last refill. Tacit signals are dependent on the environmental cue occurring at the right time and place. If the person misses this signal, they can experience a retrieval failure.

In addition to missing cues from informal reminders, participants also described breakdowns with their reminder tools. In some situations the reminder was never captured and therefore never signaled the appropriate behavior. This type of encoding failure often occurs because individuals get distracted from capturing the task or do not have access to their reminder tool when they need it. One participant described how, "*I'll make an appointment and then start doing something else so I didn't write it down and just hope that I'll remember it." [A10]*. In this situation, A10 missed an appointment for her baby because the event did not get recorded into her phone and she did not get a reminder call. A14 used a system where she printed out calendars and captured appointments, bills, and other items. However, when she misplaced it, *"I was freaking out, because I had actually taken the time to write everything down—they had a trove of information on it. I couldn't find it and then I was like how the heck am I going to do this if I don't have a backup?" [A14]*. Her situation mirrored many of the participants where, because of a busy schedule, being away from home, or not having access to their normal reminder tool, they failed to set up or retrieve the cue from their system to perform the action in the future. Despite having systems that they often described as being fairly reliable, participants still experienced situations in which some aspect of their reminder process fell apart.

Table 2. Summary of reliability system design strategies used by participants to enhance self-care reminders.

Reliability Strategy	Benefits	Drawbacks
Redundancy: *Repeated reminders, back-up systems*	• Back-ups ensure availability of reminder for retrieval at the right time. • Repeated alerts enhance retention.	• Too many back-up systems can create unwanted noise and increase chance of being ignored.
Diversity: *Independent systems, different communication modes*	• Separate clinic and personal systems reduces reliance on single operator. • Multiple modalities improves availability of reminder for retrieval.	• Additional systems increase complexity and can create new opportunities for failure.
Monitoring: *Validating reminder capture, double-checking for errors*	• Improves retention through repeated exposure. • Increases likelihood of catching errors in the reminder system.	• Additional work required of system operators • Challenges with maintaining this behavior routinely.

Strategies for Redundancy in Reminder Systems

To compensate for these types of memory and organizational errors, participants employed a number of strategies to improve the reliability of remembering certain tasks for their care management. In particular, to mitigate the chance that one reminder system might fail, participants integrated duplicative or redundant reminder systems in their homes. In many cases, having redundancy was simply a backup. D04 used the calendar on her computer to manage most of her reminders. However, she purchased a smartphone because she recently got a virus on her computer and was concerned about its reliability in the future. Other individuals in the study described how having their spouse or children aware of their health management tasks served as a useful backup. They would regularly discuss upcoming events with the family member or ask them to check-in to make sure the participant took their medication. Even though it was rarely necessary, *"they're there if we do need them" [D08]*.

Participants expressed that having multiple, redundant systems helped to ensure that reminders get encoded. D02 maintained three calendars so that the intended task was captured regardless of where she was in the home. An added value of having multiple systems was that it helped to retain what she need to do. *"It's like repetition. If you say something to me and say the same thing several times, it rings a bell and I remember it. I think that's what the calendar does." [D02]*. This system served as both a way to deal with memory deficits as well as ensure that upcoming events are always captured. A09 was worried that her husband would forget to pick up the kids and so "*I told him the night before, I told him the morning of, I sent him a text from work, I called him to make sure - don't forget." [A09]*. While that many reminders were likely unnecessary, it reassured the participant and increased her spouse's awareness.

Although redundant systems have advantages, they can be a burden as well. Providers are typically very proactive about letting a patient know of an upcoming appointment to reduce the impact of a missed appointment on their clinic workflow. Some participants expressed an interest in streamlining their different reminder systems—from both their providers as well as their personal reminder tools—to remove duplicative work and unnecessary reminders.

> *"My son, his dentist office annoys the heck out of me because they send reminders two months in advance and then send another one a month in advance and at that time they want you to click confirm on the appointment and then after you confirm it, they send another one a week in advance and then call you. It's overkill." [A09]*

While repeated reminders increases the chance that the patient is aware of the appointment or task, it also creates more noise. The participants described many redundant reminders as unhelpful in situations where they already were aware of the appointment or task or it was not applicable to their needs. If they felt that it was an unnecessary reminder, they would simply ignore it. This situation is analogous to the alert fatigue that health care providers face with poorly designed EMR and other practice management systems.

Strategies for Diversity in Reminder Systems

The individuals in this study not only performed redundant work as a protection against failures, but also used a diverse set of reminder systems (Figure 2). Diversity provides greater protection against system failures that can affect even redundant systems. For example, a clinic that sends multiple appointment reminder notices in the mail will fail if the patient's address is incorrect. A phone that runs out of power will not be able to receive a text message about taking a medication. Throughout the interviews, the study participants described an array of modalities used for communication and reminders about upcoming tasks.

Figure 2. Sample of personal reminder systems used by study participants. From left to right: a whiteboard-style calendar; a sticky note wrapped around the strap of a handbag; pill bottles placed upside down to indicate they have been taken for the day.

All of the study participants emphasized the value of traditional reminders initiated by the provider such as paper mail, phone calls, and secure messaging within a patient portal. However, participants still used a number of additional, personal reminder systems that ranged from technology-centric approaches—such as a mobile phone—to informal mechanisms such as the placement of a pillbox on the kitchen table. A06 would get multiple text messages and phone calls from her dentist leading up to an appointment, but would still enter it into her phone right away. The major tenet of the diversity principle is to ensure independence in redundant systems and subsystems. Thus, by incorporating reminders from clinics as well as their own systems, patients add a layer of reliability—they are able to rely on the provider messages if their personal system fails or rely on their own system if they do not receive a reminder from their clinic. D01 described an incident where she had a scheduled phone consult with her doctor. She recorded the appointment in her personal planner. However, the clinic did not record the phone call information correctly, and the physician didn't call. D01 ended up having to call and remind the clinic about her phone appointment.

During the interviews, participants also explained how the mode of communication can have a meaningful impact. *"The phone call I think it's an accountability thing for me, if I actually physically speak to a person, it's easier for me to go okay, I need to write it down and remember it." [A03]*. Synchronous communication modalities, particularly where the patient is interacting with a health professional, make it difficult to ignore the reminder and ensure that the reminder reaches its intended audience. Conversely, other participants discussed how it was easy to overlook or disregard asynchronous, electronic messages like emails because they get overloaded with too many messages in that format. Paper notifications were often valued because they are more tangible and visible around the home. *"Well again, because I don't get a lot of paper notifications, it feels serious and this should be done." [A01]*

Diversity can enhance reliability, but it can also create a chaotic and complex experience as the patient tries to integrate multiple systems. Several of the participants, for example, owned multiple computing devices that each had a different, incompatible operating system. This creates barriers in syncing activities across the platforms and in some situations encouraged participants to rely on a paper method instead. Additionally, participants that received care from multiple physicians described challenges with getting phone calls from some clinics and paper mail or electronic notifications from others. The diversity of communication approaches made it challenging to reliably integrate the reminders into their personal systems.

Strategies for Monitoring Reminder Systems

Study participants incorporated a habit of active monitoring of their reminder systems as an additional method for addressing reminder failures. Monitoring provided a way to identify errors, validate their reminder systems, and involve their friends and family members in supporting self-management. First, routine monitoring helps to identify when failures in self-management occurred.

> *"I have to be more conscious about did I take my pills…Did I do that? Sometimes I'll actually get up and look to see whether I took my pills. It's kind of like turning your headlights off on your car, yeah, I took my pills but when I stop and think about it, I got to go check because I don't remember doing it." [D20]*

Even if a participant forgets to do something like take a medication, the process of monitoring can lead the person to recognize the error and then be in a position to make changes for the future. Although a clinic can notify a patient when they miss an appointment or test, no feedback process informs patients when they forget activities at home. Having a system in place for monitoring can be helpful to evaluate one's behavior.

Second, active monitoring serves as a way of double-checking the reminder system and ensuring the right content is captured. The added benefit is that this helped participants retain what they needed to do in the future. Participants described deliberate efforts to consistently review and scan for future activities. *"I try to check the next couple days ahead, like I'm thinking today plus two or something so I'm aware what's coming." [A09]*. This participant also started involving her son this process by setting up a calendar in his room so he could cross off activities as they occurred. *"If I get an appointment, then I write it down...I go in [the patient website], because it shows upcoming appointments so then I'll print off the deal and go in there and check my calendar, so it's a backup type, so I got a system, my checks and balances." [D05]*. Redundant, diverse reminder systems are helpful in supporting this kind of auditing behavior by helping participants compare the content of a reminder from multiple sources.

Third, participants often shared the responsibility of monitoring activities across family members to help reduce the workload. This demonstrated a distributed process for auditing reminder systems and ensuring completion of self-care behaviors. Informal dialogue between spouses or between parent and child appeared to be a subtle but valuable mechanism for reviewing and validating upcoming appointments, medications, and tasks on a regular basis. A01 spoke about how she had transitioned from administering her child's inhaler directly to watching him do it himself. While

this created other challenges around knowing if he took the inhaler correctly, A01 experience exemplified a transition in self-care responsibility common to many of the mothers of children with asthma.

Active monitoring does require additional work by participants and may be onerous when considering the activities already required for chronic disease management. Moreover, participants mentioned difficulties with making sure this type of monitoring is routine. A wall calendar with appointments listed is only useful as a reminder of upcoming events if the target audience makes the effort to review and validate the content. One participant assumed she had the correct information for an appointment on her wall calendar, but realized she had written the appointment on the wrong week after her husband walked by the calendar and pointed it out [D08]. Wall calendars contrast with systems like email and text messaging that will push information to the target based on a predefined event. However, sometimes these push systems actually discourage any active monitoring of a reminder system. *"I guess the hope is that it'll perform how I've asked it to, or that I've remembered to ask it to perform how I want it to." [A08]*. Another participant described how he messed up an appointment twice because he did not look back at his email about the appointment and his did not have his smartphone set properly to alert him [D16]. Becoming too dependent on the reminder system's capacity to create notifications can create a new avenue for failure.

Discussion

Forgetfulness, confusion, external distractors, fatigue and even a person's health condition can all lead to failures in self-management and perception of non-adherence. These types of errors, referred to as slips in human factors research, describe instances where an individual's intentions get waylaid en route[28]. Although slips are often small failures, they are particularly relevant to breakdowns in the automatic, routine behavior that is at the heart of chronic disease management. Solely relying on memory or informal environmental cues may be adequate for a period of time, but if an individual does not retrieve the prospective action accurately or at the right time, no backup will ensure the activity happens. We observed participants adopting a variety of strategies—such as redundancy, diversity, and active monitoring behaviors—to improve the reliability of managing self-care responsibilities. Incorporating different systems, people, and modes of communication ensured multiple, repeated communication paths for reminders in the event of one system failing. Moreover, participants did not just rely on different tools and modalities, but continually audited these systems to ensure that they had the correct information and that activities were completed successfully.

The challenge is that incorporating redundancy and diversity across multiple, separate systems involves tradeoffs between reliability and complexity. Diversity inherently increases complexity, and the need for synchronization among multiple systems could create more opportunities for failure. Furthermore, as participants in this study described, there is a risk of noise fatigue when dealing with multiple reminders from multiple sources. Health care organizations need to be aware of the additional workload placed on patients at home and reduce complexity through more tailored communication and easier integration of clinic-based reminders with patient reminder systems. By evaluating chronic disease self-management through a systems lens, we argue that trying to fix breakdowns in self-management should focus on designing system-level changes that focus on the experience of patients.

Designing for Human Error

Importantly for systems-thinking, our study highlights the variety of ways that failures can occur in remembering to perform self-care management activities. Therefore, the design of reminder systems to support self-management should account for errors by making it easier to detect, evaluate, and respond to failures when they do occur. The concepts of redundancy, diversity, and monitoring represent system design concepts that, integrated with the prospective memory process (Figure 1), can inform approaches to the future design of reminder systems. In addition, well-established systems engineering methodologies and tools can support this design and evaluation process. For example, concurrent engineering and quality functional deployment (QFD) use methods similar to participatory design to explicitly capture all stakeholder needs in a complex system[29], including less visible needs—such as the personal reminder work of patients with chronic diseases. The SEIPS system model further reinforces the importance of design that incorporates the needs of patients and caregivers involved in chronic disease management work[21].

James Reason suggests that all reminders should meet certain universal criteria so that they are conspicuous at the right time, contiguous or available in time and space, provide the necessary context and content for the intended actions or tasks that need to be done[14]. While the patient reminder systems in this study incorporated many of these qualities and avoided errors in encoding, retention, and retrieval through redundant and diverse design, they often lacked a feedback loop to track if an activity was performed or to support evaluation of errors that may have occurred. An important aspect of high reliability systems is the practice of assessing failures in order to actively identify, correct, or mitigate the sources of failure in the future. Assessing variation in self-care management and if performance is

within acceptable boundaries requires better tools and processes for capturing the metrics and data to calculate the variation. Information technology has the ability to support more robust monitoring and learning through different notification processes, passive data collection on behaviors/activity, and enhanced summary reports and real-time feedback. Participants across both cohorts leveraged mobile phones and other computing devices to support their self-management efforts. Increasingly, mobile phones link with ubiquitous sensing tools to support automated, detailed tracking of health metrics and performance around daily activities. These sensing tools can reduce patient work, integrate diverse metrics, provide feedback on progress towards achieving health goals, and identify deviations that are the result of errors or other failures. However, systems thinking and systems engineering principles should be considered in the design and the use of these tools so that they integrate in the wider context of strategies for more reliable self-care management.

Study Limitations

As with any qualitative study, our findings might not be fully representative of the populations under consideration. Despite making considerable effort to sample for a representative patient population, it is possible that our participants differ from other patients in terms of self-efficacy or their organization with managing their care. Because the diabetic population in this study encompassed a narrow demographic of mostly elderly, retired individuals, it is possible that we did not adequately capture a wide enough array of experiences and strategies for managing diabetes. However, we were able to contrast their experiences with those of young mothers taking care of their children with asthma. These mothers were often working and were more likely to use technology. Finally, the way that the participants used reminder systems in this study could reflect disease-specific needs of our two cohorts.

Conclusion and Future Work

In summary, the experiences of our participants managing chronic disease at home highlights the diverse strategies they employ to manage their schedules and tasks. Moreover, even though many clinics and health systems have implemented reminder systems—such as follow-up phone calls—our study showed that patients must still do extensive work at home to integrate these reminders into their daily lives. These separate reminders enhance reliability through increased diversity, but also add to the overall complexity of the system. Participants often felt confident in relying on their memory for most routine needs, yet still valued redundant reminders as a backup to deal with any memory slips. We also note that in addition to formal systems—such as calendars—many participants in this study relied on subtle systems similar to what Donald Norman refers to as "knowledge in the world"[28]. These cues that are visible in the environment and trigger prospective memories are less visible but important to be aware of with evaluating reminders and support systems for chronic care management. Technologies that recognize and integrate with these tacit signals have the potential to provide more context-sensitive reminders.

Our findings also support evaluating failures in self-management from a systems perspective, rather than simply attributing a failure to individual's lack of responsibility. While non-adherence is a legitimate issue, our participants' experiences make it clear that some self-care failures are unintentional and can best be characterized as breakdowns in the interaction between people, machines, and environments within a system. To mitigate failures, many patients incorporated key characteristics from reliability science into their personal reminder systems—characteristics such as redundancy, diversity, and monitoring behaviors. We are not aware of other studies that have examined these strategies from a system reliability perspective. As future work seeks to support patients' ability to manage chronic conditions outside of the clinic, it will be important to design self-care and reminder tools that also capitalize on these reliability principles. Healthcare providers, systems, and designers should consider the use of engineering design, evaluation, and control methods to explore this subsystem of patient reminder work that is prevalent among individuals with chronic conditions. Greater understanding of how this patient work integrates with clinic workflows and programs can lead to more reliable care management and ideally improved outcomes.

Automatic Extraction of Drug Indications from FDA Drug Labels

Ritu Khare[1], PhD, Chih-Hsuan Wei[1], PhD, Zhiyong Lu[1], PhD
[1]National Center for Biotechnology Information (NCBI), NIH, Bethesda, MD 20894

Abstract

Extracting computable indications, i.e. drug-disease treatment relationships, from narrative drug resources is the key for building a gold standard drug indication repository. The two steps to the extraction problem are disease named-entity recognition (NER) to identify disease mentions from a free-text description and disease classification to distinguish indications from other disease mentions in the description. While there exist many tools for disease NER, disease classification is mostly achieved through human annotations. For example, we recently resorted to human annotations to prepare a corpus, LabeledIn, capturing structured indications from the drug labels submitted to FDA by pharmaceutical companies. In this study, we present an automatic end-to-end framework to extract structured and normalized indications from FDA drug labels. In addition to automatic disease NER, a key component of our framework is a machine learning method that is trained on the LabeledIn corpus to classify the NER-computed disease mentions as "indication vs. non-indication." Through experiments with 500 drug labels, our end-to-end system delivered 86.3% F1-measure in drug indication extraction, with 17% improvement over baseline. Further analysis shows that the indication classifier delivers a performance comparable to human experts and that the remaining errors are mostly due to disease NER (more than 50%). Given its performance, we conclude that our end-to-end approach has the potential to significantly reduce human annotation costs.

Introduction

Drug-disease treatment relationships, i.e. drugs and their indications, are among the top searched topics in PubMed[1, 2]. The primary application of this information is to inform healthcare professionals and patients for questions[3] like "what are the indications of fluoxetine." Such information is also valuable for developing computational methods for predicting and validating results of novel drug indications[4-6] and drug side effects[7], controlling data-entry and medication errors in the electronic medical records[8-10], feeding the Google Knowledge Graph, and assisting PubMed Health® (http://www.ncbi.nlm.nih.gov/pubmedhealth/) editors to cross-link drug and disease monographs[11]. Given the variety of applications, it is important to build a structured and normalized drug indication repository, or a computable "gold standard" of drug-disease relationships, from credible drug resources. Most existing high-quality drug resources, such as DailyMed[12], DrugBank[13], MedlinePlus[14], and MedicineNet[15] are described in free text. Figure 1 presents excerpts from DailyMed descriptions, aka *FDA drug labels*, for two drugs.

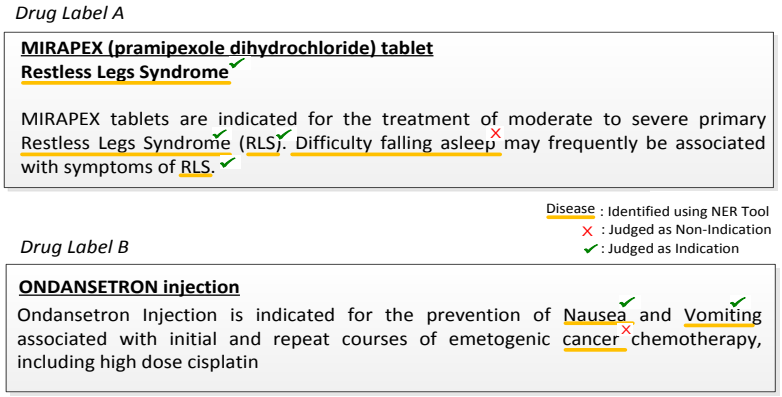

Figure 1. Illustration of Disease Named Entity Recognition (NER) and Classification Problems (Source: DailyMed Drug Labels)

Figure 1 also illustrates the two key steps in creating a drug indication repository from existing free-text resources: (i) *disease named entity recognition (NER)* to identify all the disease mentions (underlined) from drug narratives, and (ii) *disease classification* to distinguish indications from other disease mentions, demonstrated using checks for yes and 'X' for no. Disease NER, in general, is not a new problem; there exist high-performing and state-of-the-art tools

such as MetaMap[16], DNorm[17, 18], and KMCI[19] that automatically identify UMLS disease concepts from biomedical or clinical narratives. Also, many text-mining methods[20-25] have been proposed to extract disease mentions from drug resources such as DailyMed, MedlinePlus, and even Wikipedia.

The disease classification problem has not received much attention, however. Through detailed analysis of 100 FDA drug labels, we learned that even in the designated "INDICATIONS AND USAGE" section, about half of the disease mentions are not indications and include false positives such as characteristics of indications, contraindications, side effects, usages of another drug, unrelated diseases, etc[26]. There have been a few earlier attempts to address the disease classification problem in context of building a drug indication repository, e.g. SIDER-2 contains structured indications from FDA drug labels by filtering the disease mentions that overlap with its side effects repository[23], and Wei et al.[21] classify a given disease mention as an indication based on its frequency of occurrence across multiple structured and unstructured resources. However, the performances of these hand-crafted rule-based methods are limited either in terms of precision[23] or recall[21]. More recently, we resorted to manual expert annotations to identify indications from pre-recognized diseases in FDA drug labels, and curated a source-linked resource called *LabeledIn*[24, 26]. Upon systematic comparison with an existing automatically-curated resource[27], we concluded that human judgment is a reliable solution to the classification problem. However, it is time-consuming, and hence, expensive to be scalable with respect to building a repository with wide coverage of drugs.

In this study, we present an automatic end-to-end indication extraction framework that given an FDA drug label, (1) extracts the relevant section, (2) recognizes and normalizes all the disease mentions, (3) more importantly, classifies the disease mentions as "indications" vs. "non-indications," and (4) outputs the indication mentions and corresponding UMLS disease concepts that could be directly used to populate the target drug indication repository. The main contribution of this work is the use of supervised machine learning to address the under-explored disease classification problem in (3) and achieve a performance that is comparable to human experts.

Methods

The overall framework to extract drug indications from FDA drug labels is shown in Figure 2. As our data source, we use the FDA drug labels from the DailyMed website[12], which contains the most up-to-date drug labels submitted to FDA by drug manufacturers. The output of the framework is a set of structured and precisely normalized drug-disease relationships that can be used to automatically populate a computable drug indication repository. In the following subsections, we describe our disease NER and classification methods in further detail.

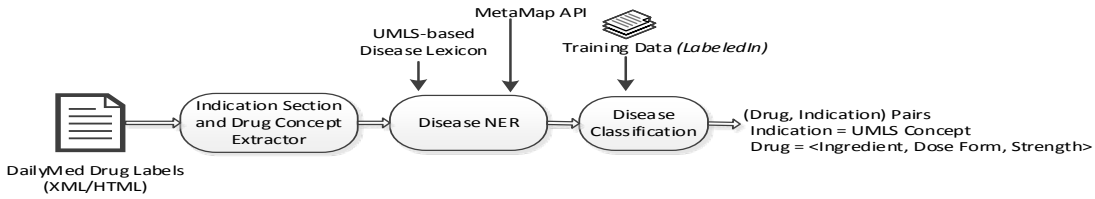

Figure 2. Overall Framework to Extract Drug Indications from FDA Drug Labels

Disease Named Entity Recognition

The goal of the method is to identify all the disease mentions, or indication candidates, from the textual descriptions of a given drug label. For this purpose, we prepared a disease lexicon using two seed ontologies, MeSH and SNOMED-CT, respectively useful for annotating scientific articles[17, 28, 29] and clinical documents[30-32]. The lexicon consists of 77,464 concepts taken from: (i) the disease branch in MeSH, and (ii) the 11 disorder semantic types (UMLS disorder semantic types excluding 'Finding') in the SNOMED-CT as recommended in a recent shared task [30]. As for the automatic tool, we applied MetaMap[16], a highly configurable program used for mapping biomedical texts to the UMLS identifying the mentions, offsets, and associated CUIs. We experimented with multiple settings of MetaMap, and the optimal setting for this study is illustrated in Figure 3.

The drug labels may contain overlapping disease mentions, e.g. the phrase "skin and soft tissue infections" denotes two specific diseases, "skin infections" and "soft tissue infections." While the final results by MetaMap do not return such overlapping mentions, these are captured in the intermediate results of MetaMap, known as the Metathesaurus candidates. Hence, we utilized these candidate concepts in our method. MetaMap provides two types of candidate

concepts: contiguous and dis-contiguous, e.g. in the phrase "skin and soft tissue infections", "soft tissue infections" is a contiguous candidate, and "skin+infections" is a dis-contiguous candidate. We found that MetaMap returns different sets of dis-contiguous candidates with and without the *term processing* feature. Hence, we conducted two runs of MetaMap for comprehensive results. Also, the *word sense disambiguation* feature was turned on to disambiguate mentions that may map to multiple CUIs, e.g. "depression." In order to restrict the returned candidates to specific semantic types from two vocabularies as mentioned above, we used a lookup against our custom disease lexicon as opposed to running multiple rounds of MetaMap for the two vocabularies. Finally, candidates with overlapping spans (e.g. "moderate to severe pain") were resolved in the following manner: (i) when both candidates were contiguous, the longer candidate was selected, (ii) when one candidate was dis-contiguous - (a) if the merged span contained conjunctions (e.g. "or," "and") or prepositions (e.g. "to"), then the merged span was pre-annotated and both CUIs were retained, e.g. the elliptical coordination in "skin and soft tissue infections," (b) if the two mentions were related by a parent-child UMLS relationship (e.g., the phrase "acute bacterial otitis media" maps to hierarchically related concepts "acute + otitis media" and "otitis"), then the longer mention was retained, else, the shorter mention was retained (e.g. the phrase "drug hypersensitivity reactions" maps to non-hierarchically related concepts "drug + reactions" and "hypersensitivity reactions").

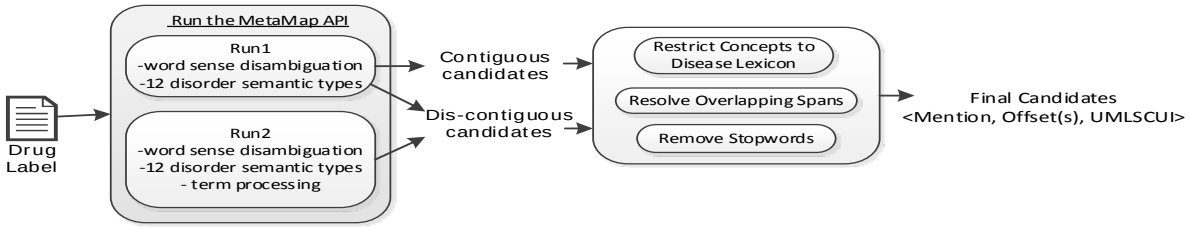

Figure 3. Disease Named Entity Recognition (NER) Method

Disease Classification

Next, we model indication extraction as a binary classification problem that judges whether a disease mention identified through NER method is an indicated usage of the drug. To build a high-quality gold standard, it is very important to judge and remove irrelevant disease mentions, e.g. "Difficulty falling asleep" from drug label A, and "cancer" from drug label B in Figure 1. This problem could also be perceived as another flavor of classifying diseases in clinical narratives into linguistic or temporal bins[33, 34].

Table 1. SVM Features for Disease Classification Problem

Feature (Description)	**Example1**		**Example2**	
	Data Point	**Feature Value(s)**	**Data Point**	**Feature Value**
Mention (Represented Surface-value)	Difficulty falling asleep (Drug Label A in Fig 1)	Difficulty falling asleep	Vomiting (Drug Label B in Fig 1)	Vomiting
Neighboring Tokens (left/right 5 tokens within sentence)		may, frequently, be, associated, with		the, prevention, of, -DISEASE-, and, associated, with, initial, and, repeat
Location (of sentence)		2		1
NDF-RT Match (the relationship of this disease concept with a concept catalogued in NDFRT[35] for this drug)		No Match		Exact Match
Semantic Category (of the UMLS concept corres.to mention)		Mental or Behavioral Dysfunction		Sign or Symptom

To address the classification problem, we used the support vector machines (SVM), a discriminative binary classifier known to be highly accurate and widely used in text classification. Given a set of data points (or examples) with known labels, the SVM assigns scores to each data point and finds a hyperplane that partitions the examples into two distinct bins, positive and negative based on the assigned score. For this problem, a data point is a disease mention at a given location, e.g. in Figure 1, the drug label A has five data points, and drug label B has three data points. We hand-picked the classification features based on our previous study with human experts, experimented with several features, and selected a set of linguistic, contextual, semantic, and dictionary-based features for this problem as described and exemplified in Table 1. Other features considered but not selected for the final classifier include the relative location of sentence in the drug label and the presence of drug name in the sentence containing the mention.

To train the SVM, we relied on a recently curated high-quality annotated text corpus, *LabeledIn*[24], that contains labeled or marketed indications for 250 frequently searched drug ingredients on PubMed Health. *LabeledIn* is unique among existing structured drug indication resources[21, 22, 27, 35, 36] in that it is human-validated, source-linked, and normalized to the most precise concepts in widely used UMLS vocabularies (SNOMEDCT, MeSH, and RxNorm). *LabeledIn* was created through double-annotation (88% kappa agreement) of 500 drug labels with assistance from a high-recall disease NER tool. In particular, for each drug label, the expert was presented with all disease mentions identified using an NER tool and was asked to assign a yes/no judgment. At the backend, the offsets of the disease mentions and the associated expert judgments were recorded. This helped in creating a fine-grained annotated text corpus that contained all disease mentions along with the associated human judgments. This becomes the training dataset for this problem as described in first row of Table 2. Since our goal is to automatically populate a computable gold standard of drug indications, we evaluate the results of the classifier at concept-level. For this purpose, we created an evaluation dataset that contains all the disease concepts (CUIs) present in a given drug label and the respective expert-determined yes/no assignments; this dataset is described in the second row of Table 2. There is a clear distinction between distribution of examples in both datasets because a mention identified as positive is likely to be repeated several times in a given drug label, e.g. the CUI represented by "RLS" has four occurrences in drug label A in Figure 1.

Table 2. Classification Data Points for 500 FDA Drug Labels

Data Point Definition	**#Data Points (+,-)**
Disease Mentions *with offset*	5,336 (70%, 30%)
Disease Concepts (UMLS CUIs)	3,013 (55%, 45%)

Results

We first measured the baseline performance on 500 drug labels from *LabeledIn* by assuming all diseases to be indications. The result is shown in the first row of Table 3. The result is a high recall and low precision. The recall is less than perfect because of the cases where the NER method identified a less-specific concept than annotated by the human experts, e.g., from the phrase "Acute Bacterial Otitis Media," the NER identified "Otitis Media" whereas annotators expanded the indication to the entire phrase.

Table 3. Indication Extraction Performance at Concept-level (micro-averaged)

Indication Extraction Method	**Precision(%)**	**Recall(%)**	**F1-measure(%)**
Disease NER *(baseline)*	54.99	93.93	69.37
Disease NER + NB	80.16	79.65	79.91
Disease NER + ME	85.02	**86.16**	85.59
Disease NER + SVM	**86.99**	85.58	**86.28**

We then conducted the experiment including a classification method in the framework. We experimented with three different classifiers, SVM, Maximum Entropy (ME), and Naïve Bayes (NB). We used an internal C++ implementation of the classifiers to conduct the experiments with 5,336 training examples and used 10-fold cross validation for evaluation against the evaluation dataset. To align the classifier results with our concept-level evaluation benchmark, we post-processed the results where multiple occurrences of the same concept were classified differently, e.g. SVM may classify the two occurrences of "RLS" in drug label A (Figure 1) as positive and negative, respectively. We

resolved this conflict by preferring the positive over negative classification. Finally, we selected SVM as it delivered the highest overall classification accuracy (optimized at score threshold 0.4) and hence leads to the highest indication extraction F1-measure on our data as shown in Table 3. The importance of each feature used for SVM is shown through the feature ablation experiment in Table 4 listing the features in decreasing order of their importance.

Table 4. Results of Feature Ablation Experiment (SVM)

Ablated (Removed) Feature	F1-measure(%)
Neighbors	79.75
Mention	83.09
Location	84.97
NDF-RT Match	85.11
Semantic Category	86.01

Using the results from the SVM-based extraction method, we randomly selected the 100 erroneous cases (50/220 false positives and 50/143 false negatives) for further analysis. Figure 4 shows the different categories of false positive errors that we observed. The two largest categories (shown separately) correspond to errors due to the NER component of the framework: either only partly identifies the correct concept (Boundary Error) or confuses with some other entities (Not a Disease Mention). About 36% of false positives represent boundary errors, e.g. from the phrase "carcinoma of the prostate," the disease tagger identified "carcinoma" and the classifier identified this mention as positive. This example is considered as a false positive as it does not match with our gold standard that contains the complete mention "carcinomas of the prostate." About 20% of false positives include non-disease mentions, such as part of an organization name (e.g. the "cancer" society), disease homonym ("seizure" used in a non-biological context), etc.

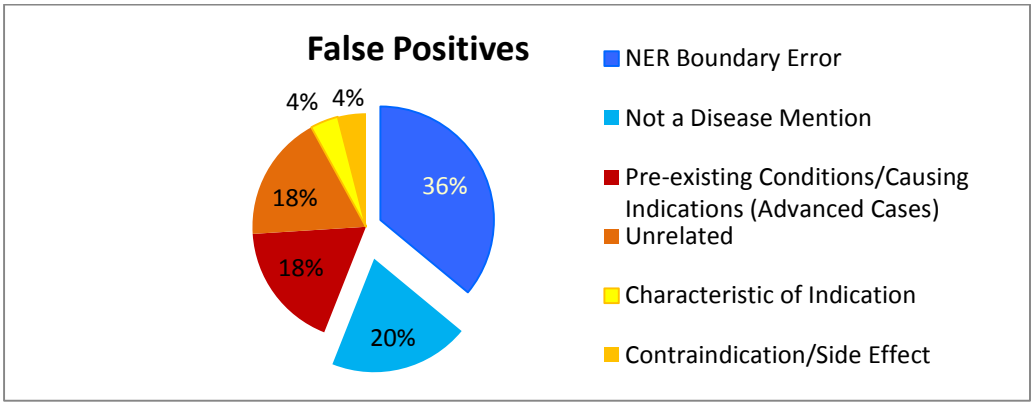

Figure 4. Analysis of 50 Randomly Selected False Positives

The remaining categories of false positive errors are due to indication misclassification as described next. About 18% include the diseases mentioned in some other context and unrelated to actual indications. Another 18% category represents the advanced cases, such as pre-existing conditions and conditions that cause indications. In our earlier study to create *LabeledIn* using expert annotations, we found some situations where experts needed to refer to additional references and drug properties to make their judgment. Consider the two drug labels in Figure 5: the "HIV infection" and "epilepsy" have similar feature values, e.g. neighbor tokens and semantic categories; however, "HIV infection" should be identified as a negative example and "epilepsy" as positive. Such cases are difficult to learn by a domain-independent classifier. Finally, the remaining few include characteristics of indications, contraindications, or side effects. In terms of false negatives, less than 5% were because of NER tool limitations, and the remaining represent misclassification errors because of poor structure of sentences (such as lists) and noisy neighbors (such as parenthesis), advanced cases, etc.

Since our final goal is to minimize human effort, we also studied how many concepts can be correctly classified by the SVM, and thereby eliminated from human judgment in a traditional machine-assisted annotation pipeline[26],

without incurring any errors. We investigated whether the scores (or ranks) assigned by SVM could be used to identify some perfectly classified examples. Figure 6 shows the variation of error rate with respect to the proportion of highest/lowest ranked concepts bypassed from further human validation; we found that we could safely eliminate 2.2% top-scored disease concepts and 5.1% bottom-scored disease concepts from further human validation.

Drug Label C

AZITHROMYCIN tablet, film coated

Azithromycin tablet, taken alone or in combination with rifabutin at its approved dose, is indicated for the prevention of disseminated Mycobacterium avium complex (MAC) disease in persons with advanced HIV infection.

Drug Label D

KEPPRA XR (levetiracetam) tablet, film coated, extended release

KEPPRA XR ™ is indicated as adjunctive therapy in the treatment of partial onset seizures in patients ≥16 years of age with epilepsy.

Figure 5. Example of Training Dataset showing an advanced case of classification ("HIV infection" and "epilepsy")

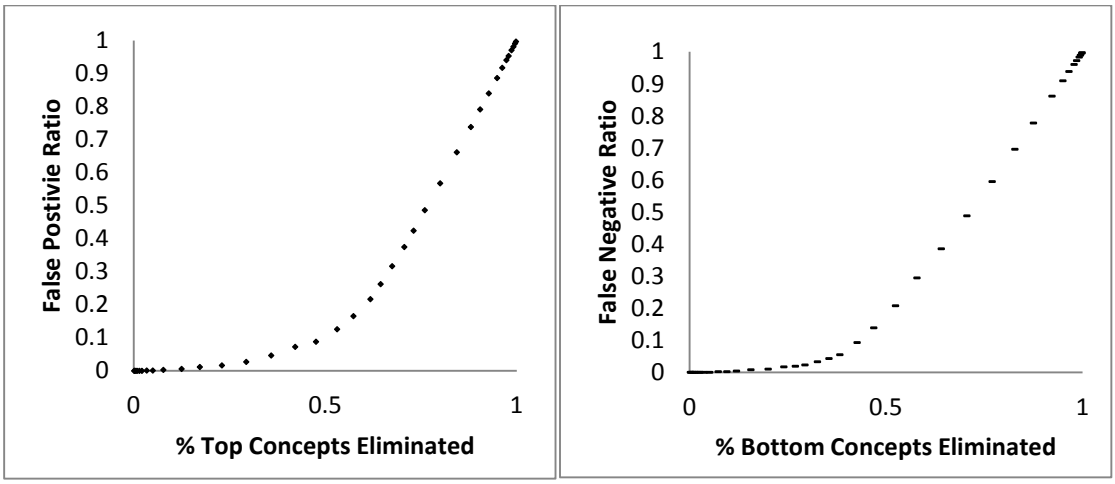

Figure 6. Effect of Eliminating Highest/Lowest Ranked Concepts on Error Rate

Conclusion

In this study, we have addressed the disease recognition and classification problems to prepare a comprehensive drug indication repository serving many critical applications. In the context of curation of a drug indication repository, there have been many important efforts primarily based on automatic recognition of disease mentions from drug narratives[20-24]. However, an important next step of classifying the automatically identified diseases as "indication"/"not indication" is largely missing from existing work, and hence the results from existing methods suffer from lower precision requiring further validation and cleaning by human experts. Taking a step forward, this study presents a framework that not only recognizes disease mentions from drug narratives, but further distinguishes indications from other disease mentions using an SVM-based classification method, thus minimizing the need to have humans in the pipeline. We experimented with 500 FDA drug labels corresponding to frequently-sought human drugs, and configured a disease NER tool to deliver an optimal recall on drug labels. We find that the combination (recognition + classification) framework achieves 32% improvement in precision and 17% improvement in F1-measure over a baseline method that is based only on recognition.

The proposed framework delivered an 86% F1-measure on 500 drug labels whereas two human experts in a previous study using similar NER mechanism[26] delivered 88% joint F1-measure on 100 drug labels after their first round of annotation. We consider these performances to be equivalent to each other, given the upper limit (94% recall) on classification performance due to natural language limitations of the NER tool. We also observed that over half of the

errors are due to the NER limitations. This clearly indicates that the proposed classifier can act as an independent or complementary annotator, saving annotation costs and time[26]. Furthermore, we find that about 7% of the training examples fed to the classifier could be altogether bypassed from further human judgments without incurring any errors. In terms of improvement, we found that several erroneous cases required advanced domain knowledge and are difficult to learn. Also, many false negative errors could be resolved by refining the neighbor calculation algorithm and adding formatting features to the classifier. Our future work also includes improving the technical aspects of the classifier such as automatic feature generation and handling imbalanced data. Lastly, we observed that certain annotated drug indications are specific to certain procedures/conditions (e.g. "nausea" and "vomiting" are associated with "cancer chemotherapy" in Figure 1 drug label B). Such information is not yet captured through NER or classification modules of our current pipeline, and requires further processing of drug labels.

ABSTRACT

Increased information availability, timeliness, and comprehensiveness through health information exchange (HIE) can support public health practice. The potential benefits to disease monitoring, disaster response, and other public health activities served as an important justification for the US' investments in HIE. After several years of HIE implementation and funding, we sought to determine if any of the anticipated benefits of exchange participation were accruing to state and local public health practitioners participating in five different exchanges. Using qualitative interviews and template analyses, we identified public health efforts and activities that were improved by participation in HIE. HIE supported public health activities consistent with expectations in the literature. However, no single department realized all the potential benefits of HIE identified. These findings suggest ways to improve HIE usage in public health.

INTRODUCTION

Public and population health benefits are an important justification for the US' significant investment in health information exchange (HIE) and associated interoperable health information technologies.[1 2] During the past decade, the federal government has invested billions to support electronic health record adoption through the Meaningful Use program, which includes requirements for the capabilities to exchange patient information. In addition, the Office of the National Coordinator for Health Information Technology (ONC) has overseen the $547 million State Health Information Exchange Cooperative Agreement Program to establish information exchange activity at a state level.[3] Other federal agencies and individual states have also invested heavily in HIE infrastructures.[4-6] These investments were made with such assumptions that information exchange "improves public health activities and facilitates the early identification and rapid response to public health threats and emergencies,"[7] or that ensuring public health "will depend on the implementation of information technology systems."[8]

HIE, the process of electronically sharing patient information between different organizations, stands to benefit public health.[9] Public health agencies are data driven organizations and HIE increases access to previously difficult to obtain clinical and demographic data. Also, by drawing on data created and stored by multiple healthcare entities, HIE can create longitudinal descriptions of individual patient care and illness. With broad provider participation, HIE data can reflect the healthcare experiences and utilizations of whole communities and populations. This is an advantage over looking at data from a single institution or healthcare system, which is by definition a restricted and limited sample. As a result of these features, HIE is expected to benefit several areas of public health practice from disease surveillance, to disaster response, to healthcare service delivery.[10]

However, public health participation in HIE efforts has historically not been widespread.[11] While some notable examples of public health usages of HIE exist, the realization of the benefits of HIE remain largely undocumented.[12] We sought to determine if any of the anticipated benefits of exchange participation were accruing to public health practitioners. Because no extant survey or tracking tool examines this question and the fact that the potential benefits to public health are so varied, we undertook a qualitative study of public health practitioners' experiences with HIE.

Identifying any successful applications of HIE to benefit public health practice, may help spur wider adoption to support the assessment and assurance of the population's health.

METHODS

We interviewed public health professionals about their usage of HIE and experiences working with exchange facilitating organizations. All of the public health professionals worked at either a state or local health department that was an active participant in an HIE effort.

Sites & Participants

First, we approached active regional health information organizations (RHIOs) and state level exchange entities with public health members to participate in this study. This excluded all RHIO/HIE efforts still in planning phases or health departments without any active users of HIE systems. Prior and ongoing research projects, as well as contacts with other HIE researchers helped to identify the potential participants. We secured cooperation from three local HIE efforts: the Rochester Regional Health Information Organization (Rochester, NY), Southern Tier HealthLink (Binghamton, NY), and the Integrated Care Collaborative of Central Texas (Austin, TX). Two statewide exchanges agreed to participate as well: the Indiana Health Information Exchange and the New Mexico Health Information Collaborative. Each of these exchanges has been in existence for 7+ years and their participation, technology, usage and effectiveness have been previously described.[13-17]

Each HIE effort identified points of contact (such as an HIE committee member) or registered active users at their member health departments for participation. After each interview, we asked informants to recommend other potential interviewees who could provide additional insight about their site's experiences with HIE activities.[18] This approach ensures that the different point-of-views would be considered. We interviewed a total of 22 representatives from 5 local health departments and 2 state health agencies screening for either direct users of HIE systems or the ultimate consumers of HIE obtained information. The interviewees had the various job titles of: epidemiologist, medical director, public health nurse, disease surveillance, case manager, and director of information technology. We obtained individual consent from each participant. To protect confidentiality, we do not report the numbers of interviews or job titles by organization.

Data collection

For each exchange effort, we reviewed instruction manuals, recruitment materials, technical documents, published reports, and websites, or obtained an overview of the exchange effort and a demonstration of their HIE system's interface, data sources, and functionalities. In this way, we were familiarized with the capabilities and objectives of each effort prior to data collection.

Data were collected through a combination of in-person and telephone interviews (PK & JV). Interviews were conducted using a semi-structured protocol developed as part of a larger evaluation of HIE in the State of New York. The guide covered the areas of job responsibilities, HIE usage, workflow fit, and technology perceptions. Consistent with the semi-structured approach, we adapted question wording and probes to match the interviewee's work role, location, and HIE experiences. The interviews were timed to last approximately 30 minutes. All interviews were audio-recorded and transcribed. All data collection began in May 2013 and ended in January 2014. We ended data collection when we had reached thematic saturation[19] and had interviewed respondents from both the state and local agency levels.

Analysis

Because we were interested in a specific set of HIE benefits suggested by researchers, practitioners, and policy makers, we opted to analyze the transcripts using template analysis.[20, 21] This approach begins with an a priori identified set of codes, as opposed to deriving codes from the data themselves like in grounded theory. We selected a template analysis as the best match to our objective of determining if the anticipated benefits of exchange participation were accruing to public health practitioners.

To identify the codes for our template analysis, we reviewed the literature for the benefits of HIE to public health departments. Our search of the phrases "health information exchange" AND "public health" in PubMed yielded 85 citations. After reviewing the titles and abstracts, we selected 16 for full text review. A review of the references of these papers resulted in 2 additional articles for a total of 18 papers. Of these, 10 described realized, potential, or anticipated benefits of HIE to public health practitioners.[10, 22-30] We were focused on the application of HIE to public

health practice, and as such we did not include the potential benefits that could be accrued to the HIE efforts or private providers from data exchange with public health agencies.

Independently, we (PK & JV) abstracted 26 effects from the included articles (kappa = 0.74). We refined this raw list in two ways. First, we divided the identified effects into the activity benefited (e.g. "clinical care") from the reason for the benefit (e.g. "increased access to data"). Next, we merged related and synonymous concepts into single codes (Table 1). We independently coded our transcripts using this template (coding by PK and JV reviewed with RK). Template analysis allows for the identification of new or expected findings within the data, so we were attentive to new themes. Emergent themes were developed independently during our closed readings. To reconcile differences, we combined our independently derived lists of emergent themes, collapsing synonymous terms, and supplying a single definition. We independently recoded our transcripts with the single emergent theme list. We undertook joint readings to resolve differences between our coding schemes.

Table 1. Codes and definitions of health information benefits to public health practice for template analysis.

Category	Code	Definition
Activity benefited		**The service, action, effort, or activity of public health practice that is improved by health information exchange (i.e. the "what")**
	Assessment & planning	All activities of a strategic nature oriented towards community or organizational planning (e.g. quality measurement or community assessments)[10, 22, 30]
	Case management & care coordination	Activities surrounding managing the clinical care and multiple needs of individual patients[26, 27]
	Clinical care	Activities related to patient care or clinical service delivery[10, 26, 27, 30]
	Communication (public)	Information from the public health agency to providers or the public (including alerts about events)[10, 22, 28]
	Preparedness	All emergency or disaster preparation and response efforts[10]
	Surveillance	Collection, monitoring, and investigation of conditions, status, or events as required by law, including syndromic surveillance and outbreak detection[10, 22, 24-30]
	Workplace efficiency	Improved efficiency for public health professionals (i.e. productivity / effort as a function of real or opportunity costs)[22, 26, 27]
Reason for the benefit		**The feature, characteristic, or process by which health information exchange generates benefit (i.e. the "how")**
	Information completeness & quality	More complete and accurate information [22-29]
	Information availability	Access to new or more types of data (including clinical information)[10, 22, 24, 25, 27, 29, 30]
	More timely information	Improvements in the temporal aspects of information (e.g. how fast information can be obtained, how it is available sooner, or how it can be used faster)[24, 25, 27, 29, 30]

Consistent with our primary objective, we reported if, and how, HIE supported each of the identified activities in our template. We then summarized the salient emergent issues. To help ensure respondent confidentiality, we avoided reporting both the location and job title of the interviewee. Instead, we focus on reporting the state in which the interviewee worked and only reported the area of public health practice if that information was relevant to the quote and if we had interviewed multiple individuals in that state with the same job.

RESULTS

According to NVivo's guidelines, we achieved a good level of agreement in our initial independent coding.[31] The kappa score for the "activity benefited" category was 0.71 and 0.82 for the "reason for benefit" category. The overall agreement was 0.75. Differences were resolved by comparing coding and joint discussion.

We identified instances or examples of all 10 anticipated benefits of HIE to public health. All sites reported at least four benefits from HIE (max was 7). All public health agencies realized benefits in the areas of surveillance and workplace efficiency. While benefits were seen across many categories, the level of activity within each was not particularly deep (i.e. few users, integrated into few programs, or applied to a small number of projects).

Assessment & planning

Interviews revealed that some public health departments were using HIE systems to develop a better understanding of their communities. As expected, the assessment activities included traditional public health target areas like Indiana's interest in infant mortality. Likewise, departments in Texas were using HIE data to complete community health assessments and strategic plans and also to understand health disparities. However, public health professionals in Texas were also interested in healthcare utilization patterns and preventable emergency department visits, which are not traditional public health areas. HIE data also supported the practical activity of grant writing.

HIE systems supported these activities by increasing information availability and access to timely data. As one interviewee from Texas noted, "*We're able to get now what we really have not had any way to look at in the past…Because we've only guessed before in terms of how people – especially without health insurance – are using the healthcare system to try to get their primary care needs met…This has given us the ability to actually see that in a way that helps us change our strategies of intervention*." In Indiana, it was the timeliness of HIE data that was particularly useful, "*…98 percent of the decisions we're making now here at the state department of health are truly data driven…*"

Case management & care coordination

Access to HIE systems supported case management activities and care coordination by increasing data availability and the timeliness of information. For example, a nurse in New York noted how the local HIE system enabled her to monitor the health of tuberculosis (TB) patients: "*If I'm treating a case or a prevent case, it's 9 to 24 months, okay? So, they're under our umbrella for a long time. They could be in the hospital from everything from a major cardiac event to they needed stitches in their hand. That all pertains to us*." The nurse further used the HIE to follow more detailed clinical information like current medications. Also in New York, a cancer screening program used the system to receive imaging reports for enrolled clients. Likewise, case managers in Texas were able access the recent emergency department encounters of diabetics.

Clinical care

Only the health departments in New York provided direct clinical care to patients. Both New York sites had active HIE users in their TB clinics. One nurse noted how she relied on HIE to obtain imaging results, reports, and laboratory values. "*That aids me. Immediately, I can see whether the results are normal or not, and if they're abnormal, we need to act quickly in determining if, if it's abnormal due to active TB disease…It's something we can act on right away when we get that information*."

Communication

In all of the other potential benefits areas, the value to public health is in the movement of information to the public health agencies. Alternatively, information and data could flow the other direction: from public health to the community or to providers. This was really only occurring in Indiana, and even then, that was narrow use case. Provider access to the immunization registry data was via local exchanges (i.e. RHIOs). Therefore, providers could use HIE to populate their own local information systems with the state's immunization data. However, this is more like bi-directional data sharing than communication as defined in the literature.

Preparedness

Two departments reported using HIE for preparedness activities, broadly defined to include both preparation and response efforts. New Mexico reported using HIE to help monitor for health complications associated with special events like Native American Tribal gatherings within the state. In New York, however, one public health department had actually put HIE to use during a natural disaster. "*When we had our flood here, 25,000 people were evacuated,*

and they didn't have meds. They didn't know who their physicians were, where they were gonna get their meds. The [HIE] came in and set up their computers and gave access to physicians from both hospitals …so it enabled them to be continued to do primary care…We sheltered people for 99 days."

Surveillance

As would be expected of systems that compile healthcare utilization, patient characteristics, and diagnoses, HIE systems were widely used for surveillance activities. Because they are a continuum of activities and tasks, this code included both those dealing with the detection of public health events and the steps public health professional undertake to respond to cases of disease. In terms of detection, HIE helped in two ways. First, HIE systems increased provider reporting. A local health department in Indiana "*we're doing a better job of capturing [reportable conditions]*," because electronic laboratory were reported through the HIE. Another professional in Indiana echoed this sentiment: "*We find a lot of cases that were not being reported to us before. Probably the largest number would be Hepatitis C cases, but we see other cases too that we don't get the reports from physicians or sometimes they weren't being reported by the labs to us*." The second application of HIE to the process of disease detection was in syndromic surveillance efforts. Both state health agencies interviewed, Indiana and New Mexico, reported using HIE for syndromic surveillance.

We also considered public health investigation, the activities public health practitioners undertake in response to identified cases or events, as part of the broader surveillance code. HIE was beneficial to these activities as well. For example, surveillance staff in Texas reported using HIE systems to collect demographic information that was not included on laboratory reports or to access historical test results to determine if cases were chronic or acute. Surveillance staff in New York also used HIE for similar information, but also noted the importance of being able to collect basic information like patient addresses, phone numbers, or dates (and locations) of hospitalizations. In these instances, the HIE systems served to provide access to information that was not available in current public health information systems, information which providers or laboratories tended not to report, or information that took more time and effort to collect (e.g. telephone calls to providers or reviews of charts).

Workplace efficiency

While respondents generally thought systems could be improved or further developed, access to HIE resulted in numerous increases in workplace efficiency. These efficiencies cut across different public health activities and, generally, the improvement was in time saved. For example, one respondent working in a cancer program in New York noted: "*This is just a lifesaver because it eases the burden on [providers] and eases the burden on us...We're not waiting and waiting and waiting and calling them five times and annoying them. We just go [to the HIE] and we get the information we want…It just streamlines the process*." HIE saved time for surveillance staff by helping them locate case information like demographics or prior test results and by automating the delivery of disease and laboratory reports. As one respondent noted, her job was easier because, "*instead of calling every hospital, I pull up in the [HIE]*." Respondents various noted things like avoiding "*delays*," being able to "*act faster*," not having to send "*someone out in the field*," not "*having to wait*," and being "*quicker*."

Respondents from New Mexico also reported operational efficiency in terms of data management. Without the services of the HIE, the state health agency would have to create individual data feeds with each hospital in the state. That approach "*is cumbersome and you have to then work with every single different system and figure out formats and all that other stuff*." In New Mexico electronic laboratory reports and emergency department data are routed through the state's HIE. In addition, a public health professional from Indiana also noted that the HIE was able to provide services and technologies that his agency was not capable to provide in-house.

Emergent Themes

During the coding phase, several themes emerged (Table 2) that primarily consisted of the concerns public health professionals faced in terms of HIE usage and the requirements necessary for the technology to reach its full potential in terms of usefulness. We grouped emerging themes into the three categories: non-technical factors, technology-related deficiencies, and requested features.

Emergent theme: Non-technical factors

Most of the public health professionals we interviewed were end users with little or no influence over the design and functionality of the HIE systems. The emergent theme of non-technical factors represented all the influences beyond the sphere of the users' interaction with the HIE that led to implementation and integration challenges. Some were unique to a particular area of public health practice, but others were common across our study sample. Financial

limitations were one such cross-cutting challenge. One public health professional summarized his state's reality succinctly: *"Our state funding is very limited"* and *"we can't spend money on infrastructure development."* Respondents from other states noted that limited financial support impeded HIE development: "*[There are] not a lot of funding opportunities for areas to begin implementing an HIE system,"* and that organizations do not have *"the financial wherewithal or the technological wherewithal right now"* to provide support for such an initiative.

Variations in the level of data comprehensiveness were evident in all states. While HIE did increase the amount of data available, universally, public health professionals wanted more. They desired more data types and more sources of data contributing to the exchange effort. However, it was non-participating providers that were seen as the primary drivers of data comprehensiveness. While those engaged in patient care noted that non-participating providers created gaps in their clinical pictures, the non-participants were particularly troublesome for disease surveillance staff. Surveillance staff and epidemiologists talked about the need to get "*the whole population,*" "*a representative sample*," "*a statewide perspective*," or the "*denominator*." Without the participation of all providers in their community, they felt the data were limited, or at least highly qualified, for surveillance purposes. Additionally, data comprehensiveness had real implications for usage. One nurse said that she was unable to find any data on a suspected case *"probably 98 percent"* times she accessed the HIE system and another professional's concerns meant that there was hesitancy to use the system: *"I have found the majority of times when I go to [HIE system] that I can't find the patient. So I don't use it very much at all."*

During interviews we noted that data access policies were variable between states and could lead to challenges. Data appeared to be most accessible in New York. A nurse reported that she was simply able to mark HIE queries as "*No Consent Needed, because it's public health needed*". However, in Texas, access of non-consented patients for public health purposes was avoided, because it "*sends out the sirens.*" Another example of a policy-generated limitation occurred in Indiana. According to interviewees, "*(S)tate law basically says, 'You can see these results when it's a reportable positive test.' And so that's become an issue is that we don't see the negative tests in the database. And so, you know, it's hard to calculate incidence or prevalence off of that when you don't see the negative.*"

Emergent theme: Technology-related factors

Technology-related factors represented the technical-orientated challenges associated with the HIE. As an example, data standards and coding reportedly created challenges for one state: "*(O)ur big reference laboratories have their own local codes, which then we have to translate into something that's meaningful, and that takes a lot of time."* A more widespread challenge was the fact that HIE systems were generally not interoperable with any other systems in use at the health departments. The HIE systems might facilitate the timely access of information, but public health practitioners still had to print out patient records and reports from their respective HIE system and hand enter the information into various public health systems. Non-integration also appeared in terms of multiple methods of exchange. A respondent from Indiana noted that not only were there five local exchanges within the state, which prevented them from getting "*the full picture,*" they also had providers "*…that want to establish direct connections with us because they don't want to go through an HIE."*

Emergent theme: Requested features

Our study also revealed that respondents shared similarities in terms of how they would like their HIE system to improve. As expected, these requests were in direct response to the limitations or challenges above or were general comments about system functionality problems. Specifically, when asked what would make HIE better support their daily work requirements, in most cases, interviewees desired more data. Access to physician notes were among the prevalent feature requests as respondents generally agreed that it would *"be nice if the doctor's office notes were in there"* and that having access to them *"would be infinitely helpful."* Similarly, interviewees also expressed an awareness of the legal basis for public health activities and wanted HIE systems to be in line with those requirements. Respondents in Indiana and New York tied their wants for data to compliance with state reporting requirements. For example, in Indiana interviewee specifically wanted the HIE to include reports on other notifiable conditions to support the "*cancer registry for TB, HIV, and some of the other state mandated reporting."*

Within the feature request theme, we also identified different levels of interest in how HIE data could be directly queried by the health departments. In our sample, it was common that any direct analysis or custom reporting queries were often handled by the HIE facilitating organization and not the health departments. The state health agency in New Mexico reported the ability to directly query HIE systems on their own, but local health departments reportedly did not have direct access to the underlying raw data. However, local epidemiologists expressed an interest in being able to do their own queries. In Indiana, one respondent stated, *"If it's something that we could do*

ourselves and not have to rely on them again, it would be just that much faster." A similar sentiment was expressed in Texas: *"epidemiology staff would love to be able to do some things themselves."* Likewise a New York surveillance staff expressed her desire as: "*...let us be public health and figure out what to do with [the data]*."

Table 2. Emergent themes and definitions.

Category	Code	Definition
Non-technical factors		**Challenges caused by factors not related to the direct user-interaction with the health information exchange technologies**
	Financial	The ability or inability of public health or healthcare organizations to fund health information exchange
	Data comprehensiveness	Limitations on 1) data types needed for day-to-day activities (e.g. physician notes, radiology data, community care charts, physicians phone number, etc), and 2) sources of data (e.g. more providers) that would increase representativeness or utility
	Policy complications	The use of health information exchange for public health practice was incompatible or was challenged by organizational or state policies.
Technology-related factors		**Challenges directly related to the limitations of the technology**
	Non-integrated systems	Systems are unable to partially or fully exchange data, resulting in other of data exchange and processing such as paper-based artifacts and end-to-end technology.
	Standards and coding	Issues in the presentation, management, and transmission of data elements and meaning.
	System functionality	Users experience trouble with the technology providing up-to-date data due to system down-time, glitches, or data load errors.
Requested features		
	Query privileges	Epidemiologist's ability to conduct queries themselves and reduce dependence on external parties to provide reports.
	Inclusiveness of state mandated reporting	Facilitation of data sharing in compliance with state mandating.
	Management system modules	Systems to aid in organizational workflow and tracking of cases and outbreaks.

DISCUSSION

Several public health activities can be strengthened by participation in HIE. In this multi-site, multi-state qualitative sample of public health professions, we documented benefits consistent with expectations in the literature. The above results indicate a positive impact of HIE on public health. Nevertheless, that impact is qualified in several key ways and HIE usage in public health is still open to improvement.

First, while each public health department reported benefits from HIE participation, no department was leveraging HIE in all seven of the activities identified in the literature. This lack of comprehensive application of HIE to public health is partially explained by the different capabilities and maturity levels of each HIE effort, the inclusion of both local and state public health agencies, and the different service offerings between the public health agencies.

However, it is also the case that usage within each agency was not widespread. Each public health agency tended to focus on a singular or narrow set of use cases. In our interviewed sites, usage tended to be focused in epidemiology / surveillance units or in clinical care, with less usage in other areas. Again, this may be a product of developing systems, but several of the HIE efforts included in this sample have long histories.

Additionally, many of the documented gains could realistically be replicated on greater scales. For example, HIE did support more comprehensive surveillance data and clearly saved public health employees a lot of time and effort. Efficiency gains are not to be dismissed and public health is always in need of better data, however, these are both intermediate steps to the ultimate goal of better population health. Likewise, public health agencies were using HIE to support community health assessments and planning, but descriptive reports and aggregated statistics are not the same as advanced analytics, modeling, or evaluation. Also, as indicated by the interviewees, not every public health agency with HIE attempted this type of aggregated analysis. Likewise, interviews indicated that little evidence for using HIE to improve communication existed; one state reported sharing data back with providers. However, examples of using shared information systems to alert providers of important public health events exist.[32] These observations are not meant to diminish any of the current accomplishments of public health agencies, but taken together with the limited usage of HIE by public health, clearly more benefits can be realized.

The types of data needed by interviewees indicated one easy fashion HIE efforts can demonstrate their value to public health. A common use of HIE by public health was to essentially "fill in" missing data, but this basic activity supported surveillance efforts and helped workflow efficiencies. Simply enabling public health practictioner access to HIE systems would result in at least these moderate wins. The information available in the HIE does not need to be overly complex, because interviewees indicated that something as simple as demographics or contact information is important to public health. Without contact information, disease control is severely hampered; without demographics, public health agencies cannot assess and attempt to remedy disparities in health. Unfortunately, these are exactly the types of data healthcare information systems have not historically collected well.[33] By pooling data from multiple sources HIE can improve data completeness[23] and be of immediate utility to public health.

The emergent themes in our data documented several areas for improvement. One clear need is better systems integration. The lack of integration and sharing of data between systems is a common problem in public health practice[34] and one that leads to many inefficiencies.[35] In too many instances, public health professionals were accessing an information system that did not directly share data with any of their other data repositories. While the HIE may have useful information, that information was printed, copied, or just remembered for entry into other systems. Also, a dominant need raised by the interviewees themselves was the desire for each exchange effort to be more comprehensive in terms of information and information sources. Public health professionals knew the difference between an information source that was a sample and that which was truly representative of the population. Consistently, the utility of HIE would be higher with more participants on board.

The emergent themes also raise some interesting questions for future research and policy discussions. For one, these findings leave unanswered the optimal approach to HIE analytics. Should health departments advocate for a larger role in analytics through direct access to HIE data as some interviewee suggested? On one hand, state and large local health departments typically employ epidemiologists and biostatisticians with sufficient skills to analyze large datasets. However, technology infrastructures in public health tend to lag behind healthcare organizations and during periods of financial constraints departments may not be able to allocate staff and financial resources necessary to manage and analyze very complex clinical datasets. From the other perspective, HIEs may see being able to offer analytic services themselves as an important revenue stream.[36] Also, as organizations that primarily serve the healthcare system, privacy concerns are paramount for RHIOs and HIEs. This could create natural hesitancies around increasing direct data access. Another question raised by these findings revolves around the consent policies for public health practices. We noted differences in the policies followed in two different states: one allowed for easier public health access and the other appeared to restrict information retrieval to only consented patients. Public health's powers to investigate tend to be broad and allow for the collection of personal health information without written patient authorization.[37] Understanding how individual public health agencies and states view access rules could be important to understanding the actual effectiveness of HIE in supporting public health.

Limitations

These findings are subject to limitations. The activities supported by HIE and the interviewees' experiences with HIE may not be reflective of all public health practitioners. The sample was limited to those experienced with HIE

and the sample represented more developed, functional exchange efforts. Furthermore, while we were able to document benefits, we were not able to quantify any of the reported gains in efficiency, organizational learning, better decision making, or health outcomes.

Conclusion

HIE supported public health activities consistent with expectations in the literature. However, no single department realized the all the potential benefits of HIE. The opportunity exists for public health to make use of HIE to a greater extent. Additionally, HIE efforts can support public health even further by increasing the number of participating providers and increasing the amount of information available.

ACKNOWLEDGEMENTS

We would like to thank the health information exchange efforts and the public health departments for their cooperation in data collection: Rochester Regional Health Information Organization (www.grrhio.org), Southern Tier HealthLink (www.sthlny.com), the Integrated Care Collaborative of Central Texas (icc-centex.org), the Indiana Health Information Exchange (www.ihie.com) and the New Mexico Health Information Collaborative (www.nmhic.org). This project was funded by the New York eHealth Collaborative as a part of the evaluation of the Office of the National Coordinator for Health Information Technology's State HIE Cooperative Agreement Program. The Institutional Review Board of Weill Cornell Medical College approved this study.

Trends in Publication of Nursing Informatics Research

Hyeoneui Kim, RN, MPH, PhD, Lucila Ohno-Machado, MD, MBA, PhD,
Janet Oh, BS, Xiaoqian Jiang, PhD
Division of Biomedical Informatics, University of California San Diego, La Jolla, CA

Abstract

We analyzed 741 journal articles on nursing informatics published in 7 biomedical/nursing informatics journals and 6 nursing journals from 2005 to 2013 to begin to understand publication trends in nursing informatics research and identify gaps. We assigned a research theme to each article using AMIA 2014 theme categories and normalized the citation counts using time from publication. Overall, nursing informatics research covered a broad spectrum of research topics in biomedical informatics and publication topics seem to be well aligned with the high priority research agenda identified by the nursing informatics community. The research themes with highest volume of publication were Clinical Workflow and Human Factors, Consumer Informatics and Personal Health Records, and Clinical Informatics, for which an increasing trend in publication was noted. Articles on Informatics Education and Workforce Development; Data Mining, NLP, Information Extraction; and Clinical Informatics showed steady and high volume of citations.

Introduction

Information technologies were identified as key factors in achieving improved patient safety and quality of care and the published literature is starting to confirm this role[1–3]. Biomedical informatics, including nursing informatics, is a fast moving field that is heavily influenced by healthcare policy and clinical practice. Professional and/or academic organizations have been dedicating substantial effort to facilitate nursing informatics research and training that address current needs. For example, many nursing education programs offer training opportunities specialized in nursing informatics and also mandate an introductory nursing informatics class to all students as part of their core curriculum[4–7]. The Nursing Informatics Working Group (NIWG) at AMIA addresses various issues in policy, research, and educational aspects of nursing informatics. The NIWG also offers two award programs to recognize noteworthy research presented in the annual AMIA symposium to encourage participation of nurse scholars [8].

Scientific journals are a venue for dissemination of research to a large community of readers. The proportion of peer-reviewed articles published in a certain area of research (and their citations) can provide interesting insights on topic trends in informatics[9,10]. Although it may not constitute a perfect measure, the number of citations is considered a de facto standard for measuring the impact of a scientific publication. Based on this idea, we have previously analyzed the publication and citation volumes in biomedical informatics that were published relatively recently (2009-2012) in the J Amer Med Inform Assoc (JAMIA) to better understand research topic trends for biomedical informatics in general.

We conducted a similar analysis to describe the trends in published nursing informatics research by analyzing the articles published on selected major informatics and nursing journals during the past 9 years. We also compared the active research areas reflected in these articles against the nursing informatics research agenda proposed by nursing informatics leaders[11–13]. Through this analysis, we aimed at (1) checking the trajectory of published nursing informatics research for the past 9 years, and (2) identifying potential gaps in particular research areas.

Background

In 1993, the National Institute of Nursing Research (NINR) of National Institutes of Health (NIH) sponsored a group of nursing informatics scholars in the investigation of research needs in nursing informatics with the purpose of developing a nursing informatics research agenda[14]. Healthcare and biomedical research are changing rapidly due to the availability of advanced technologies to collect and analyze large volumes of data.

Many nursing informatics leaders have proposed an updated research agenda over the past decade. In 2007, the AMIA NIWG proposed comprehensive nursing informatics agenda in nursing practice, education, and research [13]. A year later, Bakken et, al. identified the areas that nursing informatics research needed to expand further to better

accommodate fast moving biomedical sciences[12]. In 2012, the Nursing Informatics International Research Network (NIIRN) conducted an international survey of 468 nursing informatics researchers across the globe soliciting opinions on research topics that should be prioritized[11]. The research agenda identified in these works is summarized in **Table 1**.

Recently, Carrington et, al. reported on informatics topics that were most actively researched, the types of research, and research settings by reviewing 69 peer-reviewed articles with a nurse as the first author, published between Aug 2011 and Aug 2012[15]. They identified three broad topics of research: (1) clinical informatics research that deals with various clinical information applications such as Electronic Medical Records (EMR) and bar-code medication administration, (2) human factors such as human computer interaction and communication, and (3) data interoperability such as terminology/standardization and care transition/handoffs[15]. This work provided an important snapshot view of the research trends in that given year and provided valuable insights on the status of nursing informatics research.

Table 1. Nursing informatics research agenda

AMIA-NIWG (2007)[13]	**Bakken, et al. (2008)**[12]	**NIIRN (2012)***[11]
• Secondary use of clinical data • Use of aggregated & de-identified data • Data privacy and confidentiality • Data security and related technical infrastructure • Population health • Development and use of standards	• User friendly tools for data analysis visualization, and modeling • Evaluation methods of human and organizational factors on health IT • Consumer empowerment • Use of genomics and environmental data • Reengineering of nursing practice	• Clinical information systems that provide real-time feedback • Evaluation of the impact of health IT system on patient outcome • Nursing decision support systems • Evaluation of the impact of health IT system on nursing workflow • Management of nursing data for research and patient care • Training nurses in health IT • Identifying nursing outcomes that are important to patients

* Only the top 7 highest priority items out of 20 are listed.

Materials and Methods

Article collection

We retrieved articles relevant to nursing informatics published between 2005 and 2013 using ISI's Web of Science[16]. Here, the "articles relevant to nursing informatics" was defined according to the disciplines covered by the selected journals, keywords found in the articles, and authors' affiliations. Articles published in nursing informatics journals were considered relevant. Articles published in general biomedical informatics journals were considered relevant when at least one of the authors was affiliated with a nursing institution (e.g., nursing schools, nursing research institutes, centers of nursing excellence, etc.). Additionally, articles published in non-informatics nursing journals were considered relevant if they contained the keyword "informatics" in the title or abstract.

Nursing informatics research is published in a large number of biomedical informatics and/or engineering journals. We included one nursing informatics journal (*CIN: Computers, Informatics, Nursing*) and seven general biomedical informatics journals (*Journal of Medical Internet Research, Journal of American Medical Informatics Association, Medical Decision Making, International Journal of Medical Informatics, Journal of Biomedical Informatics, BMC Medical Informatics and Decision Making, Method of Informatics in Medicine*) in this analysis. These journals encompass a wide range of informatics topics and are among the top 20 journals with highest 5-year impact factors in the category "Medical Informatics" in ISI's Web of Science [16]. Four[1] of these eight journals were also recognized in a prior work as the journals in which the most nursing informatics works were published [15].

As many nursing informatics scholars publish informatics relevant works on non-informatics journals, we also included six nursing journals (i.e., *International Journal of Nursing Studies, Journal of Advanced Nursing, Nursing Research, Journal of Nursing Scholarship, Nursing Outlook, Journal of Nursing Administration*) that publish

[1] CIN: Computers, Informatics, Nursing; Journal of American Medical Informatics Association; International Journal of Medical Informatics; Journal of Biomedical Informatics

general clinical nursing research as well as administrative, and managerial topics. These journals are among the top 20 nursing journals with highest 5-year impact scores under the category "Nursing" of ISI's Web of Science[16]. This journal selection approach undoubtedly has limitations, which are described in the discussion section.

We retrieved citation information of selected articles from the ISI's Web of Science[16] using its citation report function. A total of 741 articles were included in this analysis, which excluded white papers, opinion papers, duplicated articles, and articles without citation reports. The largest number of articles (N=406) was collected from the nursing informatics journal, 306 from biomedical informatics journals, and 29 from nursing journals. The paper selection process is summarized in **Figure 1**.

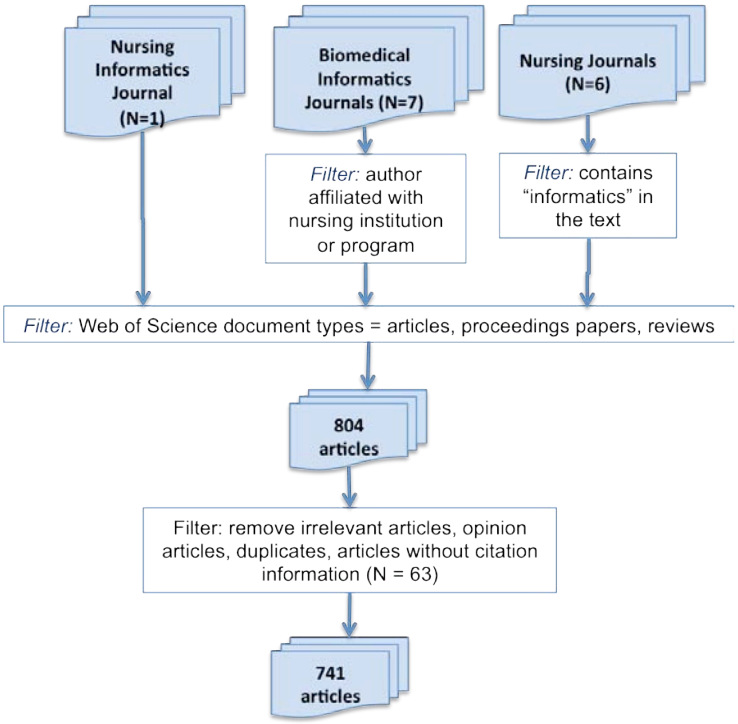

Figure 1. Article selection process

Citation score normalization

The citation report obtained from the ISI's Web of Science[16] shows the annual citation counts of an article for the indicated time period. Using the same method reported in the prior work[9,10] we produced normalized citation scores to each paper to minimize the bias introduced by the differences in publication dates. For instance, an article published in January of 2006 has more chances of being read and cited than an article published in December of 2011 as it has been available to research communities for a longer period of time. Therefore we used a unit of measure that reflects the number of citation per month (CPM) since publication, as adopted in the prior work [9,10].

The CPM scores were calculated separately for each year (i.e., annual CPM = number of citation in a given year / number of months an article was available in a given year) as well as for the entire period (i.e., overall CPM = total number of citations / total number of months an article was available). The two calculations were performed to account for the fact that articles that are old accrue a relatively small number of citations per month after several years of publication, and articles that are recent also accrue a relatively small number of citations in the first two years after publication. Hence articles published in the middle of the accounted period (i.e, 2009-2010) would account for higher overall CPMs than articles at the extremes. However, they should result in comparable annual CPM when the number of years after publication is taken into account.

Research theme assignment

We assigned a research topic category to each article using the AMIA themes proposed for the 2014 annual symposium[17]. Although the articles provide a list of keywords and/or are indexed with the terms from Medical Subject Heading (MeSH), they may not provide a single category label that represents the main topic of the study with sufficient expressivity for subdomains of informatics. We decided to use the AMIA 2014 themes after investigating various potential alternatives, such as chapter headings from biomedical informatics textbooks and subjects listed in informatics training curricula[18,19]. Although AMIA themes may focus on the contemporary topics of biomedical informatics research, they were deemed viable options for this work, as they are expressive labels designed to capture a single main topic of a research work for the purposes of directing a diverse set of attendees to the presentations that are more relevant to their interests.

We also developed annotation rules and a process shown in **Figure 2** to maximize annotation consistency and accuracy. The theme categories that were deemed straightforward to use (i.e., *Public Health Informatics and Biosurveillance, Translational Bioinformatics and Bioinformatics, Global eHealth, Imaging Informatics*) are not shown in **Figure 2** to simplify the display of the process. In addition, we did not use the theme category *Meaningful Use* as it can directly relate to many other informatics themes and was not relevant to older articles.

Two authors (HK, XJ) independently annotated the main research topics of randomly selected 100 articles using the AMIA 2014 themes. The annotation results were collaboratively reviewed and the discrepancies were resolved by reaching consensus. Also, the theme assignment rules and process were refined as necessary. One author (HK) who is trained in nursing informatics assigned themes to the remaining 641 articles following the refined rules and process. Metadata for the 741 articles with themes are available at https://idash-data.ucsd.edu/folder/504.

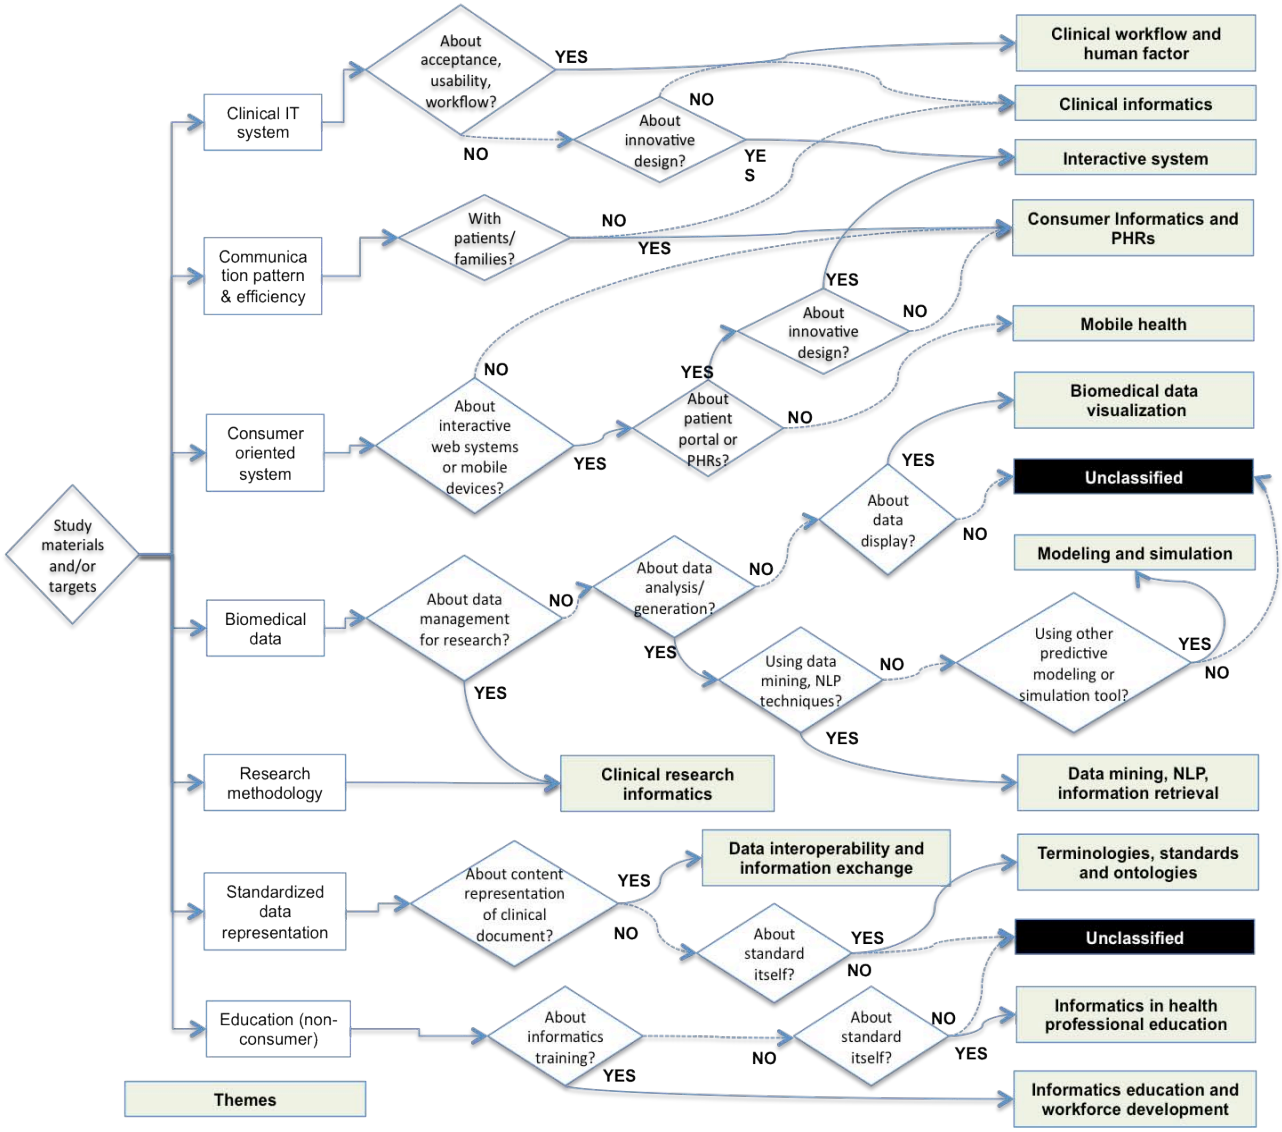

Figure 2. Topic assignment process

Trend analysis

We generated descriptive statistics on distributions of the research topics and their citation scores. We also tested whether these distributions differ significantly among journal types and whether they changed significantly over the years. SPSS (version 22) and Matlab were used to analyze the data.

Results

Among 741 articles collected, 701 were research articles and 40 were review articles. A total of 117 articles reported on work that targeted specific clinical information systems. The most frequently studied areas referred to Electronic Medical Records (EMR, N=61), Clinical Decision Support System (CDSS, N=33), Computerized Provider Order Entry (CPOE, N=10), and bar-coding medication administration (N=10).

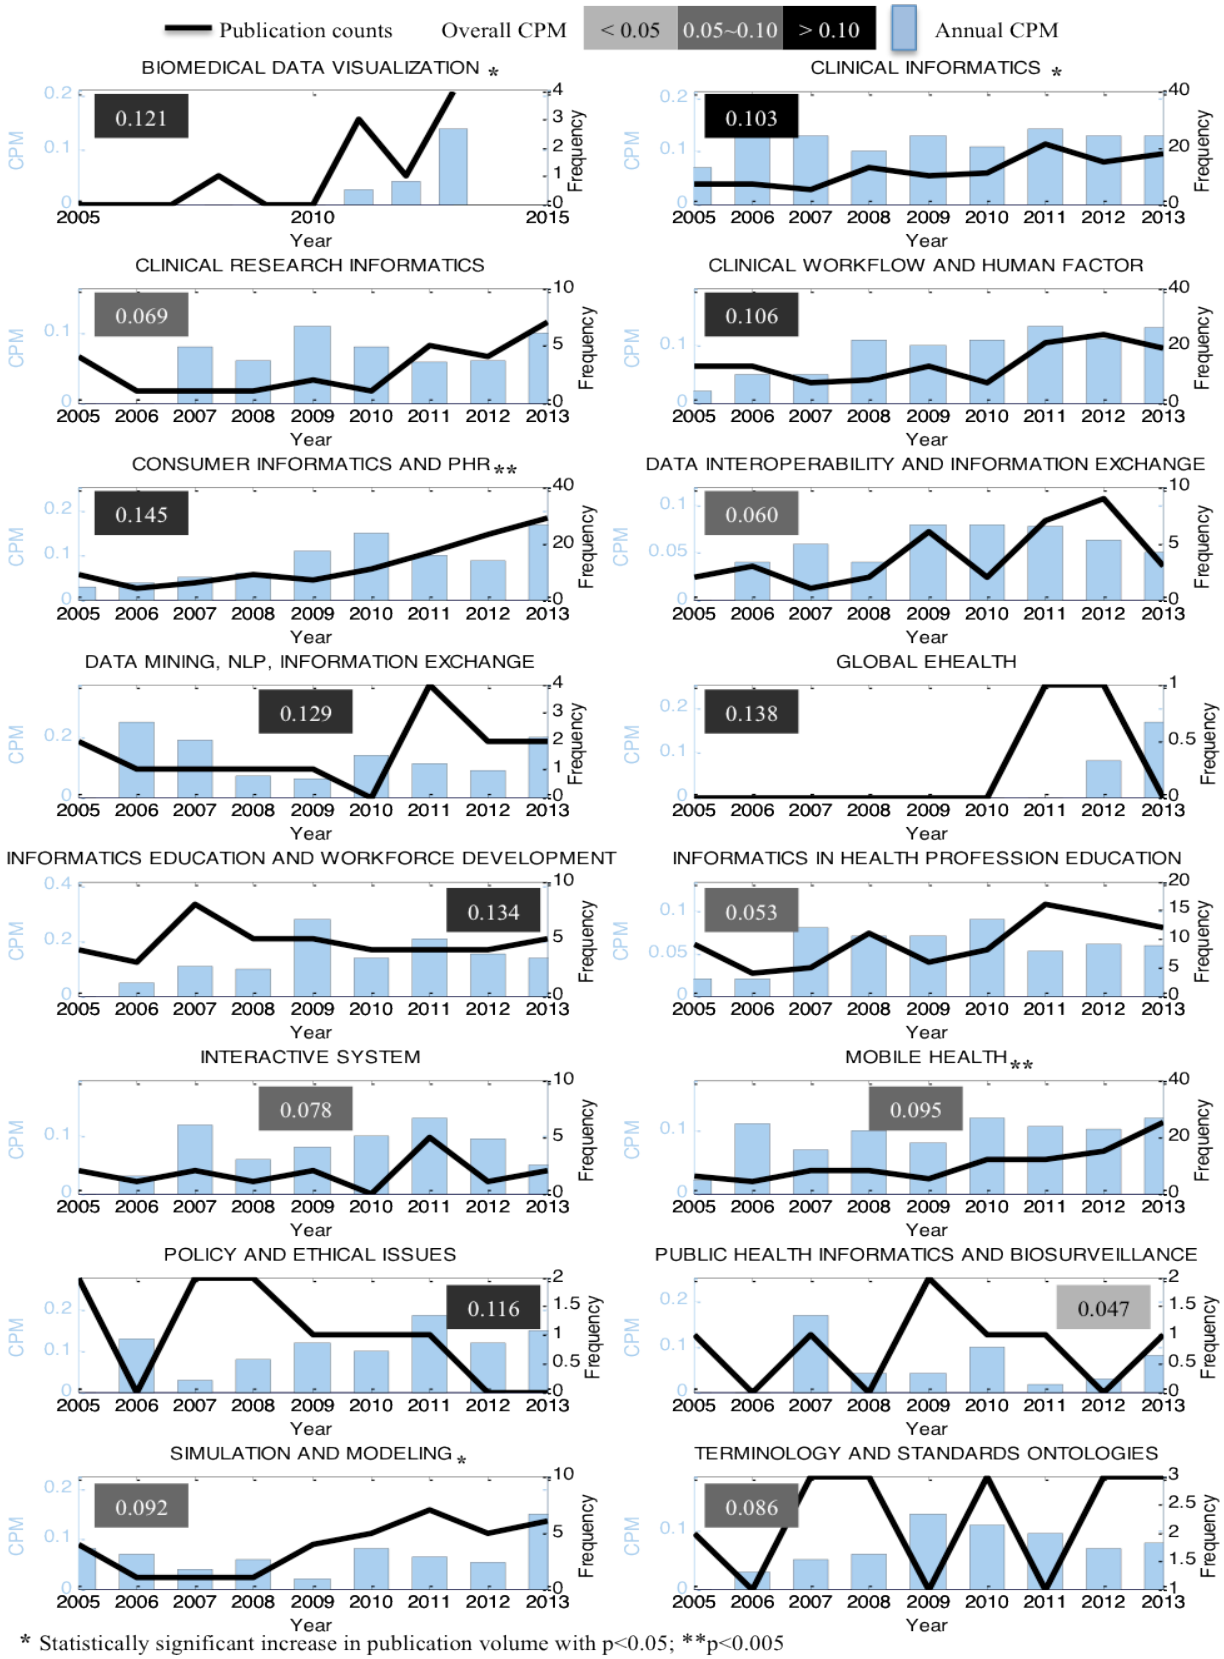

Figure 3 Annual article volume and Citation per Month (CPM), and overall CPM by Themes

Distribution of research themes

Most of the themes were utilized in the categorization of articles, except for the themes *Imaging Informatics* and *Translational Bioinformatics and Biomedicine* for which there were no articles. No article was left unassigned. The research theme most frequently appearing for the past 9 years was *Clinical Workflow and Human Factors*. *Global eHealth* was the least frequent (**Figure 3**). We analyzed the trend of publication frequencies for each research theme over the years using a parametric method. The article frequencies were used as the predictor variables and the publication year was used as the response variable to fit a linear regression model. Two parameters (constant and slope) were calculated and we conducted a t-test to check whether they were statistically significant. In **Figure 3**, the starred (*) themes are the ones that show statistically significant positive trends (i.e., increment of the article counts).

Publications focusing on *Consumer Informatics and PHR* and *Mobile Health* have been continuously growing. In addition to these two themes, *Clinical Informatics and Clinical Workflow and Human Factors* are the areas where the high volume of nursing informatics articles has been published for the past 3 years. Also it is noteworthy that the nursing informatics articles on *Biomedical Data Visualization* and *Global eHealth* started showing up relatively recently.

The articles published in informatics journals represented the broadest theme areas. Two most frequent themes from the nursing informatics journal were *Informatics in Health Professional Education*, and *Clinical Workflow and Human Factor*. *Consumer Informatics and PHRs*, and *Clinical Workflow and Human Factor* are the themes most frequently appearing in general biomedical informatics journals. Half of the articles from nursing journals were on *Informatics Education and Workforce Development* (**Figure 4**). The differences in theme distributions among journal types were statistically significant when tested with the Pearson Chi-Square test ($p<0.005$).

Table 2. Distribution of research themes by journal types

AMIA Themes	Nursing Informatics Journal	Nursing Journal	Biomedical Informatics Journal	Total
Clinical workflow and human factor	76	2	47	125
Consumer informatics and PHR	46	1	68	115
Clinical informatics	60	3	44	107
Mobile health	59	0	36	95
Informatics in health profession education	76	5	4	85
Informatics education and workforce development	22	15	5	42
Data interoperability and information exchange	21	0	14	35
Simulation and modeling	10	1	23	34
Clinical research informatics	12	0	14	26
Terminology and standards ontologies	5	1	14	20
Interactive system	10	0	6	16
Data mining, NLP, information extraction	5	0	9	14
Biomedical data visualization	2	0	7	9
Policy and ethical issues	0	1	8	9
Public health informatics and bio-surveillance	1	0	6	7
Global ehealth	1	0	1	2
Total	406	29	306	741

Research impact

The top 10 most highly cited articles (based on overall CPM) are about *Informatics Education and Workforce Development* (ranked 1st)[20], *Biomedical Data Visualization* (2nd)[21], *Clinical Workflow and Human Factor* (3rd)[22] and *Consumer Informatics and PHRs* (4th-10th). The first ranked article was published in a non-informatics nursing journal and the other 9 articles were published in general biomedical informatics journals.

Informatics Education and Workforce Development; Data Mining, NLP, Information Extraction; and Clinical Informatics were the research themes that were associated with the consistently high annual CPMs (**Figure 3**). However, *Consumer Informatics and PHRs* came out as having the highest overall CPM, followed by *Global eHeath* and *Informatics Education and Workforce Development.* It is noteworthy that the articles on *Global eHealth* and *Biomedical Data Visualization* themes showed quite high overall CPM scores in spite of their relatively short article available time. This indicates that these two themes are fastest growing research areas in nursing informatics but this observation needs to be revalidated when more data are accumulated. The overall CPMs for *Data Mining*, and *NLP, Information Extraction* and *Clinical Informatics* still remain high.

Alignment with the nursing informatics research agenda

We first aligned the nursing informatics research agenda items presented in **Table 1** with the AMIA themes. We then checked the number of articles published in those themes and the overall CPM and the most recent stable annual CPM scores as proxy information that reflects how active research in a particular agenda item has been. A research agenda item was assigned with only one theme even if it can be related to multiple themes. We excluded the agenda item "reengineering nursing practice" as it encompasses a full spectrum of research themes.

The agenda items were related to nine of the seventeen AMIA themes considered in this study. The eight of the nine mapped themes covered more than 60% of the articles analyzed in this study. The average overall CPM score of the articles on these eight themes was 0.102 (s.d. = 0.033). Of note, the average overall CPM score of the seventeen themes used in this study was 0.010 (s.d. = 0.027) (**Table 2**).

Discussion

We observed that the nursing informatics articles covered a broad spectrum of topics in biomedical informatics over a 9-year window. Highest volumes of articles were associated with *Clinical Workflow and Human Factor, Consumer Informatics and PHRs,* and *Clinical Informatics*, for which an increasing trend in publication was also noted. An increasing publication trend was also observed for the themes like *Mobile Health, Informatics in Health Profession Education, Simulation and Modeling,* and *Biomedical Data Visualization.*

In terms of citation counts, themes related to informatics training, clinical informatics and data mining dominated, possibly because they are established areas of research. When we adjust citation counts with publication dates (i.e., overall CPM), *Consumer Informatics and PHRs* and *Global eHealth* stood out as the most highly cited themes. However, the overall CPM of *Global eHealth* was calculated based on the 2 articles published only 2-3 years ago. Therefore, this high overall CPM may indicate temporary attention caused by the paucity of relevant publications thus a longer period of observation is needed to substantiate this trend.

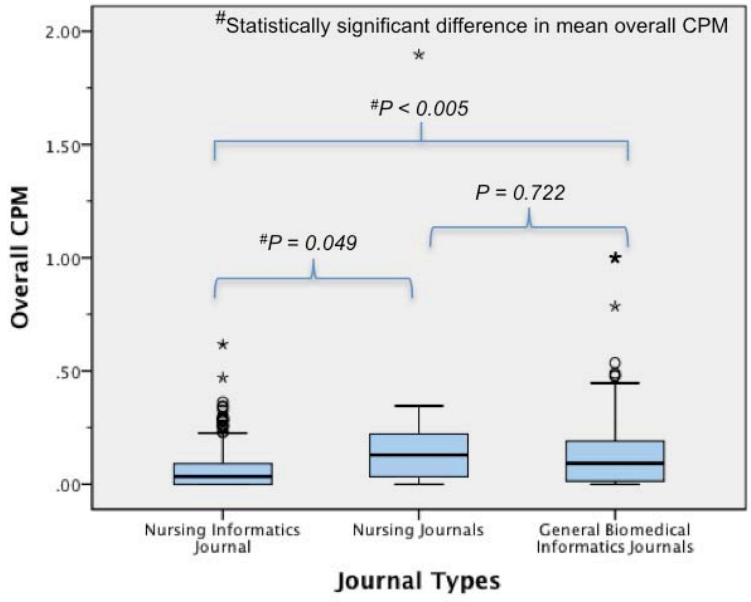

Figure 4. Overall Citations Per Month (CPM) distribution by journal type

We found that education topics published in non-informatics nursing journals are very highly cited compared to those published in informatics journals. In addition, we found that the articles published in the nursing informatics journal have relatively lower overall CPMs than the articles published in general biomedical informatics journals and non-informatics nursing journals. (**Figure 5**). This is probably related to the size of readership (the audience pool), which is much smaller for nursing informatics as it is for nursing in general, or for informatics in general.

Although most of the high priority areas of nursing informatics research were well covered, areas that may require more attention – related to public health informatics and bioinformatics – were also noted.

Table 2. Volume of articles, overall CPM, and most recent annual CPM (2012) by research agenda

Agenda items (proposed by)	Themes	Articles N (%)	CPMs: overall (2012)
Clinical information systems that provide real-time feedback (NIIRN)	Clinical Informatics	107 (14.44)	0.105 (0.130)
Nursing decision support system (NIIRN)			
Secondary use of clinical data (AMIA-NIWG)			
User friendly tools for data analysis visualization, and modeling (Bakken et, al.)			
Evaluation of the impact of health IT system on patient outcome (NIIRN)			
Evaluation methods of human and organizational factors on health IT (Bakken et, al.)	Clinical Workflow and Human Factor	125 (16.87)	0.109 (0.112)
Evaluation of the impact of health IT system on nursing workflow (NIIRN)			
Use of aggregated & de-identified data (AMIA-NIWG)	Clinical Research Informatics	26 (3.51)	0.069 (0.061)
Data privacy and confidentiality (AMIA-NIWG)			
Data security & related technical infrastructure (AMIA-NIWG)			
Management of nursing data for research patient care (NIIRN)			
Consumer empowerment (Bakken et, al.)	Consumer Informatics and PHRs	115 (15.52)	0.148 (0.087)
Identifying nursing outcomes important to patients (NIIRN)			
Population health (AMIA-NIWG)	Public Health Informatics and Biosurveillance	5 (0.94)	0.054 (0.028)
Use of genomics and environmental data (Bakken et, al.)	Translational Bioinformatics & Biomedicine	0	NA
Development and use of standards (AMIA-NIWG)	Terminology and Standards Ontologies	20 (2.70)	0.086 (0.070)
	Data interoperability and information exchange	35 (4.72)	0.059 (0.063)
Training nurses in Health IT (NIIRN)	Informatics Education and Workforce Development	27 (5.67)	0.137 (0.153)

It is noteworthy that *Clinical Workflow and Human Factor* is among the most frequently published and cited themes in nursing informatics research. This is not surprising considering the large amount of time that nurses spend working with clinical information system, especially EMRs[23]. This research trend may also imply that nurses can make significant contributions to mitigating various EMR usability issues. In July of 2013, the Office of National Coordinator (ONC) hosted a meeting with stakeholders to discuss usability issues in EMRs. Representatives from a healthcare informatics professional group, an EMR certification agency, and the American Medical Association were invited and had a chance to provide testimonials. Common criticism was that designs and workflows of many EMRs largely focused on meeting the Meaningful Use (MU) requirements rather than usability[24–26]. These testimonials addressed the usability issues commonly faced by various healthcare professionals. Also not many MU core/menu objectives are directly related to nursing documentation. Nonetheless it would be beneficial to actively seek nursing perspectives on the usability issues, considering that nurses are the major workforce for documenting and generating clinical data, as well as being heavily involved in the research on usability and workflow aspects of clinical information systems.

The findings of this study may not reflect the most comprehensive and accurate trends of nursing informatics research due to several limitations. Firstly, the operational definitions of nursing informatics research we adopted were arbitrary: research related to informatics published in nursing journals OR research done by a researcher affiliated with a nursing institution and published in an informatics journal. Ideally, nursing informatics research should be defined as any scholarly work that investigated informatics aspects relevant to nursing research, practice and education. However, operational definitions that could be readily applicable to literature search were

unavailable. Use of crude definitions of nursing informatics research may have caused either the inclusion of non-nursing informatics articles or exclusion of nursing informatics articles.

Secondly, we collected articles from a small subset of informatics and nursing journals. For example, we excluded conference papers with no citation information and specialty nursing journals, where many practical applied informatics articles are published, as they can be most beneficial to practicing nurses. Thirdly, although we used CPM to minimize the bias introduced by publication dates, CPM is still not completely free from the bias given that trends captured in the early age of articles might drastically change later. Finally, even if we found AMIA themes were robust and clear enough to label the articles collected for this study, there were cases that the authors struggled with assigning proper themes. Like in many studies that involve with human annotation of concepts, this study also carries subjectivity and inconsistency issues in theme assignment.

Conclusion

We conducted a descriptive analysis of nursing informatics articles published in the past 9 years to understand overall trends in publication of nursing informatics research in the peer-reviewed literature and to identify the research areas that may be relatively under-represented. Overall, we found that published nursing informatics research covered a broad spectrum of research topics in biomedical informatics and is aligned with high priority research agenda items advocated by the nursing informatics community. Despite limitations related to relatively narrow coverage of journals, the findings allow us to initiate a dialogue with journal editors and the nursing informatics community at large about the differences in maturity of research in each of the themes, and potentially guide authors and readers on which venue currently provides the highest number of articles related to a given theme.

Effectiveness of Evidence-Based Congestive Heart Failure (CHF) CPOE Order Sets Measured by Health Outcomes

Jacob Krive, PhD, MBA, MS[1,2,3], Joel S. Shoolin, DO, MBA[1], Steven D. Zink, PhD[2,4].
[1]Advocate Health Care, Oak Brook, IL; [2]Nova Southeastern University, Fort Lauderdale, FL; [3]University of Illinois at Chicago, Chicago, IL; [4]Nevada System of Higher Education, NV

Abstract

Objective: *Evidence-based order sets for treatment of patients with common conditions promise ordering efficiency and more consistent health outcomes. Despite ongoing utilization of order sets, quantitative evidence of their effectiveness is lacking. This study quantitatively analyzed benefits of CHF order sets as measured by mortality, readmission, and length of stay (LOS) outcomes.*
Methods*: Mortality and readmissions were analyzed by comparing "order set" and "free text" groups of adult patients using logistic regression, Pearson chi-squared, and Fisher's exact methods. LOS was calculated by applying One-Way ANOVA and Mann-Whitney tests, supplemented by comorbidity analysis via Charlson Comorbidity Index.*
Results*: CHF orders placed via sets were effective in reducing mortality [OR=1.818;95% CF 1.039-3.181;p=0.034] and LOS [F(1,10938)=8.352,p=0.013,4.75 days ("free text" group) vs. 5.46 days ("order set" group)], while readmission outcome was not significant [OR=0.913;95% CF 0.734-1.137;p=0.417].*
Conclusion*: Evidence-based medication ordering practices to treat CHF have potential to reduce mortality and LOS, without effect on readmissions.*

Keywords

Evidence-based medicine, medication order sets, health outcomes research, congestive heart failure, computerized physician order entry systems.

Introduction

For decades, hospitals have used templates for computerized physician order entry (CPOE) to standardize clinical workflow. Grounded in evidence-based care theories, physician instructions provide convenience, decrease delays, reduce errors, and improve inventory control. This resonates in the national debate over slowing growth of healthcare expenditures through more focused application of information technology not only in CPOE, but also in electronic medical records (EMR) and clinical decision support (CDS) systems to demonstrate meaningful use as mandated in the U.S. Patient Protection and Affordable Care Act. Aided by the increased sophistication of IT, expectations of CPOE benefits have moved far beyond efficiency. CPOE is now linked to reducing variability in treating well-researched patient conditions by sharpening diagnoses as well as tracking treatment plans throughout the continuum of patient care. Although expectations from CPOE may differ, they are widely deployed throughout the healthcare sector despite little quantitative evidence regarding their effectiveness in improving outcomes or cost reductions.

Early studies in treating chronic heart failure (CHF) found order sets effective in reducing mortality, readmissions, and length of hospital stay. However, none analyzed large data sets spanning several years of patient encounters. This study examines effectiveness of CHF order sets at a major community integrated healthcare delivery network using patient care history from five Advocate Health Care hospitals over five years. Advocate is the largest healthcare provider in the state of Illinois (USA), with 12 hospitals, 3500+ beds, and a total of over 250 sites of care.

Background and Significance

Specialty-specific order sets, engaged physicians, and large-scale CPOE system implementation are crucial to electronic medical records project success[1]. VA Puget Sound Health Care System in Seattle, Washington credits clinician engagement as a key success factor as they saw 50% of the order catalogs, 57% of the quick orders, and 13% of the order sets utilized within 6 months of CPOE implementation[2]. Order sets gain popularity due to their convenience, standardization, and adherence to evidence based practices features. Cowden et al.[3] conducted an order set quality improvement study to combine two orders and evaluate a combined chi-squared to predict order set correspondence to an ordering pattern. Performed at Ohio State University Medical Center, the study found that a large percentage of medication orders qualified for an order set. Dixon and Zafar[4] defined the theoretical foundation of order sets and their potential effectiveness in standardized treatment in a U.S. Department of Health and Human Services study in year 2008. Evidence suggests that order sets influence ordering practices as well as patient outcomes[5]. A study conducted at seven diverse sites across the United States showed many commonalities in physician ordering practices. Overwhelming popularity of a few sets yielded a short list of sets in common circulation[5].

Despite growing CPOE adoption and physician reliance on technology, complexity and specific concerns related to electronic medical records technologies remain high[6]. Resistance to clinical practice guidelines[7] rooted in evidence-based medicine presents a barrier to standardized order practices via sets. To address concerns over standardization and technical complexity issues, in order to take advantage of the potential patient safety benefits of evidence-based order sets, the Mayo Clinic initiated a NIH sponsored project that ensured participation of all clinicians to achieve greater respect, increased trust, and improved utilization of the order sets[8]. UCLA Children's Hospital reported success of their order sets by promulgating residents' 89% approval. Over half of the residents (58%) reported using reported using them >=90% of the time; 75% believed that medical errors were reduced[9].

Only two in-depth studies of the effectiveness of CHF order sets have been reported to date. An Advocate Christ Medical Center study evaluated the effect of improved organization and visual appearance of CHF order sets. Utilization increased for post intervention (72% vs. 9%), as well as compliance with CPG for angiotensin-converting enzyme (83% vs. 25%) and intravenous nitroglycerin (78% vs. 12%), while dosing, systolic blood pressure reduction, and urine output did not change[10]. An implementation of CHF set at Baylor University Medical Center led to increased utilization, increased core measures compliance (odds ratio=1.51), reduced inpatient mortality (odds ratio=0.49), and reduction in readmissions that approached significance[11].

Other studies have demonstrated evidence-based order sets importance in successful patient outcomes. An acute myocardial infarction study of order sets performed at seventy-eight acute care hospitals in Ontario, Canada[12] found increased core measure compliance in the fibrinolytics < 30min, primary percutaneous coronary intervention < 90min, fibrinolytics administration decided by ED physician, aspirin < 6hours of arrival, and lipid test < 24 hours of arrival categories. Patients who met the composite process of care measure had lower 30-day and 1-year mortality with odds ratio of 0.51. A pneumonia order set study at Baylor Health Care System[13] revealed reduced in-hospital mortality (odds ratio=0.73) and 30-day mortality (odds ratio=0.79), while core measure compliance remained unchanged. An earlier similar pneumonia study[14] at the same healthcare system also showed lower mortality and slightly higher core measures compliance (odd ratio=1.24). As part of the order set study with the goal of increasing prescription of calcium and vitamin D supplementation in patients receiving glucocorticoids[15], researchers found that prescriptions for calcium increased from 37% to 49% and vitamin D from 38% to 53% as a result of set implementation. In a study of septic shock management[16], researchers found that order sets were responsible for the after-intervention group receiving more intravenous fluids while in ED, more fluids of >20ml/kg body weight before vasopressor administration, and more likely to be treated with an appropriate initial antimicrobial regimen. These patients also had shorter length of stay and lower risk of 28-day mortality. Another bacteremic severe sepsis management study performed at Barnes-Jewish academic medical center[17] found similar benefits in fluids

administration, hospital length of stay, as well as reduced occurrence of renal and cardiovascular failures among patients in the intervention group.

The literature supports order set effectiveness in improving patient outcomes, with various measures leading to a number of positive conclusions. The number of studies that examined CHF order sets are more limited, and involved smaller patient populations.

Methods

This causal comparative study analyzed five years of patient data between 2007 and 2011, with the goal of determining order set effectiveness as applied to "order set" and "free text" groups of patients based on health outcomes, 30-day readmissions, length of hospital stay, and supported by comorbidity analysis using computed Charlson Comorbidity Index (CCI) score. CHF condition was originally selected due to a relatively large patient volume, higher order set utilization compared to other patient conditions, and organizational key results focus on quality metrics at the research site. As part of comparative study of the patient history, the "order set" group represented patient encounters where providers placed CHF orders using sets, and the "free text" group represented all other CHF treatment orders where physicians chose custom ordering methods and did not employ sets.

Mortality was confirmed by selecting discharge codes complying with ICD-9-CM diagnosis codes listed under AHRQ IQI-16 CHF Mortality definitions. Eligible "expired" codes were converted to a binary value of 1, with other codes converted to 0. Readmission was a 'yes/no' binary field, and length of stay (LOS) was a calculated field between the date/time values of admission and discharge. The total Charlson Comorbidity Index (CCI) score represented comorbidity. In this study, CCI could play a dual role: (1) explain LOS as an index of pre-existing conditions, thus introducing comorbidity adjustment, or (2) serve as a measure of post-treatment complications. Due to lack of a clear definition of comorbidity as a variable in this study, results are used only for discussion. Comorbidity calculations are also separate due to lack of reliable measure to adjust results by comorbidity, with CCI serving in the dual pre/post-treatment complication roles.

The main independent (cause) variable in this study was utilization of the order sets, forming two comparison groups. Health outcomes were defined as dependent (effect) variables. Race, age, and sex were mediating variables analyzed in conjunction with order set utilization to determine combined significance in predicting health outcomes. De-identified patient encounters were obtained via queries against the enterprise data warehouse containing records from CPOE and patient accounting applications. In order to increase size of the "order set" comparison group, outpatient CHF admission orders were pulled into the study, from those cases where patients visited Advocate provider on an outpatient basis, received diagnosis of CHF, and were ultimately admitted at one of the participating Advocate facilities. Under this scenario, the same inpatient hospital CHF sets were utilized for placing orders in advance of patient arrival, so there is not a mix-up of sets introduced to the study via inclusion of outpatients, who ultimately ended up being admitted. Majority of the patients were admitted to the hospital via emergency department or urgent care center. Data was manipulated in Excel to adhere to the following guidelines:

- Adults over the age of 18
- Patients with primary or secondary diagnosis of CHF
- Psych and OB patients excluded

CHF patients were assigned into two comparison groups, accounting for the above inclusion/exclusion criteria. Data was subsequently loaded into SPSS statistical analysis software to conduct statistical analysis. Binary logistic regression with chi-squared option was employed to compare groups in measuring mortality and readmissions outcomes. The Mann-Whitney non-parametric U test of independent samples was utilized to test the null hypothesis for LOS, while One-Way ANOVA was employed to compare the mean LOS scores. The latter two tests were used

for measuring comorbidity. Fisher's Exact was applied as a secondary method of measuring statistical significance, due to small "order set" group sizes.

Low utilization of the order sets in hospitals (around 7% of all CHF orders) is a challenge faced in many CPOE studies. This limits the categories in which statistically significant results can be claimed. In current practice, utilization of order sets is optional, contributing to low percentage of orders placed via sets and the disproportionally large size of the "free text" group. The choice of a method to place CHF orders is in the hands of providers. In this study, the numbers for all participating hospitals needed to be combined in order to produce sufficient data samples. Towards end of the studied date range, one system-wide CHF set was produced and released to all hospitals. All sets were evidence based and approved by clinicians to be available in CPOE for the purposes of treating CHF, with initial content differences not believed to introduce serious concerns regarding validity of outcomes from the study. An example of the content of CHF order set currently utilized at the system level is presented in Table 1.

Table 1. Example of Advocate CHF order set

Component	Order Details
LET Orders	
Code Status	No CPR for Cardiac Arrest
Code Status	Full Code
Admission Orders	
Admit Order	Diagnosis : Congestive Heart Failure
Consults	
Consult Physician	Cardiologist: CHF

Diabetic Calorie Diet	Multiple fluid restriction choices
Renal Diet	Multiple fluid restriction choices
Clear Liquid Diet	Multiple fluid restriction choices
NPO	
Respiratory Therapy	
Respiratory Oxygen PowerPlan	
Respiratory BiPAP/CPAP PowerPlan	

Results

1. ***Mortality***.

The goal of this study was to determine, quantitatively, whether utilization of CHF order sets leads to lower inpatient mortality. All tests were conducted with an assumption of null hypothesis and aimed at testing whether it could be rejected. The binary logistic regression method revealed that 1.8% of patients in the "order set" group died versus 3.2% in the "free text" group, OR = 1.818, 95% CF 1.039 – 3.181, $\chi^2 = 4.516$ ($p = 0.034$). Results were statistically significant. Population N of the "order set" group was 719, while N of the "free text" group was 10219. Due to small size of the "order set" group, a 2-tailed Fisher's Exact was calculated as an alternative to Pearson chi-squared, with statistically significant outcome of 0.04. Patients in the "order set" group, whose medications were ordered via pre-defined sets, had a nearly doubled chance of survival compared to patients in the "free text" group. The null hypothesis for CHF mortality was rejected. Mortality outcomes are summarized in Table 2.

Table 2. CHF mortality as a total for all Advocate hospitals participating in the order sets study

Outcomes and Measures	**Free Text Group**	**Order Set Group**	**Pearson Chi-Squared (χ^2)**	**2-sided Fisher's Exact**	**1-sided Fisher's Exact**	**EXP (B) – Binary Logistic Regression**
Mortality = yes	331	13				
Mortality = no	9888	706				
Percent (Mortality=yes) / total	3.2%	**1.8%**	4.516 (p= 0.034)	0.040	0.022	1.818 [1.039 & 3.181]

2. ***Readmissions.***

Another goal of this study was to determine whether placing CHF orders via sets helped reduce the 30-day hospital readmission rate. As in the mortality examination, statistical manipulations were performed to test the null hypothesis. There was insufficient information on readmissions available in the enterprise data warehouse for this study, and results were not statistically significant. Population N of the "order set" group was 538, while population of the "free text" group was 7583. Order sets made no difference on patients' chances to avoid hospital readmission within 30 days of being discharged with CHF diagnosis. Readmissions outcomes are summarized in Table 3.

Table 3. Readmissions among CHF patients as a total for all Advocate hospitals participating in the order sets study

Outcomes and Measures	Free Text Group	Order Set Group	Pearson Chi-Squared (χ^2)	2-sided Fisher's Exact	1-sided Fisher's Exact	EXP (B) – Binary Logistic Regression
Readmission = yes	1415	108				
Readmission = no	6168	430				
Percent (Readmission =yes) / total	**19%**	20%	0.659 (p= 0.417)	0.424	0.224	0.913 [0.734 & 1.137]

3. ***Length of Stay*.**

Two statistical tests, One-Way ANOVA and Mann-Whitney binary test of independent samples, were employed to address whether application of order sets in the clinical settings can help reduce the length of hospital stay. The mean length of stay among the "order set" group patients was 4.75 days vs. 5.46 days for patients in the "free text" group, indicating that CHF patients who received orders via sets stayed in the hospital almost a day less compared to patients whose orders were placed manually. Population N of the "free text" group was 10219 and 719 in the "order set" group. The One-Way ANOVA test was significant, F(1,10938) = 8.352, p=0.004. The Mann-Whitney test of independent samples for binary values confirmed rejection of the null hypothesis: [U(1,N=10937) = 3,472,652; p = 0.013], indicating the benefit of shorter stay among the "order set" group patients.

Expired patients could have contributed to shorter LOS. In order to adjust for mortality, the same calculations were repeated with expired patients excluded. Results remained consistent, showing shorter LOS for patients in the "order set" group, although the gap between comparison groups has narrowed to still significant 0.63 days compared to nearly a day for all patients: mean 4.76 ("order set") vs. 5.39 ("free text"), with N = 706 and 9888 within these respective groups. The One-Way ANOVA test was significant, F(1,10593) = 7.131, p=0.008. The Mann-Whitney test of independent samples for binary values confirmed rejection of the null hypothesis: [U(1,N=10594) = 3,301,394.500; p = 0.015].

4. ***Comorbidities/Complications***.

The mean CCI score among the "order set" group patients was 3.64 vs. 3.68 within the "free text" group. CCI is a total score attached to each patient encounter in history (where available) that is computed by adding individual weights of complications found in a patient. This score does not indicate whether a patient arrived with some of these conditions or acquired them during hospital stay referenced in the encounter. Population N of the "free text" group was 7232 and 525 in the "order set" group. Per One-Way ANOVA test, results were not significant: F(1,7757) = 0.298, p=0.585. The Mann-Whitney test of independent samples for binary values also failed to reject the null hypothesis, as follows: U(1,N=7757) = 1,840,535.5; p = 0.23. Utilization of CHF order sets did not make a difference on comorbidity rates for CHF patients, and/or pre-existing conditions did not influence health outcomes measured in this study.

Discussion

The process of patient history analysis does not allow utilizing traditional attributes of controlled or randomized clinical trials, such as variable control or manipulation of the order set content. Additionally, most EMR/CPOE applications are not designed with health outcomes research in mind, making it difficult to track patient encounters for search of patterns and causal relationships on an aggregate basis. However, multi-year analysis of large patient history data sets offers a unique opportunity to explore impact of healthcare IT innovations and major CPOE application attributes such as order sets in a community healthcare setting where these tools/interventions are utilized for routine treatments, well beyond a small experimental study with a small number of patients.

The mortality study showed that patients whose medications were ordered using custom selection methods had a nearly doubled chance of death compared to patients who received orders via CPOE sets. Lack of ability to track all causal relationships within patient history from admission to discharge means that other factors possibly influenced mortality outcomes beyond standardization of ordering practices grounded in evidence-based medicine. However, comparison of the "order set" and "free text" groups and statistical significance of the mortality outcome point to the fact that CHF ordering via sets has potentially strong influence on this health outcome. Since results of the comorbidity study that utilized CCI score did not reveal statistical significance, it is reasonable to assume that pre-existing conditions did not affect mortality outcome, although the dual meaning of CCI score could also indicate that ordering via sets did not produce the desired improvement in reduction of post-treatment complications.

The study did not establish statistical link between utilization of CHF order sets and 30-day readmissions. Yet, the length of hospital stay was almost one day shorter for patients in the "order set" group, indicating wide implications of the study for the cost cutting and patient satisfaction improvement efforts – without a corresponding reduction in mortality. Even after mortality adjustment, the difference of 0.63 days for the non-expired patients represents significant outcome to consider. Regression analysis of factors influencing mortality also revealed that order sets play a larger role in predicting the outcome compared to basic demographic factors such as age, sex, and race of the patients. Despite limitations of the study in the areas of factor control, tracking all causal relationships during CHF treatments, and small size of the "order set" group due to low utilization of CHF order sets, results that were statistically significant show potentially strong correlation between evidence-based CPOE ordering practices and CHF health outcomes.

Utilization of the order sets to treat CHF is only one of many factors in the overarching variability of care reduction process aimed at improving quality and reducing cost of treatment. Placing orders in CPOE should not be considered the sole strategy for achieving these outcomes. Other variability reduction methods could include such initiatives as shared governance among clinicians to target specific quality improvement efforts, selection of the most effective evidence-based techniques applicable to treating patient conditions within the context of local culture and clinical settings, making shared decisions on selection and maintenance of the order sets, among other undertakings. Indeed, lack of governance around sets is likely to cause low buy-in, lower core measures compliance, and potentially dangerous side effects from improper bundling of medications and other orders.

Conclusion

In reporting improved mortality and length of stay outcomes, this study contributes to the literature supporting the use of evidence-based prescribing practices in the treatment of CHF patients. These outcomes could lead to patient safety and cost efficiency gains, which, even without reduced readmission rate benefit, are significant for hospitals when reviewing their evidence-based practices, CPOE utilization guidelines, and order set governance efforts. Extensive communication and shared decision-making, resulting in high physician buy-in, are paramount in a clearly defined strategy to reduce variability of care and to enable healthcare facilities to take control over their

prescribing practices. The study also encourages further study leading to more granular approaches to investigation of order set management practices and their effect on patient outcomes.

Abstract

Electronic quality measurement (QM) and clinical decision support (CDS) are closely related but are typically implemented independently, resulting in significant duplication of effort. While it seems intuitive that technical approaches could be re-used across these two related use cases, such reuse is seldom reported in the literature, especially for standards-based approaches. Therefore, we evaluated the feasibility of using a standards-based CDS framework aligned with anticipated EHR certification criteria to implement electronic QM. The CDS-QM framework was used to automate a complex national quality measure (SCIP-VTE-2) at an academic healthcare system which had previously relied on time-consuming manual chart abstractions. Compared with 305 manually-reviewed reference cases, the recall of automated measurement was 100%. The precision was 96.3% (CI:92.6%-98.5%) for ascertaining the denominator and 96.2% (CI:92.3%-98.4%) for the numerator. We therefore validated that a standards-based CDS-QM framework can successfully enable automated QM, and we identified benefits and challenges with this approach.

Introduction

Overview of Clinical Quality Measurement (QM). Delivering quality healthcare is challenging due to ongoing and ubiquitous variation in health system processes that may lead to errors.[1] Measuring and reducing variation from evidence-based clinical best practices have been shown to improve quality and decrease costs of healthcare.[2] Despite multiple efforts undertaken to improve healthcare quality since the publication of the Institute of Medicine's reports entitled 'To Err Is Human'[3] and 'Crossing the Quality Chasm'[4], the quality of healthcare in the United States continues to be compromised by unnecessary variation in the implementation of clinical practice guidelines. Having a means to assess healthcare quality is essential for identifying deviations from evidence-based best practices and mitigating preventable errors.[3] Clinical quality measures are measures of processes, experience, and/or outcomes of patient care. There are increasing mandates and financial incentives to use electronic health records (EHRs) to measure quality as opposed to employing traditional manual processes for QM.[3,4] For example, the Meaningful Use (MU) recommendations issued by the federal Health Information Technology Policy Committee (HITPC) in November 2012 require the implementation of QM as well as decision support for high-priority conditions, and the use of related standards.[4,5] The practice and value of quality measurement has evolved over time. According to Meyer *et al.*, "in the last half century, the US has gone from defining quality, to measuring quality, to requiring providers to publicly report quality measures, and most recently, beginning to hold providers accountable for those results".[6] The National Quality Forum (NQF) was created as a public-private partnership to guide decisions regarding quality measure selection.[7] Until recently, quality measurement has relied mainly on the use of electronic claims data, manual chart abstraction, and patient surveys.[8] Currently, QM is required by public and private payers, regulators, accreditors and others that certify performance levels for consumers, patients and payers.[6] Current quality measurement systems in many hospitals include time-consuming manual paper and electronic record abstraction by a quality improvement specialist.[9,10]

At large academic medical centers such as University of Utah Health Care (UUHC), manual data abstraction is often followed by data analysis by an external organization such as the University HealthSystem Consortium.[11,12] University HealthSystem Consortium is an alliance of 120 academic medical centers and 299 of their affiliated hospitals representing academic medical centers with a focus on quality and safety excellence.[13,14] Manual chart abstraction at UUHC is performed by the Quality and Patient Safety Department, which has 28 employees, including 12 Quality Improvement Specialists.[15] There are several limitations with this process. For example, (a) three to six months may elapse between the time of a clinical procedure (e.g., a surgery) and the time when feedback

is given to a clinician; (b) human errors may be introduced during manual record review; and (c) only a subset of the clinical events is oftentimes selected for review, leading to gaps in quality assessment coverage.

Previous Work in Automating QM. One of the promises of implementing EHRs is the possibility for automatic generation of QM.[10] A MU-certified EHR must be able to export standardized quality reports, which can then "be fed into a calculation engine to compute various aggregate scores".[16] Following these recommendations, major EHR vendors such as Epic have started to integrate QM logic into their products.[17] Currently, however, only some EHR vendors offer quality measurements embedded in their system, and the scope of measures supported is not always comprehensive.[10,17] For example, KPHealth Connect has automated six of 13 Joint Commission measurement sets, and Epic has automated 44 NQF quality measures.[10,17] Vendor-based solutions may offer 'full sample' analysis, but the logic may be a 'black box.' Also, it is not always clear which version of each rule has been implemented or whether the quality measure logic is up-to-date. In addition, users may not have control over the logic to customize quality measurement. Even so, automated QM has the potential to provide quality reports on demand, may avoid human errors in manual abstraction, and can analyze 100% of patient encounters. Most ongoing efforts to produce automated quality measures are tied to a specific EHR system, and the executable logic for the quality measure is not sharable between different EHR systems.[10]

The Problem: Duplicative, Divergent Implementation of QM and CDS. It is intuitively obvious that CDS and QM are highly related, as QM focuses on who is eligible for a needed intervention (denominator identification) and who among them has received the needed intervention (numerator identification), whereas CDS focuses on who is eligible for a needed intervention and has not received the needed intervention (equivalent to numerator identification). However, to the best of our knowledge, there have been limited evaluation and validation in the literature of how technical approaches for one problem space can be re-used in the other, especially for standards-based approaches. This is important, because EHR certification criteria will likely drive much work in this field. It has been suggested that the two could be combined.[18] There have been efforts to combine CDS and QM logic, but the efforts were not standards-based and no conceptual framework was developed.[19,20]

Potential Solution: Leverage a Standards-based CDS Web Service across a Population for QM. Kawamoto *et al.* have previously suggested that a standards-based, service-oriented architecture could be used to make CDS logic sharable between different EHRs.[21] In this study, we hypothesized that this approach could be extended to encompass both CDS and QM given similarities in their functional requirements.

In pursuing this potential approach to CDS-based quality measurement (CDS-QM), a promising resource to leverage is an open-source, standards-based, service-oriented framework for CDS known as OpenCDS.[22] As shown in Figure 1, an EHR system can submit patient data to OpenCDS and obtain patient-specific assessments and recommendations that are provided to clinicians via alerts, reminders, or other CDS modalities.[23] OpenCDS is compliant with the HL7 Virtual Medical Record (vMR) and HL7 Decision Support Service (DSS) standards, and it leverages various open-source component resources, including the JBoss Drools knowledge management platform and Apelon Distributed Terminology System. Theoretically, then, OpenCDS could be used to measure quality as well as provide CDS. Moreover, the use of a CDS-based QM approach could potentially provide advantages for quality improvement compared to traditional approaches. Therefore, the objectives of this study were to: a) identify opportunities to enhance quality improvement using CDS-QM, b) design and implement a CDS-QM approach aligned with candidate CDS standards for Meaningful Use,[24] and c) evaluate the CDS-QM approach for a representative quality measure.

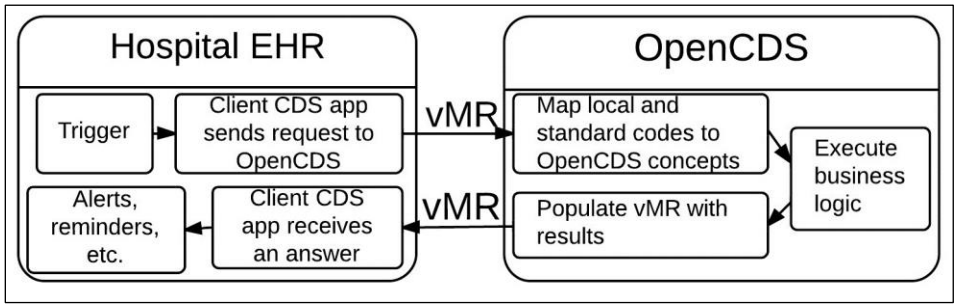

Figure 1. OpenCDS architecture: high-level interaction for CDS

Methods

Identification of opportunities to enhance quality improvement using CDS-QM

We engaged specialists from the Quality and Patient Safety Department to identify strengths and limitations of the CDS-QM approach. We documented the current process of quality assessment and reporting, and interviewed two of the 28 quality improvement specialists to identify possible ways in which the CDS-QM approach could enhance the institution's capabilities related to quality measurement and improvement.

Design and implementation of CDS-QM framework

Functional requirements

For the purposes of this implementation, our requirements were to enable the evaluation of national quality measures across the relevant patient populations in UUHC. The primary requirement was accurate evaluation of quality measure compliance.

Design principles

In designing the CDS-QM framework, a core design principle was *standards-based scalability*, so that the framework could potentially be leveraged in the context of various institutions and information systems. Related to this principle, a second principle was *open availability*, with open-source tooling used as to limit barriers to adoption related to licensing and intellectual property restrictions.

Scope and assumptions

Scope was limited to the analysis of structured data, as opposed to free text data requiring natural language processing. It was assumed that relevant patient data are available, such as in a data warehouse.

Tools and resources

In addition to OpenCDS, we leveraged the open-source Mirth Connect integration engine (v3.0.1). We also leveraged the UUHC data warehouse (DW), which contains data from the EHR systems and other ancillary clinical and administrative information systems at the institution.

Evaluation of CDS-QM approach for representative national quality measure

Quality measure

We chose the Joint Commission's Surgical Care Improvement Project (SCIP) Venous Thromboembolism 2 (SCIP-VTE-2) quality measure to evaluate the CDS-QM approach. This measure was chosen due to its technical complexity and its prioritization by the UUHC Quality and Patient Safety Department. VTE is a major cause of morbidity and mortality in hospitals.[25] In spite of evidence of their effectiveness, VTE prophylaxis by anti-coagulation and/or mechanical compression remains underutilized in US academic medical centers, particularly among surgical patients.[25] SCIP-VTE-2 is a well-established quality measure and is supported by level 1a evidence.[26,27] This measure is used to assess the percent of surgery patients that receive appropriate VTE prophylaxis within 24 hours of surgery.[28] For this evaluation, we implemented the SCIP-VTE-2 quality measure using the logic published for surgeries that occur in 2014 (version v4.2a).[28]

Data Sources

We used clinical data generated by inpatient surgeries that occurred at UUHC in 2013. A total of 8,924 cases were assessed using the CDS-QM automated method. The data elements required by the quality measure logic were documented in multiple source systems, including the inpatient EHR (Cerner) and two systems used to document anesthesia and nursing activities during the surgical event. The University of Utah Institutional Review Board performed an administrative review of this project and determined that IRB approval was not required because this effort was conducted for the purposes of quality improvement and does not meet the regulatory definition of human subject research.

Evaluation/Validation

As a reference standard for validation, we used quality measurement results produced by the University HealthSystem Consortium through an analysis of data extracted through manual chart abstraction by the Quality and Patient Safety Department. The sample used for validation was the 319 surgery cases randomly chosen for abstraction by the University HealthSystem Consortium for the first two quarters of 2013.

As the first step in our analysis, we evaluated the degree to which the data required for the evaluation was available in a structured format in the UUHC DW. Second, we compared the results from OpenCDS with the results from the reference standard approach (manual chart abstraction followed by University HealthSystem Consortium analysis). Observations were classified as true positive (TP), true negatives (TN), false positives (TP), and false negatives (FN) for denominator and numerator criteria separately. We calculated recall (sensitivity) of the OpenCDS-based process as the proportion of cases classified as positive by OpenCDS among the cases classified as positive by the reference standard (TP/(TP+FN)). We calculated precision (positive predictive value) of the OpenCDS-based process as the proportion of cases identified as positive by OpenCDS which was also classified as positive by the reference standard (TP/(TP+FP)). We assessed recall and precision for the classification of denominators, as well as recall and precision for the classification of numerators among cases that met denominator criteria. We also assessed the proportion of cases that yielded a complete match with the reference standard. Exact (Clopper-Pearson) confidence intervals (CI) were estimated for all binomial proportions. Statistical analysis was conducted using SAS version 9.3 (SAS Institute, Cary, North Carolina).

Results

Opportunities to enhance quality improvement using CDS-QM

As shown in Figure 2, the current quality assessment process at UUHC starts with data from the DW about clinical events (in this case major surgeries) being reported to the external quality benchmarking organization (the University HealthSystem Consortium), followed by this organization choosing a sample of surgery cases for manual chart abstraction. The UUHC quality specialists then perform manual abstraction of data from the EHR for the selected records. Finally, the UUHC specialist gives the information back to the external quality organization for summarization and reporting. The entire process from the time of surgery to quality reporting can take up to 6 months.

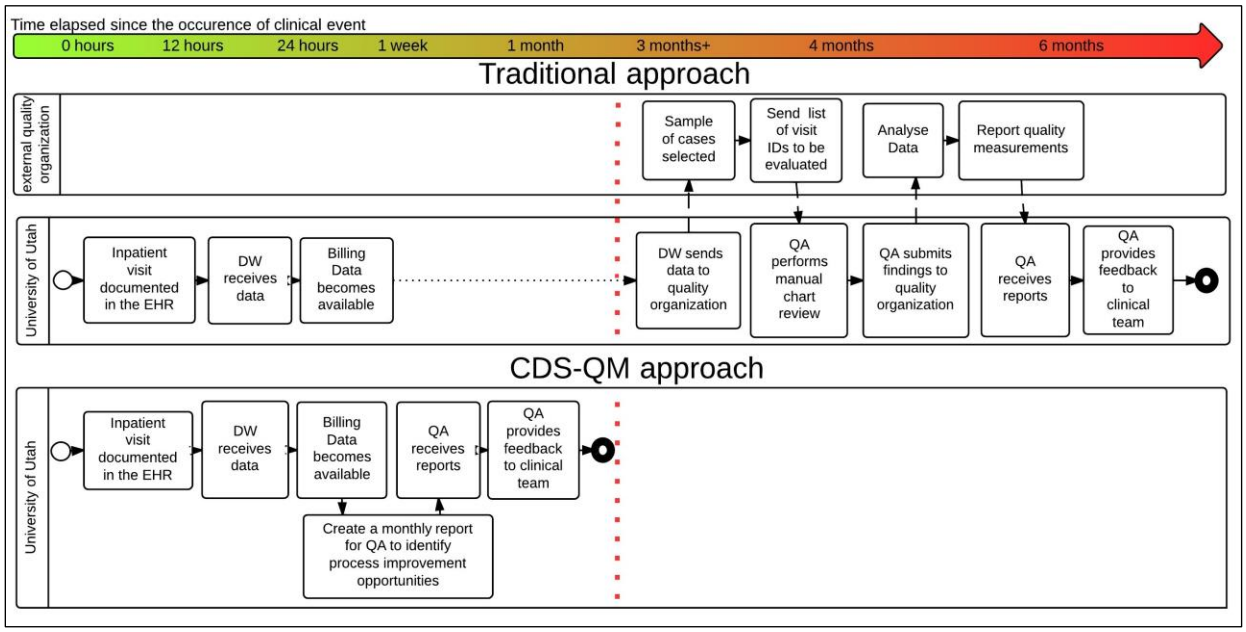

Figure 2. Comparison of traditional and CDS-QM approaches to quality measurement and improvement

Diagramming the traditional process for quality measurement and reporting was useful for identifying several opportunities using the CDS-QM approach to enhance workflow and impact clinical care. The informaticists and specialists with the Quality and Patient Safety Department identified several potential improvements. The automated approach using the CDS-QM strategy could:

- Improve the timeliness and completeness of feedback to the clinical stakeholders. The Quality Department holds monthly meetings with clinical stakeholders. Using the CDS-QM approach, a summary of the quality measure results from the previous month could be made available at these meetings to enable more rapid responses to identified quality deficiencies. The current reporting process allows such quality deficiencies to go unnoticed for potentially many months.
- Improve the completeness of assessment and feedback. While some records may still require manual review due to missing data (see Results), the vast majority of cases can be evaluated in an automated manner, as opposed to the baseline sampling approach. This more complete approach could potentially identify problem areas not yet sampled and therefore not yet identified by the quality team.
- Enable quality and clinical stakeholders to assess the impact of new rules or different versions of rules. This functionality is not available with the current process. At the same time, this functionality is critical for performing longitudinal analysis or for making predictions about future compliance.
- Provide additional useful information. A traditional quality measurement approach only identifies whether patients met denominator and/or numerator criteria. In contrast, the CDS-QM approach allows one to generate intermediate results that may be useful for better understanding the root cause underlying any deficiencies.

Design and implementation of CDS-QM framework

Figure 3 provides an overview of the CDS-QM approach. First, the Mirth Connect interface engine was used to identifying relevant surgery cases for analysis. Second, Mirth Connect was used to sequentially obtain relevant patient data from the DW. Third, the relevant patient data were converted into the HL7 vMR format used by OpenCDS. Then, Mirth Connect transmitted the vMR input data to OpenCDS using the SOAP Web service interface specified in the HL7 Decision Support Service (DSS) standard.

Within OpenCDS, the local and standard codes provided as the input were mapped to the internal concepts used by OpenCDS. The data were then evaluated by executing the relevant OpenCDS knowledge module, and the resulting patient-specific assessments were returned to Mirth Connect as vMR output objects. Finally, DW tables were populated with evaluation results by Mirth Connect.

Human workflows for developing the necessary business logic in Mirth Connect and OpenCDS were developed as well. These workflows involved identifying and characterizing the required input data, creating database queries in Mirth Connect, developing the required terminology mapping files, and developing the data processing algorithms in OpenCDS.

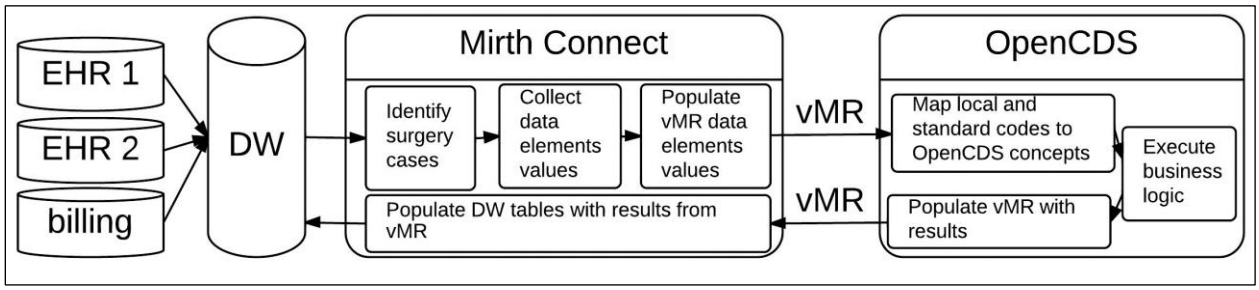

Figure 3. Major systems and processes involved in the CDS-QM approach

Evaluation of CDS-QM approach for representative national quality measure

The NQF-endorsed SCIP-VTE-2 quality measure was automated. Business logic was presented in the OpenCDS Web-based knowledge engineering platform, which uses the JBoss Guvnor platform. Figure 4 shows a sample screenshot from this knowledge engineering platform.

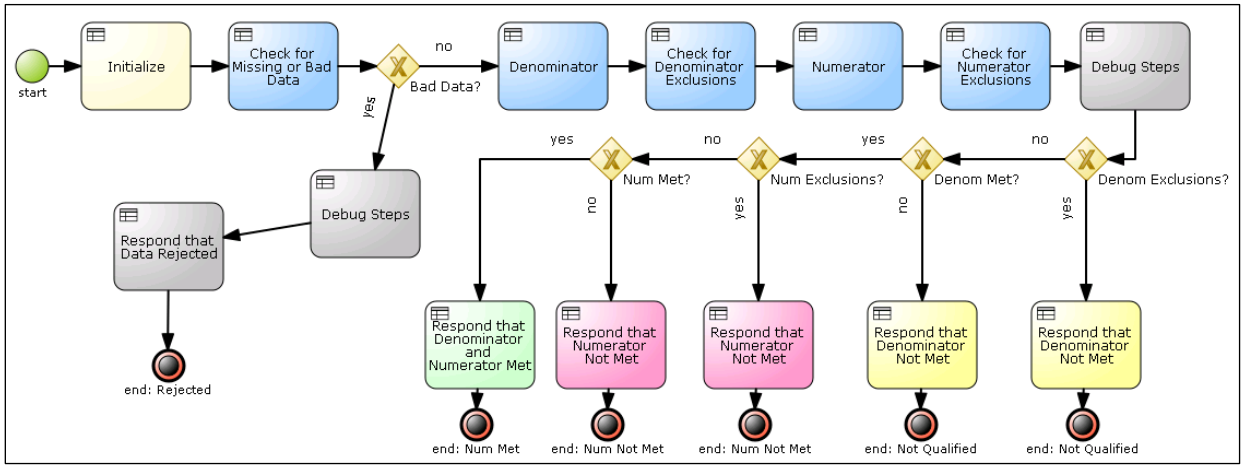

Figure 4. SCIP-VTE-2 Business Logic represented in Guvnor

Mirth queries were able to access all the necessary data elements except documentation about participation in clinical trials and the use of preadmission oral anticoagulant therapies. These two data elements were not recorded in the DW and would require manual review of the EHR text-based records for complete assessment. Among the 319 cases in the reference population selected by University HealthSystem Consortium, 14 did not have complete records stored in the DW and could not be used for automated QM. Completeness of the records was estimated as 95.6% (CI: 92.8%-97.6%). The remaining 305 cases were used to compare OpenCDS results with the reference standard.

When classifying denominators (i.e., identifying cases that should be included for quality measurement), the OpenCDS strategy yielded a recall of 100% (CI: 98%-100%) and precision of 96.3% (CI: 92.6%-98.5%) (see Table 1). A total of 183 cases among the 305 cases selected for review were found to meet the inclusion criteria. The seven cases included in the denominator using OpenCDS but excluded by the reference standard were cases with preadmission oral anticoagulant therapy. These cases were identified by the manual review process but not found by Mirth because the data is not currently saved in the DW.

Table 1. Comparison of the denominator (inclusion/exclusion) classification, using two methods (n=305)

CDS-QM approach (based on automated review using 2014 logic)	**Reference Standard (based on manual review using 2013 logic)**	
	include	exclude
include	TP=183	FP=7*
exclude	FN=0	TN=115

* had preadmission oral anticoagulants

Similarly, when classifying numerators (i.e., identifying cases that failed the quality measure among the 183 cases that met the denominator criteria), the OpenCDS strategy yielded a recall of 100% (CI: 97.9%-100%) and a precision of 96.2% (CI: 92.3%-98.4%) (see Table 2). The seven cases that passed following evaluation of the 2014 version of the SCIP-VTE-2 logic were cases that, in fact, failed according to the 2013 SCIP-VTE-2 specification version of the logic used for the manual review. These seven cases illustrate VTE-prophylaxis practices that were previously considered insufficient, but will be considered sufficient using the 2014 criteria. Thus, a complete match was found for 291 out of 319 records (91.2%; CI: 87.6%-94.1%).

Table 2. Comparison of the numerator (passed/failed) criteria, using two methods (n=183)

CDS-QM approach (based on automated review using 2014 logic)	**Reference Standard** (based on manual review using 2013 logic)	
	passed	failed
passed	TP=176	FP=7*
failed	FN=0	TN=0

* passed using 2014 logic

Discussion

We successfully prototyped an implementation of a CDS-QM-based system and demonstrated its feasibility. This use case demonstrates that, once the quality and CDS standards are fully aligned, the opportunity for meeting both goals using the same approach is quite feasible. We also identified special considerations for QM, such as the need to efficiently obtain and process data for a large cohort of patients, even while evaluation is conducted on a patient-by-patient basis.

As we engaged in the effort with the experts form the Quality and Patient Safety Department, we identified many opportunities to enhance quality improvement using CDS-QM. The currently used and proposed systems could complement one another. A CDS-QM system has the potential to be a cheaper and more efficient alternative to the analysis of quality measures relying on manual chart abstractions. However, it has a high initial cost for translating rules into executable format. Automation of the process of translating the measures into an executable format is a next logical step. Once translated into executable format, the logic can be shared with other institutions, and the logic can be modified to meet clinical needs to assess alternative or future quality measure specifications. The quality experts were particularly interested in the opportunity to apply the new SCIP VTE-2 logic specifications for 2014 to data generated from clinical practice occurring in 2013, which revealed that the new logic would reclassify their previous 'failures' as passing the new quality criteria. If the new logic had the opposite effect, it would be extremely helpful for a quality program to be able to anticipate 'failures' before they get reported six month later, as would occur using the traditional approach of manual abstraction and review by an external quality organization.

The CDS-QM approach is aligned with candidate CDS standards for Meaningful Use Stage 3. Standards proposed for 2015 voluntary EHR specification criteria were used[24]. We were able to use OpenCDS to implement quality measure logic published by the National Quality Forum, and we generated results that were either an exact match or could be explained where differences were observed. Many institutions use SQL queries instead of a CDS-QM approach because it requires less initial effort. However, maintaining an external rules repository is easier than when rules include a direct reference to the EHR or DW data, as there are no dependencies on the local database structure (i.e., the 'curly braces problem').

To maximize benefits from the use of a CDS-QM approach, high-quality structured data are necessary. Validation of the SCIP VTE-2 quality measure implementation using the CDS-QM approach highlighted gaps in documentation and problems with the transfer of information from source systems and the UUHC DW. These findings have been

shared with the DW and EHR teams, and the feedback is being used to improve processes and data being extracted into a surgery data mart. These feedback loops are important for improving data completeness and concordance. For data that was available in the DW, our automated approach shows favorable results compare to other automated approaches. For example, Kern *et al.* report that recall of electronic reporting ranged from 46% to 98% per measure, and precision from 57% to 97%.[29]

The CDS-QM approach may have limitations. Quality measures are often dependent on claims data, which are not usually available in real-time. More analysis is required to evaluate the timeliness of the availability of all the data required to implement quality measure logic. In addition, this study was performed in only one setting and focused on only one rule which may limit the generalizability of the results. However, OpenCDS uses a standard HL7 data model (the Virtual Medical Record), which potentially would allow the quality measurement rules to be implemented across systems. Additional research is necessary to demonstrate the CDC-QM approach in other EHRs and for other institutions.

In the future, we will automate more quality measures and provide additional feedback to the Quality and Patient Safety Department at UUHC, and the output metrics will be incorporated into dashboards that assess the cost and quality of care at UUHC. We are also working on modifying the OpenCDS infrastructure to support population-based queries. Instead of building one vMR at time, we are in the process of assembling thousands of vMRs at the same time. This approach to building vMRs should enable our approach to scale to quality measurement involving much larger patient samples, such as health maintenance measures for the general outpatient population.

Conclusion

In this study, we presented a prototype of the CDS-QM approach which can add value to the traditional quality reporting approaches. The CDS-QM approach allows for full case coverage, prospective use, near real-time evaluation, and is based on standards. The benefits of using CDS-QM include sampling a higher proportion of data, avoiding human error, saving abstractor time, providing more control over measurement rules, and independence from the EHR or other data source systems. To the best of our knowledge, this is the first study illustrating a framework and an approach for using an open-source, system-agnostic, standards-based CDS tool for continuous quality measurement.

A Framework for Incorporating Patient Preferences to Deliver Participatory Medicine via Interdisciplinary Healthcare Teams

Craig Kuziemsky, Ph.D.[1], Davood Astaraky, MSc[1], Szymon Wilk, Ph.D.[2], Wojtek Michalowski, Ph.D.[1], Pavel Andreev, Ph.D.[1]

Abstract

Participatory medicine refers to the equal participation of patients and interdisciplinary healthcare team (IHT) members as part of care delivery. Facilitating workflow execution is a significant challenge for participatory medicine because of the need to integrate IHT members into a common workflow. A further challenge is that patient preferences should be considered when executing a workflow. To date there is limited research on supporting patient workflow as part of participatory medicine practices. To address that shortcoming we used a two-phase approach to develop a framework for participatory medicine that integrates different IHT members and workflows including the incorporation of patient preferences about care delivery options. Our framework uses a domain ontology to define the patient, IHT concepts and relations, as well as a workflow for operationalizing participatory medicine via an IHT. Proof of concept of the proposed framework is illustrated with a palliative care pain management case study.

Introduction

An increased prevalence of chronic illnesses and the identification of the benefits of team-based healthcare delivery are resulting in more care delivery by interdisciplinary healthcare teams (IHTs) [1,2]. One of the big challenges of care delivery via an IHT is integrating the various workflows and information flows of the different IHT members [3]. While models exist for supporting clinical workflows of individual providers, these models are often unsatisfactory when they are scaled up to support IHTs [4,5]. Therefore new approaches are needed to develop distributed models that represent a meso perspective of how clinical workflows and IHTs are integrated as part of care delivery.

Participatory medicine refers to the equal participation of patients and/or their family members and clinical IHT members in decisions about care delivery [6]. Developing solutions to support participatory medicine is largely about supporting distributed IHT workflows; including having the appropriate IHT member profile for specific tasks [6]. Patient participation in care delivery can have great benefits that include reducing adverse events [8], decreasing hospital lengths of stay [9], increasing patient satisfaction, and improving outcomes such as pain management [10]. However it is a challenge to incorporate patient oriented workflows as part of delivery participatory medicine. [4,7].

In theory, health information systems (HISs) are well suited to support participatory medicine via IHTs as they can coordinate the diverse processes and information flows across different IHT members. A shortcoming with existing HISs, however, is that they often focus on individual workflows and not on the distributed workflow that defines an IHT [7,11]. Before we can design HISs to support participatory medicine we need to develop better models of participatory medicine and the distributed workflows that define it [7]. In particular there is a need for models that incorporate patients as active members of an IHT. To date most HIS applications to support patient participation are generic and focus largely on information access and not on how to support patient participation in processes like decision-making. Examples of existing patient participatory applications include healthcare specific applications like 'Patients Like Me' and generic social media platforms like Facebook or Twitter. A new term, "healthicant," has been suggested to describe technology-enabled applications to enable patient participation in their healthcare delivery [12]. HIS design to support "healthicant" activities differs from current patient-participatory applications (i.e. Patients Like Me) in that the focus of HISs needs to be on eliciting patient preferences and using them in the creation and execution of patient-oriented workflows [12].

Although the need for care delivery via IHTs and participatory medicine has been well described there is a lack of frameworks showing how to integrate patient preferences and IHT workflow to deliver such deliver care. Existing models of IHTs are conceptual and does not provide details of how to operationalize them in clinical settings [13]. Moreover most of them focus just on isolated tasks conducted by individual providers [3]. Furthermore there is a shortcoming of frameworks showing how to incorporate patients as part of participatory medicine. Patient participation is a workflow issue for clinicians who are unprepared for the impact that patient participation will have on their workflow [14].

We believe that there are three key areas related to IHTs and participatory medicine that require more research attention. First, we need more formal approaches for developing distributed models of IHTs that support the dynamic integration an IHT and a workflow including assignment of tasks and team leadership and maintenance. Second, we need to incorporate patient preferences into the models to enable true participatory medicine. Third, we need approaches to enable us to operationalize the model in clinical settings. This paper addresses these three research needs by developing a framework for participatory medicine that integrates different IHT members and workflows including the incorporation of patient preferences about care delivery options. We present a two-phase modeling approach to develop a framework for participatory medicine by an IHT that includes patient participation. We then illustrate operationalization of our framework with a case study of palliative care pain management. We conclude the paper with a discussion and implications of our research.

Method

Ontological engineering was used as the research approach for modeling participatory medicine via an IHT. Ontologies formalize knowledge by means of concepts, attributes to characterize them, and relations between the concepts [15]. In ontological engineering a domain ontology, often referred to as a knowledge base, is developed first. Application ontologies are then developed by defining instances of classes from the domain ontology for the purpose of solving specific problems [16]. Ontologies have been used in healthcare for various tasks such as systems design, execution of clinical guidelines and representation of workflow for point of care decision support system design [17, 18]. Ontologies are particularly valuable for modeling concepts that are dynamic or flexible such as healthcare teams [19].

Proposed Framework

We followed a two-phase process to develop a participatory medicine-Interdisciplinary health Team (PM-IHT) framework. In the first phase we developed a conceptual model in the form of a textual description of important concepts needed for modeling an IHT (e.g., team, patient, preferences, and workflow), relations between them, and strategies to operationalize these concepts (e.g., a strategy to form and maintain a team, integrate patient preferences). In the second phase we formalized the conceptual model into a domain ontology and a set of algorithms detailing the operationalization strategies. In the following sections we describe the results from both phases with an emphasis on the domain ontology, as it is the central component of our framework.

The conceptual modeling phase (phase 1) assumes that an IHT manages a patient according to a case-specific workflow. We define a case as a disease or specific trauma that is managed by a workflow. The IHT is formed when the disease specific workflow is identified and patient management starts and is disbanded when the execution of the workflow (and related patient management) is completed. The team has a *leader* responsible for overseeing the execution of the workflow, for handling exceptional situations and for assigning workflow tasks to appropriate team members (i.e., members who are capable of performing the task). Drawing upon the principles of participatory medicine [6], the leader may consult with the patient prior to making any relevant decisions (e.g., selecting a therapy, or selecting a team member). The team has one leader at a time but s/he can change during workflow execution (e.g., at one point a physician might be the leader, while at another this role is transferred to a nurse). Finally, an IHT can be modeled as static entity, where a team is formed and remains in place for the entire workflow, or a dynamic entity, where members are recruited as needed and discharged after the task is executed. Given that care delivery in itself is a dynamic process, our conceptual model employs a hybrid approach where the IHT always has a leader (static approach), while other team members are recruited as needed to execute tasks from the workflow and then are dismissed from the team after task completion (dynamic approach). However, it is important to stress here that the leadership role is static but the team member assigned to this role can change.

Phase 2 formalizes the conceptual model into a domain ontology that serves as the PM-IHT framework (Figure 1). The framework can be divided into three areas that define the concepts and relations associated with the team, patient and workflow respectively. These three areas are not mutually exclusive but rather there are two concepts, *valued capability* and *presentation,* that are shared between the three areas. The concept of valued capability is fundamental for our framework. It couples a capability, understood as an ability to perform a certain clinical task [20] (e.g., ability to conduct a particular assessment), with an additional score that indicates the competency associated with this capability (for example, it may correspond to the level of clinical expertise). The other shared concept, presentation, represents any presenting complaint by the patient (e.g., a disease, symptom, or other problems).

We now describe each of the three main areas (team, patient, and workflow) of our PM-IHT framework.

Team-related Concepts and Relations

Team-related concepts are *team,* representing an IHT, and *practitioner,* representing any care provider (physician, nurse, pharmacist, dietitian, etc.) who is a member of the IHT. Practitioners are characterized as having valued capabilities, which provides the fine-grained description that is necessary to allocate team members to tasks [20]. The team manages a patient case with a certain presentation by executing a workflow specific for this presentation. The workflow is formed upon the patient's arrival and dissolved once the execution of the workflow has been terminated. Team members – practitioners – are recruited dynamically based on their valued capabilities (see the description of the workflow-related concepts below) and dismissed after they have completed their delegated tasks.

The team has a leader who is responsible for considering and following the patient's preferences when executing a workflow, for delegating tasks to team members, and for handling exceptional situations (e.g., inability to reconcile patient preferences). The leader is appointed just after forming the team and the leadership may change throughout the workflow execution depending on the requirements prescribed in the workflow (see the description of workflow related concepts below).

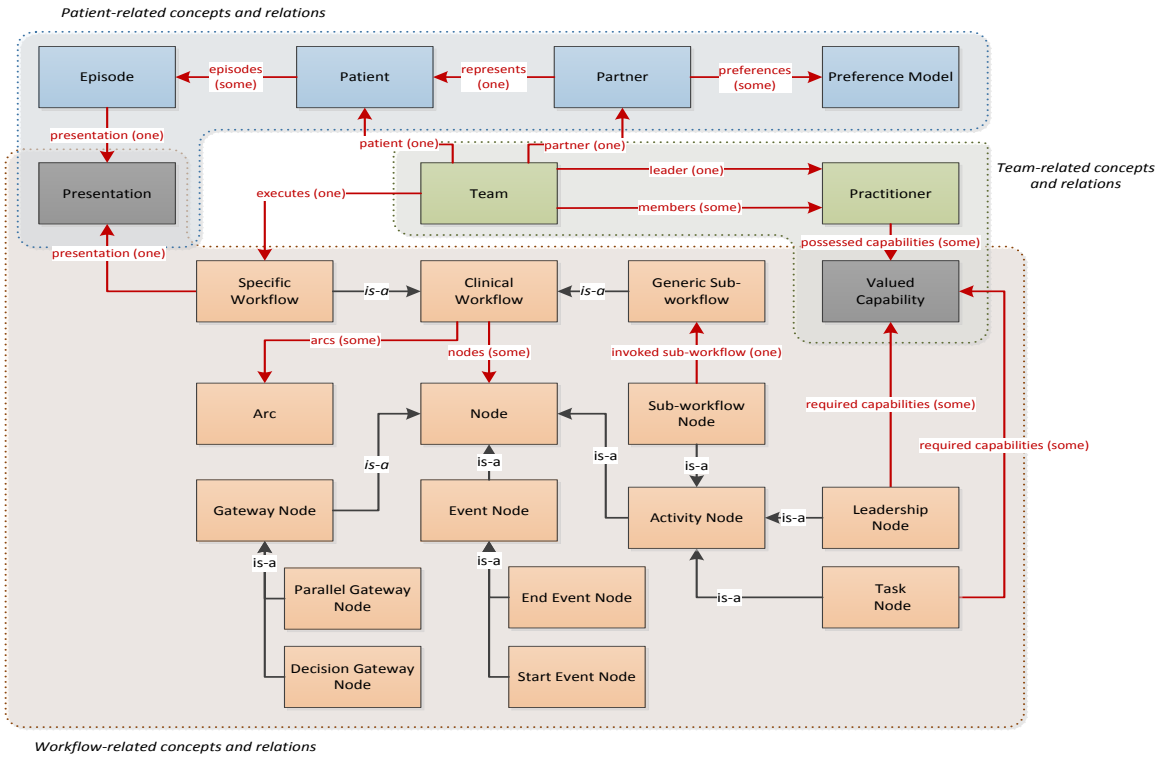

Figure 1. Domain ontology for the PM-IHT framework

Patient-related Concepts and Relations

The patient-related concepts include *patient*, *partner*, *preference model,* and *episode*. The first two concepts complement each other – patient represents a receiver of care and "provider" of clinical data (associated with an episode of specific presentation), and a partner represents the patient as an active participant in all decision-making activities that affect care delivery. The partner concept is crucial from the perspective of participatory medicine.

A partner has one or more preference models that are consulted before making various types of decisions (e.g., selecting a specific intervention among different possibilities). While there are different approaches to represent preference models, we advocate using functional models with additive value functions. Such models are well established and widely used in clinical practice in the form of various score or measures. A drawback of functional preference models is the difficulty associated with their elicitation. However, several methods, e.g., GRIP [21], have been proposed to construct such models from examples of decisions in order to structure relevant preferences.

In terms of interactions between the partner and the team, it is the leader who is responsible for communicating with the partner, presenting possible decision options, and capturing suggestions. More specifically, before recruiting any new team member, the leader presents eligible candidates to the partner who applies the preference model to identify the most preferred one. Moreover, wherever a task involves any decision-making related to the patient (e.g., selecting a therapy or a procedure), the available choices are communicated by the leader to the partner who consults a preference model in order to identify the best choice.

While in most cases the patient and partner is the same person, there are situations where it necessary to have a distinction between the two concepts because they may be two different people. For example, during the care of a pediatric patient it is parent or guardian who becomes the partner. In palliative care it may be a family member who is the partner if the patient is too ill or otherwise unable to make a decision. Thus, separation of these two concepts allows us to employ the principles of participatory medicine regardless of circumstances.

Workflow-related Concepts and Relations

The workflow-related concepts and relations between them have been inspired by Business Process and Model Notation (BPMN) [22]; however, they have been expanded to address the specificity of IHTs and participatory medicine. The central concept is *clinical workflow* that is specialized into *specific workflow* and *generic sub-workflow*. The former represents a "top-level" workflow that is associated with a specific presentation that is executed upon arrival of a patient with this presentation. The latter is a generic workflow (i.e., not associated with any presentation) that may be invoked by other workflows as a supporting workflow.

Each clinical workflow is composed of *arcs* and *nodes*, so it can be seen as a directed graph. The node concept is specialized into a *gateway node*, *event node* and *activity node*, depending on its purpose. The gateway node is further specialized into *decision gateway node* and *parallel gateway node*, which allows for conditional branching and parallel paths respectively. Event nodes are used to indicate starting and ending nodes in a workflow (via *start event node* and *end event node*). Finally, an activity node is specialized into *task node*, *sub-workflow node* and *leadership node,* corresponding to the three types of basic activities in a workflow – executing a clinical task, invoking a sub-workflow, and appointing the team leader, respectively. A clinical task can be delegated to a single practitioner who satisfies a requirement specified in terms of valued capabilities. Such a requirement is defined by associating valued capabilities with a task node. A practitioner has to possess all the required capabilities and his/her competency scores of possessed capabilities should be equal or better than competency scores of the required capabilities. The same mechanism for specifying and checking requirements is applied to leadership nodes – the only difference is that selection of the leader has a more permanent nature as the selected leader is retained until the next leadership node is encountered. Moreover, if a new leader is appointed in an invoked sub-workflow, the previous leader is retained and restored once the sub-workflow has been completed. As we explained above, the leader is selected after forming the team and the team has to have a leader at all times. This is achieved by introducing at least one leadership node into a workflow right after the start event node.

Case study: Palliative Care Pain Management

We used a case study of a palliative care pain management derived from a local palliative care unit. Palliative care aims to improve quality of life of patients and their families through the prevention and relief of suffering by means of early identification and assessment and treatment of pain and other symptoms including physical, psychosocial, and spiritual symptoms [23]. Palliative care is well suited for illustrating the interplay between participatory medicine, workflow execution, and patient management because a basic tenet of palliative care is that patients (or family members) are involved in care decisions and processes that implement decisions.

Pain management is a significant component of any palliative care management protocol as it is estimated that up to 70% of advanced cancer patients experience pain [24]. Pain in palliative care patients is complex and can include physical, spiritual, and psychosocial dimensions [25]. These different dimensions necessitates that palliative care be delivered by an IHT composed of palliative care physicians, psychologists, physiotherapists, nurses, and occupational therapists, among others [26]. The complexity of palliative pain also means that there is a range of possible pain management therapies (i.e. medical, spiritual, psychological) depending on the type and level of pain. A key aspect of palliative care pain management is that patient therapeutic preferences need to be incorporated into the decision-making and subsequent delivery of care services. For example, some patients prefer no pain and are willing to accept the side effects of opioid medications (e.g. drowsiness) to achieve that outcome. Other patients prefer to spend quality end of lifetime with family and friends and would prefer therapies that combine opioid and non-pharmacological therapies in order to manage drowsiness. Thus palliative care pain management needs to be tailored to the preference of each individual patient [27].

The process of palliative care pain management starts with assembling a palliative care team according to the framework presented earlier in order to execute the appropriate workflow. Drawing on existing pain management guidelines [25, 28] and in consultation with domain experts, we developed a set of workflows (a specific workflow and several sub-workflows) to sequence and structure all activities associated with assessing, diagnosing, and managing a palliative care patient's pain. Figure 2 shows a specific (top-level) workflow and selected sub-workflows. We used a standardized notation inspired by BMPN (Business Process Model and Notation) [22] to represent the workflows. In order to distinguish between particular types of activity nodes (represented as rounded rectangles) we use colors – sub-workflow nodes are white, task-nodes are light grey, and leadership nodes are dark grey. All task and leadership nodes are associated with required valued capabilities with competency scores expressed on the Likert scale (1 indicates the competency of a beginner/resident, 2 – the competency of a staff clinician, and 3 – the competency of an expert). The competency scores (and also the valued capabilities in table 1) are for the illustrative purposes only. They were determined from the pain management guideline in consultation with the palliative care clinicians consulting us on this research. Finally, we use the "consult with partner" tag to highlight the task nodes where the partner's preferences need to be incorporated and reconciled.

Patient management starts with the task of establishing an IHT leader who possesses the capabilities specified in the workflow. An initial assessment of the patient's condition follows. Completion of this activity requires executing an assessment sub-workflow that involves clinical and psychosocial and assessments and pain evaluation. While clinical and psychosocial assessments are tasks to be completed by appropriate team members (therefore they are ascribed with the required valued capabilities that control recruitment and selection of practitioners), pain evaluation is guided by a separate sub-workflow. This sub-workflow involves pain evaluation using the PQRST (provoking, quality, region, severity, and timing) pain evaluation tool for pain classification [29]. Once the initial assessment is completed, execution of the workflow continues. Palliative care pain management is an ongoing process that involves frequent reassessments and adjustments of the therapies in response to changing state of the patient [28]. The workflow terminates when therapy is no longer revisable and a new therapeutic workflow is needed.

In order to illustrate the versatility of the proposed framework, we will use two examples showing how the IHT is operationalized. One example involves the transition of a leader role, and the other illustrates how a partner's (patient, family member, etc.) preferences are explicitly taken into account when the therapy-planning task is executed.

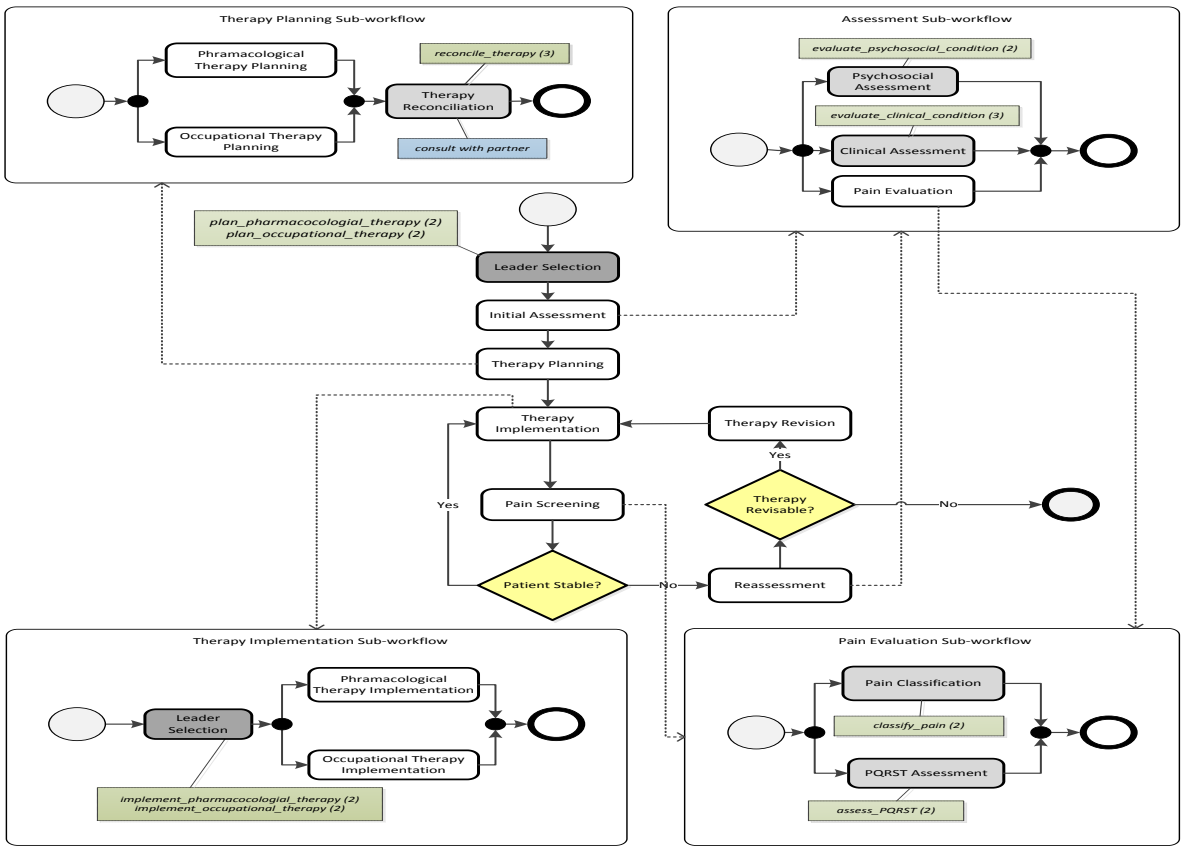

Figure 2. Overall IHT workflow for palliative care pain management (scores in brackets are competency scores for the task)

Example 1: Dynamic Selection of the Team Leader

Table 1 provides information about the practitioners who could be IHT members executing the palliative care workflow from Figure **2**. At the outset of palliative care pain management, a team leader is identified that is capable of planning the pharmacological and occupational therapies (i.e. the leader is chosen based on the competency scores ascribed to the tasks in Fig 2).

Table 1. Team members and possessed valued capabilities

Practitioner	**Possessed valued capabilities**
Palliative care physician	*access_PQRST* (2) *classify_pain* (2), *evaluate_clinical_condition* (3) *reconcile_therapy* (3) *plan_pharmacological _therapy* (3) *plan_occupational therapy* (2)
Clinical nurse specialist	*assess_PQRST* (3) *classify_pain* (3) *evaluate_clinical_condition* (2) *evaluate_psychosocial_condition* (2) *implement_pharmaceutical _therapy* (2) *implement_occupational _therapy* (3)
Nurse practitioner	*evaluate_clinical_condition* (1) *implement_pharmaceutical _therapy* (2) *implement_occupational_therapy* (1)

According to the data from Table 1, the only practitioner who meets the leadership requirement is a palliative care physician, who therefore becomes the team leader. The leadership remains unchanged until the therapy implementation sub-workflow needs to be executed. At that time new leadership requirements are encountered and in this case a clinical nurse specialist becomes the IHT leader. Once the therapy implementation sub-workflow is completed, the leadership goes back to the palliative care physician.

Example 2: Considering Partner's Preferences in Therapy Planning

Participatory medicine advocates that a patient is an active participant in decision-making and care plan development. According to the IHT framework presented in the paper, we incorporate the tenet of participatory medicine through the concept of a "partner" – who can be a patient, family member, or legal custodian. We illustrate how patient preferences interplay with a tasks' execution by the practitioners by using an example of therapy planning for pain management (specifically we focus on the therapy reconciliation task).

The patient's pain was assessed and determined to be in step 1 on the WHO Analgesic Ladder [30]. This corresponds to an assessment of a mild to moderate pain that should be managed with non-opioid analgesics, possibly combined with an adjuvant such as anticonvulsant or antidepressant medication. Assessment of the patient's psychosocial and clinical condition identified the possibility of combining pharmacological management with a non-pharmacological approach for pain management. The following three therapeutic options were identified by the IHT: (1) a standard therapy, (2) a therapy with alternative route of administration (transdermal) and (3) a less frequently applied therapy using cannabinoids (they have been demonstrated to have significant analgesic properties, but also are associated with a number of side effects like dizziness or nausea). The three therapies are given in detail in Table 2.

Table 2. Identified therapeutic options

	Pharmacological	**Adjuvant**	**Non-pharmacological**
Therapy 1	Acetaminophen administered orally	Antidepressant medication	Superficial heat & cold method
Therapy 2	NSAID with transdermal administration	Antidepressant medication	Guided imagery
Therapy 3	Cannabinoids by oral mucosal spray	None	None

The patient preference model for therapy selection in this particular case was constructed using the Generalized Regression with Intensities of Preferences (GRIP method) [21]. First, possible therapy options were characterized using two criteria: complexity of a therapy and associated drowsiness. The complexity of a therapy was defined by the compliance burden associated with this therapy – for example, a therapy that involves taking one dosage of medication per day has low complexity, while a therapy that involves multiple doses using different modes of administration has high complexity. Then, we elicit patient preferences by asking a patient to compare pairs of possible therapies. Once this preferential information is collected, it is processed by GRIP to calculate the so-called marginal value functions for the patient. These functions represent patient preferences associated with individual criteria (there is a separate function for each criterion) and constitute the patient preference model (see Table 3). It includes two marginal value functions (complexity and drowsiness), each represented as a set of numerical scores (marginal values) for all possible evaluation criteria. Higher marginal values are preferred by the patient. The patient preference model shows that the patient prefers therapies of low complexity that cause minimal drowsiness.

Table 3. Patient preference model for assessing therapies

Complexity		**Drowsiness**	
Evaluation	Marginal value	Evaluation	Marginal value
low	0.4	minimal	0.6
medium	0.2	moderate	0.2
high	0.0	maximal	0.0

The patient preference model not only gives insight into patient preferences, but it can be also used to evaluate therapies according to these preferences. The overall value of a therapy is computed by adding the marginal values

for each individual criterion. The best therapy would get the overall value of 1.0, while the worst one would get a value of 0.0. The preference model is then used to assess the potential therapies (see Table 2). Table 4 presents the evaluations for each therapy for the two criteria, as well as the overall value. Based upon the patient's preferences, therapy 3 is the most preferred therapy (overall value of 1.0) - it involves just one medication type, is simple to administer, and also causes minimal drowsiness. Therapy 3 is therefore selected to manage the patient's pain.

Table 4. Assessment of identified therapies

	Complexity	**Drowsiness**	**Overall value**
Therapy 1	medium	moderate	0.4
Therapy 2	low	moderate	0.6
Therapy 3	low	minimal	1.0

Discussion

While participatory medicine is a common healthcare objective there is a shortcoming of studies that illustrate how to operationalize it through an IHT. Further, despite calls for patient centered workflows there is a dearth of studies showing how to implement them in clinical settings. In this paper we presented a framework for IHTs that integrate multiple workflows to support participatory medicine that includes patient participation. The novelty of our research lies in the detail we provide on how the IHT is assembled for a particular situation. A patient's presenting condition drives the creation of a workflow specific for that presentation. We then use the notion of capabilities and competencies to assign IHT members to tasks as part of the workflow. We also assign an IHT leader role to the workflow that is responsible for considering and incorporating patient preferences into the workflow and for delegating tasks to IHT members based upon capabilities. Finally, we define a series of patient related concepts that enable the active incorporation of patient preferences into the IHT workflow. A preference model was developed to formalize the potential options to enable the patient or family member to make an informed decision about their preference.

To date much of the work on IHTs has focused on specific activities such as information seeking or group decision-making. However an IHT is not a set of isolated tasks but rather a distributed workflow that needs to integrate IHT members and task capabilities during workflow execution. IHT workflow is also very dynamic and a key part of workflow execution is coordinating team members to be in the right place at the right time to enable timely completion of workflow tasks and re-scoping of workflow if patient preferences change. Our framework provides the means of coordinating IHT members (through team leaders, capabilities and competencies) as well as re-tailoring the workflow if patient preferences change.

Our framework has implications for HIS design to support participatory medicine. A shortcoming of existing HISs is that they do not assume team-based management or allow for incorporating patient preferences, and therefore are not designed to support participatory medicine. The first step in HIS design is requirements definition and development of a conceptual model to drive HIS design. Our framework provides such a foundation by first developing a conceptual model of patient and IHT support as part of operationalizing participatory medicine. In phase 2 we formalize the conceptual model into an ontology that describes the concepts, relations, and workflows for participatory medicine. Two specific contributions from our framework are one, an attempt to implement participatory medicine principles by explicitly accounting for patient's preferences and two, the dynamic alignment of an IHT and a workflow, including support for assignment of tasks to practitioners, team leadership, and team maintenance. A key factor in HIS design to support participatory medicine is that system design cannot be done with a one size fits all mindset. IHT composition and the workflows that support it are dynamic and may change according to patient preferences. A key aspect of our model is that it enables a HIS to be designed to enable run time agility to support the dynamic nature of IHTs (i.e. leadership changes, evolving tasks) as part of implementing participatory medicine.

The next step in our research is translating our framework into a prototype multi-agent system (MAS). This will be done in two stages. First we first we assume that the practitioners are represented by the agents. Second, we will use the domain ontology (fig. 1) and follow ontology-driven design combined with O-MaSE [18] to design a prototype participatory medicine HIS. The HIS will be implemented using Workflows and Agent Development Environment (WADE) [31] for workflow execution.

In this paper we provided methodological foundations of our framework and illustrated them with a case study of palliative care pain management. We discussed how our framework enabled selection of team leader and how participatory medicine principle of patient involvement was explicitly modeled through inclusion of a "partner" team member and a preference model. While the research presented in this paper is illustrated using a specific case study of palliative care pain management, the proposed modeling framework is applicable for supporting other patient management situations involving IHTs.

Conclusion

There is an increasing body of knowledge calling for care delivery via participatory medicine that includes patient participation. However there are few studies that provide the means of operationalizing the workflow to deliver patient engaged participatory medicine. This paper provides a framework of how to operationalize participatory medicine, including patient preferences, via an IHT. Our framework can be used to design and evaluate informatics solutions for supporting participatory medicine.

Medical Alert Management: A Real-Time Adaptive Decision Support Tool to Reduce Alert Fatigue

Eva K. Lee, PhD [*,1,2,3], Tsung-Lin Wu, PhD[1,2,3], Tal Senior, RN[4], James Jose, MD[4]
[1]Center for Operations Research in Medicine and HealthCare, [2]NSF I/UCRC Center for Health Organization Transformation, [3]Industrial and Systems Engineering, Georgia Institute of Technology, Atlanta, GA, [4]Children's HealthCare of Atlanta, Atlanta, GA

Abstract

With the adoption of electronic medical records (EMRs), drug safety alerts are increasingly recognized as valuable tools for reducing adverse drug events and improving patient safety. However, even with proper tuning of the EMR alert parameters, the volume of unfiltered alerts can be overwhelming to users. In this paper, we design an adaptive decision support tool in which past cognitive overriding decisions of users are learned, adapted and used for filtering actions to be performed on current alerts. The filters are designed and learned based on a moving time window, number of alerts, overriding rates, and monthly overriding fluctuations. Using alerts from two separate years to derive filters and test performance, predictive accuracy rates of 91.3%-100% are achieved. The moving time window works better than a static training approach. It allows continuous learning and capturing of the most recent decision characteristics and seasonal variations in drug usage. The decision support system facilitates filtering of non-essential alerts and adaptively learns critical alerts and highlights them prominently to catch providers' attention. The tool can be plugged into an existing EMR system as an add-on, allowing real-time decision support to users without interfering with existing EMR functionalities. By automatically filtering the alerts, the decision support tool mitigates alert fatigue and allows users to focus resources on potentially vital alerts, thus reducing the occurrence of adverse drug events.

Introduction

Much research has been performed on prescribers' views on alerts and their reasons for overriding alerts, such as Hsieh et al. 2004 for drug allergy alerts, Grizzle et al. 2007 and Ko et al. 2007 for drug-drug interaction alerts, and Shah et al. 2006 and Van der Sijs et al. 2006 for multiple types of alerts.

Too many alerts and too many alert overrides could lead to alert fatigue, which could threaten patient safety. Some research focuses on improving the specificity of alerts to reduce inappropriate alerts. Hsieh et al. (2004) studied characteristics of drug allergy alert overrides and made specific recommendations for increasing the specificity of alerting. Shah et al. (2006) suggested making the least severe alerts non-interruptive, not requiring a user action. Van der Sijs et al. (2008) interviewed prescribers about turning off frequently overridden drug-drug interaction alerts, finding that most of them wanted to reduce alert overload but they did not agree on which alerts could be safely turned off. Seidling et al. (2009) deduced the upper dose limits for statins from pharmacokinetic studies, incorporating dosage checking into alerts for dose-dependent drug-drug interaction alerts. Lee et al. (2010) designed a decision-learning framework to consistently identify override alerts, which could be filtered automatically to reduce alert fatigue. Riedmann et al. (2011) comprehensively studied factors which could be used to prioritize alerts in order to present them adequately. Twenty factors were identified and grouped into three categories: organization unit, patient/case, and alert itself.

This paper extends the study from Lee et al. (2010). In the previous study we built filters from three criteria to decide which alerts could possibly be automatically turned off or become non-interruptive. The

three criteria include (1) number of alerts, (2) override rate, and (3) range of monthly override rate. The effect of the filters was validated by applying them to real datasets. In this study we propose to use a moving time-window to build the filters for real-time adaptive decision support. We also analyze the effectiveness of the criteria via linear regression.

Methods

Based on the alert datasets from Children's Healthcare of Atlanta (CHOA), we focus on three types of alerts: dose alerts, drug allergy alerts, and drug-drug interaction alerts. Drug allergy alerts consist of four severities: level 1, 2, 3, and 4. Drug-drug interaction alerts consist of three severities: moderate interaction, severe interaction, and contraindicated drug combination. We sort out drugs or interactions under each alert type and severity. The filter is built on four criteria: (1) number of previous months used for training (size of time window), (2) number of alerts, (3) override rate, and (4) range of monthly override rates. We implement moving time-windows for continuous learning of the cognitive overriding decision of users. Specifically, to filter the alerts of the current month, alert data and their associated user decision patterns from a specified number of previous months serve as the training set to establish the filter decision rule. Such a dynamic design is both intuitive and appealing as it captures users' decision characteristics from previous months to help predict the alert action at the current time. For each drug/interaction, the automatic filter is established via the following criteria on the training set:

- the total number of alerts is greater than or equal to a threshold,
- the overall override rate is greater than or equal to a threshold, and
- the range of monthly override rates (i.e., the difference between the maximum and minimum monthly override rates) is less than or equal to a threshold.

The filtered drug/interaction is considered most likely to be overridden by users based on previous patterns and the nature of the drug alert.

To evaluate the predictive accuracy and effectiveness of each of the filtering criteria, we contrast the results against filters that are established via i) static time-window prediction; ii) a time gap between training set time to the blind prediction set; and iii) regression confidence interval analysis.

Medication order alert data and their override patterns by providers from CHOA are used to validate and test our methodology. The data cover January to September 2009 and January to July 2011, and include only unfiltered alerts output by the EMR system. These alerts require manual review and actions by providers. Using moving time-windows, we build the filter for each month based on previous months. Table 1 shows the total number of unfiltered drugs/interactions for different alert types and severities as obtained from the EMR system. Table 2 shows the total number of unfiltered alerts in different months based on alert types. The last row in Table 2 reports the percentage of unfiltered alerts that were eventually overridden by the providers.

Table 1: Number of drugs/interactions in different alert types and severities

Alert type	Severity	Number of drugs/interactions
Dose alert	N/A	851
Drug allergy alert	Level 1	110
	Level 2	48
	Level 3	206
	Level 4	89
Drug-drug	Moderate interaction	184

interaction alert	Severe interaction	130
	Contraindicated drug combination	37
Total		1655

Table 2a: Number of unfiltered alerts for the period January to September 2009

Alert Type	2009								
	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep
Dose	1330	1382	1396	1323	1301	1344	1334	924	1213
Drug Allergy	580	604	585	499	463	492	549	575	682
Drug-Drug	892	1021	1178	1075	1141	892	1091	877	969
Total	2802	3007	3159	2897	2905	2728	2974	2376	2864
% overridden	65.8%	63.2%	63.5%	59.6%	64.7%	65.4%	63.9%	73.6%	74.6%

Table 2b: Number of unfiltered alerts for the period January to July 2011

Alert Type	2011						
	Jan	Feb	Mar	Apr	May	Jun	Jul
Dose	8516	8747	9878	8811	9174	8903	8736
Drug Allergy	1360	1349	1619	1281	1465	1403	1437
Drug-Drug	1293	1238	1453	1642	1305	1335	1260
Total	11169	11334	12950	11734	11944	11641	11433
% overridden	77.9%	79.1%	77.4%	77.1%	76.2%	76.8%	75.0%

There is a significant difference in the number of unfiltered alerts between these two periods as the hospital expanded the EMR alert system to cover more units. , In addition, clinical staff performs regular review and adjusts EMR alert parameters to reflect current clinical practice guidelines, thus resulting in different levels of alert reporting. . For those alerts being fired out (unfiltered), providers must review each of them manually and carefully to determine if the prescribed action is appropriate or if other actions should be taken. Those for which the current prescribed action is deemed appropriate result in alerts being overridden. Those that are not overridden require that providers take additional and/or alternative action. Reviewing all alerts can be a tedious and time-consuming task. Alert fatigue has been documented and reported on in numerous studies and can be detrimental to clinical outcome. Hence, a decision support system that can identify and appropriately handle non-essential alerts is critical because it enables providers to focus on vital ones and make proper decisions.

Results

In this section we describe a test implementation of our methodology at CHOA, a network of three pediatric hospitals in Atlanta, Georgia, which serves over half a million patients annually.

Predictive Performance of the Time Window Adaptive Filters

We consider the following criteria to construct filters:

a) *Time-Window*: Size of time window = 2, 3, 4, 5, 6 months
b) *Number*: Number of alerts ≥ 20, 30, 40, 50, 60
c) *Rate:* Override rate ≥ 90%, 92%, 94%, 96%, 98%
d) *Range*: Range of monthly override rates ≤ 10%, 12%, 14%, 16%, 18%

As an example, we use alert data from January and February 2009 for training (thus, size of time window is 2 months) and choose the number of alerts to be at least 20, with override rate of at least 90%, and override rate range to be within 10% to construct a filter, *Filter1*. *Filter1* is then applied to the March 2009 alerts, resulting in ten drugs/interactions being filtered. Figure 3a shows the type of alerts being filtered versus the actual action by the providers. Those filtered by us and overridden by providers are true negatives (that is, these are non-essential alerts). Those not overridden by providers but filtered by us are false negatives. All unfiltered alerts are reviewed manually by providers.

Counts of alerts (and associated percentages) filtered by us versus counts of alerts overridden by providers are shown in Table 3b. Of those that are manually overridden by providers, we filter 22.5% of them. Such automatic filtering can save precious time, enabling providers to tend to other important patient care issues. Of those alerts that are not overridden by providers but are filtered by us, we commit a 3.5% error. There may be serious medical implications to these errors. We pursue two actions to correct such errors: a) *adaptive learning* to incorporate these alert contents within our filtering algorithm; b) second-layer filtering with inclusion of patient risk factors to enrich our filtering algorithm's predictability. From Table 3b, we note that the predictive accuracy of this filter is 91.9% (452/(452+40)) . This high value indicates that if an alert is filtered (by our algorithm), there is a high level of confidence that the filtering result is correct in predicting the actions of the providers.

Table 3a: Drugs/interactions from March 2009 alerts that are filtered by *Filter1*.

Type	Severity	Drug name	Providers' actions	
			Overridden #	Non-overridden #
Dose	(N/A)	CHLOROTHIAZIDE SODIUM	2	1
Dose	(N/A)	FOSPHENYTOIN	8	0
Dose	(N/A)	KCL	120	11
Dose	(N/A)	ROCURONIUM	2	0
Drug-Allergy	Level 3	INSULIN REGULAR HUMAN	0	0
Drug-Allergy	Level 3	MORPHINE SULFATE	16	6
Drug-Drug	Severe Interaction	CYCLOSPORINE/AZOLE ANTIFUNGAL AGENTS	71	1
Drug-Drug	Severe Interaction	KETOROLAC / ANTICOAGULANTS	204	12
Drug-Drug	Severe Interaction	LAMOTRIGINE / VALPROIC ACID	18	1
Drug-Drug	Severe Interaction	METHOTREXATE / PENICILLINS	11	8
		Subtotal	452	40

Table 3b: Filtered alerts and associated rates for *Filter1* on March 2009 alerts

Filtering results / Providers' action		Counts		Percentage	
		Filtered by us (negative)	Not filtered by us (positive)	Filtered by us	Not filtered by us
Counts	Manual Overridden (negative)	452	1555	22.5% (*Specificity*)	77.5% (*False positive rate*)
	Non-overridden (positive)	40	1112	3.5% (*False negative rate, FNR*)	96.5% (*Sensitivity*)
Percentage	Manual Overridden (negative)	91.9% = 452/(452+40) (Negative	58.3%		

		predictive value, *NPV*)	
	Non-overridden (positive)	8.1%	41.7%

Table 3c: Predicted results of *Filter 1* -- *Time-Window*=2, *Number*≥20, *Rate*≥90%, *Range*≤10%

Predicted month / Metrics	2009							2011					Average
	Mar	Apr	May	Jun	Jul	Aug	Sep	Mar	Apr	May	Jun	Jul	
Specificity (% of overridden alerts filtered by us)	22.5%	30.4%	30.9%	33.1%	31.8%	30.3%	17.7%	14.5%	18.0%	20.6%	24.8%	26.3%	25.1%
FNR (% of non-overridden alerts filtered by us)	3.5%	4.4%	3.7%	2.3%	4.1%	7.5%	3.9%	3.3%	5.8%	5.3%	6.1%	6.9%	4.7%
NPV (% of predictive accuracy)	91.9%	91.0%	93.9%	96.4%	93.2%	91.9%	93.1%	93.7%	91.3%	92.6%	93.1%	91.9%	92.8%

To understand the tradeoffs among s*pecificity*, the false negative rate (*FNR*), and the negative predictive accuracy (*NPV*) with respect to different criteria, we derive 625 filters based on the four criteria, each taking on five potential values ($5^4 = 625$). Each filter is applied to all potential training sets and is used to predict the override pattern of the following month. For example, a filter with time window of size 5 uses alert data and associated decisions from five consecutive months to predict the override pattern of the following month. So, January to May alert data and decisions are used as a training set to establish the rule, and the override pattern of June is predicted. Similarly, February to June alert data and provider decisions are used to develop a rule that is used to predict the override pattern for July. And so forth. Performing this on all alert data from January 2009 to June 2011 leads to 5000 training sets and prediction results. The predictive status of each alert is compared against the actual providers' override action. These values are summarized via boxplots in Figures 1a-c, grouped with respect to specific values for each criterion. From these figures we observe that our filtering performance is most sensitive to *Rate*. As *Rate* increases (i.e., filters are set to be more stringent), the percentage of overridden alerts being filtered (*specificity*) decreases significantly (Figure 1a), fewer false negative errors are made by the filter (Figure 1b), and the predictive accuracy of the filter increases (Figure 1c). We also observe that *Time-Window* could have some effects on the filtering results, whereas *Number* and *Range* appear to have marginal impact.

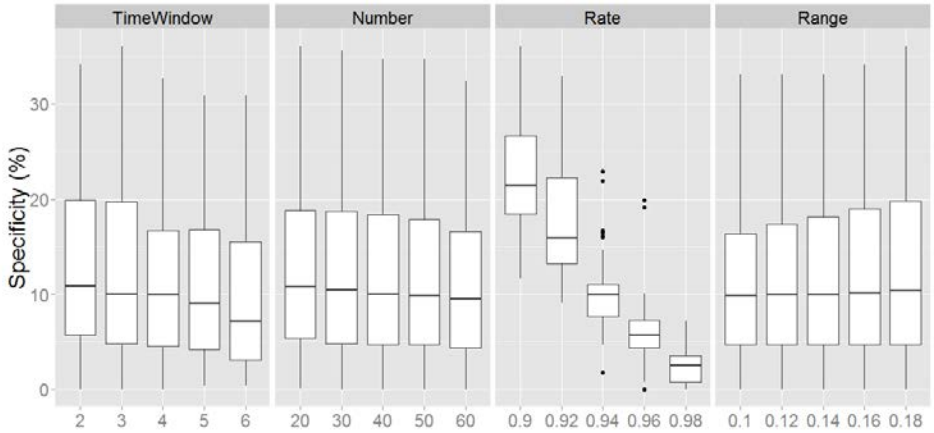

Figure 1a: Boxplots of % of overridden alerts being filtered (s*pecificity*) with respect to single-criterion value change.

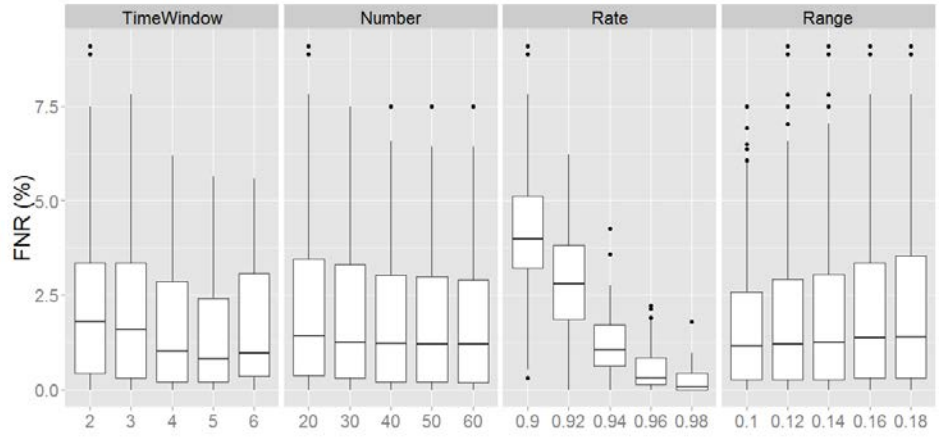

Figure 1b: Boxplots of % of non-override alerts being filtered (false negative rate) with respect to single-criterion value change.

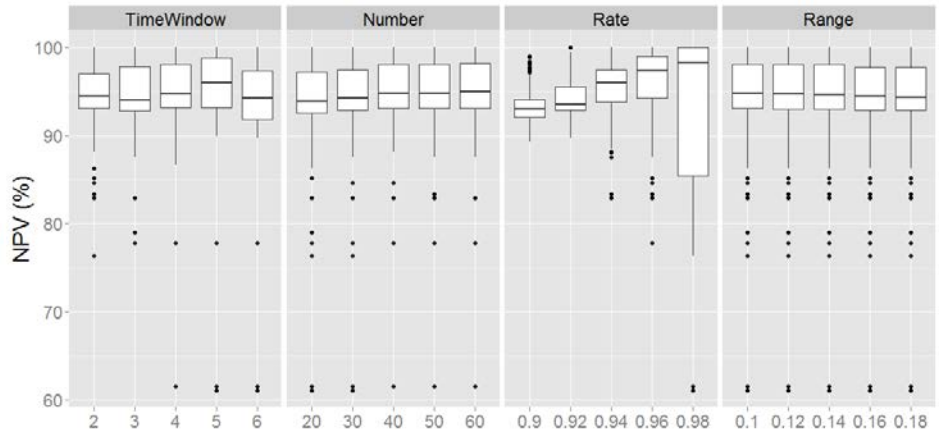

Figure 1c: Boxplots of predictive accuracy % among filtered alerts (overridden and filtered/total filtered) with respect to single-criterion value change.

Among the 625 filters, we present below the most conservative one. For each filter, the average values of S*pecificity*, *FNR*, and *NPV* over different training/prediction months are taken as consideration to measure the overall performance. The goal is to have a high-specificity, low-FNR, and high-NPV filter. However, these metrics are somewhat conflicting, as reflected in the scatterplot matrix in Figure 2. Here we pick a filter with the best average rank over these three metrics:

a) *Time-Window:* Size of time window = 5 months
b) *Number*: Number of alerts ≥ 40
c) *Rate*: Override rate ≥ 94%
d) *Range*: Range of monthly override rate ≤ 10%

Using this filter the *Specificity* ranges from 6.6%~10.8%, *FNR* ranges from 0%~1%, and *NPV* ranges from 93.8%~100%, as shown in Table 4.

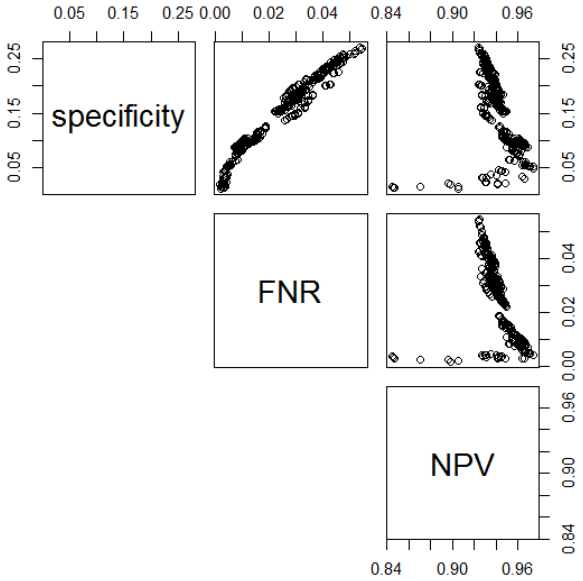

Figure 2: Scatterplot matrix of *Specificity*, *FNR*, and *NPV*

Table 4: Predicted results with *Time-Window*=5, *Number*≥40, *Rate*≥94%, *Range*≤10%

Metrics \ Predicted month	Jun '09	Jul '09	Aug '09	Sep '09	Jun '11	Jul '11	Average
Specificity (% of overridden alerts filtered by us)	9.1%	7.2%	8.2%	6.6%	10.6%	10.8%	8.8%
FNR (% of non-overridden alerts filtered by us)	0.0%	0.8%	0.6%	0.8%	1.0%	1.0%	0.7%
NPV (% of predictive accuracy)	100.0%	93.8%	97.3%	95.9%	97.3%	97.0%	96.9%

Effectiveness of the Filtering Criteria

We examine the effectiveness and significance of these criteria in more detail using regression analysis, focusing on understanding the importance of the moving time window, the allowance of time gap between the training months to the predictive months, and the degree of significance of each criterion. For brevity, we summarize the findings when the time window is set to 3.

Moving time-window versus static time-window First we compare the results of using moving time-windows as training set versus employing static time-windows. We perform the filtering by maintaining the same for all but the time window criterion. Specifically, the filters will include the parameters: number of alerts ≥ 20, 30, 40, 50, 60, override rate ≥ 90%, 92%, 94%, 96%, 98%, range of monthly override rate ≤10%, 12%, 14%, 16%, 18%.

We apply paired t-test to see whether there is significant outcome difference between that of moving time-windows and those from static time-windows. There are 5*5*5=125 filters, and for each filter we predict 8 different months (May-Sep 2009 and May-Jul 2011), so in this analysis the sample size is 125*8=1000. The average net *Specificity* of moving time-windows is 13.6% versus 11.3% from those obtained via the static time-window. The resulting p-value is less than 0.0001, indicating that using moving time-windows is more effective than static ones.

Gap between training months and predicting month Next we analyze how the filter performs if we allow a gap between the moving time-window and the month to be filtered (predicted). Under the same set of parameters in all criteria, we apply paired t-test to observe if there is any significant change in *Specificity* when using no gaps versus using gaps for the moving time-windows. The results are shown in Table 5. Regardless of the size of the gap (1, 2, or 3 months), the p-values are all less than 0.0001, indicating that using immediate previous months for training is more effective than using previous months with gaps. This reflects that the overriding patterns of immediate months reflect better the cognitive decision of the providers in the immediate next month.

Table 5: Comparison of net *Specificity* outcome between no gaps and with gaps. The gap is measured by the number of months between the months for training and the month for prediction

Size of gap	Sample size	Average net *Specificity*		p-value
		No gaps	With gaps	
1 month	1,000	13.6%	11.9%	<0.0001
2 months	750	13.9%	11.8%	<0.0001
3 months	500	13.9%	10.9%	<0.0001

Degree of Significance of Individual Criterion We conduct regression analysis to gauge the relative effectiveness of each criterion in our filtering schema. Specifically, *Specificity*, *FNR*, and *NPV* are used as the response variables separately, while size of *Time-Window*, *Number* of alerts, override *Rate*, *Range* of monthly override rate, and their pairwise interactions are the predictor variables. In the model where the response variable is *Specificity* or *FNR*, almost all predictor variables including their interactions have significantly small p-values; thus there are no nonsignificant ones. In the model where the response variable is *NPV*, only *Time-Window*, *Rate*, and their interaction term are significant, thus we can rule out *Number* and *Range*. Below is the regression equation to predict *NPV*, the predictive accuracy of the filter:

Predictive accuracy (*NPV*) ~ *0.053 + 0.265 Time-Window + 0.963 Rate – 0.287 Time-Window * Rate*

This finding validates the observations from the single-criterion boxplot results that *Rate* and *Time-Window* are the influencing criteria in determining the predictive accuracy (Figure 1c).

Discussion

With the adoption of electronic medical records (EMRs), drug safety alerts are increasingly recognized as valuable tools for reducing adverse drug events and improving patient safety. However, even with proper tuning of the EMR alert parameters, the volume of unfiltered alerts can be overwhelming to users. Studies have been performed to improve the specificity of alerts, to effectively prioritize and present the alerts for providers' review, and to automate the filtering of some unnecessary or least severe alerts. This remains a challenging problem as there is a tradeoff and disagreement between reducing alert overload versus the safety of turning off some alerts.

In this paper, we design an adaptive decision support tool in which past cognitive overriding decisions of users are learned, adapted and used for filtering actions to be performed on current alerts. The filters are designed and learned based on four criteria: moving time window, number of alerts, override rates, and monthly override fluctuations. Using alerts from two separate years to derive filters and test performance, prediction accuracy rates of 91.3% - 100% are achieved. This associates to 0.0% - 6.1% non-overridden alerts being filtered by our system. To reduce this false negative rate, we test the concept of *adaptive learning* by mining the key contents of these false negative alerts and incorporating them within our filtering algorithm. This helps to bring down the false negative rate to 0.0% - 1.5%. Further reduction may be possible by importing clinical and patient risk factors into our analysis. Added clinical features

may tag these to be non-filterable and thus correct the committed errors. Careful review of each such patient record is necessary. A follow-up study will have to be performd to validate its potential.

The moving time window works better than a static training approach. It allows continuous learning and capturing of the most recent overriding characteristics and seasonal variations in drug usage. Further, our study shows that the overriding patterns of immediate months reflect better the cognitive and clinical decision of the providers in the immediate next month. From regression analysis we conclude that the size of time window, number of alrts, override rate, range of monthly override rate, and their pairwise interaction are all critical factors in influencing specificity and false negative rate; whereas predictive accuracy is governed mostly by time window sizes and the override rates.

The clinical staff diligently reviews and fine-tunes EMR alert parameters to capture proper clinical practice guidelines. For those alerts being fired out, providers will manually review them to determine if the prescribed action is appropriate or if other actions should be taken. Those for which current prescribed action is deemed appropriate results in alerts being overridden. The non-overriding ones amount to important alerts that providers must take action on. Alerts fatigues have been reported by numerous studies and can be detrimental to clinical outcome. Our alert management decision support system helps to improve the specificity of alerts by reducing inappropriate alerts, thus enabling providers to focus their attention on important alerts and make proper decisions.

Among all the filters, some of the filtering levels are rather conservative, as roughly only 20% of overridden alerts are being filtered, with majority of the alerts remain unfiltered and require the attention of providers. Further, as the system “adapts” and ”learns” that certain drug interactions are critical and cannot be filtered and required specific actions, this knowledge will be transferred to the providers with alerts being tagged with knowledge of its importance. This provides an opportunity for training, in particular for those inexperienced providers who will benefit from the captured clinical knowledge.

From Table 2b, we observe that over 75% of alerts reviewed by providers are over-ridden. Using our system, about 20% of these are filtered. Using the estimate of 11,000 alerts per month and 1 minute per alert review, the estimated time savings is 27.8 provider-hours per month. More importantly, this enables providers to strategically allocate appropriate time to review vital alerts.

The decision tool can be plugged into an existing EMR system as an add-on, allowing real-time decision support to users without interference with existing EMR functionalities. We have tested it on EPIC. Specifically, the alerts directed out of EPIC are captured and funneled into the decision support tool. The tool grabs the data, establishes the filters, and performs the filtering. The tool then reports the alerts with status “filtered” and “not-filtered”. In the latter, it also highlights those “learnt” critical alerts. Providers can review them accordingly. By automatically filtering the alerts, the tool mitigates alert fatigue and allows users to focus resources on potentially vital alerts that require clinical decisions, thus reducing the occurrence of adverse drug events. Further, the learnt knowledge of critical alerts will facilitate the decision process. Clinical trials must be performed to fully evaluate the impact of this decision support tool on alert fatigue, patient safety and quality of care.

Abstract

Earlier studies on hospitalization risk are largely based on regression models. To our knowledge, network modeling of multiple comorbidities is novel and inherently enables multidimensional scoring and unbiased feature reduction. Network modeling was conducted using an independent validation design starting from 38,695 patients, 1,446,581 visits, and 430 distinct clinical facilities/hospitals. Odds ratios (OR) were calculated for every pair of comorbidity using patient counts and compared their tendency with hospitalization rates and ED visits. Network topology analyses were performed, defining significant comorbidity associations as having OR≥5 & False-Discovery-Rate≤10^{-7}. Four COPD-associated comorbidity sub-networks emerged, incorporating multiple clinical systems: (i) metabolic syndrome, (ii) substance abuse and mental disorder, (iii) pregnancy-associated conditions, and (iv) fall-related injury. The latter two have not been reported yet. Features prioritized from the network are predictive of hospitalizations in an independent set ($p<0.004$). Therefore, we suggest that network topology is a scalable and generalizable method predictive of hospitalization.

Introduction

Chronic Obstructive Pulmonary Disease (COPD) is the third leading cause of death in the United Sates and an important cause of disability and hospitalizations, particularly in aged populations[1,2]. Currently, about 12 million adults (aged 18 and over) have been diagnosed with COPD, but there are likely to be more who have yet to be diagnosed[3]. Deaths attributable to COPD in women are higher than men, with more than 6,000 deaths for women alone in 2010[4]. Hospitalizations for COPD account for a large economic burden to the patients and to society[5,6]. In that same year, COPD resulted in $49.9 billion in direct and indirect costs, and total costs incurred by COPD patients are approximately $6,000 higher than patients without COPD[6]. Due to its large burden on individuals and health care systems, it is crucial to find evidence-based strategies to identify those who are at the highest risk of being hospitalized in order to target preventive interventions[7,8].

Comorbidities such as hypertension, ischemic heart diseases, diabetes, and pneumonia have been known as contributing causes to COPD hospitalizations. Therefore, reducing COPD-associated comorbid conditions may decrease the hospitalization rate, which ultimately reduces the economic burden of COPD patients[7,9]. Multiple studies have developed predictive models including comorbidities of COPD hospitalizations and re-hospitalization; however, those models were constructed only on the use of regression models **(Table 1)**. These models aim at predicting COPD hospitalization from comorbidities data. However, they do not take into account the impact of all potential interactions between each comorbid condition, unless these and their interactions are specified *a priori* in the functional model. Also, COPD hospitalization risk predictions are based on labor-intensive scoring systems such as the Charlson Comorbidity Index (CCI)[10] or Elixhauser[11], which are the best-known comorbidity indices. However, these tools only provide pre-selected list of diseases[12] and therefore many diseases are not taken into account, and do not provide the level of granularity necessary to understand the clinical dynamics of COPD hospitalization risk. In other words, they exploit a biased and small number of features for predictions. As a result, comorbidities finding may be biased and have limitations for identifying novel patterns of comorbidities.

When investigating conditions or features that can predict high risks of admission in COPD patients, it is necessary to understand the association between COPD and its comorbidities. Studying the structure defined by the entire set of comorbidities with the novel methodology is required to understand the enriched association and unveil the hidden structure. Recently, network-based approaches have been applied to human disease and have revealed unknown connections between diseases, which shed new light on the clinical research realm (**Background**)[13]. For example, Hidalgo et al. introduced a Phenotypic Disease Network (PDN), which uses data obtained from the medical claims of more than 30 million patients to demonstrate that highly connected diseases are more lethal than barely connected ones[14]. However, results from these patterns have not been translated into classifiers of hospitalization.

In this study, we hypothesized that network topology modeling of COPD-associated comorbidities with higher risk of hospitalization and emergency department visits can predict future hospitalizations.

Table 1. Summary of three studies on the prediction of hospitalization among COPD patients

Background on Network Analysis

These approaches aim to discover, map, and quantify complex relationships among variables that may not be revealed by correlational or clustering methods. Combining exploratory analytics with statistical decision points and graphical displays, these methods may discover complex networks of variables that were heretofore unknown, yield new insights into the dynamics among these variables, and link these networks to clinical outcomes.

Methodology

Sample: We collected data from the Illinois Health Connect Medicaid, which included patients from 430 distinct clinical facilities and hospitals from January 1, 2010 through December 31, 2010 and covered 1,446,581 visits. These clinical institutions have been chosen using the distinct provider ID from outpatient billing and inpatient billing. If a site had multiple locations and a single billing address, then it counted as one institution. Claims include all claims adjudicated for payment through April 29, 2011. Location (emergency department, inpatient, and outpatient), admission date, primary disease and secondary disease information with ICD-9-CM code were extracted for the network analysis. Although the system provided 5 digits level ICD9-CM code, we used the ICD-9-CM at the 3 digit level for the analysis. COPD was defined as ICD-9-CM code 490–492 and 496 based on the literature. COPD with asthma (ICD-9-CM code 493) was not included in this study since the COPD with asthma is under asthma category which is different from COPD. In total, 38,695 patients and 1,049 ICD-9-CM codes at the 3 digit level for COPD and comorbid diseases were included in the dataset.

Initially, 3,862 patients had a COPD diagnosis, and potentially other comorbid conditions (886 total comorbidities). We removed from further analysis ICD-9-CM codes associated to less than 20 patients, in order to prevent any future re-identification. This filtering resulted in a final dataset of 3,831 patients and 754 comorbidities. Among those data, 880 COPD patients were hospitalized at least once, and 2,711 patients visited the ED at least one time. Further, we created a subgroup of patients that we labeled as "higher risk of acute exacerbation (e.g. bronchospasms) (AE-risk) COPD patients", given the following inclusion criteria: 1) patients with COPD as either primary or secondary diagnosis, and 2) patients who visited emergency department (ED) 5 or more times and hospitalized at least once for the condition of COPD during 1/1/2010~12/31/2010. We identified 238 AE-risk COPD patients that met those two criteria (ED $\geq$ 5 AND hospitalization $\geq$ 1).

Data analysis: First, we randomly selected 25% of the "AE-risk COPD patients" to create a validation set of 60 patients and kept the remaining 178 patients (from the 238 AE-risk COPD patients) in the background. The aim was to identify comorbidities associated with an increased hospitalization risk. Specifically, we searched among the 754 comorbidities the ones that were significantly associated with the AE-risk patients, and the associations between these morbidities. We prioritized those comorbidities by using the associated Fisher's Exact Test (FET) result as the statistical criterion to determine whether a given comorbidity was retained in the network analysis (3,771 patients; **Figure 1)**. Our model can be viewed as an alternate feature selection procedure, where features are here comorbidities with the COPD condition. We created the association network of all comorbidities with the AE-risk COPD condition, and extracted the most significant ones and their interactions/associations. The levels of significance (p-values) by FET of all tested paired associations were adjusted by False Discovery Rate (FDR[16]) to correct for multiple comparisons for multiple comparisons and the possibility of finding a statistically significant result merely because of high statistical power. The analyses were performed using custom scripts written in Python[17] and R programs[18]. We used a stringent cutoff of significance for the association between diseases: Odds Ratio (OR)$\geq$5 of the hospitalization with and without the co-morbidities and FDR$\leq 10^{-7}$. For a one-year period, the number of hospitalizations and ED visits were computed for each patient using the MySQL Community Server 5.6. We bundled the high cost of recurrent ED visits with those of hospitalizations as proxies for high risk of COPD exacerbation associated to high overall health system costs.

Network modeling: To explore the pattern of COPD with multiple systems comorbidities, we constructed the network consisting of the significant associations (according to FET) of comorbidities of the AE-risk COPD patients **(Figure 2)**. The network has been constructed using Cytoscape[19]. Next, we investigated the tendency of hospitalization and ED visits according to the topology of the network. Our research group has extensive experience and pioneered network modeling in: (1) diseases[20-23], (ii) translational bioinformatics[24-39], and (iii) between multiple scales of molecules of life[40-43].

Evaluation: After the model was constructed from the background data, significant comorbidities were prioritized. We then retained the same comorbidities from the validation set (60 patients) and applied a clustering procedure in order to automatically separate those 60 patients into two subgroups, from their associated comorbidities. We used Partitioning Around Medoids (PAM) method for unsupervised clustering, as it is a well-established method for identifying subgroup (clusters) from data[44]. The R algorithm for Partitioning Around Medoids (PAM)[44] was utilized in a parameter-free way. It resulted in two clusters on which we compared Hospitalization and ED visits distribution. The comparison was statistically assessed using two-tailed non-parametric Mann-Whitney test (GraphPad PRISM v.5.0d). Of note, the PAM algorithm utilized exclusively comorbidity data and was not presented the hospitalization rates per patient nor ED visit.

IRB: The research project was approved by the University of Illinois Institutional Review Board id#2012-0150 (non-human subject, de-identified dataset).

Results

From the total 754 comorbidities found in COPD, 215 were significantly associated to rehospitalization (OR$\geq$5 and FDR$\leq 10^{-7}$, **Methods**) linked to patients at high risk of hospitalization and ED visits (AE-risk patients). These 215 comorbidities were regarded as prioritized features extracted from the training data (**Methods**). They were associated with each other, involving 280 interactions that we represented in a network (**Figure 2b**). Since all comorbidities were connected to COPD, we removed the COPD node from the network to explore further the associations between comorbidities. Of note, for a better readability of the network structures, only comorbidities containing associations with other comorbidities are shown in **Figure 2**. We provide the full network in supplement (**Supplement Figure S1**, http://lussierlab.org/publications/COPD_networks/SuppFigureS1.pdf).

We further annotated the network with the number of hospitalizations and ED visits for each comorbidity condition, in order to highlight the patterns they create in the network topology.

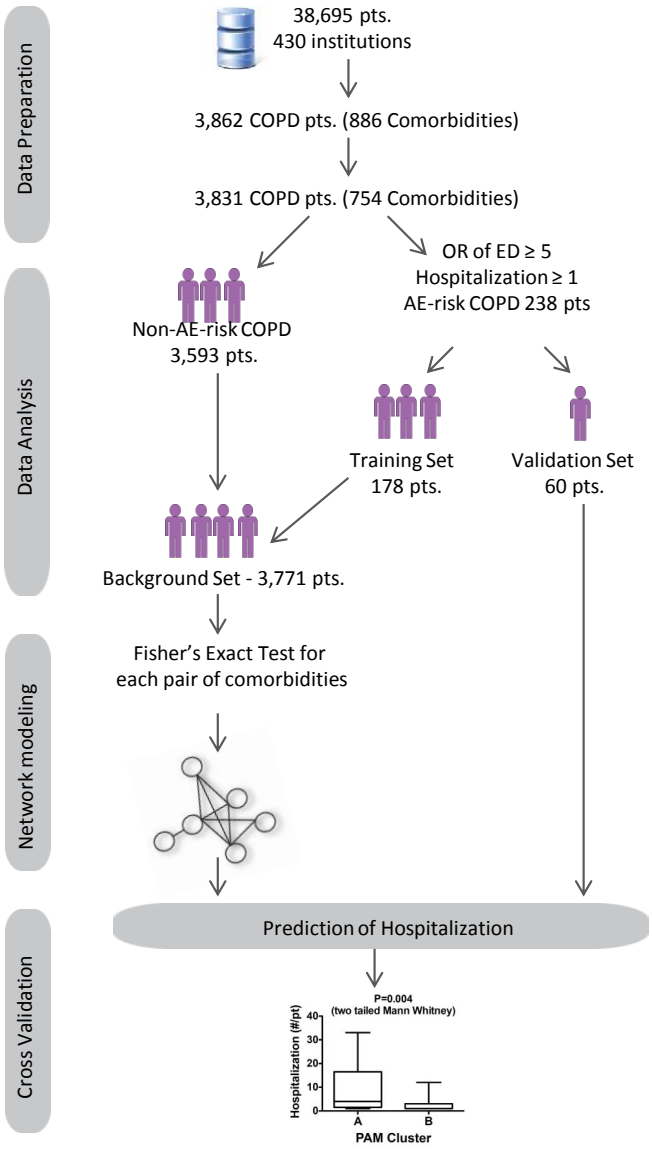

Figure 1. Summary of the study design

To express the multiplicity of information, we kept the original network but represented its nodes in three ways: 1) ICD-9-CM class of diseases and number of hospitalizations **(Figure 2, Panel A)**; 2) the number of ED visits per disease **(Figure 2, Panel B;** darker=more visits**)**; and 3) Odds ratios between AE-risk patients (≥1 hospitalization and ≥ 5 ED visits) and comorbidity **(Figure 2, Panel C;** darker for higher OR**)**. In **Panel A,** the size of the node corresponds to the number of hospitalizations, while it corresponds to the relative numbers in the other two panels. Moreover, in **Panel A**, the link thickness corresponds to the strength of the association (OR) between two comorbidity diseases (thicker link=higher OR). Of note, if patients visited the ED or were admitted to the hospital more than once, each visit or admission was counted separately. The network topology showed that among the total 754 comorbidities, the prioritized 215 comorbidities had an increased risk for hospitalizations and ED visits (FDR≤0.05 **Panel B**).

The clinical dynamics of this network analysis become evident from a pattern analysis of **Figure 2, Panel A.** Visual inspection reveals four distinct sub-networks: I = multisystem and metabolic syndrome, II = drug abuse and mental disorder, III = pregnancy-associated conditions and IV = fall-related injury. The sub-network I comprises hypertension, obesity, myocardial infarction, diabetes mellitus, disorders of lipoid metabolism, angina pectoris, and chronic ischemic heart diseases. The metabolic syndrome has already been defined as "a cluster of cardiovascular risk factors that is frequently associated with insulin resistance."[45] In this network each comorbidity disease is connected to the others, forming a complex sub-network. The metabolic syndrome is part of the largest network (**Figure 1, Panel A**), while many additional metabolic diseases are agglomerated to this multi-system. Considering the sub-network II, we can see that mental disorder and drug abuse are connected to each other (regarding their related comorbidities). This study also shows that falls, injuries and pregnancy-associated complications seem to be associated with COPD and its hospitalization (**Figure 2 sub-networks III and IV**).

The analysis of the sub-networks reveals that sub-network I is centered on the metabolic syndrome and is very complex in terms of clinical systems. Sub-networks I, II and IV each comprise diseases associated with some of the highest odds ratio of re-hospitalization and ED visits (**Figure 1, Panel C; Table 2**). Sub-network III is centered on pregnancy and while its odds ratio of re-hospitalization and ED visits is statistically and clinically significant, none of its morbidities are among the top 20 shown in **Table 2** and merit further investigation of studying separately the ED visits and hospitalizations. Additionally, Contusion to the trunk (**Sub-network IV**) stands out as a high risk for ED visits and hospitalization in COPD populations that may merit subsequent investigations for potential preventive measures.

In **Figure 2, Panel B**, the comorbidity conditions with the highest number of ED visit is 'Essential hypertension' followed by 'Nondependent abuse of drugs' and 'Diabetes Mellitus', which represents 625, 481 and 449 visits, respectively (**Table 2**). However, the number of ED visit seems not correlated to the OR; their corresponding odds ratio is "modestly" increased by 2.8. **Figure 2, Panel C** shows that 'Alcohol dependence syndrome', 'Disorders of mineral metabolism' and 'Contusion of trunk' are the top three comorbidities with highest OR (9.3, 8.2 and 8.0 respectively; **Table 2**), while their number of ED visits are low.

Table 2. Top COPD's co-morbidities associated to increased hospitalizations and ED visits as measured by OR. Of note, none of the top ORs was part of sub-network III (**Figure 1**).

Sub-network of Figure 1*	ICD-9 CM Code	Odds Ratio≥ 5 ED visits & 1 hospitalization	# patients	#ED visits	# Hosp.
I	**250 Diabetes mellitus**	2.9	**65**	**449**	229
	272 Disorders of lipoid metabolism	3.0	72	197	132
	275 Disorders of mineral metabolism	**8.2**	21	18	21

IV	920 Contusion of face, scalp, and neck except eye(s)	4.6	19	16	1
	922 Contusion of trunk	**8.0**	21	22	5
	959 Injury, other and unspecified	3.2	76	25	2
	V62 Other psychosocial circumstances	5.5	35	62	56

- I = Multisystem and Metabolic syndrome, II = drug abuse and mental disorder, IV=fall-related injury

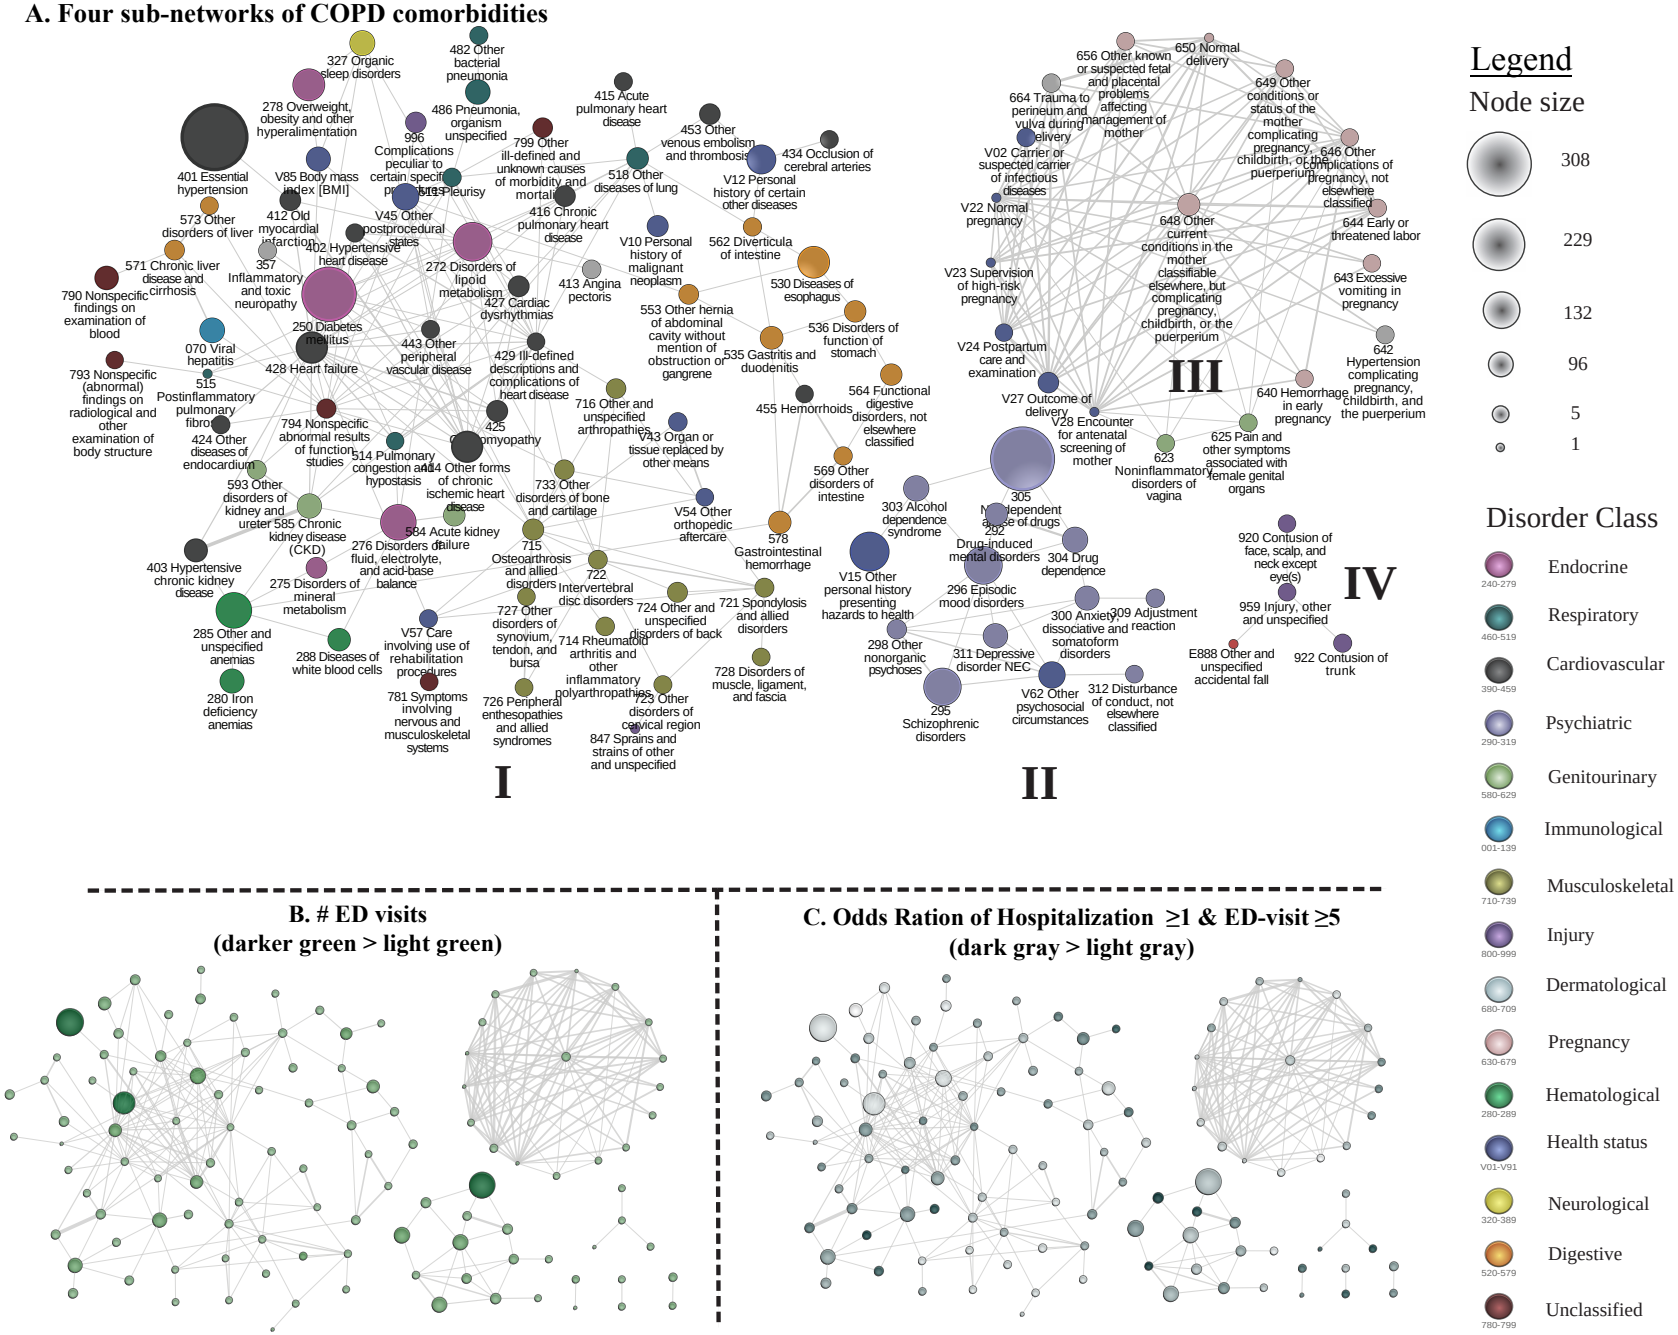

Figure 2. COPD-derived comorbidity network. Four sub-networks are shown in **Panel A** (details in **Table 2**). **Panels B and C** are highlighted for the number of ED visits and OR of hospitalizations respectively.

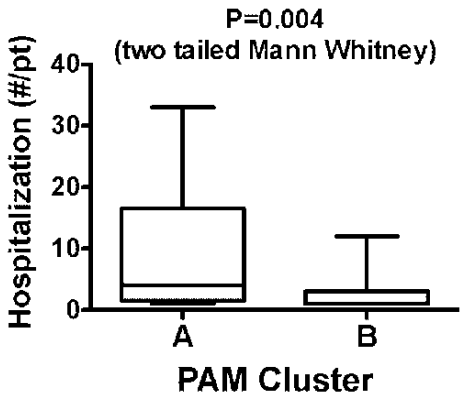

Figure 3. Evaluation in Independent Dataset Using Disease-Features Prioritized In Learning Set. Using the co-morbidities identified in the learning set (**Figure 2, panel A),** we then clustered the independent validation set using PAM clustering (restricted to two clusters), an unsupervised vectorial quantization method. Of note, PAM analysis did not have access to the hospitalization rates of the patients in the validation set. As shown here, the validation of the identified clusters was conducted by comparing the hospitalization rate of the identified clusters of the validation set.

Figure 3 describes how the 215 prioritized comorbidities are predictive of hospitalization in an independent data set. The same 215 comorbidities were retained from the 60 patients of the validation set (**Figure 1, Methods**). Then, we applied the PAM clustering procedure **(Methods)** in order to automatically separate those 60 patients into two clusters[44]. Of note, PAM divides the patients only on their comorbidity patterns and is not informed of the hospitalization data. The results showed that the two clusters generated (named A and B; respective sizes=9 and 51) yielded by the 215 comorbidities have different risk of hospitalization (p=0.004; Mann Whitney U test). This validates that the discovered patterns (the 215 comorbidities) are indeed predictive of the hospitalization rate. Of note, the PAM analysis and Mann-Whitney tests were repeated for models built from different OR and FDR cutoffs and lead to the same order of results (data not shown).

Discussion

Comorbidities have been known to be a key factor of ED admission and hospitalization among COPD patients; however, previous studies were constructed on regression models. This study showed that the network topology may contribute to hospital prediction study using comorbidity feature among COPD patients. Some of the features were consistent with previous studies. Hypertension, adult-onset diabetes, mental illnesses and substance abuse have all been previously associated to increase COPD patients' ED visits and hospitalizations rates[46], and evidence is shown in central hubs of Figure 2 panels I-II.

Meanwhile, falls and pregnant-related comorbidities have not been shown in the previous studies on COPD comorbidities. While falls are the leading cause of ED visits and hospitalizations due to an injury in the elderly population, to our knowledge the increased OR of COPD patients' fall related-hospitalizations had not been previously reported[47,48]. However, since age increases both risk of COPD and that of falls, additional studies are required to identify if the risk of falls in COPD patients is higher than that of a matched control. Furthermore, no studies have been described where pregnancy is a comorbid condition of COPD from our understanding. Since this study was extracted from Medicaid data, we included pregnant population due to the inclusion criteria of Medicaid[49]. Pregnancy Risk Assessment Monitoring System study conducted by the Centers for Disease Control and Prevention (CDC) showed that half of respondents (50.2%) were enrolled in Medicaid at any point from preconception through pregnancy and delivery[49]. Therefore, pregnancy-related comorbidities that show in our analysis may not be related with COPD. Because of this, we must interpret the conclusions from the network analysis carefully.

The strength of this study lies in using claims data, which captures a large number of diseases (n=754) as recorded through medical claims, to construct the model on hospitalization among COPD patients compared to previous studies that used a pre-selected list of about twenty to thirty comorbidities. Consequently, we discovered previously unreported comorbidities associated to hospitalization of COPD patients. Administrative data has become an essential research resource since it is easily accessible, contains heterogeneous information of a large population,

and can be promptly available. Claims data has been used to predict hospitalization and re-hospitalization in other studies[50]. CCI or Elixhauser can also be applied to administrative data; however, since they already select certain number of features, it may limit the possibility of finding new patterns or results.

Furthermore, compared to the traditional descriptive table, the network topology uncovered distinctive patterns of multiple comorbidities related COPD hospitalization and their co-dependency. The network-approach may inform clinicians which comorbidities need to be treated intensively to reduce the comorbidities. Focusing on the hub would decrease the risk of other comorbidities which are connected to it. In the network of metabolism syndrome, diabetes mellitus and heart failure are the hub of the network; making an effort to manage that hub would reduce the risk of diseases of heart, lung or pulmonary which decreases the frequency of medical utilization and economic burden. However, to construct the network, we need to be cautious about the threshold. Depending on the threshold, the network topology would vary and affect the quality of information. Too low of a threshold leads to the building of a hair-ball type of network that prevents the sharing of informative messages. Otherwise, too high of a threshold will threaten the loss of hub and may provide information that is not clinically actionable.

Future studies and Limitation

The generalizability of this study to other COPD patients is limited due to the short period of data collection time. Furthermore, we limited this proof-of-concept study to identifying valid "features" of the classifier (the co-morbidities) with a judicious model-free validation strategy. In future studies, a fully-specified classifier is required for individual patient prediction, inclusive of "features," mathematical model, and computed weighted parameters. We also intend to extend the type of features with ten years of unstructured clinical narratives (radiology reports, discharge summaries and pathology reports) that we coded in UMLS with MedLEE[51] and more relationships in SNOMED[52] to improve the predictive power and compare the accuracy rates to those reported in the literature by alternate approaches. Further studies need to include heterogeneous variable types such as severity of comorbidity, length of stay or demographic information as well as severity of comorbidities over time.

Further, this proof-of-concept study was designed to address the hypothesis that network analyses could identify co-morbidity features predictive of future hospitalizations in clinical datasets, while mitigating the curse of dimensionality that plague other feature discovery methods (such as FDR over multiple comparisons). However, future studies are required to identify to cop are the accuracy of predictions of features discovered by network analyses against those found by classical methods such as statistical regression or vector space discrimination (e.g. Support vector machine).

Conclusion

The proposed network modeling of COPD hospitalized patients unveils several sub-networks of comorbidities. The descriptive information with ICD-9 code only is insufficient to reveal the underpinnings of biologic or pathophysiologic connections of comorbidities. This network topology may show the possibility of revealing the co-dependency of comorbidities, which has been buried in the traditional prevalence study that links to those connections. Further, in high dimension datasets, reducing features by design while controlling for multiplicity of comparisons decreases the statistical power of conventional approaches. Finally, we propose that network analysis of clinical comorbidity and their dependencies provides an unbiased and straightforward predictor development that merits further investigation in order to prevent future hospitalization and ED visits for COPD patients.

Automatic Detection of Dilated Cardiomyopathy in Cardiac Ultrasound Videos

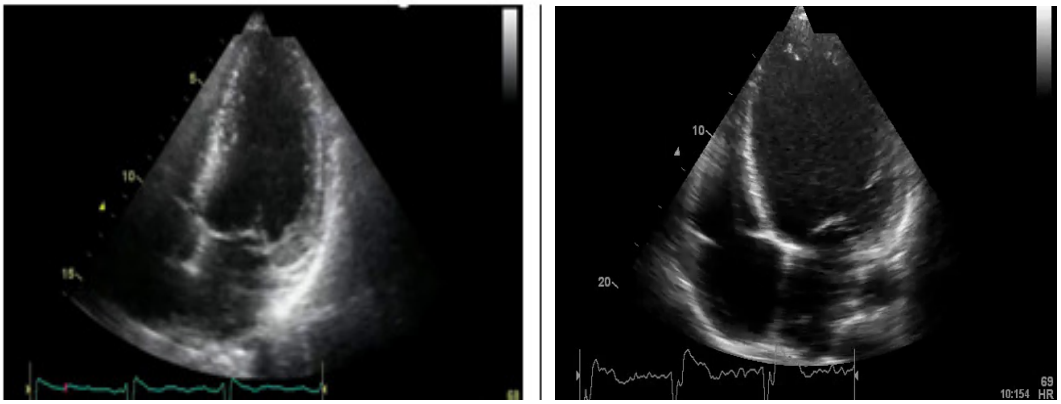
Raziuddin Mahmood[1], Tanveer Syeda-Mahmood, PhD[2],
[1]Kennedy Middle School, [2]IBM Research - Almaden, San Jose, CA

Abstract

In this paper we address the problem of automatic detection of dilated cardiomyopathy from cardiac ultrasound videos. Specifically, we present a new method of robustly locating the left ventricle by using the key idea that the region closest to the apex in a 4-chamber view is the left ventricular region. For this, we locate a region of interest containing the heart in an echocardiogram image using the bounding lines of the viewing sector to locate the apex of the heart. We then select low intensity regions as candidates, and find the low intensity region closest to the apex as the left ventricle. Finally, we refine the boundary by averaging the detection across the heart cycle using the successive frames of the echocardiographic video sequence. By extracting eigenvalues of the shape to represent the spread of the left ventricle in both length and width and augmenting it with pixel area, we form a small set of robust features to discriminate between normal and dilated left ventricles using a support vector machine classifier. Testing of the method of a collection of 654 patient cases from a dataset used to train echocardiographers has revealed the promise of this automated approach to detecting dilated cardiomyopathy in echocardiography video sequences.

Introduction

Dilated cardiomyopathy is a heart disease in which the left ventricle of the heart becomes very large and loses the ability to pump blood to the rest of the body [1]. This condition can lead to heart failure and death. Cardiomyopathy is diagnosed through an ultrasound recording. In this recording, an ultrasonic probe is moved over the heart region. Sound passes through the blood tissues and gets reflected from different parts of the body. These reflections are recorded as signal and converted to an image. The ultrasound device images the heart from different angles and depicts the chambers of the heart in views such as the apical 4-chamber views, 2 chamber views, etc. A typical cardiac ultrasound image in apical four-chamber view appears as shown in Figure 1b.



(a) (b)

Figure 1. Illustration of an ultrasound image depicting the left ventricle. (a) normal left ventricle, (b) dilated left vetricle.

In Figure 1b, the 4 chambers of the heart are seen, with the largest region being left ventricle. The shape and function of the left ventricle are important in characterizing the heart. Damage to the ventricle's shape and structure affects the function of the heart and is often seen in several diseases such as aneurysms, cardiomyopathies and infarctions. The left ventricle is often enlarged and oddly-shaped in case of dilated

cardiomyopathy [1]. This can be seen by comparing the image of Figure 1b with a normal left ventricle shown in Figure 1a which has a more normal bullet-like shape. The enlargement can be noted not only visually in Figure 1b, but also by mapping the pixels back to cm measurements using the calibration scale in the echocardiogram image. It can be seen that the left ventricle length (from apex to mitral valve) is over 90mm which usually indicates dilated cardiomyopathy in both males and females.

The goal of our work was to develop ways to automatically differentiate between normal and dilated left ventricles in echocardiography images. Such methods could aid in the development of computer-based diagnostic tools to aid clinicians in their decision making.

Automatic detection of dilated cardiomyopathy from cardiac ultrasound videos, however, is a difficult problem. In 4-chamber views, although the left ventricle is more clearly visible, the exact boundary of the left ventricle may be difficult to delineate which alters shape measurements. Using simple thresholding techniques that look for low intensity regions as potential candidate regions for left ventricles may not be sufficient as the low intensities near the apex may cause the left ventricle region to be merged with the background. Although the practice guidelines indicate the single measurement of left ventricle length for diagnosing dilated cardiomyopathy [1], errors in automated left ventricle boundary detection may require more measurements be used to provide robustness.

In this paper, we present a new method of robustly locating the left ventricle by using *the key idea that the region closest to the apex in a 4-chamber view is the left ventricular region*. For this, we (a) locate a region of interest (ROI) containing the heart in an echocardiogram image using the bounding lines of the viewing sector to locate the apex of the heart, (b) select low intensity regions as candidates, and (c) find the low intensity region closest to the apex as the left ventricle, and finally (d) refine the boundary by averaging the detection across the heart cycle using the successive frames of the echocardiographic video sequence. We then extract the eigenvalues of the shape to represent the spread of the left ventricle in both length and width and augment it with pixel area to form a small set of robust features. A set of 4-chamber view echocardiogram study videos are used for training a support vector machine classifier [3] using disease labels obtained from their corresponding reports. The machine learns the separation between normal and abnormal classes based on the provided features and their labels. New 4-chamber echocardiogram videos are then processed similarly to isolate shape feature vectors, and then classified into dilated left ventricle class or normal class using the learned support vector machine. The method has been tested on a collection of 654 patient cases from a dataset used to train echocardiographers.

Related work:

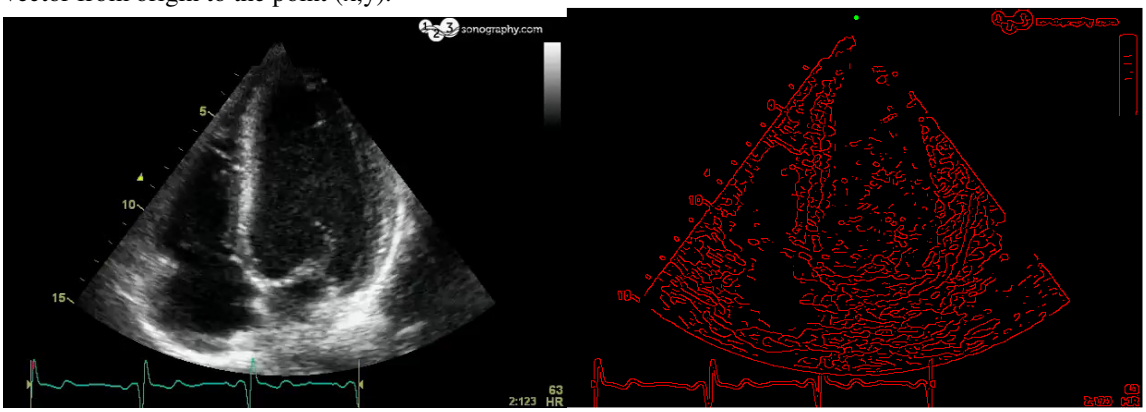
Automatic detection of diseases from echocardiography videos, however, has not been widely addressed. Most of the attention has been paid to valvular diseases from Doppler imaging [13], or measuring hypokinesia (reduced heart motion) and wall thickness in echocardiography videos [10]. Recently, work has been reported on the detection of differences between normal and abnormal left ventricular shapes in echocardiography videos using a modeling approach[12]. Our approach focuses on the detection of dilated cardiomyopathy condition, which to our knowledge has not been investigated earlier by other automated methods.

In medical imaging community, the left ventricular (LV) shape itself has been well-studied primarily for the purpose of segmenting the left ventricle in echocardiography images. A variety of techniques including active shape and appearance models [3, 4, 5], snakes and active contours [6,8], parametric shape descriptors of endocardial contours[8], deformable models and templates [6], and level set techniques are available. Model-based approaches such as active shape models are difficult to learn from a class of shapes as they need manual marker identification as well as prior registration of shapes during model training. Our experimentation also revealed that many region-based approaches over or under-segment the left ventricle, particularly, in diseased cases, resulting in inaccurate boundaries for shape characterization. We also experimented with an active shape model approach to localize LV as described in [10] but found it could locate the left ventricle accurately in only 35% of the cases of 4-chamber views. As a result, we implemented a new bottom-up approach to LV detection. Our approach consists of 4 major processing

stages, namely, (a) ROI identification, (b) LV candidate region generation, (c) LV region selection using apex, (d) LV region refinement using spatio-temporal information. Each of these processing steps are explained below.

Identifying the region of interest and apex:

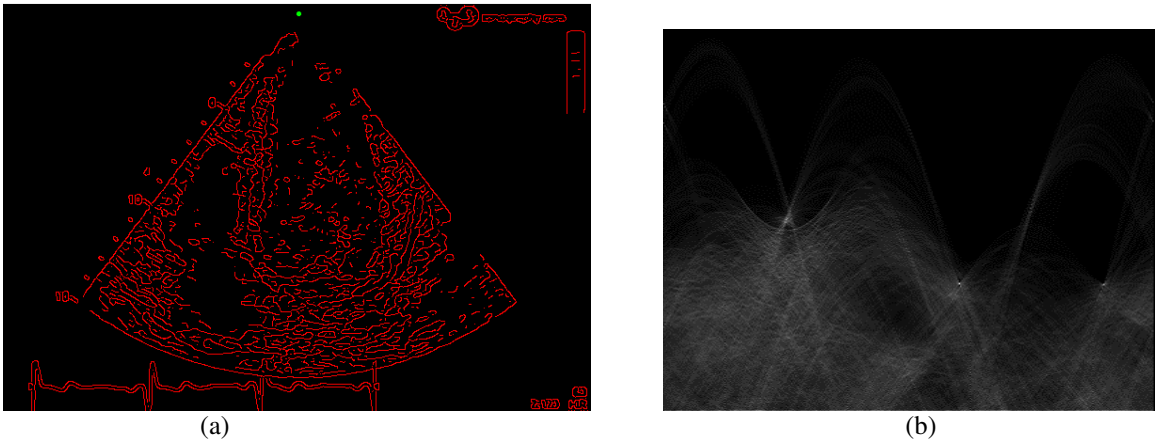
The ultrasound scan sector in the image is usually bounded by dominant lines which can be highlighted using an edge detector, such as the Canny edge detector [14]. Figure 2b shows the edge image generated for the original image of Figure 2a. The popular way to detect strong lines is through the Hough transform [15] which detects the pixels that fall on a line in polar coordinate system by converting lines to points in the Hough space of (r,d) where r is the distance of a point (x,y) from the origin and d is the angle of the vector from origin to the point (x,y).



(a) (b)

Figure 2. (a) Original image. (b) Edge image showing the potential bounding lines of the sector or region of interest. Image source: 123sonography.com

By recording the lines passing through all edge pixels in various orientations, we get the Hough image as shown in Figure 3b. Here the dominant edges seen in the edge image are noted as bright spots in the Hough transform corresponding to the number of pixels that voted for the line, with longer lines getting more votes than short line segments. Of these, the bright spots that are on a horizontal line indicate lines of the same radius and could be potential bounding lines of the sector. Further, if the angle between them as seen by the horizontal separation between the bright spots is within a reasonable angle for a viewing sector (80 to 120 degrees), then they are very likely to be the bounding lines of the sector.



(a) (b)

Figure 3. Illustration of Hough transform. (a) Edge image. (b) Hough transform rendered as an image. The horizontal axis in (b) is the angle, and the vertical axis is the radius in the polar coordinate system.

Our method exploits this observation to analyze the bright spots in the Hough transform image and project them back as bounding lines in the edge image. Verification with the pixels underneath further establishes the bounding lines of the sector. Once the bounding lines are found, the point of intersection can be easily located. Figure 3a shows the point of intersection found in the edge image by a green dot. This is our best estimate of the apex of the heart as well based on the visible content in the sector.

Identifying candidate left ventricle regions:

Since the left ventricle in the 4-chamber views is usually a darker region, we analyze the histogram of the image and separate it into intensity levels to pick relatively low intensity regions. Specifically, we use the multi-level Otsu thresholding method [9] to divide the histogram into 5 intensity levels capturing the 5 ranges of intensities typically seen in echocardiogram images. Of these the second lowest intensity level is used to threshold the original image into two classes. Choosing the second lowest ensures that we also capture cases where due to noise in imaging and phase in the heart cycle, the left ventricular region appears brighter than usual. The region within the bounding lines is then retained in the thresholded image to yield the image shown in Figure 4b. As can be seen, the potential merging of left ventricular region with the background is avoided due to the prior detection of region of interest.

(a) (b)

Figure 4: Illustration of candidate region generation within the bounding sector. (a) Original image. (b) Candidate low intensity regions within the region of interest.

Identifying the left ventricle:

We then use a connected component grouping algorithm to collect all bright pixels in the thresholded image to form candidate regions. Using the observation that the left ventricle is the closest chamber to the apex in a 4-chamber view image on the right, we obtain the distance of the centroid of each region to the point of intersection previously identified during the region of interest localization, and retain the closest rightmost region as our choice for left ventricle.

Depending on the time in the heart cycle where the echocardiogram image is taken, the left ventricular region may be merged with the left atrium (when the mitral valve is open). This can cause the left ventricular region size to be overestimated. In the next step, we integrate information across successive frames in the video to more precisely localize the boundaries of the left ventricle.

Integrating time-varying information:

We process each successive frame of the echocardiography video sequence and extract the left ventricle. The left ventricular shape is best segmented in the end-diastoli position just after the closure of the mitral valve. By tracking the size of the delineated left ventricle through the heart cycle, we pick the end-diastoli

frame as the one with the smallest size region indicated for the left ventricle. When multiple heart cycles are present in the echocardiography sequence, we average the detected size of the left ventricle across all such end-diastoli frames. Finally, we remove small holes within the LV region to form smoothly filled left ventricle region as shown in Figure 5. In this figure, Figure 5a shows a left ventricle detected among the regions of Figure 4b. Figure 5b shows the result of averaging the detection in the end-diastoli frames over the heart cycles found in the echocardiogram video sequence.

(a) (b)

Figure 5. Illustration of LV region detection. (a) Raw region from a single image. (b) average region from end-diastoli frames within the echocardiography video sequence.

Extracting shape features:

Once the LV region is identified, we extract shape features by using the eigenvalues of the 2D shape. Although the practice guidelines for dilated cardiomyopathy recommend measuring the length of the left ventricle from the apex to the mitral value, we adopted the eigenvalues over the exact extremal point-based length measurements in order to provide robustness to boundary localization errors in the left ventricular region. This can also be seen in Figure 5b where the apex region is included in the left ventricle region identification and would alter shape measurements based on the extremal points. Using the ratio of the two largest eigenvalues of the shape, we get a more robust estimation of the spread of the left ventricle in both length and width. Finally, to avoid overestimation of the area in the case of nonconvex shapes of the left ventricle (which can happen in other diseases such as aneurysms), we add a third shape feature based on the pixel area of the left ventricle.

Extracting scale:

The above measurements of shape features must be normalized for zoom effects found in the echocardiography images (when echocardiographers zoom into the regions of interest). The calibration markers found on the region of interest can help identify the scale. The scale difference can be seen in Figures 1a and 1b for the echocardiogram images of two patients from the respective calibration markers shown. In our approach, we detect the number unit markings on the calibration scale using the method described in [12] that is based on an optical character recognition (OCR) algorithm called Tesseract [16]. Using the recognized units, the distance between markers is then converted to pixel coordinates to mm ranges as described in [12]. The resulting shape features are thus normalized and presented for discrimination based on actual physical dimensions rather than the sizes in pixels.

Discriminating between normal and dilated left ventricles:

Given a set of labeled training videos depicting normal and dilated left ventricles, we locate the left ventricle as described above and extract the normalized shape feature vectors. We then find the separation between normal and dilated left ventricle using the Support Vector Machine (SVM) framework. An SVM is a classifier that, when used with two classes, tries to find a boundary in the data space such that the two classes are separated by the maximum possible margin. Given a set of training data which is composed of a set of vectors and their labels, SVM tries to find the parameters of this maximum margin boundary. This

boundary can be thought of as a high dimensional line, which is characterized by a set of weights (α). Since the objective of this work is to discriminate between normal and dilated LV, we build a single SVM model in which the positive examples (+1 labels) are dilated cases and normal cases are the negative examples (-1 labels).

Given a new test echocardiogram video, we proceed as before to extract the left ventricle region and normalized shape features. The trained SVM model is then used to predict the label for the test case as normal or dilated left ventricle indicating dilated cardiomyopathy.

Results:

We evaluated the validity of this approach on an echocardiogram dataset made available from 123sonography.com. This is an educational site for training echocardiographers in the interpretation of echocardiograms. Each video sequence is labeled with the observed condition in the video by their clinical experts. The dataset has over 2000 videos. After automatically analyzing the reports for textual phrases indicating normal or diseased left ventricle, we isolated cases of normal and dilated left ventricles. Figure 6 shows an extract of a report from which the deduction of dilated left ventricles was made and added as a positive example label for the corresponding echocardiography sequence. Raw textual analysis was followed up by manual verification before retaining the labels as ground truth labels. From the 2000 cases, we found about 254 cases of dilated cardiomyopathy and 400 normal cases. We then analyzed all the selected video sequences to locate the left ventricle and selected 124 cases as training data which had accurate detection of the left ventricle and used their shape feature vectors for training data. Of these there were 52 normals and 72 dilated cardiomyopathy cases. The trained support vector machine was then used to classify the rest of the data.

```

Figure 6. Extract of an echocardiogram report with the first column indicating the number of the corresponding echocardiography study.

Since all data tested already has a ground truth disease label of dilated cardiomyopathy or normal, the classification accuracy was evaluated as follows. Let F= (f1,f2,…fM) denote the dilated cardiomyopathy videos identified by the classifier. Let G= (g1,g2,…gN) denote the dilated cardiomyopathy cases identified in the ground for the same video. Then the classification accuracy per class is defined as $\frac{|F|}{|G|}$. The overall accuracy is averaged over the test samples of the two classes.

Training normals	Training dilated LV	Test normals	Test dilated LV	Total correct detections	Total false detections	Overall accuracy %
52	72	348	182	412	117	77.8

Table 1. Illustration of normal versus dilated LV classification accuracy by SVM.

ROI detection accuracy%	LV region selection accuracy %	LV size estimation accuracy %
92.5	89.3	87.2

Table 2. Illustration of performance of the image processing modules

The results of the evaluation are shown in Table 1. The average classification accuracy is currently at 77.8% across all the test sequences. The overall classification accuracy is affected by (a) accuracy of region of interest (ROI) localization, (b) Left ventricle detection, (c) left ventricle region size and boundary estimation besides SVM classifier accuracy reported in Table 1. The relative contribution of each of these was measured by visually inspecting the images produced in each step of the process for each of the test video sequences. The results are summarized in Table 2. As can be seen, many of these steps have good accuracy but due to the cumulative errors from their application in sequence, the overall accuracy reduces to 77.8%. As the first approach to attempt this problem, we believe these results are promising and encourage further research in this area.

Conclusions:

In this paper, we have addressed, for the first time, the problem of automatically detecting dilated cardiomyopathy from cardiac ultrasound videos. A robust left ventricle detector was proposed and shape features extracted and fed to machine learning framework based on support vector machines to separate normal from dilated left ventricles. The performance of the classification shows the promise of the method towards developing a reliable decision support tool in future.

Abstract

Secure access to patient data is becoming of increasing importance, as medical informatics grows in significance, to both assist with population health studies, and patient specific medicine in support of treatment. However, assembling the many different types of data emanating from the clinic is in itself a difficulty, and doing so across national borders compounds the problem. In this paper we present our solution: an easy to use distributed informatics platform embedding a state of the art data warehouse incorporating a secure pseudonymisation system protecting access to personal healthcare data. Using this system, a whole range of patient derived data, from genomics to imaging to clinical records, can be assembled and linked, and then connected with analytics tools that help us to understand the data. Research performed in this environment will have immediate clinical impact for personalised patient healthcare.

Introduction

Secure access to patient data, coupled to analysis tools running on that data, promises to revolutionise the clinical decision making process for the treatment of a wide range of diseases. The problem of sharing clinical data presents a major hurdle to overcome if patient specific data analytics and computer-based modelling are to be developed for medical research purposes and, ultimately, incorporated into clinical practice.

Because of this, the data sources held by hospitals represent a major resource that is currently not adequately exploited, either by researchers or clinicians. Digitised patient data collected as part of routine clinical practice, and which can be used as input to a wide range of analytics techniques, initially resides in information systems based within the individual hospital where the data is acquired. These data include medical images obtained through techniques such as magnetic resonance imaging (MRI) or computed tomography (CT), biopsy microphotographs, DNA and RNA sequence data, proteomics, metabolomics, and other kinds of medical records.

The data held by clinical data systems can be used in at least two different ways: (1) to compose large, (pseudo)-anonymised datasets from multiple sources, in order to perform inference based machine learning and to structure and support clinical trials; (2) to run workflows in support of clinical decision making processes on individual patients.

To make this personal data available to scientists and clinicians, we have developed a data warehouse as part of the EU FP7 p-medicine project, coupled to a medical informatics platform, into which data sources from multiple hospitals can be aggregated to generate substantially larger data collections upon which more comprehensive data analytics can be performed. The benefit of this informatics platform is clear: not only do our solutions allow data from diverse sources to be linked and integrated, they also provide a common platform that scientists and clinicians can use to initiate analytics workflows based on that data, as they offer standards compliant interfaces and APIs into which many existing and future tools and services can be plugged. The flexibility of the triplestore approach (described below) also allows us to model data in new and innovative ways. These capabilities are key to meeting the needs of the new and rapidly growing field of personalised medicine. In this paper, we describe the components of our medical informatics platform, as well as how external tools can be interfaced to the warehouse to upload, download and analyse data. In our view, the flexibility and generic nature of this platform make it applicable to a whole range of medical informatics problems. It permits immediate biomedical and clinical research to be conducted. Its novelty resides in its ability to seamlessly integrate large scale heterogeneous medical

data in a secure, federated and distributed environment, spanning all levels from local, regional to national and international scales.

Healthcare Information Management Systems

There are many different approaches to building electronic health record and hospital information systems. Systems such as PatientCentre from iSOFT[1] are deployed within an individual hospital to manage patient data, although the GP2GP system[2] in the UK allows GP practices to transfer records amongst themselves. There are emerging standards for integrated electronic health record systems, such as HL7[3], which facilitate data transfer between systems. Online "cloud" based systems such as Microsoft HealthVault[4] allow individual patients to store and manage their health records via an online service.

Clinical data management systems are designed to manage data coming from clinical trials, and thus are often used to federate data from multiple administrative domains. Systems such as the IBM Cognos platform[5] provide business intelligence services to pharmaceutical and life sciences companies conducting clinical trials. Microsoft's Amalga platform[6] brings historically disparate data together and makes it easy to search and gain insight from that data.

However, while these systems are designed to manage and integrate large amounts of data (potentially all of the patients treated in a hospital), they do not generally deal with sharing patient data for research purposes between multiple institutions, including the ones located in different countries. In addition, traditional electronic health care record systems do not go beyond basic data management to provide advanced analysis and decision support capabilities, which rely on high performance computing platforms currently out of the control of the administrators of the data management system.

The caBIG project[7] has developed an informatics platform designed to share basic research, clinical trials imaging data, and biobanking samples between researchers, and allow them to use the data to run analytics techniques. However, caBIG's approach has been viewed as being too broad and technology led, and not designed around the needs of clinical users and researchers[8].

tranSMART[9] is an interesting recent development in the area of clinical research data management, and has found significant use in the pharmaceutical industry. tranSMART is a knowledge management platform that enables scientists to develop and refine research hypotheses by investigating correlations between genotypic and phenotypic data, and assessing their analytical results in the context of published literature and other work. However, tranSMART does have a number of limitations: it is focused around clinical records and molecular data and it does not integrate imaging data, nor does it provide access to high performance computation for data analytics.

i2b2 provides a scalable computational framework to address the bottleneck limiting the translation of genomic findings and hypotheses in model systems relevant to human health. New computational paradigms and methodologies are begin developed and tested as part of the i2b2 project in several disease cases. The server side of the software provides file and data repository facilities, as well as ontology and identity management tools. Plug-ins allow system capabilities to be expanded, with high performance computing capabilities for data analysis for example. Users access the system from client workbench and web portal tools.

System Design Overview

Our platform is organized inside a secure framework in order to ensure the confidentiality of the stored clinical data. Inside this framework there are five main components: the upload tools, the clinical trials manager (ObTiMA, described in more detail below), the data warehouse, the ontology annotator/data translator and the pseudonymisation services. Figure 1 shows a diagram of the system's design.

Upload tools and clinical trials manager components are the ones that interact with the world outside the secure framework but, at the same time, ensure that the connections with the inner components are secure. The data warehouse is the core component that stores all the data and makes it available through a public API that can be accessed only by secure connections. The ontology annotator/data translator is the component that takes complex data uploaded to the data warehouse and adapts it to conform to standard formats and protocols in order to make it easier to use and transforms it to a common vocabulary in order to enable the semantic integration of the data. Finally, the secure framework in which the system is embedded is responsible for authentication, authorization and accounting across the informatics platform. In addition, it ensures that data is pseudonymised when it is pushed into the data warehouse.

The following sections describe in detail the data ingestion workflow, the data warehouse, the pseudonymisation process, the integration of data and ontology markup and the use of the informatics platform.

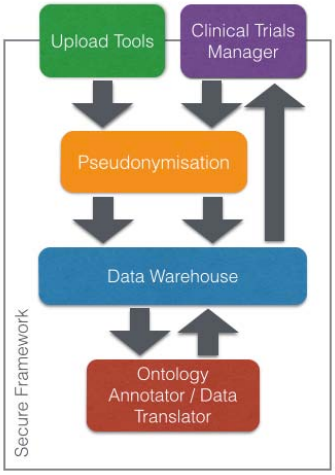

Figure 1. System design overview diagram. All traffic is secured by the authentication and authorization services in the secure framework. In addition, all data pushed into the data warehouse must pass through the pseudonymisation process to assure the privacy of the data stored in the warehouse. Finally, when data to be annotated is uploaded to the data warehouse, it triggers the ontology annotator and the data translator modules.

Data Ingestion Workflow

Health data from patients is collected by the treating physicians and stored within the treating hospitals. This data is exported by uploading it to the data warehouse. Data can also be entered into the platform's Clinical Trial Management System, ObTiMA (described in a following section). From there, data can then also be further transferred to the data warehouse. Researchers and users within the network of trust (the research domain) only have access to the *de facto* anonymous data in the data warehouse. Re-identification is only possible through the Trusted Third Party (TTP) towards the hospital.

The process of uploading new data in the data infrastructure consists of several steps: export of the data from primary sources, transformation of the data to a data format that is supported by the "upload infrastructure", pseudonymisation of the data to remove or obscure the patient identifiers, semantic annotation to attach "meaning" to the uploaded data, and semantic translation to transform the uploaded information to the semantic framework and its set of supported ontologies. The general flow of the data between the main components in the "data push" scenario is shown in Figure 2.

As in the well-known "Extract-Transform-Load" (ETL)[10] process, we can identify three main stages in the overall "upload data" scenario:

(i) Export of data from their original data sources. Our platform supports three different ways of exporting data from their sources. In the first case the data are already available on the user's computer where the user has full access to the files to be updated and the only foreseen complexity is to ensure that the data formats are supported by the upload infrastructure either directly or through a suitable transformation tool. In the second case, the data, in a multitude of formats, are stored within a "system" that allows the user to export them. In the third and most challenging case the data are stored in a Relational Database where the users need to know about the internal details of the source system, its relational schema, and must define in Structured Query Language (SQL) what is to be exported. In the latter case there are certain concerns raised with respect to the security and stability of the primary data providing systems (e.g. Hospital Information Systems) when accessed directly during their mission critical operation in the treatment domain. For these reasons the proposed architecture does not include in its design generic adapters or gateways for retrieving the information stored in the original data sources. Rather, such special data export adapters can be provided on case-by-case basis depending on the operational characteristics of a given data providing system.

(ii) Format of the uploaded data. In general the data format can be domain specific (e.g. DICOM images) and either structured or unstructured. For the raw binary formats such as medical images, the uploaded format can

be identical to the original one after the pseudonymisation process. For structured data, Comma Separated Values (CSV) can be used, a plain text format that stores tabular data. In the case of a relational database where multiple tables are to be exported, the adoption of the CSV format requires that multiple CSV files be created. Although there are certain, more expressive alternatives such as XML (Extensible Markup Language) and RDF, the CSV format provides a "lowest common denominator" for the exchange of clinical data and enjoys the best support within the pseudonymisation infrastructure; moreover, it is "natively" supported by spread sheet applications and all relational database management systems[11].

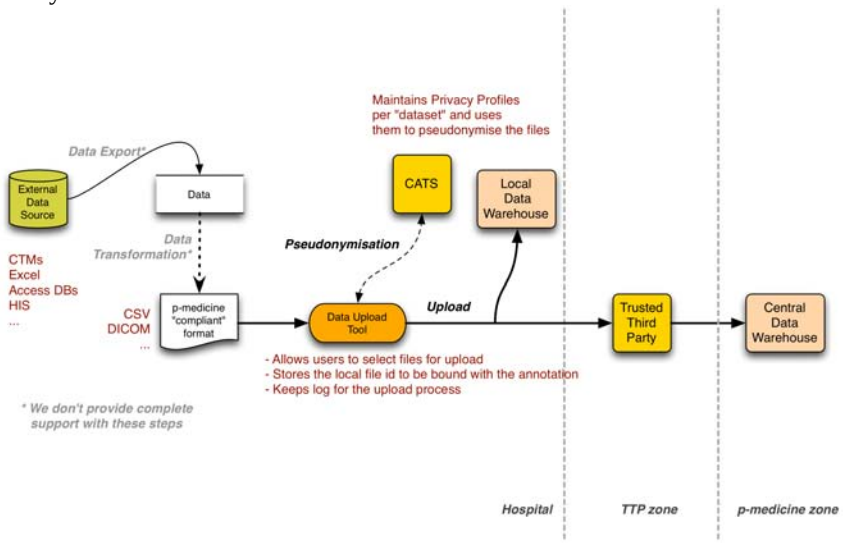

Figure 2. The data upload process. Data is exported in a p-medicine "compliant" format before being pushed into the local data warehouse and the central data warehouse via the trusted third party.

(iii) Data anonymisation and upload. The Data Upload tool is a desktop GUI application for "pushing" the data through the security infrastructure to their final destination, which is the data warehouse. It provides a graphical user interface for the push services, a user-friendly tool hiding all the complexity behind its easy-to-use interface. Its main functionality is to allow a user to load files containing patient data in a variety of formats, including CSV or DICOM, perform a first round of anonymisation through the use of the Custodix Anonymization Tool Services (CATS), see the Pseudonymisation section below), and then upload the data to the data warehouse..

Data Warehouse

The data warehouse (DWH) provides the main information storage system at the core of our platform. It consists of three main components: the triplestore, the filestore and the imagestore. DWH is built to address the central notion of reproducible research. The key concept that is implemented to make research reproducible is the automatic versioning of triplestore contents: any modification of the triplestore creates a new and unique version of the triplestore (a modification of the triplestore is also called a transaction). All responses to the triplestore queries contain explicit information on the triplestore version used to fulfil the request. Any of the triplestore versions can be queried, but cannot be modified at any time.

Semantic data held in the triplestore originate from the "raw" source files, which may be stored in the DWH filestore. There is a well-defined process of extraction of semantic data from some of the common file formats; this data is transformed after extraction using the data annotation and data translation tools, and the semantically translated data is added to the DWH triplestore. Changes to the annotation of the source data are immediately reflected in the triplestore by rolling back the transaction containing the old data originating from this file's extraction and translation chain, and by creating a new transaction with new data.

Image data upload is not supported by the DWH; however, they are accessed via DWH since it acts as a protocol proxy between the DWH user and the associated Picture Archiving and Communication System (PACS) servers. Imaging metadata is automatically transformed into raw semantic form which can be used as input for the data annotation and translation chain (explained in a following section), equipped with matching triplestore update semantics similar to the filestore.

A data warehouse can be deployed centrally in the research domain or locally in the treatment domain. In the central data warehouse (CDW) the data has been pseudonymised twice (the second pseudonymisation performed by the TTP) and is protected by a contractual framework and access controls, meaning the data can be regarded as *de facto* anonymous and can be used for research. In a local data warehouse (LDW) the data is pseudonymised only once, with the pseudonymisation key kept by the hospital. That means re-pseudonymisation of the data in the LDWs and therefore reuse of that data for treatment purposes is possible, whereas for data stored in a CDW this is only possible under very limited circumstances. From the technical point of view, LDWs and CDWs are identical.

Triplestore, Filestore, Imagestore

The DWH triplestore API permits querying the triplestore contents using SPARQL queries. It also allows plain export of the statements matching the given criteria (subject, predicate and/or object match filters). Updates to the triplestore can be made either by direct upload/deletion of specified statements, or by using the SPARQL UPDATE language. Raw data and the final processed triples added to the triplestore are tightly coupled as the user is allowed to update the annotation description at any time and then the old triples generated by this file can be updated to the new format at any time. In addition, to maintain the versioning control, the new triples are put in a new version of the triplestore together with all other triples already existent. Each triple may appear in some triplestore version exactly once, so the concept of modification rollback (transaction rollback) requires a more precise definition.

Filestore manages the storage of any type of file into DWH. Its API allows uploading and downloading a file just by providing the appropriate URL with the file identifier. In addition, when uploading a new file, whether a comma-separated value (CSV) file or an Access database, a mechanism to extract triples from the file is triggered and they are stored in the triplestore.

Finally, the imagestore manages the DICOM (Digital Imaging and Communications in Medicine) image storage while its API allows two different actions: downloading of DICOM image files and accessing the extracted triples pertaining to a DICOM image file. This is achieved by simply providing the appropriate image ID in the request URL.

Pseudonymisation

There is a clear distinction between the health treatment domain and the research domain. Medical data contain sensitive information about many patients' health and wellness. For research purposes, such data must be used in anonymised form whenever possible for legal and ethical reasons. Anonymisation is the best way to protect a patient's privacy. The platform should allow the re-identification of a patient when the research results reveal that a certain therapy would be highly effective for that given patient. Therefore data cannot be fully anonymised.

The secure framework is thus based on *de facto* anonymised data. Pseudonymous data can be regarded as *de facto* anonymous data[12,13] whenever the researchers working with the data do not possess the key linking it back to the patient and there are protection measures in place that prevent the researchers from trying to re-identify patients.

Where authorisation is given to upload data to the data warehouse, it is the clinician who triggers the transmission of the respective medical data to the warehouse. The data is first pseudonymised at the source, i.e. the hospital, and only then uploaded through the Trusted Third Party (TTP) into the data warehouse. The TTP anonymises the data through a second pseudonymisation round. The TTP, which does not dispose of any health data, also serves as a vault containing the link back to the patient if needed. The use of a TTP also assists in linking data from the same patient emanating from multiple sources.

Researchers and users within the network of trust (the research domain) only have access to the anonymised data in the data warehouse. Re-identification is only possible through the TTP and is provided unidirectionally to the source hospital.

In the current version of our health informatics platform, we make use of Custodix Anonymisation Tool Services (CATS), a set of tools and services responsible for the de-identification or anonymisation of patient data files, provided by the Belgian company Custodix, which acts as TTP. CATS anonymises or pseudonymises a data file based on a set of pre-configured transformation rules through so-called privacy profiles. The adequate definition of the transformation functions to be applied to an input file involves a thorough risk assessment. This is largely a manual task but, once defined, CATS can handle data without much effort. Once the transformations have been defined on a generic data model, all that the data uploader needs to do is map the data to that generic model. This two-step approach allows for uniform processing of data in different formats. It is also more convenient for setting up a project and provides a higher assurance level with respect to compliance.

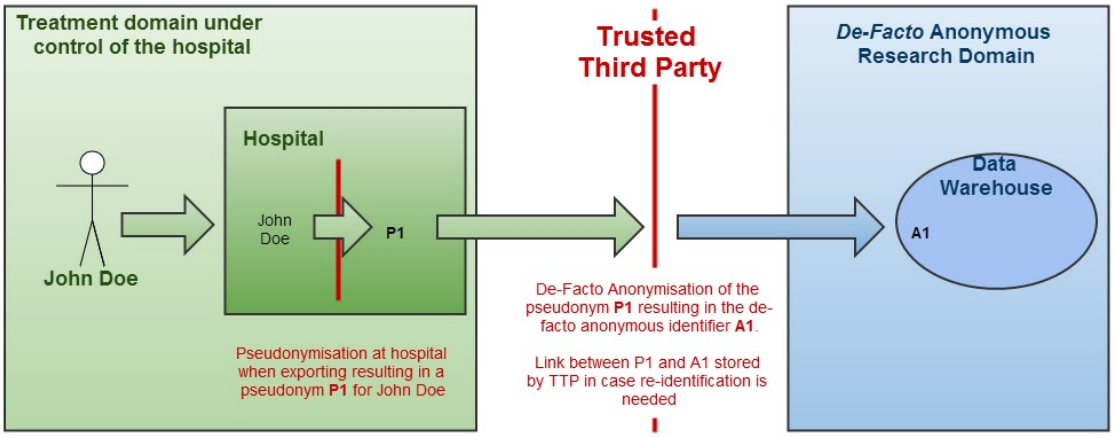

Figure 3. Pseudonymisation overview. Each user receives a pseudonym when data is pushed from the hospital. Then it is sent to the trusted third party (TTP) and it generates an anonymous identifier for this user, which is the one that is stored in the data warehouse. However, the TTP stores the link in case re-identification is needed.

Pseudonymisation functions typically generate a pseudonym based on a patient's identifying information (such as ID, name, date and place of birth). CATS therefore uses the Patient Identity Management System (PIMS) to issue pseudonyms. PIMS tries to assign the same pseudonym to the same patient by checking whether that patient has already been registered in the common PIMS database. A new pseudonym will only be assigned when there is no such patient registered so far. If the patient had already been registered the existing pseudonym will be attributed to him/her. Thus PIMS avoids the creation of different pseudonyms for the same patient (synonyms) as well as the creation of the same pseudonyms for different patients (homonyms).

Ideally, though, identifying information should never leave the source. Therefore CATS encrypts individual identifying attributes (name, data of birth, address, etc.) before sending them to PIMS. Due to the nature of cryptographic algorithms, very similar attributes (e.g. typographical errors) will be transformed to different encrypted values. Encryption does not maintain the similarity between records. For this reason, fault-tolerant matching (implemented by the matching engine in PIMS) on individual attributes is not possible. It is important to keep in mind that there is still a risk of re-identification when using encrypted attributes. Through statistical or frequency analysis techniques, re-identification of (parts of) encrypted attributes can still be achieved. To tackle the problem of matching encrypted records PIMS uses Q-grams[14] and bloom filters[15].

A Q-gram is a word with length Q that is a substring of a given word. Q-grams are used in fault-tolerant matching of words. The biggest disadvantage of this algorithm is the massive amount of subsets that are generated and encrypted at the source. Each encrypted subset must be sent to the matching service that will match with all previously received subsets. This requires substantial resources (network, storage, memory, etc.). A bloom filter is a compact data structure that allows checking for whether a given element is part of a collection, without the need to store the complete collection. Due to the compact representation false positives are possible. A bloom filter could indicate that an element is part of a collection but in reality it is not. On the other hand, false negatives can never occur. Bloom filters can be applied to investigate whether a given substring is part of a given word, without showing the complete word. To overcome the disadvantages of the Q-gram technique, we use bloom filters to match encrypted data. The algorithm itself is similar, but the collection of Q-grams for a given attribute is encrypted in a bloom filter instead of a collection of subsets.

Integration of Data and Ontology Markup

To apply meaning to the data in the data warehouse, and perform reasoning across datasets, all uploaded data is annotated with an ontology. To do this, we have coupled a data annotation tool, called Ontology Annotator (OA) with our data warehouse. The OA is a web-based tool for annotating the databases prior their integration in the DWH. The annotations generated with the OA consist of the semantic alignment of databases with HDOT (Health Data Ontology Trunk). This tool is aimed at end-users–scientists and clinicians as well as database administrators–who must have some comprehension of basic database concepts, but do not necessarily have expertise in the RDF paradigm. The OA receives as input the RDF schema of a database and provides a graphical interface that represents

both the schema and the HDOT ontology elements in a graph-based representation. The output is an XML-based serialization of the semantic equivalences of elements of the database with elements of HDOT, as defined by the user. The resulting annotation is submitted to the DWH, and associated to the corresponding database. This information is later used to translate the database to an HDOT-compliant form at the entity and attribute levels.

The OA relies on a view-to-view alignment approach, as opposed to the classical element-to-element approach. This means that database annotations store pairs of semantically equivalent views, instead if single elements. While there can be found works that already apply this approach[16,17], these are restricted to tabular format, and ours is the first one that employs it with RDF sources, as described elsewhere[18]. The atomic elements mapped in our alignment format are RDF views, instead of classes or properties. This results in a novel capability to solve cases of semantic heterogeneity which cannot be handled by other approaches. As a consequence, a database annotation is formed by a set of pairs of RDF views, one belonging to the annotated database, and one to HDOT, which we refer to as *entries*. Figure 4 shows the structure of the annotations in the semantic layer of our platform.

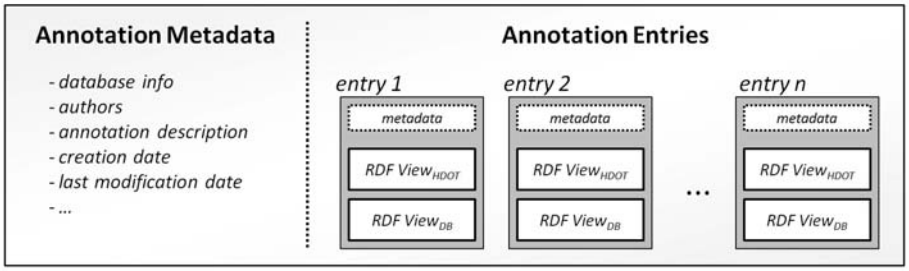

Figure 4. Structure of the annotations defined for each database. Semantic equivalences are defined with the set of entries, each containing an equivalence of a database view and an HDOT view.

This approach has been successfully applied in experiments with real data, where two heterogeneous datasets (one from the SIOP clinical trial, and one with miRNA data from some of the patients if this trial) where homogenized and merged. The former dataset contained clinical information of patients, with attributes such as age, the presence or absence of relapse, and patient identifier. The latter dataset was formed by a CSV file with 848 columns for each described miRNA molecule expression, and one column for the patient identifier. This was automatically translated to RDF by the DW. The two datasets schemas were annotated and properly aligned with the HDOT ontology. In the SIOP database, the RDF view for accessing the patients' identifiers (formed by two RDF paths, <"*patient_identifier*" → "*patient_identifier_patient_id*" → "*patient*"> and <"*patient_identifier*" → "*patient_identifier_value*" → "*string*">) was aligned with an HDOT view with similar semantics (formed by a single RDF path, <"*patient*" → "*denoted by*" → "*patient identifier*" → "*has value*" → "*string*">). In the miRNA dataset, the RDF view denoting patients' identifiers ("*Row*" → "*PatientID*" → "*string*") was aligned with the same HDOT view, thus achieving the effective merge of the two datasets in the DW triplestore.

The developed approach for annotating RDF databases is extremely generic, and allows translating any possible data model to HDOT, as long as it is modeled in RDF. The limit is actually imposed by the availability of appropriate concepts and relations in the HDOT ontology, which can be easily extended if required.

View-based annotations produced by the Ontology Annotator are used as input by the data translation process to generate HDOT-based data, achieving the desired semantic integration of the information. The output of this process is a set of RDF triples which are loaded into the DWH triplestore. These triples include provenance information and a timestamp, to allow tracking the merged data in the DWH. Translation of each annotated database is performed independently from each other. The failure in the translation of one database does not affect others, as the only consequence is that the triplestore does not receive triples from that database (upon this event, the user that created the annotation is duly notified). Figure 5 depicts the translation process performed by the data translator.

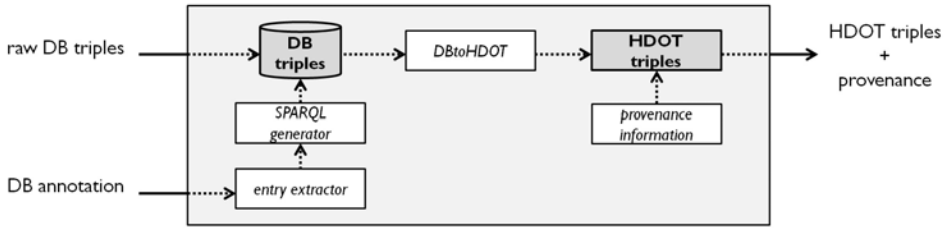

Figure 5. The data translation process uses database annotations as input. Resulting data conform to a common vocabulary provided by a cancer-related ontology. Provenance information is added to the transformed data.

Use of the Data Warehouse

The data warehouse outlined in this paper is designed to provide a flexible, robust, scalable, federated, distributed informatics platform within which to store heterogeneous medical data, ranging from clinical records, to medical images, to genomic data, in a linked, patient oriented format. In addition it has an easy use and deployment. In order to access this data, the warehouse provides a RESTful API to access, query and manipulate data. The API means that the warehouse can act as a back end to a whole range of data analytics tools, from generic statistical packages such as R, to bespoke processing tools (e.g. MINFI, LUMI, LIMMA, BWA, PICARD, SAMTOOLS, GALAXY, etc). It also makes it possible to quickly and easily tailor specific interfaces, such as web portals or mobile apps, to different groups of data warehouse users. This means that we can respond rapidly to the requirements of users to couple in the interface and analytics tools required by project researchers. By way of an example, we discuss how we have coupled our data warehouse to a clinical trials management platform.

The Ontology-based Trial Management Application[19] (ObTiMA) system is intended to support clinicians in both designing and conducting clinical trials in a user-friendly way. It has the ability to integrate an ontology into the trial building process, which makes it an extremely attractive platform for managing clinical trials. The HDOT ontology has been integrated into ObTiMA and a trial chairman is enabled to design a Case Report Form (CRF) compliant with the HDOT ontology. Therefore, data that is collected during a trial can be easily mapped to terms in the HDOT ontology. In order to integrate ObTiMA with our data warehouse, two modules have been developed for ObTiMA, which enable users to exploit the features of the platform and integrate ObTiMA with the DWH, namely the sync and the push services. Sync services enable the reuse of data stored in hospital information systems in running multicentric trials in ObTiMA. They facilitate clinical research by enabling a single entry of data for both research and healthcare avoiding redundant data entry and maximize the use of information from healthcare for research purposes. Push services have been developed in order that data collected via ontology-based CRFs in ObTiMA can be pushed into the DWH and provided in a format compliant with HDOT ontology, fully automatically without any manual preprocessing or annotation steps.

Sync Services

The sync services enable the reuse of data stored in hospital information systems in running multicentric trials in ObTiMA. In such trials several hospitals, with different heterogeneous hospital information systems (HISs), are involved, where the patient data is stored that can be reused. In such settings many authors have endorsed reusing electronic health record data in clinical trial management systems to enhance clinical trial processes and especially to avoid redundant data entry into these systems[20,21]. There are several projects that aim to link electronic health record (EHR) and clinical trial management systems (CTMS)[22,23], focusing especially on approaches to avoid redundant data entry. One of the main obstacles is the lack of semantic interoperability between different HIS systems and between HIS systems and trial management systems, partly resulting from a lack of harmonized semantic standards in the areas of health care and clinical research. The ObTiMA sync services solve these problems by utilizing the platform's semantic layer and retrieving data from the DWH. This approach has the advantage that it does not require for each new trial a full manual mapping of the data models in the EHR onto the CRFs of the trial as required in current approaches. Furthermore, it does not put restrictions on the hospital information systems used, such as compliance to standard data sets that are in general not fulfilled by current systems.

The relevant data flow for the sync services is shown in Figure 6 (left). In order to enable the reuse of data from the HIS in each hospital a local data warehouse (LDW) needs to be installed into which the data from the HIS is pushed. During this step the data is pseudonymised and semantically integrated. The sync services retrieve data from the LDWs into ObTiMA. Since the data is already integrated compliant with HDOT, the data can be mapped semi-automatically into the ontology-based CRFs of the clinical trial. Although the data in the LDW is pseudonymised, it is ensured by the Patient Identity Management Services (PIMS) of the platform's security infrastructure that appropriate data for patients in ObTiMA can be found in the LDW. The retrieved HIS data with the information as to which CRF item they are mapped into and information about its origin is shown to the clinician for confirmation. Only data originating from a hospital information system or electronic health record will be shown. The user then needs to review and confirm the data. The user can then either allow the data to be stored in the associated CRF or delete the data. Data that has been accepted are stored in the associated CRFs in the same way as if the user would have entered it manually.

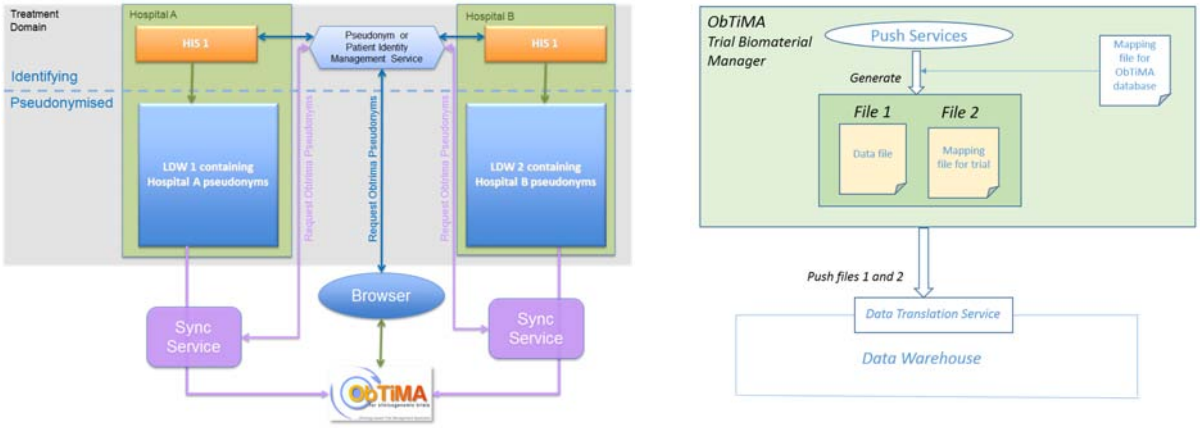

Figure 6. Data flow for sync services (left) and push services (right). The sync services retrieve data from the LDW installed in the hospital. The Patient Identity Management Service ensures that pseudonyms can be mapped to patients in ObTiMA. The push services are able to push trial data from ObTiMA either to the LDW or DWH. To translate trial data to a format compliant with HDOT the Data Translation Services are used.

Push Services

ObTiMA is seamlessly integrated with the DWH via push services whereby the data collected in ontology-based CRFs is ingested into the DWH and provided in a format compliant with the HDOT ontology without any manual pre-processing or annotation step. Pushing the data can be easily triggered by a trial chairman from the ObTiMA user interface. The process of pushing data from ObTiMA into the DWH is depicted in Figure 6 (right). In order to translate the data from the ObTiMA database to a format compliant with HDOT that can be stored in the DWH the Data Translation Services of the platform's semantic layer are used. These services require two input files: a "data file" and a "mapping file" for the selected trial. The "data file" contains the trial data that will be pushed in the form of RDF triples. The "mapping file" contains the ontology-annotations necessary to translate the trial data into an HDOT compliant format. The two files are automatically generated and sent to the ontology annotator and data translator tools and stored in the DWH.

Conclusion

The digitization of patient health care records, and the diversity of data sources comprising these, make imperative the development of easy-to-use, standardised health informatics platforms. The system we have presented in this paper is designed to do just that, linking pseudonymised patient data from multiple clinical sources, on which analytics and modelling tools may be applied. The flexible, distributed nature of our system makes it highly robust and scalable, and the use of pseudonymisation means that, unlike many similar platforms, should results from the analytic processess we apply to our data be found to have an impact on an individual patient, we can, via the trusted third party, feed back those results to the clinicians treating the patient.

In contrast to the similar systems presented at the beginning of this paper such as tranSMART and i2b2, our system is characterized by an advanced data warehouse, which is capable of automatically processing a variety of uploaded file formats to extract relevant data and store it in our data triples. Unlike other systems, our platform is designed from the ground up to integrate heterogeneous data types, including imaging, genomic and clinical records data. Our system also provides unique capabilities to trace the provenance of research data and to roll back commits on the data held in our warehouse. Having a central knowledge base with such heterogeneous types of data makes the data warehouse a novel and powerful way to do research. This ability to combine data of widely varying types and perform analyses on them facilitates the opportunity to make entirely new medical discoveries.

Abstract

In this paper, we present the results of a method using undirected paths to determine the degree of semantic similarity between two concepts in a dense taxonomy with multiple inheritance. The overall objective of this work was to explore methods that take advantage of dense multi-hierarchical taxonomies that are more $graph\text{-}like$ than $tree\text{-}like$ by incorporating the proximity of concepts with respect to each other within the entire $is\text{-}a$ hierarchy. Our hypothesis is that the proximity of the concepts regardless of how they are connected is an indicator to the degree of their similarity. We evaluate our method using the *Systematized Nomenclature of Medicine Clinical Terms* (SNOMED CT), and four reference standards that have been manually tagged by human annotators. The overall results of our experiments show, in SNOMED CT, the location of the concepts with respect to each other does indicate the degree to which they are similar.

1 Introduction

The automated discovery of groups of semantically similar concepts and terms is critical to improving the retrieval[1] and clustering[2] of biomedical and clinical documents, and the development of biomedical terminologies and ontologies[3]. Additionally, semantic similarity measures could be used indirectly in applications such as finding articles with similar content in PubMed[4], and clustering symptoms and disorders found in the text of clinical reports for post-marketing medication safety surveillance[5 6]. Similarity measures quantify the degree to which two concepts are similar based on their taxonomical proximity through the $type\text{-}of$ (or $is\text{-}a$) relationships that exist between them. This is often referred to as a hyponym relationship where one term's ancestral pedigree is included within that of another term. The path passing through a common descendant would link the two concepts. The $undirected\ path$ ($u\text{-}path$) measure is a method to obtain the degree of semantic similarity between two concepts in lexical resources with significant multiple inheritance and are more *graph-like* than *tree-like*. This measure quantifies this degree based on the reciprocal of the shortest path between two concepts regardless of the direction of graph traversal.

Other similarity measures use the shortest path in their calculation but require that the concepts be connected through their least common subsumer (LCS) such as the conceptual distance measure proposed by Rada, et. al[1] and subsequently implemented by Caviedes and Cimino[7], the measure proposed by Leacock and Chodorow[8], and the path measure, which we refer to as $lcs\text{-}path$, as implemented by Pedersen, et. al[9]. The $lcs\text{-}path$ measure and the measure proposed by Leacock and Chodorow[8] were initially developed with WordNet[10] as their lexical resource. Concepts in WordNet are primarily organized in a acyclic hierarchy, free from multiple inheritance, therefore the shortest path between any two concepts would contain the LCS. This is not the case though for other taxonomies such as the *Systematized Nomenclature of Medicine Clinical Terms*[11] (SNOMED CT), which is a dense multi-hierarchical taxonomy of clinical terms.

The $u\text{-}path$ measures relaxes the requirement that the path between the two concepts must go through the LCS. Figure 1 shows the individual shortest path lengths used by the $lcs\text{-}path$ and $u\text{-}path$ measures to calculate the degree of similarity between Neuropathy and Paralysis in SNOMED CT. Neuropathy and Paralysis are both disorders that may involve the peripheral nervous system. In this example, the length of the shortest path is four but increases to ten when requiring the path to be connected through the concepts' LCS.

The overall objective of this work is to begin exploring methods that take advantage of dense multi-hierarchical taxonomies. Our hypothesis is that the proximity of the concepts, regardless of how they are connected, is an indicator of

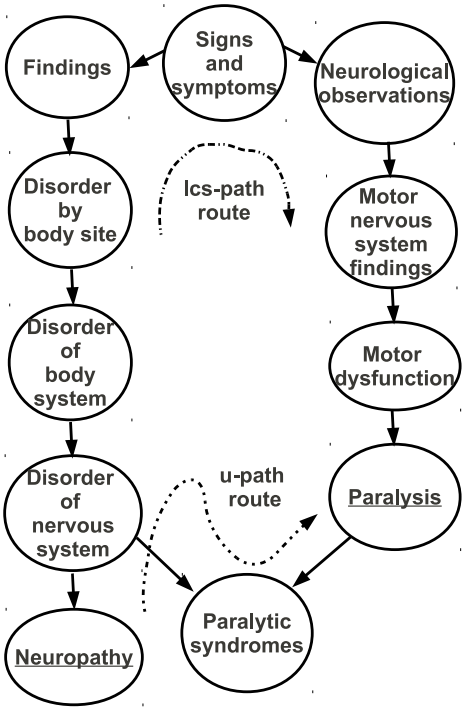

Figure 1: Example of the $lcs\text{-}path$ and $u\text{-}path$ measures

the degree of their similarity. Towards this end, we evaluate $u\text{-}path$ using SNOMED CT and four reference standards that have been manually tagged by human annotators. The results show, in SNOMED CT, the location of the concepts with respect to each other regardless of their LCS can be used to indicate the degree to which they are similar.

2 Semantic Similarity Measures

Existing semantic similarity measures can be categorized into two groups: path-based and information content (IC)-based. Path-based measures rely solely on the shortest path information, whereas IC-based measures incorporate the probability of the concept occurring in a corpus of text.

Path-based Measures

Rada, et al.[1] introduces the conceptual distance measure ($c\text{-}dist$), which is calculated as the length of the shortest path between two concepts that connects the concepts through their least common subsumer (LCS). The LCS is the most specific ancestor shared by two concepts. The length is calculated by counting the number of nodes between the two concepts. The $lcs\text{-}path$ measure is a modification of this and is calculated as the reciprocal of the length of the shortest path as shown for concepts c_1 and c_2 in Equation 1.

$$\text{sim}_{path}(c_1, c_2) = \frac{1}{\text{minpath}(c_1, c_2)} \tag{1}$$

Wu and Palmer[12] extend this measure by incorporating the depth of the LCS. In a multi- hierarchical taxonomy, we define the depth to be the minimum path between the concept and the root. In this measure, the similarity is twice the depth of the two concepts LCS divided by the sum of the depths of the individual concepts as defined in Equation 2.

$$\text{sim}_{wup}(c_1, c_2) = \frac{2 * \text{depth}(\text{lcs}(c_1, c_2))}{\text{depth}(c_1) + \text{depth}(c_2)} \tag{2}$$

Leacock and Chodorow[8] extend the path measure by incorporating the depth of the taxonomy. Here, the similarity is the negative log of the shortest path between two concepts divided by twice the total depth of the taxonomy (D) as defined in Equation 3.

$$\text{sim}_{lch}(c_1, c_2) = -\log \frac{\text{minpath}(c_1, c_2)}{2 * D} \tag{3}$$

Nguyen and Al-Mubaid[13] incorporate both the depth and LCS in their measure. In this measure, the similarity is the log of two plus the product of the shortest distance between the two concepts minus one and the depth of the taxonomy (D) minus the depth of the concepts LCS (d). Its range depends on the depth of the taxonomy.

$$\text{sim}_{nam}(c_1, c_2) = \log(2 + (\text{minpath}(c_1, c_2) - 1) * (\text{D} - \text{d}))) \tag{4}$$

Batet, et al.[14] introduce a measure that takes in account the common concepts shared (referred to as shared superconcepts) between the two concepts (c_i and c_j) and their LCS ($lcs(c_i, c_j)$. A concept's (c_i) set of superconcepts ($T(c_i)$) consist of all of the concepts found in all of the shortest paths between c_i and the LCS. In this measure the log ratio of the shared superconcepts as defined in Equation 5 where $T(c_i) = \{c_j \in C | c_j \text{is a superconcept of} c_i\}$.

$$\text{sim}_{batet}(c_1, c_2) = -\log_2 \frac{|T(c_1) \cup T(c_2)| - |T(c_1) \cap T(c_2)|}{|T(c_1) \cup T(c_2)|} \tag{5}$$

Information Content-based Measures

Information content (IC) measures the specificity of a concept in a hierarchy. The fundamental assumption with the IC measures is that the more frequent a concept is, the less specific it is. Therefore, a concept with a high IC value is more specific to a topic than one with a low IC value. IC is formally defined as the negative log of the probability of a concept (c^*) as shown in Equation 6.

$$IC(c^*) = -1 * log(P(c^*)) \tag{6}$$

The probability of a concept is determined by summing the probability of the concept ($P(c)$) occurring in some text plus the probability its descendants ($P(d)$) occurring in some text as shown in Equation 7

$$P(c*) = P(c) + \sum_{d \exists descendant(c)} P(d) \tag{7}$$

The initial probability of a concept ($P(c)$) and its descendants ($P(d)$) is obtained by dividing the number of times a concept is seen in the corpus (freq(d)) by the total number of concepts (N) as seen in Equation 8.

$$P(d) = freq(d)/N \tag{8}$$

Resnik[15] modified IC to be used as a similarity measure. He defined the IC of two concepts (c_1 and c_2) to be the IC of their least common subsumer (LCS) as seen in Equation 9. The LCS is the most specific concept two concepts share as an ancestor; if two concepts have more than one LCS, we use the most specific one.

$$\text{sim}_{res} = \text{IC}(\text{lcs}(c_1, c_2) = -\log(P(\text{lcs}(c_1, c_2))) \tag{9}$$

Jiang and Conrath[16] and Lin[17] extended Resnik's IC-based measure by incorporating the IC of the individual concepts. Lin defined the similarity between two concepts by taking the quotient between twice the IC of the concepts' LCS and the sum of the IC of the two concepts as seen in Equation 10.

$$\text{sim}_{lin} = \frac{2 * \text{IC}(\text{lcs}(c_1, c_2))}{\text{IC}(c_1) + \text{IC}(c_2)} \tag{10}$$

Jiang and Conrath defined the distance between two concepts to be the sum of the IC of the two concepts minus twice the IC of the concepts' LCS. We modify this measure to return a similarity score by taking the reciprocal of the distance as seen in Equation 11.

$$\text{sim}_{jcn} = \frac{1}{\text{IC}(c_1) + \text{IC}(c_2) - 2 * \text{IC}(\text{lcs}(c_1, c_2))} \tag{11}$$

3 Method

As discussed in Section 2, $lcs\text{-}path$ is the reciprocal of the length of the shortest path between two concepts in a hierarchy in which the shortest path is calculated by first finding the LCS of the two concepts and then aggregating the distance of all paths that connect the concepts through the LCS. In the $u\text{-}path$ measure, the paths are not required to contain the LCS and may meander through the hierarchy. We view $u\text{-}path$ as a measure of similarity because it is based strictly on path information found in $is\text{-}a$ relations, but we have relaxed the requirement that the path between the two concepts must go through the LCS.

The $u\text{-}path$ measure is related to the measure proposed by Hirst and St. Onge[18] (hso) that, like $u\text{-}path$, quantifies the strength of similarity between two concepts based on their closeness within a hierarchy. The measure assumes that two concepts are semantically close in a taxonomy if they are connected by a path that is neither too long nor too meandering and the relations between them are either $is\text{-}a$ or $has\text{-}a$ relations. The $u\text{-}path$ measure has a similar assumption but does not put restrictions on the length or meandering of the path, only the type of relation used.

In a subsequent studies using WordNet, Budanitsky and Hirst[19] report that hso obtains similar results to the path-based measure proposed by Leacock and Chodorow[8], which is similar to the results reported by Patwardhan, et. al[20]. We believe this is because hso, like $u\text{-}path$, relies on the concepts being densely connected. Unfortunately, the disadvantage of using hso on a densely connected graph is that it requires keeping track of the length and direction changes of all of the paths between the two concepts. This becomes difficult and in some cases infeasible when using dense multi-hierarchical structures, like SNOMED CT. The $u\text{-}path$ measure presented here, does not have this limitation.

4 SNOMED CT

The Systematized Nomenclature of Medicine–Clinical Terms[11] (SNOMED CT) is a comprehensive clinical terminology created for the electronic representation of clinical health information and is one of the terminology sources in the Unified Medical Language System (UMLS) Metathesaurus. The 2010AB version of the Metathesaurus contains over 1.7 million biomedical and clinical concepts from over 100 different terminology sources that have been semi-automatically integrated into a single resource. The terminology sources in the Metathesaurus can be treated independently or in combination with other sources. Currently, SNOMED CT is the largest hierarchical terminological source in the Metathesaurus.

The Metathesaurus contains a variety of different links between concepts specifying their relationship. The two hierarchical relations, used in this study, are parent/child (PAR/CHD) and broader/narrower (RB/RN) relations. A PAR/CHD is a hierarchical relation between two concepts that has been explicitly defined by the source. An RB/RN relation is a hierarchical relation that does not explicitly come from a source but is created by the UMLS editors during the integration process. In the case of SNOMED CT, the PAR/CHD relations are strictly $is\text{-}a$ relations and the RB/RN relations contain $part\text{-}of$ and $was\text{-}a$ relations. We use the PAR/CHD relations for our experiments.

In version 2010AB, SNOMED CT contains 280,695 concepts with a PAR/CHD relation; 198,241 leaf nodes and 82,454 non-leaf nodes. The depth of the taxonomy is 34, the average depth of a non-leaf node is 9.2 and the average depth of a leaf node is 11.8. The average branching factor of a non-leaf node is 5.1 and on average each node (concept) has 51 distinct paths to the root.

5 Reference Standards

We use four reference standards [a] to evaluate the $u\text{-}path$ measure: the UMNSRS tagged for similarity, the UMNSRS tagged for relatedness, the MayoSRS tagged for relatedness and the MiniMayoSRS tagged for relatedness. We include reference standards tagged for relatedness in our evaluation in order to conduct a comparison with previous work and due to the scarcity of datasets tagged strictly for similarity. Relatedness measures quantify the relationship between two concepts that are not necessarily in a strict $is\text{-}a$ or hyponym relationship; it is domain-dependent and grounded in human perception which takes into account that two concepts may be related in other ways. For example *up* is the opposite of *down*, an *elbow* is part-of an *arm*, and a *scalpel* cuts *tissue*. In this section, we describe the reference standards and then briefly discuss some of their differences.

MayoSRS: MayoSRS, developed by Pakhomov, et al.[21], consists of 101 clinical term pairs whose relatedness was determined by nine medical coders and three physicians from the Mayo Clinic. The relatedness of each term pair was assessed based on a four point scale: (4.0) practically synonymous, (3.0) related, (2.0) marginally related and (1.0) unrelated. We evaluate our method on the mean score of the physicians and medical coders as provided by Pakhomov, et al.[21].

MiniMayoSRS: MiniMayoSRS is a subset of the MayoSRS and consists of 30 term pairs on which a higher inter-annotator agreement was achieved. The average correlation between physicians is 0.68. The average correlation between medical coders is 0.78. We evaluate our method on the mean of the physician scores and the mean of the coders' scores in this subset in the same manner as reported by Pedersen, et al.[22].

UMNSRS: UMNSRS, developed by Pakhomov, et al.[23], consists of 725 clinical term pairs whose semantic similarity and relatedness was determined independently by four medical residents from the University of Minnesota Medical School. The similarity and relatedness of each term pair was annotated based on a continuous scale by having the resident touch a bar on a touch sensitive computer screen to indicate the degree of similarity or relatedness. The Intra-class Correlation Coefficient (ICC) for the reference standard tagged for similarity was 0.47, and 0.50 for relatedness. Therefore, as suggested by Pakhomov and colleagues, we use a subset of the ratings consisting of 401 pairs for the similarity set and 430 pairs for the relatedness set which each have an ICC of 0.73.

Comparison of Reference Standards

There are primarily two main differences between the UMNSRS, MayoSRS and MiniMayoSRS reference standards. The first difference is that the scores assigned to the UMNSRS term pairs by the human annotators are on a continuous scale, where the scores assigned to the MayoSRS and MiniMayoSRS are on a four point scale.

The second difference is the range of semantic groupings of the term pairs. A semantic group is a coarse-grained grouping of the semantic types in the UMLS developed by McCray, et al.[24] to provide a coarse-grained distinction between UMLS concepts based on their semantic validity, parsimony, completeness, exclusivity, naturalness, and utility. Fifteen such semantic groups have been currently defined for the UMLS Metathesaurus concepts [b].

Over half of the term pairs consist of Disorder-Disorder term pairs for each of the reference standards, although MayoSRS and MiniMayoSRS contain the largest percentage. The second largest percentage of term pairs in the UMNSRS reference standards are Disorder-Chemical & Drug term pairs which occur only a few times in MayoSRS and MiniMayoSRS. Examples of these type of term pairs such as Obesity (C0028754) and Orlistat (C0076275) which the annotators found more similar/related than the term pairs Glipizide (C0017642) and Haemophilia (C0684275). The third largest percentage of term pairs in the UMNSRS reference standards are Chemical & Drug term pairs which do not occur in MayoSRS or MiniMayoSRS. The MayoSRS and MiniMayoSRS reference standards contain the most

[a] http://rxinformatics.umn.edu/SemanticRelatednessResources.html
[b] http://semanticnetwork.nlm.nih.gov/SemGroups/

diverse term pair groupings, eleven and eight respectively, where the UMNSRS reference standards only contain the three. Table 1 shows a breakdown of the semantic groups for each of the reference standards.

Table 1: Semantic Groupings of Term Pairs in the Reference Standards

Semantic Group		MayoSRS	MiniMayoSRS	UMNSRS	
Term 1	Term 2	relatedness	relatedness	similarity	relatedness
Activities & Behaviors	Phenomena	1			
Anatomy	Anatomy	1	1		
Chemical & Drug	**Chemical & Drug**			**77**	**82**
Chemical & Drug	Devices	1			
Chemical & Drug	Procedures	1	1		
Disorder	Anatomy	4	2		
Disorder	**Chemical & Drug**	**10**	**1**	**113**	**126**
Disorder	Concepts & Ideas	3	1		
Disorder	**Disorder**	**66**	**21**	**211**	**222**
Disorder	Devices		1		
Disorder	Physiology	5			
Disorder	Procedures	7	1		
Physiology	Physiology	1			
Total		101	30	401	430

6 Experimental Framework

We conducted our experiments using the freely available open source software package UMLS::Similarity [25] version 1.13 [c]. This package takes as input two terms or concepts and returns the similarity between any two concepts using the path information in any of the sources available in the UMLS, including SNOMED CT, for each of the measures discussed in Section 2.

For our experiments, the path information was obtained using the PAR/CHD relations between concepts in SNOMED CT from the 2010AB version of the UMLS. This work was initiated in 2010 and for the sake of continuity and comparability of results, the 2010AB version was used throughout.

We calculated the IC of a concept for the IC-based measures using frequency information obtained from the National Library of Medicine's *UMLSonMedline* dataset. This dataset consists of concepts from the 2009AB UMLS and the number of times they occurred in a snapshot of Medline taken on 12/01/2009. The frequency counts were obtained by using the Essie Search Engine which queried Medline with normalized strings from the 2009AB MRCONSO table in the UMLS. The frequency of a CUI was obtained by aggregating the frequency counts of the terms associated with the CUI to provide a rough estimate of its frequency.

7 Results and Discussion

Table 2 shows the Spearman's Rank Correlation coefficients between the human scores and the scores obtained by $u\text{-}path$, $lcs\text{-}path$, and the measures proposed by Wu and Palmer [12] (wup), Nguyen and Al-Mubaid [13] (nam), Resnik [15] (res), Jiang and Conrath [16] (jcn) and Lin [17] (lin) for the four reference standards.

The results show that for MiniMayo and MayoSRS the $u\text{-}path$ measure obtained a higher correlation with human judgments than the other measures, but this was not the case for the UMNSRS reference standards. For both the UMNSRS tagged for similarity and relatedness, $lcs\text{-}path$ or jcn obtained the highest correlation scores.

The results also show that jcn and lin obtain a higher overall correlation on the UMNSRS reference standards tagged for similarity and relatedness than the $u\text{-}path$ measure, but this is not the case for the res measure. The difference between res and the other IC-based measures is that jcn and lin incorporate the IC of the individual concepts in conjunction with the IC of the LCS, where res just uses the IC of the LCS. We believe the lower results of res may

[c] http://search.cpan.org/dist/UMLS-Similarity/

Table 2: Spearman's Rank Correlation Results

Measure	Reference Standard				
	MiniMayoSRS		MayoSRS	UMNSRS	
	coders	physicians		sim.	rel.
u-path	**0.7142**	**0.5527**	**0.3187**	0.4776	0.2725
lcs-path	0.5341	0.3628	0.2324	**0.5182**	0.2903
wup	0.5346	0.4139	0.2344	0.4912	0.2425
nam	0.4228	0.2985	0.1461	0.3252	0.1634
res	0.5150	0.3852	0.2549	0.4737	0.2550
jcn	0.5437	0.4298	0.3145	0.5132	**0.3418**
lin	0.5524	0.4315	0.2948	0.4981	0.2909

indicate that it is the IC of the individual concepts that are providing the additional relevant information rather than the IC of the LCS.

One main difference between the UMNSRS and the MayoSRS and MiniMayoSRS datasets are the semantic groupings of the term pairs. The MayoSRS and MiniMayoSRS contain only Disorders-Symptom pairs while the UMNSRS data contains a mixture of Disorder, Symptom and Drug pairs. Table 3 shows a breakdown of the correlation results based on the term pairs' semantic groups in the UMNSRS tagged for relatedness; as well as the overall correlation score for reference. Table 4 shows the same results on the UMNSRS tagged for similarity; and Table 5 shows the results for the MiniMayoSRS and MayoSRS.

Table 3: Spearman's Rank Correlation of UMNSRS tagged for Relatedness

Semantic Groups	u-path	lcs-path	jcn
Disorder-Disorder	0.4028	0.4290	0.4383
Disorder-Chemical&Drug	-0.1037	-0.1188	0.1369
Chemical&Drug-Chemical&Drug	0.3925	0.3761	0.4356
UMNSRS rel.	0.2725	0.2903	0.3418

For the UMNSRS tagged for relatedness, the results show that $u\text{-}path$ obtains a higher correlation for Chemical & Drug term pairs than $lcs\text{-}path$ but not for Disorder term pairs. The jcn measure obtains a higher correlation than either path-based measures for each of the semantic groups.

The results also show that for $u\text{-}path$, $lcs\text{-}path$ and jcn the correlation results are low for Disorder-Chemical & Drug term pairs. We believe this is because in SNOMED CT there does not exist many $is\text{-}a$ relationships between drugs and disorders which is the relationship all of the similarity measures are exploiting. We hypothesize that relatedness measures, rather than similarity measures, maybe a better measure for these type of relations.

Table 4: Spearman's Rank Correlation of UMNSRS tagged for Similarity

Semantic Groups	u-path	lcs-path	jcn
Disorder-Disorder	0.4521	0.5055	0.4329
Disorder-Chemical&Drug	0.1449	0.1489	0.1783
Chemical&Drug-Chemical&Drug	0.5693	0.5977	0.6885
UMNSRS sim.	0.4776	0.5182	0.5132

For the UMNSRS tagged for similarity, the results show that $lcs\text{-}path$ and jcn obtain a higher correlation with humans than $u\text{-}path$ over each of the different semantic groups except for Disorder pairs in which $u\text{-}path$ obtains a higher correlation than jcn. The low correlation results for Disorder-Chemical & Drug term pairs confirms our previous analysis above that there is a limited number of $is\text{-}a$ relations between drugs and disorders for the similarity measures to exploit.

Table 5 shows the correlation results for the semantic groups in the MiniMayoSRS and MayoSRS that have at least twenty term pairs. The results show that for Disorder term pairs, the $u\text{-}path$ obtains a higher correlation with the human judgments than $lcs\text{-}path$ and jcn for these two reference standards. We believe that this indicates that the

related disorders in these reference standards are co-located in similar areas in the taxonomy and not necessarily in a direct path through the LCS.

Table 5: Spearman's Rank Correlation of MayoSRS and MiniMayoSRS

Semantic Groups for MayoSRS	u-path	lcs-path	jcn
Disorder-Disorder	0.3535	0.2649	0.2579
MayoSRS	0.3187	0.2324	0.3142
Semantic Group for MiniMayoSRS	**u-path**	**lcs-path**	**jcn**
Disorder-Disorder (physicians)	0.4223	0.2580	0.2733
Disorder-Disorder (coders)	0.5933	0.3958	0.3353
MiniMayoSRS (physicians)	0.5527	0.3628	0.4298
MiniMayoSRS (coders)	0.7142	0.5241	0.5437

To further analyze the difference between the $u\text{-}path$ and $lcs\text{-}path$, Table 6 shows the number of term pairs in each of the reference standards, and the corresponding percentage whose shortest path did not go through the LCS. The percentage of non-LCS paths in the reference standards indicate that SNOMED CT is indeed a dense multi-hierarchical structure in which the shortest path between concepts does not always contain the LCS. The overall higher percentage of non-LCS paths in the MiniMayoSRS and MayoSRS may explain why $u\text{-}path$ obtained a higher correlation with human judgments than $lcs\text{-}path$. Although, this is not seen when analyzing the semantic grouping results in the UMNSRS reference standards, where the Chemical & Drug pairs contain the lowest number of non-LCS paths and $u\text{-}path$ obtains a higher correlation than $lcs\text{-}path$. However, we believe that given the relatively large percentage of concept pairs that have a path between them shorter than the LCS path indicates that $u\text{-}path$ has certain possibilities and merits further exploration.

Table 6: Non-LCS Shortest Paths

reference standard	semantic groups	# term pairs	# non LCS paths	% of non LCS paths
MiniMayoSRS	all	29	17	0.59
MayoSRS	all	101	57	0.50
UMNSRS (relatedness)	all	430	184	0.43
	Disorder pairs	223	110	0.49
	Disorder-Chemical&Drug	125	63	0.50
	Chemical&Drug pairs	82	11	0.13
UMNSRS (similarity)	all	401	183	0.46
	Disorder pairs	212	106	0.50
	Disorder-Chemical&Drug	112	63	0.56
	Chemical&Drug pairs	77	14	0.18

8 Conclusions and Future Work

In this paper, we present the results of a method that quantifies the degree of similarity between concepts in a dense taxonomy with multiple inheritance using undirected path information. We show that it obtains a higher correlation than other path-based measures on two reference standards. We also analyze the semantic groupings of the term pairs showing that different measures perform better on different groupings. In the future, we plan to explore more fully the impact of the semantic groups of term pairs on the similarity measures.

The overall objective of this work was to explore a method that takes advantage of dense multi-hierarchical taxonomies that are more $graph\text{-}like$ than $tree\text{-}like$. Our hypothesis was that the proximity of the terms regardless of how they are connected is an indicator to the degree of their similarity. The overall results show, in SNOMED CT, the location of the concepts with respect to each other indicates the degree to which they are similar. In the future, we plan to explore more complex measures that take advantage of this information such as graph-based centrality metrics and the measure proposed by Batet et al. [14 26].

The results showed that $u\text{-}path$ obtained higher correlation results on the reference standards tagged for relatedness.

The multiple inheritance within the taxonomy implies the potential existence of ancestral pedigrees that represent different, although related, dimensions of a concept. Therefore, a path passing through a common descendant would then link two concepts that belong to two dimensions allowing for the connection between the two concepts to fall outside the traditional strict $is\text{-}a$ relations. In the future, we plan to explore this further comparing the results to relatedness measures such as those proposed by Lesk[27]; Patwardhan[28]; Dagan, et al.[29]; Workman, et al.[30]; and Pivovarov and Elhadad[31].

We also plan to explore weighting the undirected path based on its turns within the path. Hirst and St. Onge[18] limited the degree in which the path is allowed to meander based on the types of turns the path is taking. The underlying thought behind this is that the deeper the undirected path passes through a common descendant the less similar the two concepts would be, although the relatedness between the two concepts would still be maintained.

9 Acknowledgments

This work was supported in part by the National Institute of Health, National Library of Medicine (NLM) Grant #R01LM009623-01. We would like to thank Russel Loane, Jim Mork and Lan Aronson from NLM for providing the UMLSonMedline dataset.

First-Order Logic Theory for Manipulating Clinical Practice Guidelines Applied to Comorbid Patients: A Case Study

Martin Michalowski, PhD[1], Szymon Wilk, PhD[2], Xing Tan, PhD[3], Wojtek Michalowski, PhD[3]

[1]Adventium Labs, Minneapolis, MN; [2]Poznan University of Technology, Poznan, Poland; [3]University of Ottawa, Ottawa, Canada

Abstract

Clinical practice guidelines (CPGs) implement evidence-based medicine designed to help generate a therapy for a patient suffering from a single disease. When applied to a comorbid patient, the concurrent combination of treatment steps from multiple CPGs is susceptible to adverse interactions in the resulting combined therapy (i.e., a therapy established according to all considered CPGs). This inability to concurrently apply CPGs has been shown to be one of the key shortcomings of CPG uptake in a clinical setting[1]. Several research efforts are underway to address this issue such as the K4CARE[2] and GuideLine INteraction Detection Assistant (GLINDA)[3] projects and our previous research on applying constraint logic programming to developing a consistent combined therapy for a comorbid patient[4]. However, there is no generalized framework for mitigation that effectively captures general characteristics of the problem while handling nuances such as time and ordering requirements imposed by specific CPGs. In this paper we propose a first-order logic-based (FOL) approach for developing a generalized framework of mitigation. This approach uses a meta-algorithm and entailment properties to mitigate (i.e., identify and address) adverse interactions introduced by concurrently applied CPGs. We use an illustrative case study of a patient suffering from type 2 diabetes being treated for an onset of severe rheumatoid arthritis to show the expressiveness and robustness of our proposed FOL-based approach, and we discuss its appropriateness as the basis for the generalized theory.

Introduction

Clinical practice guidelines (CPGs), as knowledge-based tools for disease-specific patient management[5], encapsulate evidence-based practices for devising the most appropriate treatment for patients with regard to relevant patient information and possible diagnoses. CPGs are normally created by a panel of experts and in a number of instances are computerized. However, CPGs are not designed for use on patients with comorbid diseases and who require a combined therapy (i.e., a therapy established according to all simultaneously applied CPGs). This problem was identified as one of the major shortcoming of CPG uptake in practice and as such there exists a need for research to address it[1]. Given a comorbid patient's available medical information, it is likely that the application of multiple disease-specific CPGs results in direct adverse interactions between individual medical actions that manifest as contradictory recommendations (e.g., "administer NSAID" in one CPG and "do not administer NSAID" in the other). The concurrent application of disease-specific CPGs for such patients can also result in undesired consequences due to drug-drug or drug-disease interactions, a term we refer to as indirect adverse interactions[4]. More broadly, the synthesis of two or more guidelines for treating patients with comorbidities is a challenging problem involving sophisticated design of processes for the identification and elimination of potential redundancies, contradictions, and discordances[6]. Therefore, combining CPGs in order to cross-check CPG-based medical recommendations requires the introduction of new combinatorial, logical, or semantic approaches[7].

Our recent research[4,8,9] responds to this need by introducing and formally defining a logical model of CPGs and developing a mitigation algorithm that operates on these models in order to identify and address adverse interactions. In the mitigation algorithm, clinical knowledge is encoded as interaction and revision operators within the constraint logic programming (CLP) paradigm. The operators characterize adverse interactions and describe revisions to logical models required to address encountered interactions. CLP allows one to efficiently solve these models where a solution represents a consistent combined therapy free of any adverse interactions.

More specifically, we apply our CLP-based approach to a situation when at least two CPGs are applied to a comorbid patient in order to obtain a combined therapy – a combination of at least two individual therapies derived from disease-specific CPGs. With available patient information, a combined therapy might not be consistent if there are adverse (in)direct interactions between the diseases, between medications that are applied to the patient as suggested by the disease-specific CPGs, or between diseases and prescribed medications. In these cases, CPGs and

associated therapies need to be revised using secondary clinical knowledge. This knowledge is not encoded in the guidelines themselves but comes from domain experts, textbooks, or repositories of clinical evidence.

While the CPG mitigation paradigm proposed in our earlier research is powerful enough to handle a number of different clinical scenarios associated with the management of comorbid conditions, it also has several limitations. The critical limitation is the lack of support for using temporal and associated precedence relationships between CPG actions. It is well documented that medical actions (tests or administration of medication) often follow time-dependent sequences that need to be preserved, even when new or modified actions are introduced. Our desire to capture the time dependencies commonly found in CPGs motivates the research presented in this paper that extends the CLP-based approach.

Our current research focuses on extending the CLP-based approach to handle the temporal relationships and more broadly it aims at developing a general framework for the concurrent application of CPGs. Towards this end, we present our work on representing CPGs as first-order logic (FOL) theories. FOL allows us to define CPGs as logical theories, take patient information and mitigation strategies that incorporate time and precedence relations into account, and include the modeling capabilities developed in our earlier CLP-based work. As a matter of fact, precedence relationships are only FOL definable. Further, using FOL to represent and manipulate the CPGs allows us to introduce semantics to guide the interpretation of the concepts and relieve the user of "manual" interpretations of the mitigation results – an additional limitation of our CLP-based work.

Our current methodological foundation is adopted largely from our previous work[4,8,9] and expanded as required. The conceptual framework describing this extension, using a case study based on the concurrent management of type 2 diabetes and rheumatoid arthritis, is the focus of this paper. We start by providing a brief overview of FOL and theorem proving – the methods used in our research. We then describe the methodological foundation of our proposal to model the mitigation problem as a FOL theory. Next we present a case study to ground the theory in a clinical example, and we conclude with a discussion of our contributions and potential areas for future work.

Methodology

In order to better illustrate the proposed FOL-based mitigation of guidelines, we start with brief introductions of the basic concepts and notation of FOL and theorem proving. We then present the methodological foundations of our approach.

First-Order Logic and Theorem Proving

First-order logic (FOL) is a formal system in which formulas of a formal language may be interpreted to represent propositions (particular sentences, such as "administer NSAID"). FOL distinguishes itself from propositional logic by providing additional expressive power through the use of quantified variables (for example $x > 1$ meaning all values of x must be greater than 1). With FOL, properties of objects in the domain and relationships between objects can be specified by introducing predicates and a set of inferences rules and axioms allow the derivation of theories from this language. In FOL, a theory is a collection of sentences describing some domain (i.e. CPGs). We further assume that it is possible to reason over a theory, and the result of this reasoning is referred to as a model. Thus, given a theory D and a sentence φ in the language of D, we say that φ is consistent with D if there exists a model of the theory that satisfies φ. The sentence φ can be deduced (or implied) from D if the sentence is satisfied by all models for D. Formally, we write

$$D \vDash \varphi$$

Therefore, the notion of theorem proving is a procedure to check whether a theory is satisfiable (meaning if it is possible to derive models from this theory). One way to check for satisfiability is by formulating an entailment problem (understood as a logical consequence of the sentences where one follows from the other) over D. Moving from our previous work[4,8,9] to a FOL-based approach substantially increases our ability to represent and reason over clinical knowledge by representing CPGs, patient information, and basic properties of mitigation as FOL-based theories. As part of this reasoning, we generate an entailment problem over the generated theory to check for the satisfiability of the theory. A so-called grounded instance of a satisfiable theory represents a consistent therapy.

FOL Theory for CPG Mitigation

Before introducing the main concepts and components of FOL theories employed to mitigate adverse interactions between CPGs, we briefly recall the notion of an *actionable graph* $(AG)^4$ which we use as a representation of an individual CPG. An AG expresses a single CPG in form of a directed graph composed of three types of nodes –

context, *action*, and *decision*, and arcs that correspond to transitions between nodes. A *context* node defines an entry point and indicates the disease associated with the CPG, an *action* node indicates a medical action that needs to be executed, and finally a *decision* node indicates a selection from several alternative choices and it allows for conditional branching. An AG may contain loops however, in this paper we assume an AG contains no loops, and is thus an acyclic graph. The formal definition of an AG, based on the SDA* notation, and several examples are provided in our previously published work[4].

The three key components of using FOL for CPG mitigation are: (1) a vocabulary used to construct the theory, (2) a set of "sub-theories" to describe various components of the mitigation problem, and (3) a set of operators that define the secondary knowledge needed to identify and mitigate adverse interactions in the theory. We describe each in turn below.

The vocabulary is made up of constants (denoted with lower case letters, e.g., *x*, *a*), variables (denoted with upper case letters, e.g. *X*, *Z*) and predicates. Table 1 lists core predicates that are central to the case study described later (the vocabulary includes other predicates as well, but we have omitted them for the sake of simplicity). We note there is no predicate corresponding to a context node, as information embedded in this node is provided by the predicate *disease*(*d*).

Table 1. Defined predicates

Predicate	**Explanation**
node(*x*)	*x* is a node in AG
disease(*d*)	CPG is associated with disease *d*
action(*x*)	*x* is an action node in AG
diagnosed(*d*)	disease *d* is diagnosed for the given patient
decision(*x*)	*x* is a decision node in AG
executed(*x*)	task node *x* is or has been executed
value(*x*, *v*)	value *v* is associated with decision node *x*
dosage(*x*, *n*)	task node *x* is characterized by dosage *n*
directPrec(*x*, *y*)	node *x* directly precedes node *y* (in AG there is an arc from *x* to *y*)
prec(*x*, *y*)	node *x* precedes node *y* (in AG there is a path from *x* to *y*)

A FOL theory is a collection of logical sentences constructed using the defined vocabulary. In our research we create the following theories that represent relevant components of the mitigation problem:

- D_{common} – a common theory that axiomatizes the universal characteristics of CPGs as part of a FOL-based representation for mitigation. It introduces axioms that ensure important properties of precedence and relations between various types of nodes and their characteristics. More specifically, introduced axioms ensure anti-symmetry and transitivity of precedence, uniqueness of node types (a node cannot be both an action and decision node, only an action node may be associated with medication dosage, etc.) and similar properties,
- D^{d}_{cpg} – the theory that represents an actionable graph AG (and thus the underlying CPG) for disease *d*. It encapsulates treatments for this disease, enlists all paths in the AG in the form of disjunctions of conjunctions (where each conjunction corresponds to a path), gives information about direct precedence between nodes, and finally provides information on dosages associated with selected action nodes,
- D_{pi} – the theory that represents available patient information, where each data item is given as a separate logical sentence,
- D_{mit} – the theory (initially empty) that stores new sentences introduced during the mitigation process.

These theories are used as building blocks to construct a combined theory that describes a particular mitigation instance personalized to a patient encounter. Formally, the combined theory D_{comb} is defined as the union of the theories described above:

$$D_{comb} = D_{common} \cup D_{cpg}^{d_1} \cup D_{cpg}^{d_2} \cup \cdots \cup D_{cpg}^{d_m} \cup D_{pi} \cup D_{mit},$$

where $d_1, d_2, \cdots, d_m$ are the diseases a comorbid patient suffers from and for which the patient is concurrently managed according to the associated CPGs. To further simplify the presentation in this paper yet without the loss of generality we limit the number of concurrently applied CPGs to two, thus we define the combined theory as follows:

$$D_{comb} = D_{common} \cup D_{cpg}^{d_1} \cup D_{cpg}^{d_2} \cup D_{pi} \cup D_{mit}$$

FOL-based Mitigation of Adverse Interactions

The process of mitigating (identifying and addressing) adverse interactions consists of two main phases. The first phase aims at mitigating direct adverse interactions that manifest as inconsistencies in the combined theory D_{comb}. Their identification is relatively easy as it involves checking the satisfiability of D_{comb}. If the theory is satisfiable, then there are no direct interactions. Otherwise the theory needs to be revised by applying revision operators. These *revision operators* capture expert knowledge that is not encoded in CPGs and they are formally defined later in the text.

The second phase of the mitigation process aims at identifying and addressing indirect adverse interactions. Checking the satisfiability of D_{comb} is not sufficient for identifying indirect interactions and additional expert knowledge is required. This knowledge is encoded in form of *interaction operators*. An interaction operator IO^k is formally defined as

$$IO^k = \langle \alpha^k \rangle,$$

where α^k is a logical sentence that describes a particular interaction. Checking whether a particular IO^k is applicable to D_{comb} is formulated as the entailment problem $D_{comb} \vDash \alpha^k$.

Encountered interactions (both direct and indirect) need to be addressed by applying relevant revision operators to D_{comb}. A revision operator RO^k is formally defined as

$$RO^k = \langle \beta^k, Op^k \rangle,$$

where β^k is a logical sentence that defines the applicability of the operator (the relevance of a revision operator for a particular theory given specific patient information), and Op^k describes the revisions introduced by RO^k. In particular, Op^k is a list of *n* pairs of logical expressions $\langle \varphi_i^k, \phi_i^k \rangle$ $(i = 1 \ldots n)$ that define individual operations carried out as part of applying the revision operator. To ensure that patient information is not modified and general practices of mitigation are not violated as part of the revision process, the operations Op^k are only applicable to a subset of the theories that comprise D_{comb} – namely $D_{cpg}^{d_1}$, $D_{cpg}^{d_2}$ and D_{mit}. Furthermore there are three possible types of operations in Op^k - *removal*, *addition*, and *substitution*. These types are defined as follows, where $\otimes$ represents an empty expression:

- $\langle \varphi_i^k, \otimes \rangle$ – φ_i^k is removed from any sentence that appears in $D_{cpg}^{d_1}$, $D_{cpg}^{d_2}$ or D_{mit},
- $\langle \otimes, \phi_i^k \rangle$ – ϕ_i^k is added as a new sentence to D_{mit},
- $\langle \varphi_i^k, \phi_i^k \rangle$ – φ_i^k is replaced by ϕ_i^k in any sentence that appears in $D_{cpg}^{d_1}$, $D_{cpg}^{d_2}$ or D_{mit}.

Checking the applicability of RO^k is analogous to checking the applicability to IO^k and translates to formulating and solving the entailment problem $D_{comb} \vDash \beta^k$.

In the context of FOL, a consistent combined therapy is a model of D_{comb} that represents an assignment of values to predicates.

Case Study: Management of a Patient with Type 2 Diabetes and an Onset of Severe Rheumatoid Arthritis

To ground the theoretical concepts presented above, we use the following case study. Let's consider a 70 year old male with type 2 diabetes (DB2), who suffers from symptomatic hyperglycemia and has consistently measured over 8.5 on the A1C test. As such, his sugar level is being controlled by a daily insulin dosage of 40 international units.

The patient also suffers from relatively mild rheumatoid arthritis (RA) (comorbid condition) that is being managed using a maintenance dosage of plaquenil. In the two clinical scenarios described below, we will show how the patient's therapy can be revised through the mitigation of adverse interactions using the formalism described above. For the sake of simplicity we only present the relevant interaction and revision operators and omit the details of the FOL-based theories D_{cpg}^{db2} and D_{cpg}^{ra} representing CPGs for type 2 diabetes and a rheumatoid arthritis.

Clinical Scenario 1: Managing the Administration of Glucocorticoids

In the first scenario we assume there is a sudden relapse of RA accompanied by the onset of severe pain and significantly reduced mobility. Typically in such cases, the patient is initiated on glucocorticoid treatment to control the onset of pain. However, considering that the patient is diabetic, the increased sugar level associated with the administration of glucocorticoids needs to be mitigated with an increased maintenance dosage of insulin. In this clinical scenario, the daily dosage is increased to 48 international units and maintained until sugar level stabilizes or the patient no longer requires glucocorticoid therapy.

Supporting this scenario requires the codification of secondary knowledge describing the use of and interactions with glucocorticoids. As stated in medical literature, glucocorticoids increase the blood sugar level and require the dosage of insulin in DB2 patients (if administered) to be increased by 20%. The interaction operator IO^1 represents the drug-drug interaction when a DB2 patient, also being treated for RA, is prescribed with glucocorticoids while taking insulin.

$$IO^1 = \langle \alpha^1 \rangle,$$

where $\alpha^1 = diagnosed(db2) \wedge\ diagnosed(ra)\ \wedge executed(gluco)\ \wedge executed(insulin)$.

The revision operator RO^1 modifies the theory representing this DB2 and RA patient by increasing the dosage of insulin by 20%.

$$RO^1 = \langle \beta^1, Op^1 \rangle,$$

where $\beta^1 = \alpha^1$ and $Op^1 = \langle dosage(insulin, X), dosage(insulin, X * 1.2) \rangle$. We note the definition of the operation in Op^1 employs variable *X*. Variables act as "wildcards" that can be bound to different constants to increase the flexibility of operations, thus in this case it is possible to define a substitution operation that increases the dosage of a medication by a certain ratio.

For this particular scenario we have the following subset of sentences describing the patient's state D_{pi}.

$$D_{pi} = diagnosed(db2).\, diagnosed(ra).\ executed(gluco).\ executed(insulin).$$

The following sentence is part of the theory for DB2 prescribing 40 international units of insulin to the patient.

$$D_{cpg}^{\mathrm{db2}}\ \ni dosage(insulin, 40)$$

To check for the existence of an indirect interaction we formulate the entailment problem $D_{comb} \vDash \alpha^1$. Because α^1 is consistent with D_{comb}, we know an indirect interaction exists. We then formulate the entailment problem $D_{int} \vDash \beta^1$ -- since $\beta^1 = \alpha^1$ we immediately know RO^1 is applicable to D_{comb} and we consequently apply Op^1 to substitute the dosage of insulin with a dosage that is 20% higher. This is done by removing $dosage(insulin, 40)$ from D_{cpg}^{db2} and adding $dosage(insulin, 40 * 1.2)$ to D_{mit}, which resolves to the dosage of insulin being adjusted to 48 international units (*X* is bound to 40). Note the use of variables to support different values for the same expression, rather then creating an expression for each possible value.

Clinical Scenario 2: Managing Immunosuppressive Medication

In this clinical scenario we consider the same patient that was initiated on glucocorticoid therapy supplemented with a calcium antagonist (in place of a NSAID that is not recommended for diabetic conditions). The daily insulin dosage was increased (as explained in Scenario 1) to manage the elevated sugar level, however the prescribed therapy did not work as expected. In order to better control the relapse of rheumatoid arthritis, the next therapeutic option is to put the patient on DMARD combination therapy that normally includes cyclosporine. While all immunosuppressive medications are diabetogenic (with hyperglycemia being a common adverse event), some like azathioprine proved in clinical trials to be better tolerated by type 2 diabetics. Therefore, the revised DMARD combination therapy is prescribed for this patient, and it uses azathioprine as a replacement for cyclosporine.

The interaction operator IO^2 represents the drug-disease interaction that occurs when a DB2 patient, being treated for RA, is prescribed cyclosporine as part of DMARD combination therapy.

$$IO^2 = \langle \alpha^2 \rangle,$$

where $\alpha^2 = diagnosed(db2) \wedge diagnosed(ra) \wedge executed(cyclosporine)$.

The revision operator RO^2 modifies the theory D_{comb} for the DB2 and RA patient by replacing cyclosporine with azathioprine. As we show below, this revision also maintains the precedence of executed tasks when performing the replacement.

$$RO^2 = \langle \beta^2, Op^2 \rangle,$$

where $\beta^2 = \alpha^2$ and Op^2 is the following list of logical expressions.

$$\langle node(cyclosporine), node(azathioprine) \rangle. \langle action(cyclosporine), action(azathioprine) \rangle.$$

$$\langle directPrec(methotrexate, cyclosporine), directPrec(methotrexate, azathioprine) \rangle.$$

$$\langle directPrec(cyclosporine, observ\_ra), directPrec(azathioprine, observ\_ra) \rangle.$$

To check for the existence of an indirect interaction we formulate the entailment problem $D_{comb} \models \alpha^2$ and subsequently $D_{comb} \models \beta^2$ to find the relevant revision operator. Using patient information represented in D_{pi} above, we infer that RO^2 is in fact applicable to this patient encounter and we apply the corresponding logical expressions to the theory.

We note here that we are revising the theory for the patient to replace cyclosporine with azathioprine **and** maintain the order in which tasks are to be executed according to the CPG for RA (not shown here due to space limitations). Specifically, we are ensuring that the task of administering *methotrexate* (to treat RA) is done before the administration of *azathioprine* (as was the case for cyclosporine), and that the patient's onset of RA is observed (*observ_ra*) after administering azathioprine. Similarly to the first clinical scenario, the removal of sentences is done from D_{cpg}^{ra} and sentences are added to D_{mit}.

Discussion and Conclusions

In this paper we described our preliminary research on developing a general theory of mitigation expressed in FOL for concurrently applied CPGs. This research builds upon our foundational work in using the CLP paradigm to handle mitigation and extends it by using a paradigm with greater expressive power (FOL) to handle temporal relationships such as task precedence. We used a case study of a patient suffering from type 2 diabetes while being treated for an onset of severe rheumatoid arthritis to illustrate the added benefit of our new approach. Through two simple scenarios we demonstrated the power of our FOL-based approach by applying an adjustment of medication dosage and through the substitution of tasks while maintaining the task execution order as defined by one of the CPGs.

Our proposed FOL-based approach provides an expressive and robust language in order to represent and apply temporal relationships represented in CPGs while also easily capturing common knowledge applicable to all mitigation scenarios. Furthermore, by separating the overall theory (D_{comb}) into "sub-theories" we are able to provide finer grained control over how to apply revisions to a proposed theory. Specifically, we limit the addition, deletion, and substitution of logical sentences to the theories representing CPGs ($D_{cpg}^{d_i}$) and to the theory representing added mitigation actions (D_{mit}). As such, we ensure that a patient's state is consistent since information describing a patient (D_{pi}) cannot be inadvertently changed. Additionally, the common characteristics of mitigation, applicable to all mitigation instances, are maintained in a single theory (D_{common}) and cannot be altered by any mitigation operations.

As future research, we are exploring ways to make the proposed approach more general and robust. As stated at the beginning, our ultimate goal is to develop a general framework of mitigation and towards this end we are studying various clinical situations involving comorbid patients to extract the full set of properties that hold across all mitigation scenarios. Furthermore, we are working on inductive reasoning techniques to automatically infer precedence relationships as logical operations are applied to the theories representing CPGs. The addition, deletion, and substitution of logical sentences impacts the underlying structure represented by these theories and automating

the maintenance of correct precedence relationships goes a long way to realizing our goal of using FOL-based methods to drive a point-of-care clinical decision support system.

An empirically derived taxonomy of errors in SNOMED CT

Abstract
Ontologies underpin methods throughout biomedicine and biomedical informatics. However, as ontologies increase in size and complexity, so does the likelihood that they contain errors. Effective methods that identify errors are typically manual and expert-driven; however, automated methods are essential for the size of modern biomedical ontologies. The effect of ontology errors on their application is unclear, creating a challenge in differentiating salient, relevant errors with those that have no discernable effect. As a first step in understanding the challenge of identifying salient, common errors at a large scale, we asked 5 experts to verify a random subset of complex relations in the SNOMED CT CORE Problem List Subset. The experts found 39 errors that followed several common patterns. Initially, the experts disagreed about errors almost entirely, indicating that ontology verification is very difficult and requires many eyes on the task. It is clear that additional empirically-based, application-focused ontology verification method development is necessary. Toward that end, we developed a taxonomy that can serve as a checklist to consult during ontology quality assurance.

Ontologies and Errors
Ontologies enable researchers to describe and reason about data and knowledge in a computable fashion using a common vocabulary. Because of these properties, ontologies are key to many biomedical tasks ranging from decision support and data integration to search and billing.[1] As a sign of the wide-spread use of ontologies, the National Center for Biomedical Ontology's BioPortal contains over 350 ontologies and terminologies describing almost any biomedical subdomain.[2] The U.S. government has required the use of terminologies such as SNOMED CT and LOINC in Electronic Health Records (EHR) as part of meaningful use.[3] Ontologies also play an essential role in biomedical research, helping to combat the data-deluge. Researchers use ontologies to perform pharmacovigilance using unstructured clinical text, to analyze gene modules, and to integrate biosimulation models,.[4–6] In the life sciences, the Gene Ontology is central to many methods (e.g., micro-array enrichment analysis), and has over 10,000 citations.[7] These examples all demonstrate the importance and diverse uses of biomedical ontologies.

Unfortunately, those same biomedical ontologies we rely on contain errors. Researchers have published reports about critical domain-specific errors in two widely-used biomedical ontologies, the National Cancer Institute Thesaurus (NCIt)[8] and SNOMED CT[9–13]. For example, Rector and colleagues manually explored SNOMED CT and identified errors such as "The foot *is-a-part* of the pelvis".[10] As ontologies increase in size, scale, and number, these domain-specific errors become even more difficult to identify or prevent. Current methods used to identify these errors are either human based or computationally based. In human-based methods, domain experts manually browse an ontology searching for errors. This approach is costly and cannot scale to the size of recent biomedical ontologies. For instance, it is likely impossible for a human to check the nearly 400,000 stated concepts in SNOMED CT, let alone the millions of logical entailments. Computational methods rely on inconsistencies within ontology syntax, structure, or semantics to find errors.[14–17] These methods scale more easily but do not detect accurately *domain-specific* errors. Considering the limitations of current methods, additional research is still needed to achieve scalable and accurate ontology verification.

Adding to these challenges of ontology verification, the real-world impact and true extent of errors is unknown. For example, it is unclear what costs are associated with an EHR that incorrectly classifies a patient due to errors in SNOMED CT. By understanding error patterns in ontologies, one can begin to identify the real-world cost of a certain pattern and prevent it. Using these patterns as a reference, engineers can develop best practices that prevent the creation of errors in the first place. In addition, these patterns can direct additional research efforts focused on the automated, scalable methods that we now require. In this work, we perform an empirical error analysis on a subset of the SNOMED CT hierarchy.

[†] Current Affiliation: Google Inc., Mountain View, CA 94043

Specifically, we make the following contributions:

1. A logic-based heuristic to identify subsets of an ontology likely to contain errors.
2. An expert-curated and validated set of relations in a subset of SNOMED CT.
3. A taxonomy describing the common types of errors. This taxonomy can serve as a checklist during verification.

Methods

To characterize the common error patterns in SNOMED CT, we first selected a subset of SNOMED CT to verify using the CORE Problem List Subset, a listing of terms provided by National Library of Medicine that are most frequent in multiple hospitals across the US, and a logic-based heuristic.[18] Next, we asked 5 experts with both ontology and medical expertise to verify the subset of relations independently. With expert votes and comments collected, we then asked experts to update their response after reviewing responses other experts in the study. The updated responses provided a final enumeration of errors from which we developed a taxonomy of common error patterns. We describe each step in detail below.

Logic-Based Heuristic Filtering

To obtain a reasonably sized set of relations for verification, we elected to filter the entire set of relations in the SNOMED CT by frequency and complexity. In doing so, we made two key assumptions: (1) real world term frequency is a proxy for importance, and (2) complex relations are more likely to contain errors. We began with the January 2013 version of the SNOMED CT ontology. We then extracted an ontology module from SNOMED CT using the CORE Problem List Subset as the signature.[10,18,19] The CORE Problem List Subset serves as the proxy for "importance". We used Snorocket, an OWL reasoner designed for SNOMED CT, to compute the concept hierarchy of this module.[20] To further narrow a set of relations likely to have errors, we selected complex SubClass (*is-a*) entailments from the classified module. A complex entailment has the following characteristics:

- non-asserted – not explicitly stated during ontology design but is a logical conclusion of stated axioms (e.g., the relations "Hypertension *is-a* Cardiovascular Disorder" and "Cardiovascular Disorder *is-a* Disorder" entails a non-asserted axiom "Hypertension *is-a* Disorder")
- non-trivial – the justification for that entailment contained at least 2 axioms
  (e.g., the non-asserted axiom "Hypertension *is-a* Disorder" from the above example is also non-trivial because it requires the interplay of 2 axioms)
- direct – there exists no concept in the inferred SubClass hierarchy between the two concepts in the relation, removing basic subsumption entailments that are not non-trivial, but still rather basic (e.g., "Hypertension *is-a* Disorder" is ***in***direct because "Cardiovascular Disorder" lies between "Hypertension" and "Disorder" in the inferred hierarchy.)

This process selects ~35,000 SubClass relations. We focus solely on SubClass relations in this work because they are the most common type of relation in biomedical ontologies.[21] To reduce further the set of relations, we required that both parent and child be explicitly in the CORE Problem List Subset, not just contained in the module, leaving ~1000 relations. From this set, we randomly sampled 200 relations for verification.

Expert Verification and Delphi

We asked 5 domain experts known directly by the authors who are have expertise in both in medicine and ontology, to verify the filtered set of 200 relations. Specifically, we presented each expert with an online survey of randomly ordered relations reformulated as natural language questions (e.g., "Diabetes is a kind of Disorder of the Abdomen. True or False?") (Fig. 1). In addition, we provided concept definitions when available from the UMLS.[22] In previous work, we developed the optimal format to ask in natural language the verification question (e.g., "is a" vs. "is a kind of") and to provide appropriate context through definitions.[21,23,24] Experts marked each relation as "True" or "False" and also justified their decision. After each expert independently completed the survey, we performed one round of the Delphi method on relations where all experts did not reach agreement (i.e., they did not all give same response). In Delphi, experts saw their responses and justifications along with those of other experts in an anonymized fashion.[25] The experts then had an option to update their response in light of other expert comments and votes.

Analysis and error classification

With the expert verification complete, we determined which relations were truly in error by supermajority voting after the Delphi round (i.e., at least 4 of the experts agreed). In addition, we calculated expert agreement using a free-marginal kappa statistic (κ).[26] The free-marginal kappa does not assume a fixed number of true or false relations, making it appropriate for our application. Finally, the authors qualitatively reviewed the errors and identified common characteristics among them in an ad-hoc fashion. From these common characteristics, we developed a taxonomy of errors.

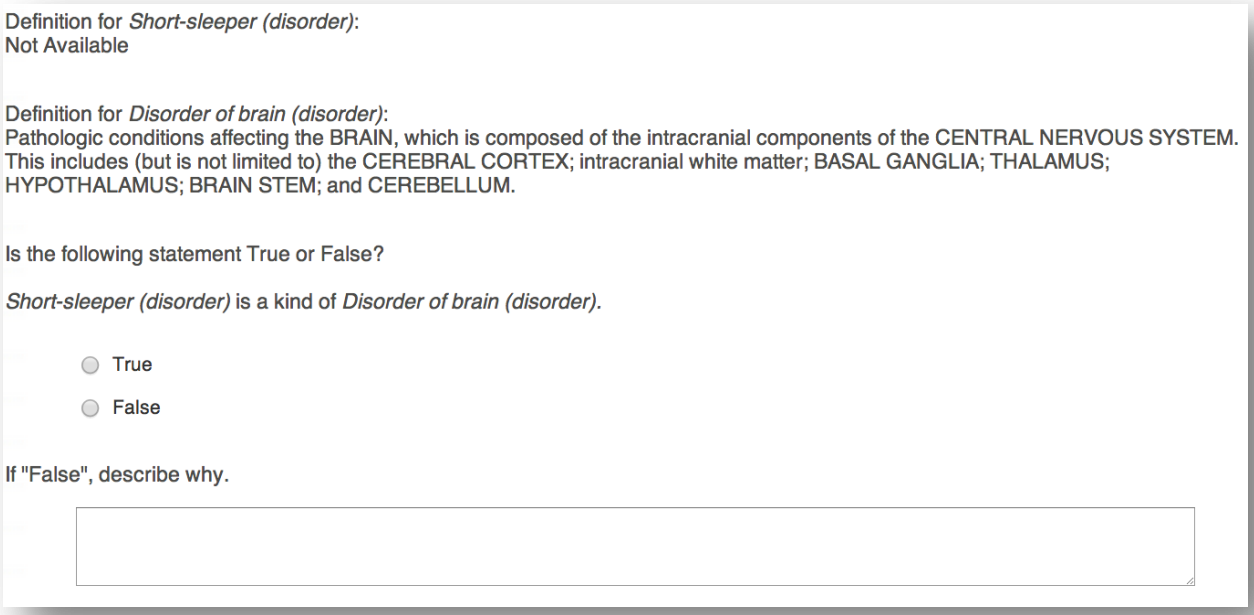

Figure 1. Screenshot of the question form that experts completed to verify relations in SNOMED CT. All 200 questions were randomly ordered per expert.

Results

The experts identified 9 errors in the 200 relations before the Delphi round by supermajority. After the Delphi round, the experts flagged 30 additional relations by supermajority. Table 2 presents all 39 errors. Most errors fall into the categories of anatomical confusion or issues related to cause and effect.

After the experts identified the errors, we developed a taxonomy that specifies the patterns of errors they encountered. Table 1 lists this taxonomy with error descriptions and expert agreement on errors in that category. Table 2 indicates where a specific error falls in this taxonomy. Before Delphi, expert agreement on errors was low (κ=-0.5); agreement increased after Delphi by a marked margin (κ =0.69). For comparison, expert κ was 0.73 before Delphi and 0.9 after Delphi on 148 correct relations (by supermajority). Experts were unable to reach consensus on 13 relations.

Error Type	Description	κ Pre-Delphi	κ Post-Delphi	Error Count
Term Ambiguity	Term representing a concept has an unclear meaning	-0.16	0.73	9
Naming Convention	Convention causes interpretation difficulty (e.g. use of a conjunction within a term)	-0.07	1	3
Modeling	Incorrect domain representation	-0.03	0.69	36
Cause and Effect	Conflation of root disorder and its effects	0.1	0.7	8
Disorder vs. Symptom	Confusion of a disorder and its symptoms	0.07	0.73	3
Disorder vs. Sequelae	Confusion of a disorder and its potential consequences	0.2	0.8	4
Multiple Etiology	Ignoring alternate etiologies of disorder	0.04	1	5
Anatomic Confusion	Improper anatomic location (e.g., regions vs. structure)	-0.1	0.69	28

Table 1. Error taxonomy constructed by observing common characteristics between 39 errors in SNOMED CT. The categories are not disjoint, and thus errors may be members of multiple classes. The κ describes expert agreement before and after Delphi and range between complete disagreement (-1) and complete agreement (1). As reference, on the 148 correct relations, κ was 0.73 Pre-Delphi and 0.9 Post-Delphi. (Error type names shortened for presentation.)

Child	Parent	Term Ambiguity	Naming Convention	Modeling	Cause and Effect	Disorder vs. Symptom	Disorder vs. Sequelae	Multiple Etiology	Anatomic Confusion
Anterior shin splints	Disorder of bone			✓					✓

Table 2. Summary and classification of 39 errors identified in 200 relations from the SNOMED CT CORE Problem List Subset by 5 domain experts. For presentation and readability, fully specified names are shortened and all lack semantic tags (e.g., "(disorder)"). Complete, unabridged list available at request.

Discussion

We identified and classified 39 errors (19.5% of 200 relations) in SNOMED CT into a taxonomy of error patterns. At a high level, the errors were due to ambiguous concept terms, anatomic confusion (the most common), and mix-ups of cause and effect. Such errors include "Septic Shock *is-a* Soft Tissue infection" and "Frontal Headache *is-a* Pain in face". The former error is due to cause (infection) and effect (sepsis) while the latter is due to anatomic confusion (face vs. head/skull). These results are surprising; in summary, they suggest that:

1) the extent of errors in SNOMED CT, particularly in complex relations, is quite large
2) errors are very subtle -- in the first round of verification, the majority of experts missed **20%** (8/39) of the errors
3) it is therefore essential to develop quality assurance with many eyes checking for errors

These results support empirically the results of previous exploratory studies by Rector and colleagues who identified similar errors in SNOMED CT.[10] In contrast to the work by Rector et al., this study used a panel of experts to verify a pre-defined set of relations in multiple stages, allowing us to measure expert disagreement. Furthermore, it confirmed the subtlety and difficultly of ontology verification through an empirical, systematic experiment.

A checklist to focus ontology engineering and verification

This work provides three elements to help future verification and method development. First, it presents a taxonomy of errors. The taxonomy should serve as a checklist during ontology verification (i.e., during verification, an expert should consult the list to ensure that none of these types of errors occur). Recent literature describes the importance of checklists when working with complex domains and complex tasks.[27] Please note that our taxonomy enumerates some of the kinds of errors that can occur, but not the *causes*, of which there are many. The taxonomy does not serve as a solution manual to ontology bugs, but instead helps us find them. Second, this paper presented an expert-curated and validated gold standard set of relations from the CORE Problem List Subset against which researchers can now compare methods. While the standard we developed cannot capture or represent the entirety of relations in biomedical ontologies, it serves as a "first stab" at a gold standard, of which, currently, there are none of any useful size. Finally, we developed a generalized logic-based heuristic to saturate errors in an ontology of interest (i.e., the heuristic selects relations that are likely to be in error).

The difficulty of identifying ontology errors

Our two-step Delphi approach to verification, wherein 5 domain experts initially did not reach agreement, highlights the difficulty of identifying ontology errors. It appears that having more eyes on the problem is essential. However, we believe that the next challenge in identifying errors is finding those that are salient (i.e., that impact a system that uses an ontology). To do so, it is necessary to understand the ontology in the context of the system that uses it. In this experiment, part of the difficulty was reaching consensus not only about errors but also about context. In certain contexts, errors may have no significant impact or instead have a positive impact. For example, the incorrect relation "Local Infection of wound *is-a* Wound" may in fact be helpful in retrieval tasks but not with clinical decision support. The taxonomy we developed can guide researchers as they begin to focus on finding errors in the context of ontology applications in a scalable fashion. For example, one might find that cause and effect errors are particularly important to catch in the context of clinical decision support. With an understanding of context and common error patterns, researchers and developers can develop best practices to avoid and repair salient errors. Finally, these results highlight that ontologies are generally tied to particular contexts of use. We suggest that ontology developers become more explicit in how they represent and communicate the context and appropriateness of an ontology for a given application.

Conclusion

Reinforcing results in the literature, experts identified 39 errors in a set of 200 relations from SNOMED CT. We found this task was rather difficult for domain experts, underlining the need for multiple eyes when error-checking and the need for additional method development. We developed a taxonomy of common error patterns. This taxonomy can focus future development of scalable, automated ontology verification methods, giving researchers a pointer toward salient, common patterns of errors. More importantly, ontology engineers can view the taxonomy as checklist to consult when performing ontology quality assurance. Such efforts are imperative, given the prevalence of biomedical ontologies and our reliance upon them.

Abstract

Twenty-six million Americans are estimated to have chronic kidney disease (CKD) with increased risk for cardiovascular disease and end stage renal disease. CKD is frequently undiagnosed and patients are unaware, hampering intervention. A tool for accurate and timely identification of CKD from electronic medical records (EMR) could improve healthcare quality and identify patients for research. As members of eMERGE (electronic medical records and genomics) Network, we developed an automated phenotyping algorithm that can be deployed to identify rapidly diabetic and/or hypertensive CKD cases and controls in health systems with EMRs It uses diagnostic codes, laboratory results, medication and blood pressure records, and textual information culled from notes. Validation statistics demonstrated positive predictive values of 96% and negative predictive values of 93.3. Similar results were obtained on implementation by two independent eMERGE member institutions. The algorithm dramatically outperformed identification by ICD-9-CM codes with 63% positive and 54% negative predictive values, respectively.

Introduction: Chronic kidney disease (CKD) affects an estimated 10% to 15% of individuals in the United States, Europe and Asia. (1) CKD is a largely asymptomatic ('silent') yet serious condition associated with premature mortality, decreased quality of life, and increased health care expenditure. Approximately two thirds of CKD are attributable to diabetes (40% of CKD cases) and hypertension (28% of cases). (2) CKD is defined in most cases clinically by loss of kidney function as estimated by glomerular filtration rate (eGFR) below a threshold of 60 ml/min/1.73m^2 (normal eGFR range 90 to 120 ml/min/1.73m2) and/or persistent increased urinary albumin excretion lasting more than 90 days. (2)Thus, identification of the vast majority of cases of diabetes- and/or hypertension-attributable CKD rests on appropriate and timely ordering and interpretation of eGFR and/or urinary albumin excretion laboratory results.

Untreated CKD can result in end-stage renal disease (ESRD) and necessitate dialysis or kidney transplantation in 2% of cases. (3) CKD is also a major independent risk factor for cardiovascular disease, all-cause mortality including cardiovascular mortality. (2) Current practice guidelines recommend tight control of blood pressure and/or hyperglycemia in particular in the presence of albuminuria to reduce ESRD and CVD risks in CKD patients. (4) However, CKD is alarmingly under diagnosed in affected primary care patients, even those with diabetes and/or hypertension. For example, among 122,502 adults enrolled in Kidney Early Evaluation KEEP, only 20% of participants with CKD stage 3 and 50% with stage 4-5 were aware of their disease. (5) Alarmingly, 43% or patients with newly diagnosed ESRD had not received specialist nephrology care and of those who did, only 25% had done so for more than one year. (5) As a result of the systematic and widespread failure to establish the diagnosis of CKD with inexpensive routine laboratory tests in primary care, affected yet unaware patient populations may not benefit from preventive measures to reduce major outcomes. The Electronic Medical Records and Genomics (eMERGE) Network is a National Human Genome Research Institute (NHGRI)-funded consortium tasked with developing methods and best-practices for the utilization of the Electronic Medical Record (EMR) as a tool for genomic research. (6) The Network's phenotyping workgroup established best practices to develop and use phenotyping algorithms processing EMR data from disparate sources such as diagnosis and procedure codes, laboratory data, medication use, and imaging studies in order to identify cases and controls with a high degree of accuracy and confidence. The Network's PheKB is a repository for phenotype algorithms. Phenotype algorithms on PheKB are validated at the creating site as well as at least 2 other Network institutions.

Here we describe the development of an automated algorithm as part of the eMERGE phenotyping framework that combines data from various EMR sources to identify diabetic and/or hypertensive patients with CKD. To the best of our knowledge, there have been no previous attempts to combine disparate sources of EMR data to identify CKD cases/controls. Positive and negative predictive values of the algorithm were validated extensively at the primary

development site, Mount Sinai Medical Center, and significantly outperformed common recorded International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes associated with CKD. Finally, the CKD algorithm was successfully implemented and validated at two additional eMERGE member institutions. Thus, our novel phenotyping tool can be readily deployed by modern health systems to identify undiagnosed cases together with established cases of CKD associated with diabetes and/or hypertension for population management, quality improvement or research initiatives.

Materials and Methods

Participating Site Overview: Three institutions participated in the validation of this algorithm. Each institution uses an EMR and the key features of this are presented in Table 1. All participants represent the population receiving routine clinical care at the study institutions.

Table 1. Overview of participating institutions' EMR and recruitment models

Institution	EMR Overview	Recruitment Model
Icahn School Of Medicine at Mount Sinai (New York, NY, USA)	Comprehensive vendor-based inpatient and outpatient EMR (Epic Systems, Verona, Wisconsin, USA) since 2003 with 10+ years ICD-9 data	Clinical population based
Marshfield Clinic Research Foundation (Marshfield, Wisconsin, USA)	Comprehensive internally developed EMR since 1985 75% participants have 20+ years medical history	Clinical population based
Columbia University Medical Center (New York, NY, USA)	Comprehensive vendor-based and self-developed inpatient and outpatient EMRs (Allscripts and iNYP) since 1990s with 22+ years of structured and unstructured data	Clinical population based

Algorithm development: We used the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) criteria for defining CKD stage 3 or higher (eGFR<60 ml/min/1.73m^2 for duration ≥3 months, based on documentation or inference. The approach utilized common EMR data including diagnostic codes, medications and laboratory results. All sites utilized the International Classification of Diseases, 9th revision, clinical modification (ICD9-CM) diagnostic codes. Table 2 shows the ICD9 diagnosis and procedure codes applied in the algorithm along with the stages in the algorithm where they were used. ICD9 codes for diabetic/hypertensive kidney disease (A1, B2); kidney transplant (B1); dialysis (B3) were used for inclusion while codes for acute kidney failure (B5) and other causes of kidney disease including HIV, immunologic and developmental causes (B9) were used for exclusion criteria. We also implemented text searches to identify terms in physician observation reports for exclusion criteria. These text searches were picked by GNN and EPB using professional expertise as nephrologists and are listed at the end of Table 2. We chose to utilize a rule-based methodology because this approach has been deployed at eMERGE member institutions collaborating on phenotype development and has proven to be replicable across institutions and to produce strong predictive values.

Text search terms used in exclusion criteria	HIVAN/HIV associated nephropathy; Congenital [within 2 words of) kidney(s)]; APKD [adult polycystic kidney disease]; Sickle Cell Disease; IgA Nephropathy; Nephrotic Syndrome; Nephritic Syndrome; Glomerulonephritis; Glomerulosclerosis; Lupus Nephritis; Wegener's granulomatosis; Goodpasture's syndrome

With respect to laboratory results, since various formulae are used to estimate the GFR leading to non-uniformity of eGFR results reported by clinical laboratories to the EMR. We overcome the apparent non-uniformity of eGFR lab results calculation and reporting in EHR by recalculating eGFR de novo with the CKD-EPI formula. (7) The CKD-EPI creatinine equation is based on the same four variables as the MDRD Study equation, but uses a 2-slope "spline" to model the relationship between estimated GFR and serum creatinine, and a different relationship for age, sex and race. The equation was reported to perform better and with less bias than the Modification of Diet in Renal Disease (MDRD) Study equation. We did not allow patients that had serum creatinine tests on consecutive days or within the same day as we assumed these were inpatient encounters. This was done to exclude acute kidney injury (AKI) events from the laboratory tests used for the algorithm. For patients that had duplicate serum creatinine tests meaning they had two tests at the same date/time but different values we kept the test with the maximum value in the algorithm. The patients fulfilling the criteria were then filtered through eMERGE Network's type 2 diabetes (8) and a hypertension algorithm that was developed at Icahn School of Medicine at Mount Sinai. These validated algorithms are shown in Figure 1 and 2. The patients then were classified into diabetic CKD (DCKD), hypertensive CKD (HCKD) or diabetic/hypertensive CKD (DHCKD) cases. The complete algorithm for cases is shown in Figure 3.

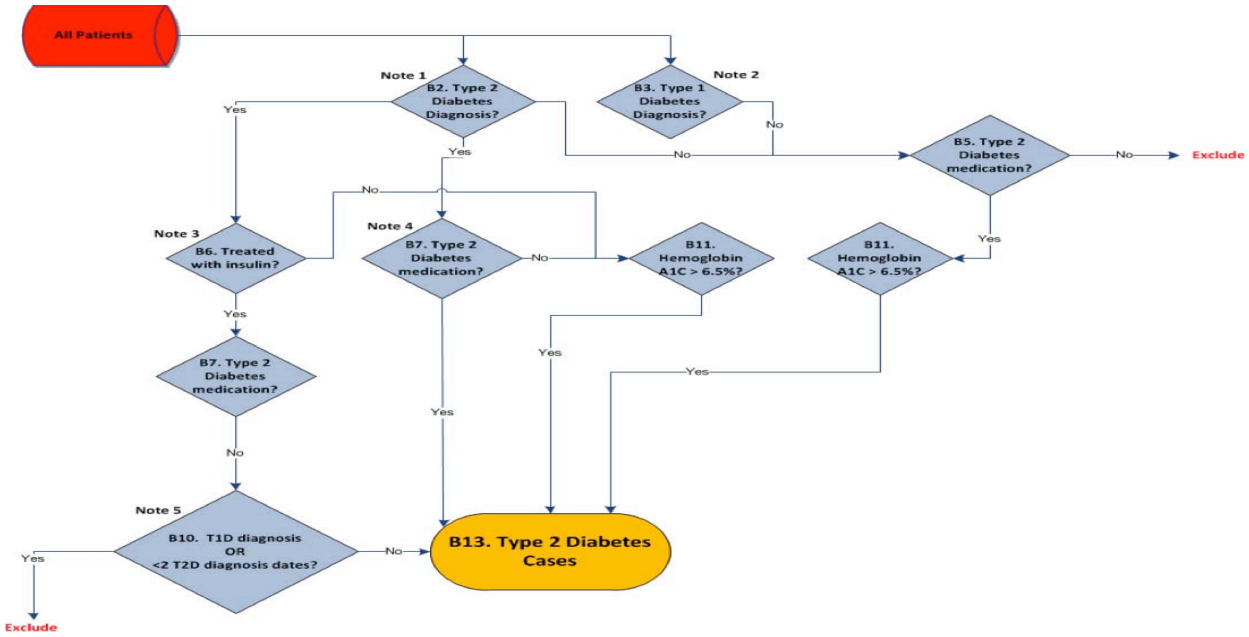

Figure 1. Type 2 Diabetes case algorithm from the eMERGE Network

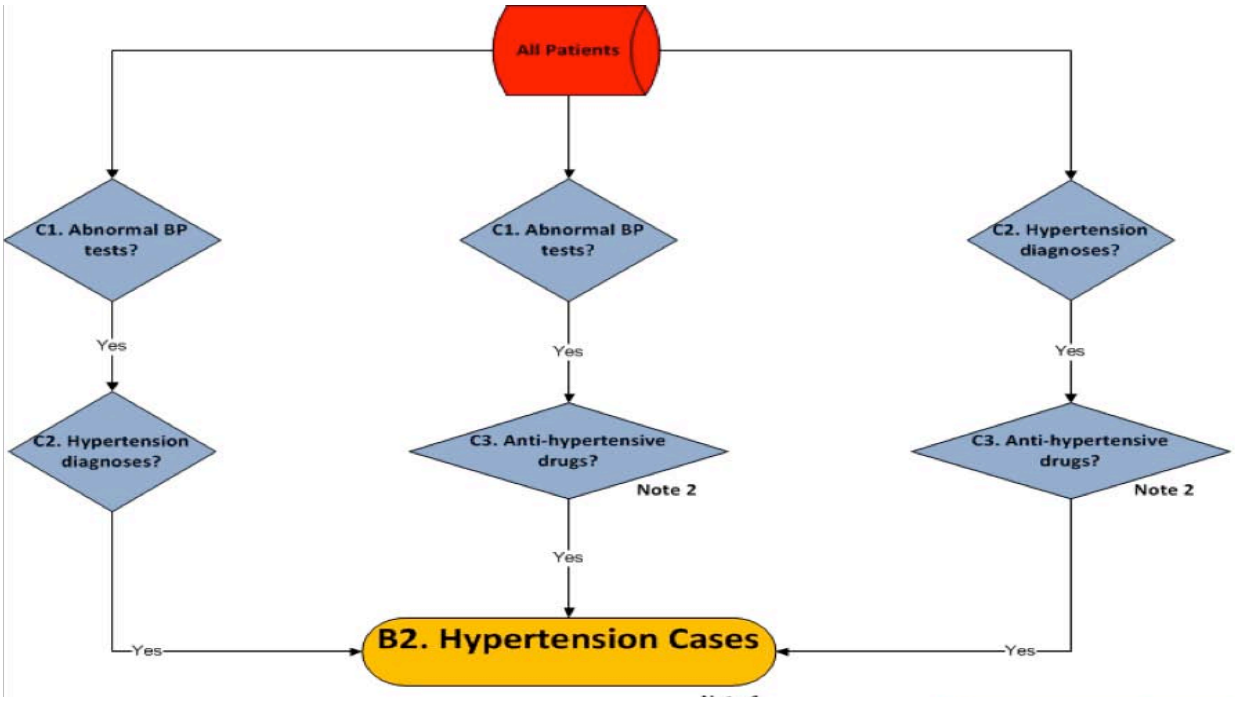

Figure 2. Hypertension case algorithm developed at Icahn School of Medicine at Mount Sinai

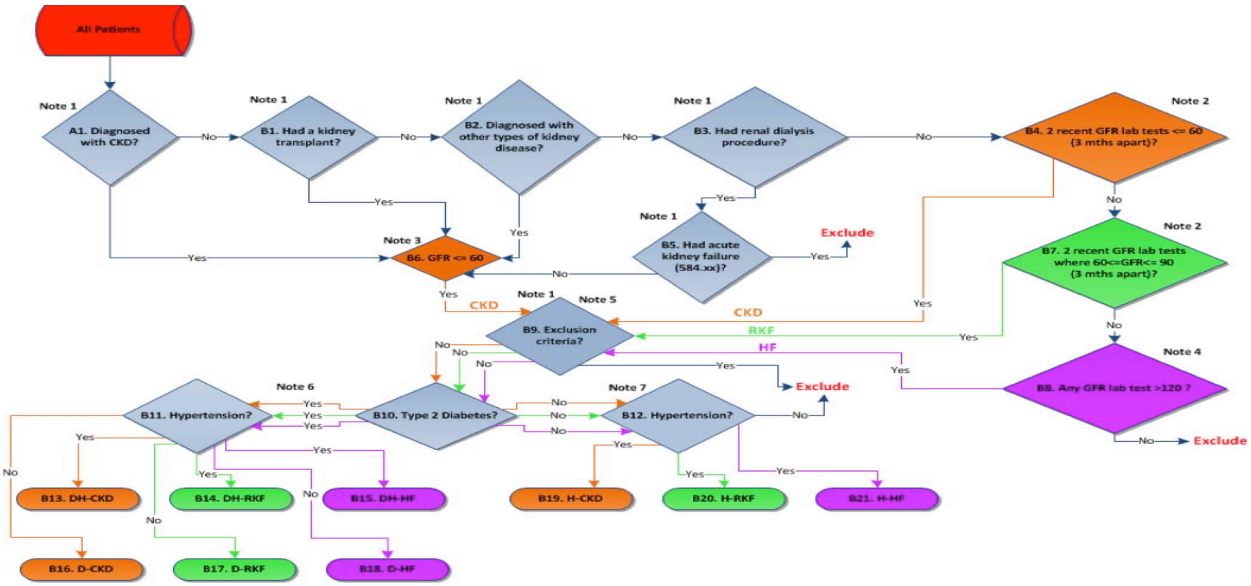

Figure 3. Phenotyping algorithm for chronic kidney disease cases

A similar approach was also adopted for the CKD controls algorithm with identical diagnostic codes, laboratory tests and text searches for exclusion criteria. Participants with 2 eGFR values from 60-89 ml/min/1.73m^2 (reduced kidney function) and at least one eGFR>120 ml/min/1.73m^2 (hyperfiltration) were also identified during this process. Since both reduced kidney function and hyperfiltration indicate an unrecognized early stage of kidney disease, including diabetic and hypertensive CKD they were excluded from all control sets. Once controls were identified, they were then filtered through eMERGE networks type 2 diabetes and hypertension algorithms and then classified as diabetic, hypertensive or diabetic/hypertensive controls. The algorithm for CKD controls is shown in Figure 4.

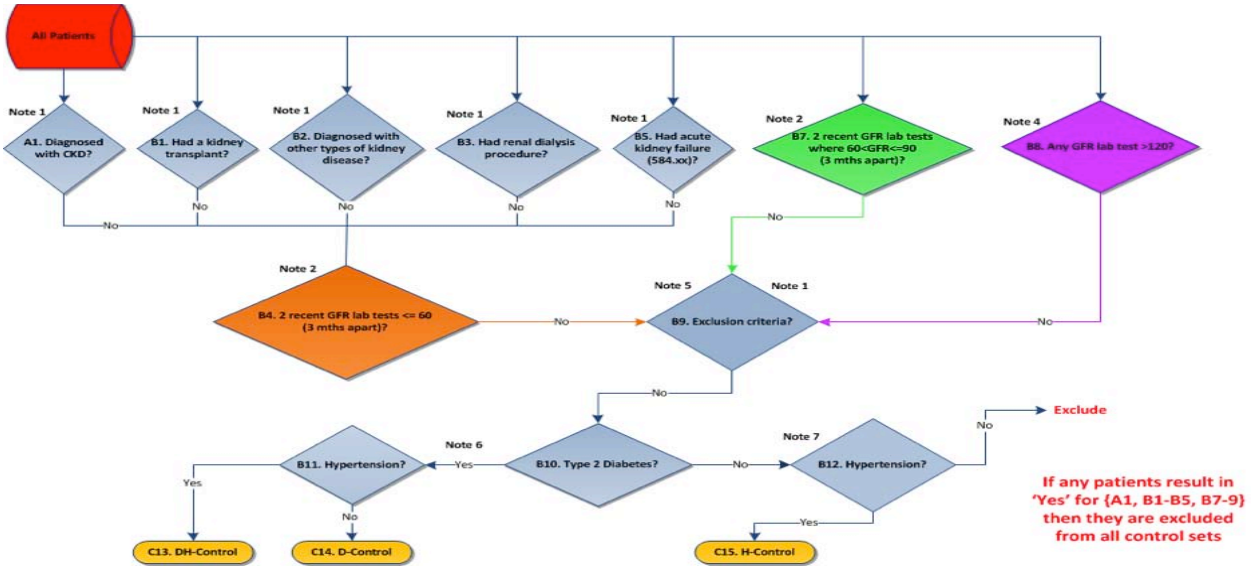

Figure 4. Phenotyping algorithm for chronic kidney disease controls

Implementation: Data elements needed for identification of cases or controls were extracted from the EMR and stored in a shadow relational database. Deidentificaton, pruning (elimination of redundant data points), transformations (for example, separating units from numeric values when they come from the EMR as a single string) and data cleansing were performed as needed. SQL queries were developed and unit-tested for each object in the cases and controls algorithms. The queries were then combined to implement the logic of the algorithms. In the Mount Sinai implementation, the subjects and observations qualifying at each step of the algorithm were saved,

facilitating subsequent validation reconciliation and algorithm refinements. A similar process of extracting EMR data to a shadow database and developing standalone queries was used at the validating sites. The decision logic for this algorithm and the use of specific terms extracted from textual clinical documentation (Table 2) exceed the clinical decision support capabilities embedded in commercial EMR's. However Mount Sinai has developed an external CDS engine that is capable of executing complex coded decision support logic and is integrated with the Epic EMR, thereby enabling the automated CKD algorithm to be integrated into clinical workflows to provide alerts to clinicians of patients at risk for CKD. (9)The validating sites have internally developed EMR's into which they can embed complex CDS code to provide alerts within existing clinical workflows. Sites using commercial EMR's would most likely not be able to implement the CKD algorithm with the available technology.

D**ata collection:** The algorithm was deployed to randomly select 600 each of CKD cases and controls from the EMR. Two independent physician reviewers (GNN and SF) at Mount Sinai Hospital manually reviewed each medical record. The gold standard for a case or a control was considered to be manual review by the physician reviewers. Any differences in agreement were arbitrated after discussion between the two reviewers. Identification of CKD in the EMR was ascertained using the CKD hierarchy of ICD9 codes (Table 3). A control was considered as correctly identified by ICD-9 codes if there was a diagnostic code identifying hypertension and/or diabetes as shown without an accompanying code for CKD (Table 3). While reviewing the charts, urine protein measurements as microalbumin/creatinine ratio and/or urine protein/creatinine ratios were also abstracted. When multiple measurements were available, the most recent measurement was recorded. In addition, documented referral to a nephrologist was abstracted. The algorithm was then deployed at Marshfield Clinic and Columbia University for secondary validation. Chart review by physician reviewers was used to validate 50 cases and 50 controls at each secondary site

Table 3. ICD-9 codes used for identifying cases and controls

Disease	ICD-9 code
End stage renal disease	585.1 to 585.9
Hypertensive chronic kidney disease, unspecified, with chronic kidney disease stage I through stage IV, or unspecified	403.90
Hypertensive nephropathy	403.10
Hypertensive renal disease	403
Hypertensive heart and renal disease	404
Diabetic nephropathy	583.81
Diabetic nephrosis	581.81
Diabetes with renal manifestations, type II or unspecified type, not stated as uncontrolled	250.40
Diabetes with renal manifestations, type II or unspecified type, uncontrolled	250.42
Diabetes with other specified manifestations, type II or unspecified type, not stated as uncontrolled	250.80
Diabetes with other specified manifestations, type II or unspecified type, uncontrolled	250.82
Intercapillary glomerulosclerosis	581.81
Kimmelstiel-Wilson syndrome	581.81
Hypertension	401-405 excluding 403 and 404
Diabetes Mellitus Type 2	250.00 to 250.93 excluding 250.40, 250.42,250.80 and 250.82)

Data analysis: After manually reviewing the cases, the inter-rater agreement/kappa statistic was calculated. Summary statistics (positive and negative predictive values) for identification of cases and controls with the algorithm and ICD-9 codes with manual as the gold standard were estimated. Medians and interquartile ranges and proportion of missing values for the urine protein measurements and the percentage of patients that had been referred to a nephrologist were also calculated for the primary site. Positive and negative predictive values were then calculated individually for both secondary sites. All analyses were performed using STATA SE version 12, College Station, TX.

Results: A total of 1200 medical records were reviewed. Out of these, 14(1.16%) were excluded due to confidential status or missing data, leaving 1186 patients included in the final analysis. The inter-rater agreement/kappa statistic between the two independent reviewers (SF and GNN) was 92%. After arbitration of disagreements there were a total of 609 cases (202 for Diabetic CKD [DCKD], 207 for Hypertensive CKD [HCKD] and 200 for Diabetic and Hypertensive [DHCKD]) and 577 controls (190 for DCKD, 190 for HCKD and 197 for DHCKD) by manual review. The summary of the comparison between the algorithm and ICD9 codes are presented in Table 4 for the primary site. The comprehensive algorithm correctly identified 569/609(93.43%) of cases and 553/577(95.84%) of controls. In contrast, conventional screening with ICD9 codes only identified 244/609(40.06%) of cases and 433/577(75.04%) of controls. The positive predictive value (PPV) for the algorithm was 95.95% and the negative predictive value (NPV) was 93.25% compared to a PPV of 62.89% and a NPV of 54.26% compared to identification using ICD9-CM diagnostic codes. The algorithm performed similarly at secondary sites with a PPV of 92% and a NPV of 100%[Table 5].

Table 4. Comparison of phenotyping algorithm and ICD-9 codes at primary site (Mount Sinai Hospital)

	Manual chart review			Manual chart review			
Phenotyping Algorithm	Case	Control	Total	ICD-9 Codes	Case	Control	Total
Case	569	24	593	Case	244	144	593
Control	40	553	593	Control	365	433	593
Total	609	577	1186	Total	609	577	1186
Positive Predictive Value (95% Confidence Interval)	95.95 (93.95 -97.33)			Positive Predictive Value (95% Confidence Interval)	62.89 (57.84-67.67)		
Negative Predictive Value (95% Confidence Interval)	93.25 (90.85-95.08)			Negative Predictive Value (95% Confidence Interval)	54.26 (50.73-57.75)		

Table 5. Performance of phenotyping algorithm at secondary sites (Marshfield Clinic and Columbia University Medical Center

Control	0	50	50	0	50	50
Total	46	54	100	46	54	100
Negative Predictive Value (95% Confidence Interval)	92 (79.89-97.41)			92 (79.89-97.41)		
Negative Predictive Value (95% Confidence Interval)	100 (91.11-100)			100 (91.11-100)		

As part of secondary analysis the urine protein/creatinine or the urine microalbumin/creatinine values for DCKD, HCKD and DHCKD cases (Table 6). For DCKD, the median microalbumin/creatinine ratio was 39 microgram/mg of creatinine. Similarly for HCKD the median microalbumin/creatinine ratio was 5.5 microgram/mg of creatinine and the protein/creatinine ratio and for DHCKD, the median microalbumin/creatinine and protein/creatinine ratios were 35 microgram/mg of creatinine and 15 mg/mg of creatinine, with 37% and 61% of patients respectively lacking measurements at any point of time. However, there was no record of a urine albumin or protein excretion for

a significant proportion of patients (ranging from 30-98%) depending on the subcategory of CKD. (Table 6) We also determined the proportion of participants that were referred to a nephrologist during any point of their clinical course in the EMR. Out of a total of 599 cases, only 112(18.7%) were referred to a nephrologist at any point during their course.

Table 6. Microalbuminuria and proteinuria measurements in CKD cases and controls

	Diabetic CKD	
	Median (IQR)	N (%) of missing values
Microalbumin/Creatinine	39(10-215)	59/200(30)
	Hypertensive CKD	
	Median (IQR)	N (%) of missing values
Urine microalbumin/creatinine	5.5(3-28)	196/200(98)
Urine protein/creatinine in mg/gm	30(30-300)	173/200(87)
	Diabetic and hypertensive CKD	
	Median (IQR)	N (%) of missing values
Urine microalbumin/creatinine	35(8-127)	74(37)

Discussion: In the near future, EMRs will become one of the most important sources of data for both clinical and genomic association studies. Since data are present longitudinally, it may facilitate studying natural history of a disease process as well as the response to treatment in a "real world" scenario. However, identification of particular phenotypes, especially chronic, complex diseases, is challenging because of the complexity of data itself and the way in which it is recorded in EMR. However, with government interest driving the widespread use and adoption of EMR's, this provides a vast and as-yet relatively untapped resource. (10) If robust phenotypes were constructed using meaningful information from various EMR sources, it would provide significant value for identifying patient cohorts that satisfy complex criteria. There has been significant debate about the optimal way to identify phenotypes in the EMR. (11) Automated approaches using electronic phenotyping and statistical analyses are popular as compared to simpler rule based systems. The utility of such phenotyping algorithms is manifold, including discovering novel genetic associations of complex diseases, tracking their natural history, isolating patients for clinical trials, and ensuring quality control in large institutions by ensuring that standard of care guidelines are met in these patients.

Kidney disease is a complex, common problem challenging modern healthcare. It is a major independent risk factor for all-cause mortality including cardiovascular mortality and adjusted rates of all-cause mortality are seven times greater for dialysis patients than for individuals in the general population. (3,12,13)As CKD is a significant health problem, accurate identification of diabetic and/or hypertensive CKD cases and controls for both research and clinical purposes is imperative. Accurate identification of individuals satisfying specific criteria from a large institutional population allows us to enroll for randomized trials, predict/track outcomes/progression, and perform retrospective cohort studies. (14,15) Studying the progression of complex diseases such as CKD is difficult as the recruitment of cohorts is a laborious process that creates a bottleneck in both clinical and translational research. In order to streamline this process, there has been an impetus to create EMR linked biobanks to enroll individuals in routine clinical care settings. The push from healthcare regulatory agencies for electronic medical records (EMRs) that provide a large amount of information available for research purposes has also been integral in improving the formation of research cohorts. (16) With appropriate patient consent and de-identifying data, the EMRs of patients are available and allow the studying of evolution and progression of disease. (17,18) In clinical care settings, a wealth of data is available through ICD-9 codes, discrete laboratory results, test reports, patient demographics, and notes written by the treating physicians. All of these data are available in a longitudinal form with multiple patient visits over several years. If matched to biobanks, the EMR can be used to identify traits/phenotypes in a large number of patients for biomarker/genomics research, thereby substantially reducing the effort and time needed to identify markers or variants that influence disease development, progression, or medication response. (18–20)

Although there are novel genetic associations including *UMOD*, *APOL1* and *SHROOM3*, there are other potential genetic associations that explain the differential rates of CKD in different ethnic populations. (21,22) Clinical decision making is challenging due to variability in the rates of progression and lack of widely-accepted guidelines to identify patients most at risk of progression to ESRD. (23,24) For studies to assess progression over the course of the patient's history in the EMR, accurate identification of large numbers of patients is needed. Currently the only way of identifying CKD cases/controls is by manually reviewing laboratory values, which is cumbersome, or through ICD9 codes. To accomplish these goals, researchers need robust phenotyping algorithms to effectively leverage disparate data sources in the EMR. To the best of our knowledge, this algorithm is one of the first automated phenotyping algorithms for diabetic/hypertensive CKD. It significantly outperformed conventional screening with ICD9 codes and could be deployed to different EMRs in various healthcare institutions. Thus, an integrated approach using diagnostic codes, medications, and laboratory tests yielded significant improvement over non-integrated approaches.
Although there are no recommended guidelines for nephrologist referral in CKD stage 3, there are studies suggesting that such referrals may improve prognosis. (25,26) However, we demonstrated that only 18.7% of confirmed CKD cases were referred to a nephrologist at any point during their EMR course. Thus, identifying appropriate patients for referral to a nephrologist is one of the many clinical applications of this algorithm.

Limitations: This algorithm does not include proteinuria or albuminuria measurements that are used to diagnose and stage CKD in addition to eGFR. This decision was based on the observation that in many instances urine albumin or protein excretion results are not recorded in the EMR. This approach was developed to classify co-existing prevalent CKD and T2D and/or HTN because in the vast majority of cases, T2D and/or HTN precede CKD, especially when other etiologies of kidney dysfunction are excluded (as they are in the algorithm). In a sub-analysis, we found that $\geq$ 95% of patients had a prior diagnosis of HTN and/or T2D before CKD, thus validating that the number of patients that might have CKD due to other etiologies are likely minimal. There was also a consideration of overfitting due to the high dimensionality of this problem under consideration. However, since the algorithm was replicated at multiple sites with near-identical results, this is likely to be negligible. Also, considering the low referral rate, it is possible that patients without EMR documented referral may have been referred to nephrologists outside the EMR.

Conclusions: In summary, we describe the development and validation of an automated algorithm for identifying diabetic/hypertensive CKD cases and controls and also demonstrate its superiority over traditional identification using ICD-9 diagnostic codes. We believe that this algorithm could be used to accurately and rapidly identify a specific target cohort within the EMR for both research and clinical purposes.

Using TURF to Understand the Functions of Interruptions

Abstract

Interruptions are an often lamented and frequently studied aspect of clinical practice. However, some interruptions, such as updates on patient care decisions and notifications of detrimental patient lab values, are in fact necessary to the work process. In this paper, we explore the interruptions as an emergent feature of communication in teams. Looking beyond the frequency of interruptions, we consider the source and intent of interruptions with the goal of discovering the functions served by such communications. Furthermore, in this study of an emergency department, we classify interruptions into those activities that support required work and those interruptions that create unnecessary breaks in workflow. The intent of our larger body of work is to develop health information technology systems that support team efforts including the functions currently served by interruptions.

Introduction

Interruptions

Interruptions, or a break in task to execute an unplanned task initiated by an internal or external source resulting in the pause or termination of the original task[1], are an often bemoaned and frequently studied aspect of clinical practice[2-7]. While unnecessary interruptions have the potential to lead to increased patient risk[6-9], some interruptions such as updates on patient care decisions by clinicians and notifications of detrimental patient lab values or irregular imaging results, are in fact necessary to the work process[1]. In this paper, we explore interruptions as an emergent feature of communication in teams. We focus on emergency medicine as this complex environment requires team based concurrent management of multiple patients coping with limited resources in a life-critical and interruption-laden environment[10].

U.S. emergency department physicians experience interruptions, on average, 10 times per hour during a shift[6, 8]. These routine breaks in task are more frequent in nursing, where emergency department nurses are interrupted every 4.5 minutes[6, 9]. Such interruptions not only impact the clinical care by potentiating medication errors or tasks on the wrong on the wrong patient[2, 4, 5, 11], and have also been correlated to lower patient satisfaction[12].

Interruptions are not always to the detriment of care. It has also been found that the act of interruptions can help increase shared knowledge amongst team members. With efficient communications between team members, new knowledge or work routines are exchanged and such conversations improve the team's performance on completing tasks[13]. Other positive impacts on task performance, the emotional state, and social attribution of people, depending on their current cognitive load, have also been found[14].

In addition to the above studies, much of the literature has focused on identifying the rate of interruptions, tasks that are interrupted, and the participants engaged in the interruption[1, 8, 9, 15, 16]. Understanding the reasoning for interruptions, or the function that interruptions serve, will allow us to create interventions, here in the form of a health information technology, that support required interruptions while mitigating unnecessary breaks in work. Inherent in our assumption is the need for this type of communication as part of ongoing clinical practice.

TURF

The TURF framework, a method of Work-Centered Design, provides a qualitative and quantitative means of developing useful and usable systems. TURF stands for Task, User, Representation, and Function (TURF) analyses[17, 18]. TURF is intended to aid in the creation of tools that provide a more useful and satisfying experience for system users while promoting patient safety and quality. This is accomplished by understanding the needs of users while supporting the functions to be accomplished as part of overarching goals and the tasks that are required in those efforts. Additionally, the users and their preferred visualizations make up other components of well thought out systems.

The objective of this study is to understand the function of interruptions by describing their place in the workflow. Namely, are the interruptions serving the functions of clinical work or do they reflect issues within the system (*e.g.*, the interface does not fulfill the needs of the clinician in providing patient care) or environment (*e.g.*, clinicians failing to understand roles and responsibilities required for completing overarching patient care goals). Our findings will help to inform our design of a team support tool to help clinical teams manage interruptions in the emergency department.

Domain versus Overhead Functions

The term overhead has traditionally been used in the business organizational context to refer to expenses required in operating a company such as paying rent for the facilities to manage production. Overhead is *not directly connected* to the items produced. In such examples, these extraneous outlays are part of "operating costs." Similarly, the term has been used in the engineering and computational domain to describe design and algorithm features that require additional features from the system in order to reach a goal such as expending additional energy to run a circuit or transmitting signals in addition to computing data. By contrast, in these contexts, domain functions are used to describe the elements *directly required in the work*. That is what is needed to create the product.

Zhang, Butler, and colleagues (2007 & 2011) expand on the use of domain and overhead terms to describe required and extraneous functions used to operate systems[17, 18, 19]. For example, a well designed interface would only display the domain, or required, operations users must click through in order to execute a command. A poorly designed system would have additional overhead, or unnecessary, operations interspersed throughout the system which may generate unnecessary effort. Couched more tangibly, when domain and overhead functions were applied to an electronic health record (EHR) allergy entry workflow, researchers discovered 99 overhead, and thus, extraneous functions. This is in stark comparison to the 28 domain functions[20]. This nearly 4:1 ratio of overhead to domain functions had the potential to dramatically impact the usability of this system.

For this paper, we further expand on the use of domain and overhead functions by using these terms to describe the interruptions within a clinical context. An overhead interruption refers to non-clinically dependent communications that disturb existing work processes. Some examples of overhead interruptions include: tracking down clinicians, repeating tasks already completed by other clinicians, completing tasks unrelated to the realms of your responsibilities, and performing workarounds of poorly implemented systems. Domain interruptions are therefore, interruptions whose communication fits within the needs of work. Examples of domain-type interruptions are providing updates on patient care plans, interpreting electrocardiography (EKG) or lab results, or verifying patient disposition decisions. Overhead interruptions can delay or impede the patient care process as they are not a necessary part of the required work while domain interruptions clearly support the patient care process as they are a part of the required work. Differentiating between these two types of interruptions may help us further understand how to better manage communications. We seek to support domain interruptions while mitigating the cognitive and workload burdens created by overhead-type interruptions.

Table 1 provides the definitions we used to classify interruptions by their function.

Table 1. Definitions used to classify interruptions by function.

Terms	Definitions
Interruption	"A break in the performance of a human activity initiated by a source internal or external to the recipient. This break results in the suspension of an initial task to perform an unplanned task which results in a break or termination of the primary task[1]."
Overhead	Interruptions that are not clinically dependent and create disturbed work processes (*e.g.*, Technology Workarounds). Often caused by the implementation of poorly designed systems or workflow methods[17, 18, 19].
Domain	Interruptions necessary for the completion of clinical tasks and create undisturbed work processes (*e.g.*, Interpreting EKGs)[17, 18, 19].

Methods

Data for this study was drawn from a larger project examining decision making and information foraging in the emergency department. The dataset includes ethnographic non-participant observations of emergency medicine work from multiple clinical perspectives at a Gulf Coast Trauma 1 Center Teaching Hospital. This hospital sees

about 6065 trauma cases per year and employs fifty-two attending physicians, fifty-three residents, and fifty nurses. The emergency department at this hospital uses an EHR system with clinical provider order entry functionalities, trackboard, and a traditional pager and phone communication procedure.

Here, we shadowed emergency department attending physicians, residents, and nurses. From this dataset, a convenience sample of six attendings, five residents, and five nurses were included in this secondary analysis. Each participant was observed on two different days for a time period of four hours each during each participant's start of shift. A total of 128 hours of observation are included in this study. Following our IRB approved procedure, participants gave written informed consent before observations began[a].

Two non-clinical graduate students shadowed the clinicians. Observations were collected using pen and paper, a digital wristwatch with the time in seconds, and an audio recorder. Information was collected using a field note taking procedure established in our previous ethnographic studies[21]. The audio recording device was placed within a pocket on the participant's person and its microphone clipped at the participant's white coat or scrub shirt collar[21].

Using a categorization framework created by Brixey et al. (2007) and Franklin et al. (2011), we identified the types of interruptions and task transition decision making (*i.e.*, interruptions, opportunistic decisions, or protocol based actions) that occurred among the emergency department team during[21, 22]. Interruptions were noted from all types of communications ranging from patient updates to general social behaviors during the observed work hours. Observation notes were supplemented with the audio recording for clarification. The observers had a reliability of κ=.80 indicating strong consistency in data collection and the reliability of initial categorization.

In this paper, we then further classified the interruptions from the above dataset. We identified whether the clinician observed was the recipient or initiator of the interruption[16], and whether or not the interruption was an overhead (*i.e.*, unnecessary communication for the completion of a task or maintaining team shared knowledge and awareness) or domain-type (*i.e.*, necessary for completing task or maintain team needs) interruption[17, 18, 19].

We were able to capture a snapshot of the emergency department team from the attending, resident, and nurse perspective on the directionality and interruption type by a member of the emergency department team.

Results

Attending Perspective

910 interruptions occurred during the 48 hours of observations of the six emergency department attending physicians (M = 18.96 interruptions per hour). First, considering the directionality of the interruptions, that is creator or receiver, we found that attending physicians are more often interrupted (91%) rather than the source of interruptions (9%). 52% of interruptions were initiated by residents with only 13% initiated by nurses.

When we consider the function, domain or overhead, served by these interruptions, we found 23% are overhead-type interruptions unnecessary for completing clinical tasks or maintaining teamwork needs. Common overhead-type interruptions that attending experienced were: being asked to help locate other clinicians, relaying information to other clinicians, and EHR problems (*i.e.*, technical issues). Again, residents were the primary source of these overhead interruptions (35%) with a small portion contributed by consultants (10%) and nurses (14%).

Resident Perspective

For the resident physicians, a total of 697 interruptions occurred during the 40 hours of observations (M = 17.43 interruptions per hour). 26% of interruptions received by the residents were initiated by attendings while nurses initiated 21% of these breaks in task. As initiators of interruptions, residents caused (52%) interruptions for attendings and (20%) interruptions for nurses.

For our functional analysis, we found 30% of the interruptions (n = 208) were classified as overhead-type interruptions. The overhead-type interruptions that residents experienced were: finding information for other clinicians, helping clinicians find patients, and helping other clinicians navigate the EHR. Overhead-type interruptions were initiated by attendings (24%), consultants (14%), other residents (15%), and nurses (12%).

[a] All clinical team members provided consent for each day of observation, including non-shadowed members of the group.

Nurse Perspective

Forty hours of nursing data was included in this secondary analysis. In that time frame, nurses experienced a total of 1053 interruptions (M = 26.33 interruptions per hour). Of the total interruptions, nurses initiated breaks in task on only 18% of the occasions observed. Residents contributed to 17% of the nurse-recipient interruptions.

Considering the function of the interruptions, 40% of the total interruptions observed were classified as overhead-type interruptions. These most often included inquiries by other nurses (45%).

Triangulation of Clinical Perspectives

After categorizing the interruptions by directionality and type of function from each clinical role's perspective, we performed a triangulation of the data comparing the occurrences of overhead and domain-type interruptions for a comprehensive analysis of the emergency department team's interactions (Figure 1). By comparing the difference perspectives of interruptions, we can validate each angle and further understand how each clinical role communicates and interacts with one another to determine how to better manage interruptions in the emergency department environment.

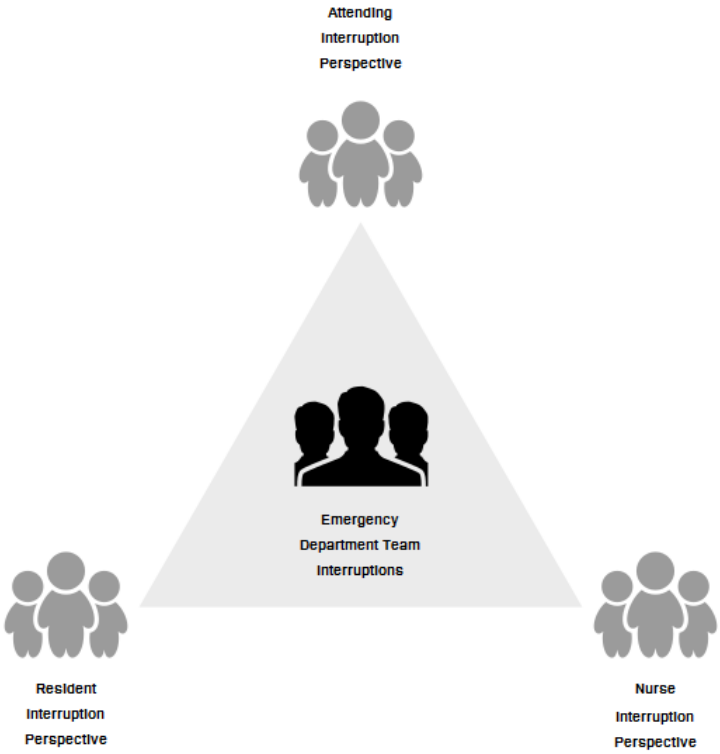

Figure 1. Triangulation of interruption perspectives by clinical role to validate the clinical team perspective.

Comparison of the different clinical role perspectives indicate an increasing number of domain interruptions from attending physician to nurse (Figure 2).

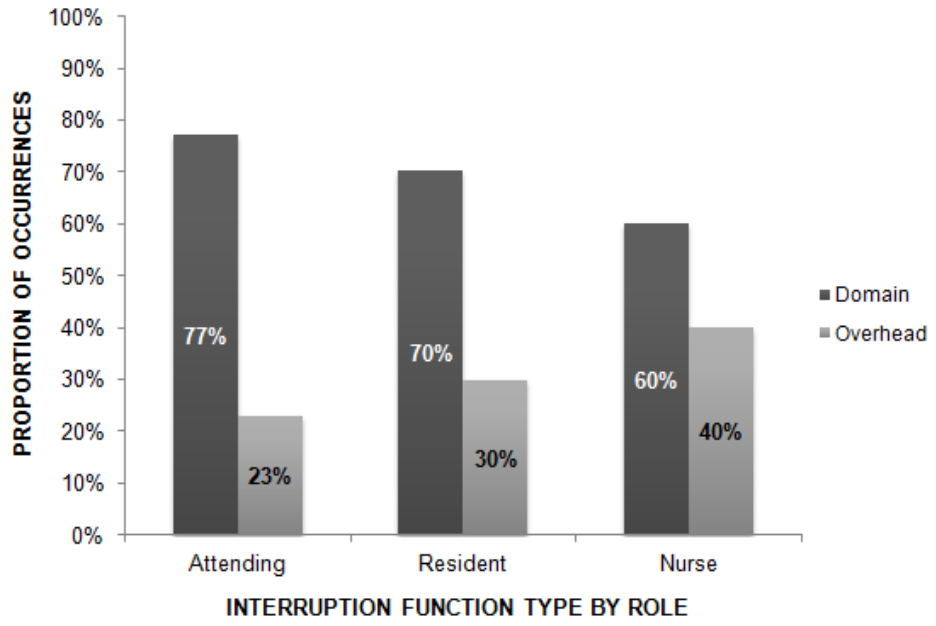

Figure 2. Percentage of domain and overhead types of interruptions experienced by role.

Breaking down the interruption functions by initiators and recipients of interruptions along with role demonstrates that although everyone received more interruptions than they initiated, there are differences in clinical role and interruption role (Figure 3). Nurses initiated more domain interruptions when compared to physicians, and though comparable, residents initiated more overhead breaks in task.

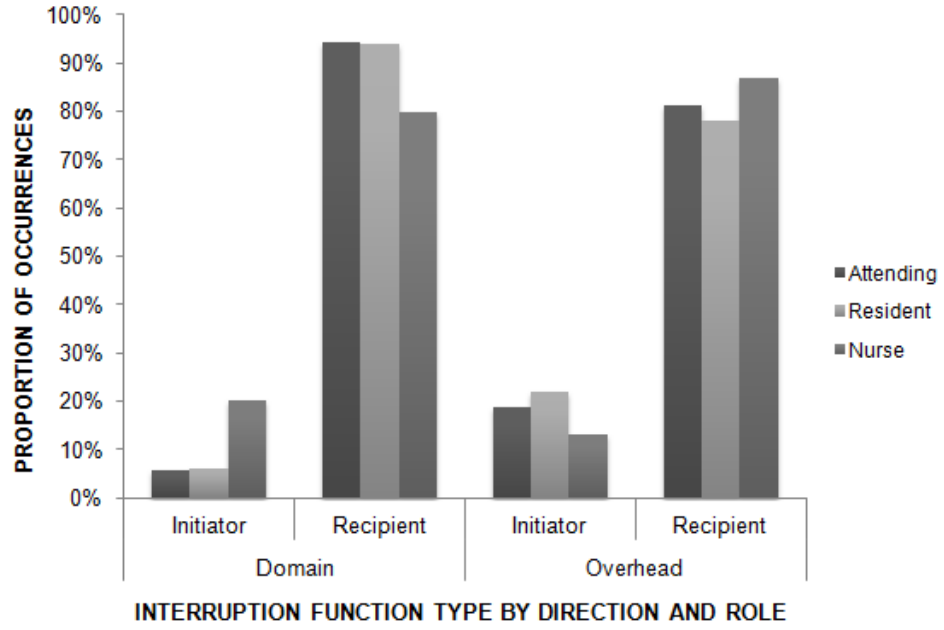

Figure 3. Classification of the identified interruptions by function, domain/overhead, direction of communication, and clinical role.

Discussion

In 128 hours of shadowing, 2660 interruptions were observed. Across clinical roles, this is the equivalent of 21 interruptions per hour. 61.1% of these breaks in task were classified here as received domain interruptions (n = 1626).

These findings demonstrate the ubiquitous nature of interruptions in emergency care and suggest a need for the management of interruptions, especially interruptions unnecessary to clinical tasks. Falling in line with expectation, residents and nurses received the majority of the domain-type interruptions as they are subordinates in the team and these types of interruptions may be natural to their workflow as task directives. For nurses to initiate a majority of the domain-type interruptions suggests that some communication gaps may be bridged by nurses between the attending, residents, and other nurses.

Residents were the main initiators of overhead-type interruptions. These types of interruptions may be used to manage responsibilities outside of clinical work, but related to duties of promoting standard social work behaviors and maintaining a team environment.

In addition to the overhead interruptions, the domain interruptions also require support. The use of interruptions as a communication strategy is an emergent feature of clinical teams. Currently, breaking the process of someone's effort may be necessary in some instances, but may be disruptive in other instances. We believe building from these initial classifications with additional effort, we will be able to design a team support tool to help better manage the necessary interruptions while mitigating the unnecessary interruptions for clinicians. These team support tools could be more informative dashboards or smart phone applications which could help clinicians obtain a better sense of when to push communications based on the overall workload of the emergency department.

Improving our understanding of team user's needs and interruption content and function may help in the interface design of systems in healthcare settings. Our application of the TURF framework in the design of a support tool managing the activity of interruptions can help provide further support in the importance of designing systems for clinicians. Patient safety and quality may improve through the enhancement of each clinician team's efficiency, effectiveness, coordination, communication, and, more broadly, future acceptance and use of possibly any implemented technology, such as health information technologies.

Limitations

This study used a limited convenience sample of participants within the trauma portion of a major emergency department. Consequently, these results may not be generalizable to other clinical settings. We were also unable to follow patients through their care outcomes and were therefore unable to verify if the impact of overhead interruptions greatly hampered the patient care process. Despite these limitations, we were able to outline the emergency department workflow, clinician communication and interaction patterns, and the function of interruptions.

Future Work

The scope of this work focuses on one emergency department. We are working to replicate the study in two other emergency departments using different health information technology systems, workflow, and patient sizes. Additionally, we are creating and testing more informative dashboards and communication tools (*e.g.*, smart phone applications) for clinicians to help better manage their workload and communications. We will compare the results of using these team support tools against the baseline findings of this study in determining how helpful the team support tools are to providing safer and faster patient care process outcomes.

Conclusion

In this paper, we explored interruptions between attendings, residents, and nurses in the emergency department environment. We looked beyond identifying the frequency of interruptions and considered the function of the interruptions. The interruptions we observed in the emergency department were classified into activities that supported required work and those that create unnecessary breaks in workflow. The results from this study will help inform our design of health information technology systems to support teams in better managing their communications.

Pharmacovigilance on Twitter? Mining Tweets for Adverse Drug Reactions

Karen O'Connor[1], Pranoti Pimpalkhute[1], Azadeh Nikfarjam, MS[1], Rachel Ginn[1], Karen L Smith, PhD[2], Graciela Gonzalez, PhD[1]

Abstract

Recent research has shown that Twitter data analytics can have broad implications on public health research. However, its value for pharmacovigilance has been scantly studied – with health related forums and community support groups preferred for the task. We present a systematic study of tweets collected for 74 drugs to assess their value as sources of potential signals for adverse drug reactions (ADRs). We created an annotated corpus of 10,822 tweets. Each tweet was annotated for the presence or absence of ADR mentions, with the span and Unified Medical Language System (UMLS) concept ID noted for each ADR present. Using Cohen's kappa[1], we calculated the inter-annotator agreement (IAA) for the binary annotations to be 0.69. To demonstrate the utility of the corpus, we attempted a lexicon-based approach for concept extraction, with promising success (54.1% precision, 62.1% recall, and 57.8% F-measure). A subset of the corpus is freely available at: http://diego.asu.edu/downloads.

Introduction

Prescription drug usage continues to grow as part of health care strategies to increase health and improve quality of life. The National Center for Health Statistics (NCHS) reported that over a 10 year period, the percentage of those who were taking either 'one', 'two or more', or 'five or more' drugs increased 4%, 6% and 5% respectively.[2] While these drugs are prescribed for their therapeutic properties, their use may result in unintended or adverse effects.[3] An adverse drug reaction (ADR), as defined by the World Health Organization (WHO), is: "Any response to a drug which is noxious and unintended, and which occurs at doses normally used in man for the prophylaxis, diagnosis, or therapy of disease, or for the modifications of physiological function."[4] The morbidity and mortality rates associated with ADRs are considerable.

Pharmacovigilance is defined as "the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other possible drug-related problems".[5] ADRs are the primary focus of pharmacovigilance. ADRs may be detected in either the pre-marketing clinical trials or post-marketing surveillance of a drug. Post-marketing surveillance has traditionally been dependent on spontaneous reporting systems (SRS), which are maintained and monitored by various regulatory agencies, such as the FDA's Adverse Event Reporting System (FAERS). The FAERS provides consumers and providers with a system to report suspected ADRs. One of the main problems with SRS is that they are generally under-utilized due to the voluntary nature of reporting. A systematic review, conducted in 2006, estimated an under-reporting rate of 85-94%.[6] Recognizing the limitations of the SRS, the FDA launched an active surveillance initiative in 2008.

One of the FDA's Sentinel Initiative's aims is to use existing health data, such as electronic health records and claims data, to actively monitor for adverse event signals.[7] In addition to using existing health data to automatically detect ADRs, research has explored other data sources for this information. One such source is online social networks, in particular health related networks such as DailyStrength or PatientsLikeMe. Here, patients can freely discuss and share their experience with drug products. One of the first efforts to find ADRs in user posted comments was made by Leaman et al.[7] They used a modified lexicon based approach to extract drug and ADR relationships from user comments in the health networking and forum site DailyStrength.com. The authors concluded that user comments do contain extractable information regarding ADRs and these consumer reported effects do overlap with the known adverse effects. Generic social networking sites, such as Twitter, have also been found to contain valuable health related information. Recent research has shown that Twitter data analytics can have broad implications on public health research. Paul and Dredze demonstrated that public health topics, including syndromic information, geography based risk factors, and information about symptoms and medication, could be extracted from Twitter.[8] One limitation they note is the need for more data in order to produce better results.

Twitter is a valuable resource for researchers because the discussions are publicly available and can be accessed through the Twitter's streaming application programming interface (API). This unfettered access to volumes of up-to-date information is not without its challenges for natural language processing (NLP) researchers looking to

automatically extract relevant information. One difficulty is the paucity of relevant data, preliminary analysis demonstrated that less than 1% of tweets that included a drug name had an actual ADR mention. In contrast, our recent analysis of data from the health forum DailyStrength.com shows approximately 24% of the comments mention an ADR. Twitter would seem too sparse for exploration. However, with over 645 million users, 58 million tweets per day[9], and 80% of users posting tweets about themselves,[10] the value of Twitter as a source of similar data calls for careful reconsideration, even if one has to collect data over a longer period to get a large data volume.

Another challenge with Twitter is in the lack of structure in tweets. Tweets are restricted in character count, forcing users to condense their sentiments while still conveying the intended meaning. This leads to highly unstructured text that contains many abbreviations, some of which are unique to Twitter. They contain frequently misspelled words, colloquialisms, idioms, and metaphors that make automatic processing more difficult. For the task of mining for ADR mentions, these issues compound an already challenging problem.

Ritter et al. examined the performance of standard natural language processing tools (NLP) for named entity recognition (NER) in tweets.[11] They found that standard NLP tools performed poorly due to the compressed nature of the tweets, which eliminates the context needed to find an entity's type, and the relatively infrequent use of unique entity types, which makes it difficult to amass sufficient training data. They developed a set of NLP tools, specific to Twitter that outperformed the standard tools by a margin of 25%.

Research into the use of Twitter for detection of drug and adverse effect events has been sparse. Bian et al. utilized a data set of 2 billion tweets to explore the use of Twitter for real-time pharmacovigilance.[12] They chose five cancer drugs and mined the data set for mentions of those drugs. They then developed a SVM classifier to identify adverse effects caused by the drugs. Their results were qualified by the authors as "rather low", which they ascribe to: the nature of the tweets (unstructured, abbreviated words), the use of NLP tools that were created for more structured text and the use of nonmedical terms by the users that made matching difficult.

In this paper, we used a specifically selected corpus to evaluate the viability of Twitter as a source of ADR mentions and its potential value for pharmacovigilance. We anticipate that our findings could help augment other signals used to detect relationships between a drug and an adverse reaction.

Methods

To create a corpus of highly relevant data for our task, we collected tweets for 74 drugs (*target drugs*). A total of over 187,000 tweets that contained a mention of one of our target drugs were collected. After filtering out likely advertisements and balancing the data set, our final corpus consisted of 10,822 tweets. The corpus was annotated in two stages. The first was a binary annotation of each tweet indicating whether it contained an ADR mention or not. A combination of the tweets identified as containing an ADR and a randomly selected sample of 1,000 tweets that were marked as not containing a mention of an ADR were then annotated for specific concept spans and UMLS concept IDs. We annotated the spans and UMLS IDs for each adverse effect or indication mentioned, such that one tweet could have multiple mentions. We distinguished mentions about *adverse reactions* (an unexpected, negative effect resulting from the adequate use of the drug) from mentions about *indications* (the sign or symptom for which the drug was prescribed in the first place). This distinction is important, and it is a hard distinction to make even for annotators, let alone automated systems. A detailed description of these steps follows.

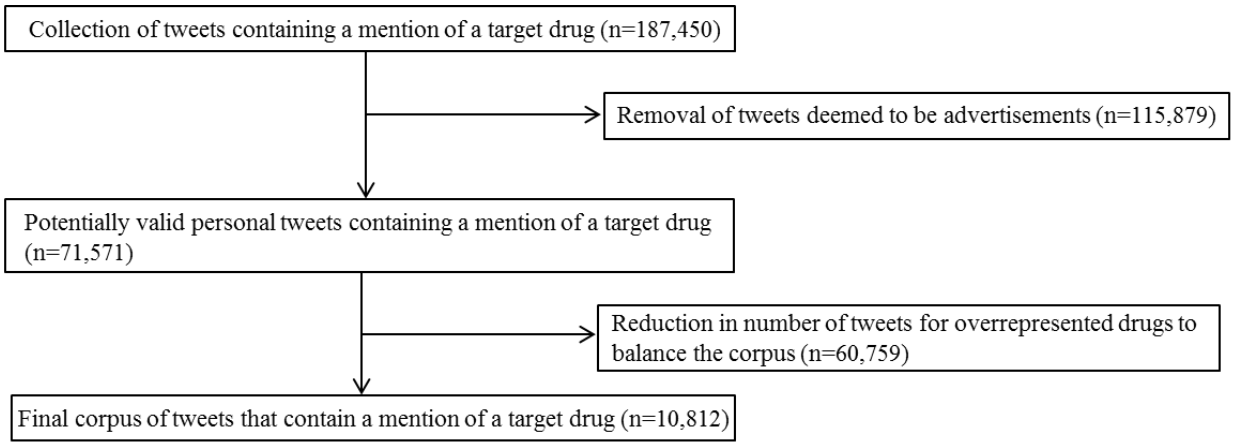
Data Acquisition: The 74 drugs included in this study are broadly used drugs whose adverse effects are well known (*truth set*), plus drugs released between 2007 and 2010, for which not all adverse effects are yet known and will only become visible as the drugs are more widely used (*test set*). Drugs in the truth set were selected on the basis of their widespread use, as demonstrated by their presence in the Top 200 products by volume in the US market published by IMS Health; and also based on whether they had a known adverse effect in at least one of the categories of interest. Many of the drugs for the truth set have come into widespread use recently, which allows for testing the capability of the NLP methods to confirm signals that are now known, but not so at the time of release. For the newer drugs, going back to 2007 allows for market growth leading to common prescribing and thus, likely presence in tweets. The list was narrowed based upon forecasts for widespread use, the prevalence of disease states and conditions, and on whether the drug was new in class. Major categories include drugs for central nervous system and mental health conditions such as Alzheimer's disease and schizophrenia. Treatments for age-related diseases (such as diabetes, cardiovascular diseases, urinary dysfunction, and musculoskeletal disorders) also met the criterion for potential widespread use, considering increased life expectancy. Additionally, biologics are an important class that was included because adverse events have traditionally been difficult to detect. Given the lag between FDA approval and recognition of

serious adverse events in this category, we selected four biologics to follow as part of the experimental set, and one is included in the truth set.

The drugs names, both the generic and brand, were used as keywords in the Twitter Search API. One of the first challenges we faced with acquiring the relevant tweets was accounting for a wide variety of drug name misspellings. To ensure that as much data as possible was obtained, we also used projected misspellings of drug names as keywords. The misspellings were created using a *phonetic spelling filter* that generates variants based on the phenomes of the correct spelling.[13] The filter generated many variants, and about 18% of them were added to the keyword list for reasonable coverage. Those were selected based on their Google search web prevalence.

The expanded drug list was used to search Twitter via the API. A total of 187,450 tweets were collected over a seven month period (August 2013 – February 2014). These required further filtering to remove advertisements and to balance the dataset among the drugs. This was accomplished by first removing texts containing URLs. Retweets were not removed. The number of tweets was thus reduced to 71,571. Next, to balance the number of tweets for each drug in the corpus, a maximum of 500 to 800 tweets for each drug name variant was randomly selected. This was necessary due to the vast imbalance of tweets containing mentions of some popular drug names as compared to others. Also, maintaining a soft limit, rather than a hard one, ensured that drugs that are highly commented upon also contain a higher number of samples in the corpus. This reduced the final corpus to 10,822 tweets. This process is summarized in Figure 1. A full description of the corpus appeared in Ginn et al.[14] A subset of the corpus is available online at http://diego.asu.edu/downloads.

Figure 1. Summary of tweets collected and subsequent reductions to obtain the final corpus.



Annotation. For annotation, we defined an adverse reaction as "an undesired effect of the drug experienced by the patient." This included mentions where the patient expressed the notion that the drug worsened their condition. An indication was defined as "the sign, symptom, syndrome, or disease that is the reason or the purpose for the patient taking the drug or is the desired primary effect of the drug. Additionally, the indication is what the patient, or prescriber believes is the main purpose of the drug." The annotated spans were mapped to UMLS concept IDs found in the lexicon.

Our lexicon was derived from our earlier work, presented in Leaman et al.,[7] and includes terms and concepts from four resources: the Coding Symbols for a Thesaurus of Adverse Reaction Terms (COSTART) vocabulary created by the U.S. Food and Drug Administration for post-market surveillance of adverse drug reactions (a subset of the UMLS Metathesaurus), which contains 3,787 concepts[15]; the side effect resource (SIDER), which contains 888 drugs linked with 1,450 adverse reaction terms extracted from pharmaceutical insert literature[16]; the Canada Drug Adverse Reaction Database, or MedEffect, which contains associations between 10,192 drugs and 3,279 adverse reactions.[17] We added terms from SIDER 2[16] and the Consumer Health Vocabulary (CHV)[18], which includes more colloquialisms.

The corpus was manually annotated in two stages by two expert annotators. The entire corpus was initially annotated for binary classification of the tweets as either '*hasADR*' for those with a mention of an adverse reaction, following the definition described above, or '*noADR*' for those without. The purpose of the binary classification was to validate our assumption that people would discuss their personal experiences with prescription drugs via tweets.

In the second stage of annotation, a combination of all tweets from the corpus classified as '*hasADR*' and a random selection of 1,000 tweets from the corpus that were classified as '*noADR*' were annotated to capture the spans in the

text that expressed either an adverse reaction or an indication. The spans of the mentions were annotated by the same annotators who performed the binary annotations following the rules set forth in the annotation guidelines. Some general guidelines include: *only capturing mentions if the concept was experienced by the patient*; *if the patient reported the concept as the reason for taking the drug than that mention would be labeled as an indication*; *all concepts were to be mapped to the UMLS id that most closely matched the meaning of the span*; and *when annotating a span, the smallest number of words needed to convey the meaning were chosen*. Table 1 illustrates a sample of tweets and their annotations.

Table 1. A sample of the tweets collected from Twitter and their annotations

Sample Comments	Classification	Annotations
20s 8th day with #Effexor still experiencing some side effects (drowsiness,sleepiness,GI effects). Moderate improvement in mood #depression	*hasADR*	"drowsiness" - *drowsiness: adverse effect*, "sleepiness" - *sleepiness: adverse effect*, "GI effect" – *gastro intestinal reaction: adverse effect*, "depression" – *depression: indication*
Over-eaten AGAIN just before bed. Stuffed. Good chance I will choke on my own vomit during sleep. I blame #Olanzapine #timetochange #bipolar	*hasADR*	"over-eaten" – *increased appetite: adverse effect*, "bipolar" – *bipolar disorder: indication*
@brokenmind_ Quetiapine was horrific for me in relation to wait gain. Such a horror story. But the weight will come off one day at a time.	*hasADR*	"wait gain" – *weight gain: adverse effect*
Tomorrow, my second infusion of Tysabri! Good luck for me! #Godblessme #MSLife	*noADR*	"MS" *multiple sclerosis:indication*
Do not take Cymbalta if you breathe – stolen from Tay	*noADR*	
Rules of Prozac: 1: You can never sleep, ever again. NEVER EVER 2: No you may NOT switch your brain off. Ever. 3: Exhaustion is your friend.	*hasADR*	"never sleep" – *insomnia: adverse effect*, "not switch your brain off" – *racing thoughts: adverse effect*, "exhaustion" – *exhaustion: adverse effect*
@FriarDanny I appreciate it. I gained over 30lbs with Paxil so I'm trying something different, tired of the appetite side effects.	*hasADR*	"gained over 30lbs" – *weight gain: adverse effect*, "appetite" – *increased appetite: adverse effect*
This cipro is totally "killing" my tummy .. hiks..	*hasADR*	""killing" my tummy" – *gastric pain: adverse effect*
Well played tysabri...kicking butt #nosleep.	*hasADR*	"nosleep" – *insomnia: adverse effect*
@Sectioned_ @bipolarlife7 @BBCWomansHour ah yes, I'm starting to think my paroxetine turns panic attacks into fat.	*hasADR*	"panic attacks" – *panic attack: indication*, "fat" – *weight gain: adverse effect*

The annotation of both adverse drug reactions and indications was necessary due to the fact that these two categories can have the same concepts associated with them. For example, a user may state "I take it for *insomnia*", while another may say, "Had to stop treatment, it was causing *insomnia*." The first mention is an indication and the second an adverse reaction but both would be mapped to the same UMLS concept id for *insomnia*. Thus, the type of the mention (adverse effect or indication) can vary, while the concept id can be the same.

Automatic Concept Extraction. We aimed at measuring the utility of lexicon-based techniques for the automatic concept extraction from Twitter data. Our proposed concept extraction method is based on an information retrieval technique that is flexible enough to deal with term variability in user posts. We used Apache Lucene[1] for both indexing and retrieval of the ADR lexicon concepts. A Lucene index was built from concepts and the associated UMLS IDs in the lexicon. Before indexing, we preprocessed the concepts which included removal of stop words and lemmatization. The lexicon entries were lemmatized to WordNet[2] roots using the Dragon toolkit[3].

To identify the indexed concepts present in a tweet, we generated a Lucene search from preprocessed tokens in the tweet sentences. We split tweets into sentences using Stanford Tokenizer[4]. The preprocessing of the sentences included spelling corrections, stop word removal, and lemmatization. For spelling corrections, we used Lucene SpellChecker that was customized to suggest a list of correct spellings for a given word based on ADR lexicon and a list of common English words from SCOWL[2] (Spell Checker Oriented Word Lists).

[1] http://lucene.apache.org
[2] http://wordnet.princeton.edu
[3] http://dragon.ischool.drexel.edu/features.as
[4] http://nlp.stanford.edu/software/tokenizer.shtml

The spans of the mentions associated with the retrieved lexicon concepts were then identified in the sentences using string comparison with regular expressions. The technique is flexible enough to identify both single and multi-word concepts, regardless of the order of the words in sentences or presence of other words in between.

Since the focus of this study is to extract adverse effects from the tweets, a manual filtering method was implemented to remove indications. This method filters the terms based on verbs that precede the term, such as "helps" or "works" for indications.

Results

Annotation statistics. After filtering out advertisements, the corpus contained tweets for 54 of the 74 target drugs. The number of tweets returned for four of these drugs was considerably higher than the rest and their numbers were reduced by making a random selection of tweets from each in order to balance out the dataset. From the resulting corpus of 10,822 tweets, 1,008 were determined during the binary phase of annotation to contain at least one mention of an adverse effect. These tweets were from 31 of the target drugs. The total number of adverse effects annotated was 1,285. The top ten drugs in order of the number of adverse effect mentions annotated are listed in Table 2.

Table 2. Top 10 drugs by sorted by the number of ADR mentions annotated. The generic name is indicated for those that were added to the original drug list for searching.

Drug Brand/Generic Name	ADR Mentions Annotated per Drug	Total Number of Tweets in Corpus
Seroquel/quetiapine	237	1,082
Effexor/venlafaxine	176	461
Vyvanse	122	800
Paxil/paroxetine	92	683
Prozac/fluoxetine	76	1,307
Lamictal/lamotrigine	73	395
Zyprexa/olanzapine	68	377
Humira	64	560
Cymbalta/duloxetine	63	832
Trazodone	58	530

Agreement between the annotators was measured by calculating inter-annotator agreement (IAA). We calculated IAA for span using a partial matching criterion. This means that the annotators were considered to be in agreement if there was some overlapping portion in the span selected by each annotator. IAA for concept ID and binary annotations was calculated using an exact matching criterion. The precision, recall and F-measures[19] associated with IAA of the annotations are shown in Table 3. For binary annotations, a kappa value of 0.69 was calculated.

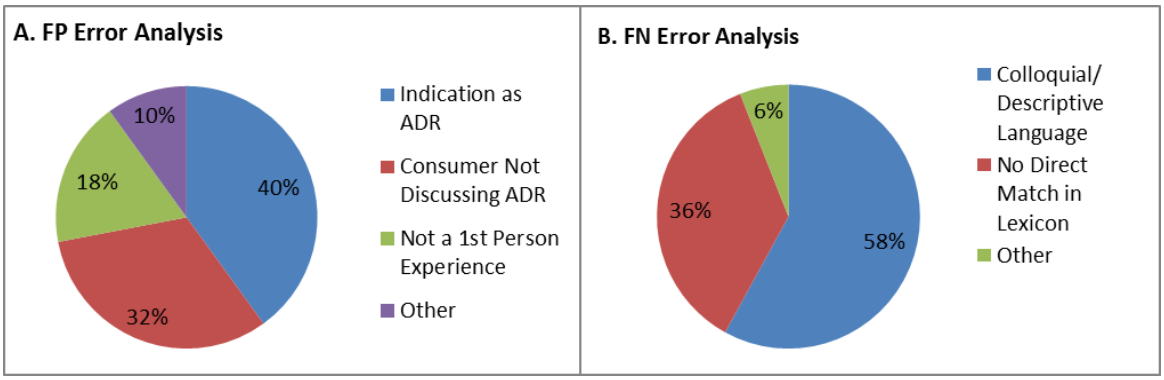
Table 3. IAA for span, concept ID and binary classification

IAA Type	Precision	Recall	F-measure
Span	0.8099	0.9802	0.8869
Concept ID	0.7278	0.9688	0.8311
Binary Classification	0.8155	0.8829	0.8448

Automatic concept extraction and identification. The system was evaluated on 1,873 annotated tweets, for adverse reactions only. We defined true positives as those extracted by the machine that match with the mentions labeled by annotators using partial matching. . Our system achieved 54.1% precision, 62.1% recall, and 57.8% F-measure for this experiment.

Error Analysis. For error analysis of the system, we chose a random sample of 50 false positive (FP) and 50 false negative (FN) results to review. We analyzed each group separately and categorized the errors by error type (Figure 2). For FPs, the errors fell into three main categories: the extraction of indications as ADRs, the extraction of terms from the tweets that were in the lexicon but not being used to discuss an ADR, and extraction of ADR mentions that were not experienced directly by the user. FN results were separated in to two main categories: the ADR was expressed using colloquial or descriptive terminology, or the ADR mention was expressed in a similar but not a direct match to the lexicon entry.

Figure 2. 2A shows the category and prevalence of the 50 FP errors analyzed. 2B shows the category and prevalence of the 50 FN errors analyzed.



Discussion

To assess the validity of finding ADRs in tweets, we compared the adverse effects that were found in the tweets to known and documented adverse effects. The results are reported in Table 4 for the top ten drugs as determined by the number of ADR mentions annotated. We found at least one corresponding adverse effects in all ten. In a few instances, the most frequent adverse event in the tweets aligned with the most frequently found adverse event in the clinical trials. We only assessed the relationship between the most frequent adverse reactions. Given the known adverse effects were from clinical trials, it may be interesting to examine less frequently occurring events in the trials as compared to the mentions. The relatively small sample size and short duration of the trial may not adequately represent such rare events, but these may get elucidated in the wide spread, long term Twitter evidence.

Compared to the 78.3% precision and 69.9% recall we reported in Leaman et al.[7], for the DailyStrength corpus for concept extraction, we see that the performance against the Twitter dataset is much lower. This could be due to the inherent characteristics of a tweet, with greater presence of "creative" expressions that do not match even the augmented lexicon. There is evidence of this when we look at the sources of FN errors. The largest source of these errors was the language used to describe the ADR.

Some of these issues stem from using inexact terminology to describe the effect, which has no match in the lexicon; examples include 'in a haze' or 'wired'. Not surprisingly, this issue also arises when the user uses an idiomatic expression or metaphors to describe the effect. For example, to express the adverse effect of dry mouth, a user tweeted "….*it feels like the Sahara desert in my mouth*". This was also the largest reason for errors reported by Leaman et al.[7], but with a slightly smaller percentage of their associated FNs (55%). In order to mitigate these errors, other approaches that are less reliant on lexicon matching are being explored. Nikfarjam and Gonzalez[21] have proposed using association rule mining to extract ADR mentions from colloquial text, extracting frequent patterns to find mentions instead of using a dictionary match. Pattern-based extraction showed improvements over the lexicon based approach, but the method requires a large amount of training data.

The FP errors were mainly due to misclassifying extracted terms as ADRs when they were not used as such. The biggest source of these errors was instances where an indication was misclassified as an ADR. There were also FP errors caused by the extraction of terms that were not used for discussing either an ADR or an indication. Some examples of this include a user name that contains a lexicon term ('*TScpCancer*') or the use of a term that is not necessarily related to an ailment ('*Sick* of meds'). Although the post-processing rules were effective in filtering some of the non ADR mentions, machine learning classification is needed in future research to examine the effectiveness of modeling the contextual and semantic features of the tweets in distinguishing different semantic types. In the future, we will explore the effectiveness of training a sequence labelling classifier such as Conditional Random Fields (CRFs) for this extraction task.

Another smaller, though notable, source of errors for FPs was the system's extraction of adverse effects that were not experienced by the user. Our guidelines for annotation stipulated that mentions of adverse effects were to be annotated only if they were experienced by the patient, in order to prevent annotations of song/movie quotes, social gossip, or potential advertisements. This presents a challenge when utilizing a social networking site that is not devoted solely to health topics. The unstructured, informal, and isolated nature of the tweets compounds this challenge by making some tweets unclear. It can be difficult for annotators to discern the relationship of the person writing the tweet with the drug they are mentioning. There are tweets that seem to be a commentary or report on the drug and its side effects ("Effexor XR side effects : - sucidal thoughts - insomnia - feeling high & unresponsible. -Dry mouth."), or of a song lyric ("I'm too numb to feel, blow out the candle, blindness #np #cymbalta") but without any context of why the person is tweeting about it, it is difficult to know. It could be a way to relay a personal experience or a repetition of something they heard. The determination of whether these are first person accounts requires the annotator to make a judgment call or the use of specialized knowledge about commonly used conventions in Twitter. In the song example above, using a common abbreviation to express a song you want to share on Twitter is #np ('*now playing*') and this is often followed by #name_of_artist. However, the user who used #Cymbalta possibly indicated they are ascribing the meaning of the lyric to the drug. Training a system on the nuances of Twitter conventions, or being able to discern 3rd person from 1st person accounts, is a very significant challenge — especially when tweets are preprocessed with techniques that affect symbol and punctuation placement.

From Table 2, we can see that the number of tweets collected for a drug is not necessarily indicative of the number of ADRs that we can expect to find. This may be attributed to the fact that Twitter is a general social networking site and will contain a lot of noise when attempting to utilize its data for a specific research purpose. The prevalence of tweets may be due to the drug being the news, or the drug may have a catchy slogan used in its advertisement that gets tweeted frequently (such as Cymbalta's "Depression hurts, Cymbalta can help"). To try to eliminate some of the noise, the binary data in the annotated corpus will be used in future work to refine our methods for searching and filtering for tweets that may contain ADRs.

In this study we aimed at exploring Twitter as a resource for the automatic extraction of ADRs, and the effectiveness of the commonly used lexicon-based techniques for ADR extraction from tweets. In the future, with more annotated data available, we will examine the utility of state-of-the-art machine learning classifiers such as CRF for concept extraction. Our current study has a number of limitations, which are as follows:

- Modified distribution of comments: Although we attempted to enforce a soft limit on the number of comments for each drug in the annotation set, their distributions in the annotation set are not representative of their actual distribution in real life data. A thorough analysis is required to identify if this will affect the performance of our system when applied to real life data.
- For some drugs, we were only able to collect a small number of tweets. More tweets associated with those drugs will be required to make reliable predictions in future tasks.
- We have not performed detailed experimentation to assess how the data imbalance problem posed by Twitter data affects performance of ADR detection systems. We will address this aspect of research in the future.

Conclusion

We have shown that people do tweet about their adverse effects experiences with their prescription drug use. In these tweets, they mention the drug name, along with the adverse effect(s), making it possible to automatically extract the drug and adverse effect relationship. We were, however, only able to achieve moderate success with the lexicon based system used to automatically extract the adverse effect mentions. A large part of this difficulty is due to the problem of using a formal lexicon to match to colloquial text. Another significant problem is the large data imbalance associated with data collected from Twitter. In the future, we will also explore machine learning algorithms that take into account the data imbalance issue with Twitter data. Our continuing efforts at annotation of data makes the application of supervised learning approaches a lucrative future possibility.

Table 4. List of drugs included in preliminary analysis**,** with their most common adverse reactions, frequency of incidence in adults, as listed in the FDA's online drug library.[22] The last column shows the most frequent adverse effects extracted from the Twitter data using our automated system. Effects found in both are highlighted in bold.

Drug Brand/Generic Name	**Primary Indications**	**Documented Adverse Effects (no order)**	**Adverse Effects Found in Tweets (Frequency)**
Seroquel/ Quetiapine	Schizophrenia, Bipolar I Disorder: manic episodes, Bipolar Disorder	**somnolence**, dry mouth, headache, **dizziness**, asthenia, constipation, fatigue	**somnolence (22.2%)**, abnormal dreams (9.6%), feel like a zombie (8.1%), weight gain (6.6%), restless leg syndrome (6.6%), increased appetite (5.9%), sleep paralysis (2.9%), **dizziness (2.2%)**, psychosis (2.2%), tremors (2.2%)
Effexor/ venlafaxine	Major Depressive Disorder (MDD)	**nausea**, **headache**, somnolence, dry mouth, dizziness	withdrawal syndrome (21.3%), insomnia (11.1%), **headache (4.3%)**, malaise (4.3%), abnormal dreams (4.3%), **nausea (3.4%),** shaking (3.4%), fatigue (3.4%)
Vyvanse	ADHD	decreased appetite, **insomnia**, dry mouth, diarrhea, nausea	**insomnia (38.2%)**, OCD (9.3%), anger (5.6%), heart racing (5.6%), depression (3.6%), psychosis (3.6%), headache (3.6%), feel weird (3.6%)
Paxil/ Paroxetine	MDD, Obsessive Compulsive Disorder (OCD), Panic Disorder, Social Anxiety Disorder, Generalized Anxiety Disorder (GAD), PTSD	nausea, **somnolence**, abnormal ejaculation, asthenia, tremor, insomnia, sweating	withdrawal syndrome (27.7%), weight gain (12.8%), depression (8.5%), headache (6.4%), **somnolence (6.4%)**, allergic (6.4%), feel sick (6.4 %), emotional (6.4%)
Prozac/ Fluoxetine	MDD, OCD, Bulimia Nervosa Panic Disorder	nausea, headache, insomnia, nervousness, anxiety**, somnolence**	**somnolence (22.2%),** withdrawal syndrome (8.9%), feeling ill (8.9%), abnormal dreams (6.7%), suicidal thoughts (6.7%), tremors (6.7%), allergic reaction (4.4%)
Lamictal lamotrigine	Epilepsy, Bipolar Disorder	vomiting, coordination abnormality, dizziness, rhinitis, dyspepsia, nausea, headache, diplopia, ataxia, **insomnia**, fatigue, back pain	**insomnia (17.9%)**, rash (12.8%), lethargy (7.7%), joint pain (5.1%), feel like a zombie (5.1%), feel sick (5.1%)
Zyprexa/ olanzapine	Schizophrenia, Bipolar I Disorder	dizziness, constipation, personality disorder, **weight gain**, akathisia, **somnolence**, dry mouth, asthenia, dyspepsia	**weight gain (40.0%)**, **somnolence (11.4%)**, increased appetite (8.6%), dependence (5.7%)
Humira	Rheumatoid Arthritis, Juvenile Idiopathic Arthitis, Psoriatic Arthitis, Crohn's Disease, Ulcerative Colitus, Plaque Psoriasis	**upper respiratory infection**, **rash**, **headache**, sinusitis, accidental injury	somnolence (24%), feel sick (8%), palpitations (8%), ache/pains (8%), joint pain (4%), **headache** (4%), **rash** (4%), **respiratory disorder (4%)**
Cymbalta/ Duloxetine	MDD, GAD, Diabetic Peripheral Neuropathy, Fibromyalgia, Chronic Muscoskeletal Pain	nausea, headache, **dry mouth**, **fatigue**, **somnolence**	withdrawal syndrome (16.3%), **fatigue (14.0%)**, **somnolence (7.0%)**, dizziness (7.0%), **dry mouth (4.7%)**, depression (4.7%), rash (4.7%), migraine (4.7%)
Trazodone	MDD	**somnolence**, **headache**, dry mouth, dizziness, nausea	**somnolence (24.3%)**, abnormal dreams (16.2%), hangover effect (8.1%), **headache (5.4%)**, insomnia (5.4%), withdrawal syndrome (5.4%)

Computerization of Mental Health Integration Complexity Scores at Intermountain Healthcare

Thomas A. Oniki, PhD[1], Drayton Rodrigues, MBBS, MS[1], Noman Rahman[1], Saritha Patur[1], Pascal Briot, MBA[1], David P. Taylor, PhD[1], Adam B. Wilcox, PhD[1], Brenda Reiss-Brennan, PhD[1], Wayne H. Cannon, MD[1]

Abstract

Intermountain Healthcare's Mental Health Integration (MHI) Care Process Model (CPM) contains formal scoring criteria for assessing a patient's mental health complexity as "mild," "medium," or "high" based on patient data. The complexity score attempts to assist Primary Care Physicians in assessing the mental health needs of their patients and what resources will need to be brought to bear. We describe an effort to computerize the scoring. Informatics and MHI personnel collaboratively and iteratively refined the criteria to make them adequately explicit and reflective of MHI objectives. When tested on retrospective data of 540 patients, the clinician agreed with the computer's conclusion in 52.8% of the cases (285/540). We considered the analysis sufficiently successful to begin piloting the computerized score in prospective clinical care. So far in the pilot, clinicians have agreed with the computer in 70.6% of the cases (24/34).

Introduction

Frequently in today's primary care setting, providers are confronted with diagnosing and treating mental health concerns. Gatchel and Oordt estimated that 70% of primary care visits stem from psychosocial issues.[1] And Kessler et al. found that almost 50% of mental health disorders were treated in primary care.[2] Unfortunately, as Collins et al. lament, "most primary care doctors are ill-equipped or lack the time to fully address the wide range of psychosocial issues that are presented by the patients."[3] Indeed, Vermani et al. cite evidence of low detection rates and poor quality of care for a variety of mental health disorders in the primary care setting.[4]

In this context, researchers at Intermountain Healthcare have sought to assist the Primary Care Physician (PCP) with the task of managing mental health issues in the primary care setting. Intermountain has organized itself around key clinical processes and developed "Clinical Programs"[5] in nine clinical areas to address those processes. In multi-disciplinary fashion, the clinical programs identify best practices and standardize the care delivered within the organization. The Primary Care Clinical Program is one such program. Within the Primary Care Clinical Program, Intermountain researchers and clinicians have developed a Mental Health Integration (MHI) program[6,7] that espouses a patient-centered, team-based approach to diagnosing and treating mental illness in the primary care setting. The central concept of the program is to eliminate "the chasm between physical health care and mental health care—rolling both into a comprehensive whole that is addressed by a high-functioning team."[6] The program standardizes processes and supports the PCP with expanded team support (including mental health professionals, community advocates, and care management) to address the mental health needs of their patients and families. Each member of the team is trained in specific responsibilities (communication, shared decision-making, etc.) that contribute to a collective whole health care plan. A standardized process is outlined via a Care Process Model (CPM).

A primary objective of the CPM is to determine which of three levels of care is appropriate for the patient -- routine (PCP-based) care, collaborative care (which adds care manager and mental health specialist participation), or enhanced care (which further increases care manager and mental health specialist participation). The care determination is made by assessing "Mental Health Complexity." A complexity of "mild" suggests routine care is appropriate, a complexity of "moderate" suggests collaborative care, and a complexity of "high" suggest enhanced care.

To assess complexity, the PCP asks the patient to fill out a paper-based "MHI packet" as a screening mechanism when a patient presents to the PCP with possible mental health concerns. The packet solicits 47 pieces of data from the patient on 21 facets related to mental health (some facets involve more than one piece of data) such as:

- Previous mental health treatment
- Level of chronic pain

- Family Rating Scale (assessing level of support of family relationships)
- Validated tools for diagnosing and treating patients with mental health conditions, such as the Patient Health Questionnaire (PHQ-9)

Our researchers have developed classification criteria for each facet that classify a patient as "mild," "moderate," or "high" complexity for the facet. (These will be referred to as "sub-scores" for the rest of the paper.) For illustration purposes, Table 1 shows the criteria for several sub-scores. Some sub-score classification criteria, such as those for the Patient Health Questionnaire, are drawn from published, validated instruments. Other sub-score criteria, such as those for chronic pain severity, are based on the experience of Intermountain clinicians and researchers. Over the past decade, Intermountain MHI researchers have refined and formalized the sub-score complexity classification criteria and have documented and published them internally.

Currently, a portion of the patient responses (corresponding to 14 of the 21 facets) is transcribed by clinical staff into Intermountain's HELP2[8] clinical information system. This portion represents those items most frequently filled in by patients and most influential in determining complexity based on our experience. The PCP is then asked to apply the sub-score criteria to the information to obtain sub-scores. Finally, the PCP aggregates the sub-scores into an overall "high"/"moderate"/"mild" complexity score that will dictate the initial level of care for the patient. The guidelines for aggregation have heretofore been incompletely specified; examples of sub-scores and corresponding overall complexity had been published internally, but logically-complete criteria had not been defined. The PCP reviews the sub-scores and the examples and makes his or her best judgment of an overall complexity.

The MHI program has shown positive clinical and financial outcomes.[6,7] However, improving the consistency and appropriateness of complexity scores is critical to the long-term success of the program. Consequently, the MHI researchers sought the assistance of the Intermountain Medical Informatics group to automate the scoring process. Together, we reasoned that computerization would accrue three benefits:

1. More scores will be generated. Clinician scoring has not been mandatory. Thus, in the busy clinic environment, some patients do not receive a score, even though the patient has filled out a Mental Health packet. We theorized that more scores would result in more appropriately directed care.
2. Scores will be more consistent. Undoubtedly, there has been variability in clinicians' scoring – especially in the aggregation of sub-scores into an overall complexity. Computerization would process inputs objectively and consistently, promoting standardization of care and enabling more reliable stratification of patients for research purposes.
3. Scores will be more appropriate. There is no "correct" or "gold standard" overall complexity; our clinician researchers have conceived of it in experience-based fashion to assist the PCPs in managing issues outside their expertise. We anticipate, though, that we can continually improve the complexity criteria as our researchers and the PCPs learn from each other through an iterative process of applying the criteria to patients, evaluating the care levels dictated, and refining again.

Table 1. An extract of sub-score criteria for several sub-scores.

Mild	Moderate	High
Previous mental health treatment: 1 episode	**Previous mental health treatment:** ≥ 2 episodes	**Previous mental health treatment:** multiple treatment failures
Chronic Pain Severity: 0-3 on a scale of 10	**Chronic Pain Severity:** 4-6 on a scale of 10	**Chronic Pain Severity:** 7-10 on a scale of 10
Family Rating Scale: Style III (balanced/secure)	**Family Rating Scale:** Style II (confused/chaotic)	**Family Rating Scale:** Style I (disconnected/avoidant)
Patient Health Questionnaire: Symptom score: <5 (out of a list of 9) Severity score: 10-14 (maximum possible=27)	**Patient Health Questionnaire**: Symptom score: >=5 (out of a list of 9) Severity score: 15-19 (maximum possible=27)	**Patient Health Questionnaire**: Symptom score: >=5 (out of a list of 9) Severity score: >=20 (maximum possible=27)

Our plan was as follows:

- Implement the classification criteria in Intermountain's decision support system
- Execute the classification criteria on retrospective data
- Analyze results and refine the classification criteria
- Pilot the classification criteria with several primary care providers and solicit their feedback
- Make necessary refinements

Once these steps are completed, the intent is to implement the classification in Intermountain's production system. When the patient's packet information is entered, the computer will deduce a complexity and present it to the patient's PCP, thus suggesting a level of care to begin with. The PCP will be able to either accept that level of care or set another level based on his or her clinical judgment.

We report here on our efforts through the piloting step.

Materials and Methods

Availability of data in the system

The first step in implementation of the algorithm was to verify the availability of the input data. We verified that the 24 pieces of data needed to conclude the 14 sub-scores were available in HELP2. Table 2 shows the 14 sub-scores included in the computerized algorithm, with the number of data items involved in concluding each sub-score. These

Table 2. The 14 sub-scores addressed by the computerized algorithm

Sub-score	Category	Number of Data Items (Data Items)
Number of Somatic Complaints	S1	1 (Number of Somatic Complaints, 0-9)
Chronic Pain Severity	S1	1 (Chronic Pain Severity, 0-10)
Sleep Problem Severity	S1	1 (Sleep Problem Severity, 0-10)
Substance Use	S1	1 (Current Substance Use, Y/N)
Overall Impairment	S2	1 (Impairment Rating Score, 1-7)
Overall Health	S2	1 (Overall Health, 1-10)
Family Relational Style	O1	3 (Family Style I Score, Family Style II Score, Family Style III Score)
Family Pattern Profile (Support Person)	O1	1 (Most Common Support)
Patient Health Questionnaire (PHQ-9)	O1	2 (PHQ-9 Symptom Count, PHQ-9 Severity Score)
Suicide Assessment	O2	3 (PHQ-9 Q9 response, Suicide State, Suicide Risk)
Anxiety/Stress Disorders (GAD-7)	O3	3 (GAD-7 Q1 Score, GAD-7 Q2-5 Score, GAD-7 Q6-7 Score)
Mood Disorder Questionnaire (MDQ)	O3	3 (MDQ Q1 Score, MDQ Q2 Response, MDQ Q3 Response
Mood Regulation	O3	2 (Symptom Score, Impairment Score)
Attention Deficit Hyperactivity Disorder (ADHD)	O3	1 (ASRS-v1.1 Part A Score)
Total number of sub-scores: 14		**Total number of data items: 24**

PHQ-9: Patient Health Questionnaire-9[9]
GAD-7: Generalized Anxiety Disorder-7[10]
MDQ: Mood Disorder Questionnaire[11]
ASRS-v1.1: Adult ADHD Self-Report Scale (ASRS) Version 1.1[12]

24 data items became the basis of the computerization.

Adequately expressive logic

Morris[13] asserts, "An adequately explicit clinical method is one that contains adequate detail to generate specific instructions (patient-specific orders) without requiring judgments by the clinician." Adequate explicitness is essential in the computerization of clinical decision support criteria.[13-16] We held several discussions in which we strengthened the explicitness of the sub-score algorithms. For example, the last row of Table 1 shows the original logic for deducing one particular sub-score – the sub-score for the PHQ-9.

Examination found that cases such as the following would have indeterminate results:

- A symptom count < 5 with a severity score < 10
- A symptom count of 5 with a severity score of 10-14
- A symptom count of 5 with a severity score < 9

As we completed the logical "decision table," we recognized that the "symptom" component was actually superfluous to the logic. Refining the criteria resulted in the simplification shown in Table 3.

Discussions regarding boundary conditions, logical operations (clarification of ORs vs. ANDs), and logical completeness resulted in fully computerizable sub-score classification criteria.

The next step was to fully specify the criteria for aggregating sub-scores into an overall complexity. In the clinical judgment of our MHI researchers, subjective data items contributed differently to complexity than did objective items. They consequently categorized each sub-score as either a subjective (S) or an objective (O) measure, depending on whether the data contributing to the sub-score were subjective or objective in nature. They further divided the subjective scores into two subcategories (S1 and S2), the S1 scores being more critical (based on their clinical experience) to the overall complexity. The resulting categories are shown in Table 2. This allowed the researchers to develop the empiric rules shown in Figure 1.

Note the rules were arranged in waterfall fashion (IF-THEN-ELSEIF), the last condition being

ELSE overall complexity = "mild"

In essence, the "default" complexity in the absence of data was "mild," i.e., the patient should receive routine care.

Table 3. A simplification of the sub-score criteria for the Patient Health Questionnaire**.**

Mild	Moderate	High
Patient Health Questionnaire: Severity score: <15 (maximum possible=27)	**Patient Health Questionnaire:** Severity score: 15-19 (maximum possible=27)	**Patient Health Questionnaire:** Severity score: >=20 (maximum possible=27)

IF O2 = HIGH THEN OVERALL = HIGH
ELSE IF O2 = MODERATE AND 1 or more O1s = HIGH THEN OVERALL = HIGH
ELSE IF O2 = MILD AND 1 or more O1s = HIGH AND 2 or more O3s = HIGH THEN
OVERALL = HIGH
ELSE IF 2 or more S1s = HIGH AND 1 or more S2s = HIGH AND 1 or more Os = HIGH THEN
OVERALL = HIGH
ELSE IF 1 or more SUB-SCORES = HIGH THEN OVERALL = MODERATE
ELSE IF 2 or more S1s = MODERATE AND 1 or more S2s = MODERATE AND 1 or more Os
= MODERATE THEN OVERALL = MODERATE
ELSE OVERALL = MILD

Figure 1. Logic for aggregating sub-scores into overall complexity.

Computerization and execution

Two medical knowledge engineers converted the classification criteria into Java code within Foresight, Intermountain's existing Computerized Decision Support (CDSS) system.[17] Foresight is a J2EE-compliant, Intermountain-developed decision logic execution engine coupled with a sophisticated clinical data monitor. Foresight rules are written in Java and deployed in an Oracle Weblogic server.

We executed the classification criteria on 500 patients for whom providers had entered a complexity score in HELP2 between August and November of 2012. The results were exported into Oracle tables and made available to the clinical experts for review and analysis.

Preliminary Analysis

We narrowed our preliminary analysis to 273 patients who had suicide assessment (the most critical facet to complexity) or greater than 80% of the 24 items. In this population, the clinician agreed with the computer in 53.1% of cases. An MHI researcher (BR) reviewed the results of the classification criteria for twenty randomly sampled cases. Upon reviewing the patient data, she judged that the classification was not weighing two factors heavily enough: an MHI packet question regarding the patient's level of thoughts of death and suicide, and a question regarding the patient's access to a support person. We recognized this would result in a general increase in complexity – possibly higher than the clinicians might tend to score – but we reasoned that at this learning and improvement stage it was better to "overstate" complexity (and hence "over-involve" the mental health specialists than "under-involve" them). If, as a result, the specialists told the PCPs their involvement was unnecessary, learning would occur and the criteria could be adjusted. We adjusted the criteria to be more sensitive to these factors.

We re-ran the classification on the 2012 patients and on 500 patients whose complexity was entered between June and October of 2013. Again, we focused analysis on patients who either had suicide data entered or who had greater than 80% of the 24 data items entered. These criteria left 540 patients to analyze.

Results

Retrospective Data Analysis Results

Clinician agreement frequency on the set of 540 patients is shown in Table 4. The clinician agreed with the computer in 285 of the 540 cases (52.8%). Of the 255 cases in which the provider and the computer disagreed, the algorithm was "higher" 179 times (70.2%). A graphical view of the frequencies, comparing the frequency of cases in which the clinician agreed with the computer, cases in which the clinician was "higher," and cases in which the computer was "higher" is shown in Figure 2.

We (BR and PB) performed a case-by-case examination of the forty cases in which the clinician gave a complexity score of "high" while the computer gave a lower score, to gain greater insight into such cases and ensure that the algorithm was not "missing" complexity it should have been detecting. We reviewed charts to determine what data might have influenced the providers to score the patients as "high." In most of the cases, we found evidence of comorbidities (diagnoses or multiple medication orders). Comorbidities are considered in the paper version of the algorithm, but were not included in this first version of the computerized algorithm, i.e., they were not included in the "top 14" sub-scores that were included in HELP2 and computerized.

In some cases, chart review did not reveal the reasons for the provider's score of "high." We reasoned that

Table 4. Clinician and computer agreement in the retrospective data.

		Computer			
		Mild	Moderate	High	TOTAL
Clinician	Mild	47	89	14	150
	Moderate	36	178	76	290
	High	4	36	60	100
	TOTAL	87	303	150	540

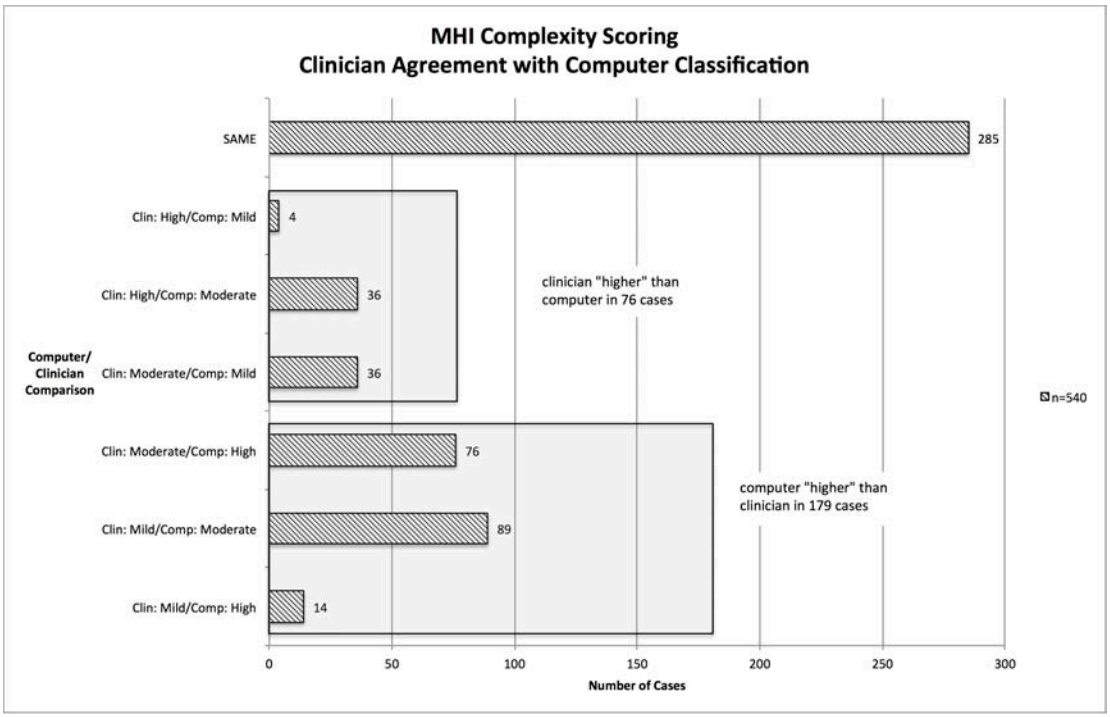

Figure 2. Clinician agreement with computer classification.

occasionally the computer algorithm might not be able to generate a "high enough" score because it did not have access to the proper data elements, and in such situations, the provider seemed to be properly disagreeing.

In general, we hypothesized that disagreements could have stemmed from several sources:

- The clinician and the computer may have been using different sets of inputs. There may be factors that are salient to complexity that the clinician was privy to but that were not available to the classification criteria.
- The clinicians may have disagreed with the MHI researchers' judgment that was reflected in the criteria logic.
- The clinicians may have agreed with the criteria logic, but may have committed errors, e.g., overlooked data or misapplied the criteria.
- There may be certain combinations of inputs which were not considered in the development of our classification criteria.

The rate of agreement was not a major concern at this point. There have been extensive examples of computerizing guidelines and protocols at Intermountain in which compliance is initially low. But as clinicians become more comfortable with the logic of the computer and the logic is adjusted according to clinician feedback, compliance increases. We view this effort as akin to those experiences.

Pilot

We moved forward with a pilot to learn why the clinicians were disagreeing and to see which of the hypothesized reasons for disagreement were in operation. To date, two licensed providers – a psychiatric nurse practitioner and a PhD psychologist – have participated. When they sign a Mental Health Integration note in HELP2, an alert is sent to their HELP2 message queue, indicating the complexity score the algorithm has generated. The participants acknowledge the alerts, either accept or reject the scores, and provide feedback (especially what a rejected score should have been in their judgment). This functionality is only operational for the participating clinicians.

To date, the two participants have responded to 34 scores. They agreed with the computer scores in 24 of the 34 cases (70.6%). Table 5 presents the agreement results. Table 6 presents data availability data for the ten cases in which the clinician disagreed with the computer. For each case, the table shows the computer's assessment vs. the clinician's and the number of data items (out of the maximum of 24 possible) that the computer actually found entered in HELP2 for that patient.

Discussion

Summary and Findings

In the retrospective data, the clinicians would have agreed with the classification only a little more than half the time. When they disagreed, the classification tended toward greater complexity. We purposely tended toward overstating complexity because at this stage of the algorithm's development we thought we could learn more by identifying all potential contributors to complexity, even at the cost of some "false positives." In the pilot, the clinician has agreed with the classification even more (70.6%).

Our process of defining and refining the classification criteria naturally aligned with the hypothetico-deductive process[18,19] common in medical problem solving. From experience and data, the researchers formulated a hypothesis (the original criteria), exhibiting data-driven inductive reasoning characteristic of experts.[19] By identifying different classes of data that would be helpful in formulating the criteria (S1, S2, O), our researchers were using "schemes," a characteristic of expert problem solving.[20] We then tested the hypothesis against data. Computerization assisted us here, allowing us to more easily validate all the criteria against real patient data. We identified test cases where the resulting complexity score did not match the researchers' expert judgment (i.e., they conflicted with the hypothesis)

Table 5. Clinician and computer agreement in the pilot.

		Computer			
		Mild	Moderate	High	TOTAL
Clinician	Mild	13	0	0	13
	Moderate	6	9	1	16
	High	0	3	2	5
	TOTAL	19	12	3	34

Table 6. Data availability for disagreement cases in the pilot.

Case	Computer	Clinician	Number of data items available (out of 24)
1	Moderate	High	24
2	Mild	Moderate	3
3	Mild	Moderate	3
4	Mild	Moderate	6
5	Mild	Moderate	6
6	High	Moderate	6
7	Mild	Moderate	3
8	Moderate	High	24
9	Mild	Moderate	3
10	Moderate	High	22

and adjusted the criteria to produce better results for those cases without impairing its performance with regard to the rest of the cases. We will continue to repeat the cycle.

The effect of "missing data" on criteria execution warrants further examination. Others have noted the impacts of incomplete data on inference and suggested strategies, both in the general case[21-24] and in the case of electronic health records and decision support.[25-27] In the pilot so far, as shown in Table 4, in six of the ten cases in which the clinician disagreed with the computer, the computer concluded "mild" while the clinician viewed the patient as "moderate" complexity. As shown in Table 5, in two of the six cases, clinicians had only entered six out of 24 possible elements into HELP2 while in the other four cases, they had only entered three of the 24 elements. As has been explained, the criteria conclude "mild" if not presented with any data that drive another conclusion. Consequently, as might have been predicted, the pilot showed that, in the face of sparse data, the criteria are unable to conclude anything but "mild." The clinician, on the other hand, with more data available to him or her, is able to make a more educated assessment of complexity. We need to investigate:

- Why did they enter so few elements? Is it because the ones they entered are most important to complexity? Or were they the most conveniently collected from the patient?
- What are the most salient elements that the clinician is using that the computer does not have access to, either because 1) the MHI packet is not addressing them, 2) the MHI packet is addressing them but HELP2 is not storing them, or 3) the MHI packet is addressing them, HELP2 is storing them, but the clinicians are not entering them?

We recognize that interpreting missing data as "mild" complexity may appear inconsistent with our earlier stated preference to err on the side of "over-involving" the mental health specialist. However, in our tendency to over-state complexity, we were satisfied based on our data analysis that the criteria would result in a slight over-statement, but not so much that would cause skepticism toward the result (i.e., "alert fatigue"). In contrast, we felt that making sparse data case generate "moderate" or "high" would indeed cross that threshold. A better solution may have been to not generate a result at all if some pre-determined number of items were not present, with an "insufficient data" notification. A variant of this idea would be to always conclude a complexity, but also generate an accompanying confidence measure based on the amount of data available. Still another possibility is to improve MHI data entry via reminders.

Computerization of scoring algorithms has been undertaken in Intensive Care Unit (ICU) acuity, readmission risk, community acquired pneumonia risk, and other areas.[28-32] Little if any computerization of algorithms has been performed in the mental health complexity scoring. One reason is likely the subjective, self-reported, and often sensitive nature of the data. But we venture to capture and utilize this data in our automated scoring because patient engagement is a critical component of Intermountain's MHI efforts. They in fact reflect the enterprise's Shared Accountability strategy, which aims to engage all stakeholders – the healthcare organization, employers, caregivers, the community, and patients – in providing better care and better health at sustainable cost levels. This underscores a cultural shift at Intermountain – and in the nation as a whole – in which patients and their families are being invited to become more engaged and invested in their care. In this climate, researchers in informatics and the social sciences will need to develop innovative, engaging, and nonintrusive technical and cultural solutions for interacting with patients and collecting reliable data from them.

Limitations and Future Work

A thorough, formal examination of the criteria before computerization may have isolated computerization issues from criteria issues. But our motivation for omitting this step may be found in our view of the criteria and in the environment at Intermountain. It would be preferable to validate a diagnostic algorithm (i.e., ensure the algorithm generates a sensitive and specific outcome by comparing its result to the "gold standard") before computerizing. In contrast, the classification criteria have been developed based on MHI researchers' experience as an aid to the PCP. No "gold standard" exists. Our computerization is actually a quality improvement exercise aimed at refining the criteria and, when clinicians disagree, learning more about why they do. Further, continuous quality improvement and computerized data capture and decision support are so firmly engrained in our culture at Intermountain that it was natural and convenient to expedite the implementation of the criteria in HELP2, allowing us to easily collect feedback and continuously improve clinician understanding on the one hand and the criteria on the other.

After the pilot, we intend to do more thorough analysis on both the agreement cases and disagreement cases. We will explore whether there is correlation between individual clinicians or clinician roles and agreement/disagreement and whether certain sub-scores are responsible for an inordinate amount of disagreement.

The work described is analysis of retrospective data and pilot results to date. Prospective evaluation of refined criteria on larger numbers of patients is anticipated after incorporation of pilot findings. The criteria specifically address a narrow subject – MHI complexity. The classification is not intended to be applicable to any other clinical domain. However, the Foresight architecture has been used in a variety of domains.[33-35] And we can conceive of a Foresight-based framework to more generically address scoring/classification problems like the MHI complexity problem.

We performed the retrospective analysis only on patients for whom most of the 24 data elements had been entered. This did not give us insight into those cases in which data were sparse. The pilot is our passage into exploration of how to appropriately interpret and address missing data.

We focused our criteria on the data elements that experience, best practices, and external sources suggested. Starting with the pilot, we can endeavor to identify which of the elements truly contribute most to MHI complexity and which elements are not contributing.

The capstone of the effort will be incorporating the criteria into Intermountain's production system and the clinician workflow. During the pilot, the generation of a complexity score results in an alert message to the clinician. The clinician must navigate to his or her message queue to view the generated score. The message displays the complexity score and prompts for feedback, but does not self-explain. In contrast, when implemented in production, the system will ideally generate and display the score at the point the clinician enters or reviews the data, display the sub-scoring that constituted the complexity, track clinician responses, and assist the clinician in launching workflow (for example, orders for consults) if the clinician desires. Also envisioned is direct patient-entry of the MHI data at our patient portal instead of the current transcription process.

Conclusion

We have been able to effectively computerize classification criteria to assess a primary care patient's mental health complexity. Over time, as we analyze our data, further our understanding of the nature of MHI complexity, refine the criteria to incorporate the most important data elements, and educate clinicians on our findings, we hope the scoring will yield a true representation of the patient's MHI complexity and assist PCPs in an area outside their expertise. The computerization of the MHI complexity scoring will provide more scores, more appropriate scores, and more consistent scoring, which we anticipate will further the MHI objective of integrating more appropriate and directed mental health care in the primary care environment and facilitate future research.

Abstract

The Electronic Medical Records and Genomics (eMERGE) Network is a national consortium that is developing methods and best practices for using the electronic health record (EHR) for genomic medicine and research. We conducted a multi-site survey of information resources to support integration of pharmacogenomics into clinical care. This work aimed to: (a) characterize the diversity of information resource implementation strategies among eMERGE institutions; (b) develop a master template containing content topics of important for genomic medicine (as identified by the DISCERN-Genetics tool); and (c) assess the coverage of content topics among information resources developed by eMERGE institutions. Given that a standard implementation does not exist and sites relied on a diversity of information resources, we identified a need for a national effort to efficiently produce sharable genomic medicine resources capable of being accessed from the EHR. We discuss future areas of work to prepare institutions to use infobuttons for distributing standardized genomic content.

Introduction

The Electronic Medical records and Genomics (eMERGE) Network[1] is a national consortium funded by the National Human Genome Research Institute (NHGRI) to develop methods and best practices for using the electronic health record (EHR) for genomic medicine and research. Methods and best practices span from using EHR data to discover genotype-phenotype associations, to incorporating genotype data into the EHR for clinical use. There are however significant challenges to using genotype data to make informed healthcare decisions. These include lack of evidence-based clinical guidelines for using genotype data and barriers to implementation (i.e., practice change).

In collaboration with the Pharmacogenomics Research Network[2], the eMERGE network is using clinical guidelines prepared by the Clinical Pharmacogenetics Implementation Consortium (CPIC)[3, 4] in patients who are preemptively genotyped and who have an increased probability of receiving target drugs including clopidogrel, warfarin and simvastatin in the next 3 years. In order to achieve impact, however, changes in healthcare practices are critical. Institutions participating in this eMERGE Pharmacogenomics (PGx) project are therefore establishing various implementation strategies that encourage healthcare providers to individualize drug therapy using CPIC guidelines.

While implementation strategies must be localized[5-7], developing sharable tools and resources increases the likelihood of a successful local implementation. To this end, the eMERGE Network is exploring use of infobuttons[8-10] as a decision support tool to provide context-specific links within the EHR to relevant genomic

medicine content about drug-gene associations. A previous study showed providing infobuttons that link to specific content topics was more effective than links that point to general overview content[11]. We therefore aimed to design an infobutton-compatible information resource[12] that is likely to impact decision-making. Our goal was to: (a) characterize the diversity of information resource implementation strategies among eMERGE-PGx project participants; (b) develop a master template containing content topics important for genomic medicine practices; and (c) assess the coverage of content topics among information resources developed by eMERGE sites.

Methods

Characterize the diversity of eMERGE-PGx information resource implementation strategies

Through early research team discussions, we found that many eMERGE-PGx project participants had already established local approaches to synthesize evidence and manage content for healthcare providers and/or patients. We therefore characterized implementation strategies among eMERGE-PGx project participants by assessing the target audience, purpose and format for their information resources. We also assessed authoring, editing and reviewing, and updating processes. In addition to efforts related to eMERGE-PGx, for comparison purposes, we evaluated resources from three national efforts: two to synthesize genomic medicine evidence (GeneReviews®[13-15] and PLoS Currents Evidence on Genomic Tests[16, 17]) and one to publish clinical guidelines (CPIC guidelines). In order to design an information resource that accounts for diverse implementation strategies, we developed a master template for authoring and adapting genomic medicine content from existing resources.

Develop a master template for eMERGE-PGx content using DISCERN-genetics criteria

The research team developed an initial list of content topics based on the quality assessment tool, DISCERN-genetics.[18, 19] The DISCERN criteria was developed for assessing information on treatment[20, 21], and is widely used for both appraisal[21-25] and to guide the production of health information on treatment for the public[26, 27]. The DISCERN methodology was more recently used to develop the DISCERN-genetics criteria to assess the quality of information on genetic screening and testing for a lay audience.[18] We chose to use this tool given the criteria were developed to facilitate applying information covering a broad range of genetic screening and testing situations to a variety of settings and conditions. The DISCERN-genetics criteria have also undergone an extensive evaluation involving testing with health information consumers, producers and providers. Moreover, the focus of DISCERN-genetics is on information content, rather than the way information is packaged, presented and made accessible. These characteristics are appropriate given the diversity of implementation strategies among eMERGE institutions.

One author (CO) developed a master template from the initial list of content topics. Initial revisions were then made to the template based upon discussions among three authors on this manuscript with expertise in clinical and biomedical informatics (CO, LR, AH). Following revisions, we piloted the template by adapting content from one information resource (MyResults.org[28]) developed by the Children's Hospital of Philadelphia. Specifically, three authors (CO, LR, JC) each adapted content for one of three drug-gene pairs (clopidogrel/*CYP2C19*, warfarin/*CYP2C9* & *VKORC1* and simvastatin/*SLC01B1*) to the master template. Pilot efforts informed our approach to provide training to eMERGE network participants interested in using the master template.

Assess the coverage of template content topics among eMERGE institutions

One author (CO) led a 20 minute training session that provided eMERGE participants with an overview of the master template, the process for adapting content, and study questions. At the conclusion of this session we identified individuals from eMERGE institutions interested in contributing to this study and each identified one or two PGx scenarios for which they would either author or adapt content from an existing information resource to the master template.

We used the Qualtrics online survey platform (http://qualtrics.com/) to collect descriptive data (i.e., institution, name of existing information resource, topic/scenario), content that was adapted to the master template and that was uploaded as an attachment, data on the adaption process, and data that was useful for configuring information resources for infobuttons (e.g.,where in the EHR should the resource be accessed). Quantitative data were downloaded and saved as an Excel file, and then read into STATA[29] for summary statistics. We report summary statistics for descriptive data and data on the adaption process. Two questions about the adaption process were asked for each content topic (i.e., "Please indicate how you were able to adapt text from the original resource?" and "Was there an equivalent section in the original resource?"). Data collected for questions relevant for configuring information resources were not within the scope of this manuscript and therefore were not analyzed.

We also included an open-ended comment field for each content topic. Qualitative narrative responses were used to provide a more thorough understanding of challenges faced when using the master template.

Results

Diversity of eMERGE PGx resource implementation strategies

We characterized seven information resources, including four developed by eMERGE institutions and three from national efforts to synthesize genomic medicine evidence. **Table 1** summarizes the target audience, purpose and format of the information resource. With the exception of MyResults.org that targets a patient audience, all of the resources we reviewed target healthcare professionals. Other target audiences among the resources we evaluated include researchers, public health professionals and decision-makers (providers, patients, managers and policy makers). The purpose of two information resources (MyDrugGenome.org and MyResults.org) was to provide education. The purpose of five information resources (AskMayoExpert, CPIC Guidelines, GeneReviews, MyDrugGenome.org, and Northwestern Clopidogrel Fact Sheet) was to allow healthcare providers to manage and treat patients that have specific genetic conditions or genetic test results. One information resource (PLoS Currents Evidence on Genomic Tests) aimed to provide a forum for sharing genomic medicine content with a wide audience.

Table 1. Scope of existing genomic medicine resources.

Information Resource (Institution)	Target audience	Purpose	Format (how information is made accessible)
AskMayoExpert* (Mayo Clinic)	Mayo Clinic healthcare providers	To provide access to expert clinical information on a wide variety of topics related to patient care including prevention, diagnosis and treatment.	Custom web-based content system; in the context of pharmacogenomics, the content is also used to develop clinical decision support logic.
CPIC Guidelines (PGRN and PharmGKB)	Clinical professionals (MD, PharmD, NP), other healthcare professionals, researchers and genetics professionals.	To provide guidance to healthcare providers about how genetic tests should be interpreted to improve drug therapy.	Published in the journal *Clinical Pharmacology and Therapeutic*s and made available at PharmGKB[30, 31]
GeneReviews® (University of Washington)	Genetics professionals (MD, PhD, MS), and other healthcare professionals.	To allow healthcare providers who are not experts in a given disorder to manage the first encounter with a patient with a given diagnosis.	Online web-based resource publically accessible on the National Center for Biotechnology Information (NCBI) Bookshelf website[32]
MyDrugGenome.org* (Vanderbilt University)	Clinical professionals (MD, NP), other healthcare professionals, Researchers and genetics professionals	To educate healthcare providers on pharmacogenetics and to allow healthcare providers to interpret the impact of specific pharmacogenetic diplotypes on target medications.	Online web resource linked to implemented clinical decision support available in order entry and e-prescribing applications
MyResults.org* (Children's Hospital of Philadelphia)	Patients in the eMERGE network, resources for professionals planned for future implementation.	To educate patients on the purpose of the eMERGE network and eMERGE projects relevant to their healthcare.	Online web-based resource
Northwestern Clopidogrel Fact Sheet* (Northwestern University)	Northwestern University clinical professional (MD, NP), other healthcare professionals, researchers and genetics professionals.	To allow healthcare providers to interpret new genomic test results.	Custom web-based content system accessible through infobuttons in the EHR
PLoS Currents Evidence on Genomic Tests	Public health and healthcare practitioners and decision-makers.	To bring together data from multiple sources (e.g., basic research, clinical trials, epidemiological and clinical studies), and provide a forum for sharing data, with the goal of making it actionable.	Published using the PLOS Currents Annotum publishing platform[33] and archived at PubMed Central[34]

*Resources developed by eMERGE institutions

Table 2 (on the next page) summarizes content management processes for these resources including authoring, editing and reviewing, and updating processes. Four different approaches to authoring materials are described among the seven resources we reviewed. For four resources (CPIC Guidelines, GeneReviews, MyDrugGenome.org[35], and MyResults.org) content is team-authored, for one resource (Northwestern Clopidogrel Fact Sheet) a single individual authors materials, and for two resources (AskMayoExpert and PLoS Currents Evidence on Genomic Tests) one or more individuals author materials. In terms of editing and reviewing, three resources are externally peer-reviewed (CPIC Guidelines, GeneReviews and PLoS Currents Evidence on Genomic Tests). In all three instances reviewers are provided detailed guidance on how to review the materials. Conversely, a team of individuals reviews content for the four information resources that are developed by eMERGE institutions (AskMayoExpert, MyDrugGenome.org, MyResults.org and Northwestern Clopidogrel Fact Sheet). Prior to

publishing, some institutions require a formal approval (e.g., as with AskMayoExpert) and some require team consensus (e.g., as with MyDrugGenome.org). Three resources we evaluated, CPIC Guidelines, GeneReviews and MyResults.org, have established a formal process to regularly update their content.

Table 2. Content management processes for genomic medicine resources

Information Resource (Institution)	Authoring	Editing and reviewing	Updating
AskMayoExpert* (Mayo Clinic)	Internally authored by one primary author. Additional authors/contributors to information are optional.	The Mayo Clinic Pharmacogenomics Task force, comprised of a multidisciplinary team of subject experts reviews and approves pharmacogenomics modules. (Internal review)	A formal review is conducted 1 year from publication, unless stated otherwise by the authors.
CPIC Guidelines (PGRN and PharmGKB)	Distributed (international); a multidisciplinary writing committee composed of scientists, pharmacologists, and healthcare providers that have expertise in the topic area; a PharmGKB scientific curator; and a biomedical informatics professional.	The writing committee and members of CPIC review the guideline manuscript internally. The manuscript then undergoes external scientific peer-review by the journal *Clinical Pharmacology and Therapeutics* prior to publication. (Internal and external review)	A formal review is conducted every two years or as needed based on important new information that would modify prescribing recommendations. All versions are archived and separately citable.
GeneReviews® (University of Washington)	Distributed (international); experts include at least one healthcare provider (target audience member).	Editors with expertise in clinical genetics, laboratory genetics, and genetic counseling review disease descriptions for accuracy. Descriptions are then peer-reviewed by internationally acknowledged subject experts. (Internal and external review)	A formal review is conducted every two or three years, depending on the topic. The editorial staff or authors initiate time-critical revisions when a clinically significant development needs to be published.
MyDrugGenome.org* (Vanderbilt University)	Internally authored by members of the Vanderbilt pharmacogenomics implementation team.	The Vanderbilt pharmacogenomics team, made up of a multidisciplinary group of subject experts, review clinical and pharmacogenomics content related to each drug-gene interaction. (Internal review)	Updates are concurrent with release of new drug-gene interactions within the PREDICT program.[36]
MyResults.org* (Children's Hospital of Philagelphia)	Led the research/outreach team at Children's Hospital of Philadelphia and supported by other eMERGE members.	A genetic counselor from Northwestern University reviews the content. (External review)	Several components are still under development. The website is updated every three weeks. There is a formal review by two individuals that occurs annually.
Northwestern Clopidogrel Fact Sheet* (Northwestern University)	Primarily developed by one genetic counselor as a synthesis of existing resources.	A physician reviews the content to ensure wording is succinct, informative and actionable. Genetic counselors also review content for accuracy and appropriate wording. (Internal review)	No formal process is established at this time.
PLoS Currents Evidence on Genomic Tests	Manuscript submission. Most authors are researchers in genetics, knowledge synthesis, or related fields.	A board or reviewers determine whether contribution is intelligible, relevant, ethical and scientifically credible. The reviewers focus on 5 criteria: Methodology, Results and interpretation, Quality of the written English, Data availability, and Ethical standards. (External review)	Revisions to contributions are possible with approval by the Reviewer Board. All versions are archived and separately citable.

*Resources developed by eMERGE institutions

Master template developed for eMERGE-PGx content

Following discussions among three research team members, 19 DISCERN-genetics question themes[19], were translated into 13 content topics that comprise the eMERGE master template (see **Box 1**). All content topics correspond to DISCERN-genetics question themes, with the following exceptions: (1) five themes about testing ("purpose of the test," "testing procedure," "test accuracy," "after the test," and "access to test results") were translated into three content topics (see **Box 1**, #5-7); (2) three themes ("discrimination," "psychosocial consequences," and "consequences for others") were collapsed into one content topic (see **Box 1**, #9); (3) two themes ("aims are clear" and "sources of information used") were replaced (see **Box 1**, #1 and #12, respectively); and (4) two themes ("aims achieved," and "balance

Box 1. Content topics captured by eMERGE template

1. Clinical scenario/Overview
2. Background and effects of the condition
3. Treatment and management choices for the condition
4. Risk of developing, carrying or passing on the condition
5. Types of tests available or being offered
6. Testing procedure
7. Test accuracy and reliability
8. Shared decision making
9. Potential risks (psychosocial consequences, implications of discrimination, potential consequences for others)
10. Local information
11. Additional sources of support and information
12. Content contributors
13. Date of the information

and bias") were dropped all together. We also used hints provided for questions in the DISCERN-genetics questionnaire in the master template to help individuals identify relevant content to adapt from another information resource (e.g., Question #1: Are the aims clear?; Hints: What is it about? What is it meant to cover [and what topics are excluded]? Who might find it useful?).

Piloting the master template with the MyResults.org resource informed the design of reference material used in our training session. This material was shared by email to all individuals who volunteered to adapt content to the master template. In addition, our pilot effort informed changes to MyResults.org format and content. The MyResults team continues to revise their template to align with the 13 content topics listed in **Box 1**, in an effort to achieve consistency across eMERGE informational projects.

Individuals from six eMERGE institutions contributed pharmacogenomics information resources. Resources and drug-gene pairs we covered are summarized in **Table 3**. All together we assessed eleven information resource/drug-gene pair combinations (e.g. AskMayoExpert/Clopidogrel[*CYP2C19*] is one information resource/drug-gene pair combination). One resource provided clinical guidelines for using pharmacogenomics data (CPIC guidelines). The other six resources summarized evidence and recommendations from systematic reviews and evidence-based clinical guidelines. Five were existing information resources prepared by eMERGE institutions (AskMayoExpert, MyDrugGenome.org, MyResults.org, Northwestern Patient Handout, Northwestern Clopidogrel Fact Sheet). One resource contained content that was authored using the master template (Geisinger-authored).

Table 3. Information resources and sample of pharmacogenomic drug-gene pairs adapted to the eMERGE template

Information Resource	**Pharmacogenomics Drug-Gene Pairs Adapted to the Master Template**				
	Carbamazepine (HLA-B)	***Clopidogrel (CYP2C19)***	***Simvastatin (SLC01B1)***	***Thiopurine (TPMT)***	***Warfarin (CYP2C9 & VKORC1)***
AskMayoExpert		X	X		
CPIC Guidelines on PharmGKB	X				X
Geisinger-authored			X		
MyDrugGenome.org		X		X	
MyResults.org			X	X	
Northwestern Patient Handout		X			
Northwestern Clopidogrel Fact Sheet		X			

NOTE: empty cells denote that they were not included in this study (not that they do not exist for a given information resource).

Coverage of template content topics among eMERGE institutions

We assessed the coverage of content topics in our template by authoring or adapting content for seven resources (eleven information resource/drug-gene pair combinations). **Table 4** summarizes for each content topic whether relevant text existed and whether a specific sub-section existed in the resource for the drug-gene pair.

All information resources contained text relevant for four content-topics ("Clinical scenario/Overview", "Background and effects of the condition", "Treatment and management choices for the condition", and "Additional sources of support and information"). All but one information resource contained text relevant for the "Risk of developing, carrying or passing on the condition" content topic. Text on "Types of tests available or being offered," "Testing procedure," "Test accuracy and reliability" existed for seven (64%), eight (73%), and eight (73%) of the information resource/drug-gene pair combinations, respectively. Text on "Content contributors" existed for eight (73%) of information resource/drug-gene pair combinations.

Less than half of the information resource/drug-gene pair combinations covered each of the remaining content topics: 45% covered "Shared decision making," 45% covered "Potential risks (psychosocial consequences, implications of discrimination, potential consequences for others)," 45% covered "Local information" (e.g., information about re-imbursement), and 45% covered "Date of the information."

Two resources had only a few sub-sections (Northwestern Patient Handout and Northwestern Clopidogrel Fact Sheet). The remaining five resources (AskMayoExpert, CPIC Guidelines on PharmGKB, Geisinger-authored, MyDrugGenome.org, MyResults.org) included a minimum of eight sub-sections that corresponded to template content topics. For MyDrugGenome.org we also assessed other local resources for content (e.g., the PREDICT project Smarter Prescriptions webpage[37], See [a] in **Table 4**).

Table 4. Resource text and sub-sections corresponding with eMERGE template content topics.

Resource (Drug-gene pair)	Content topic number (See Box 1 for a brief description)

Discussion

This work characterized the diversity of information resource implementation strategies among eMERGE-PGx project sites; developed a master template containing content topics important for genomic medicine practices (as identified by the DISCERN-Genetics tool); and assessed the coverage of content topics by authoring and adapting content to our master template at six eMERGE institutions.

Implementation strategies were diverse, despite our common start and end points. While the target audience and purpose for information resources we reviewed were comparable across sites, we found that authoring, reviewing and editing processes were different. In addition, with the exception of CPIC Guidelines, GeneReviews and MyResults.org, updating processes were largely informal and in one case had not yet been established. This finding is consistent with the finding that despite adopting a common sequencing platform among Clinical Sequencing Exploratory Research (CSER) institutions[38], there were a range of approaches to annotate and prioritize genomic variants and generating whole-genome clinical reports for integration into the EHR.[6]

The master template contains 13 content topics that are important for genomic medicine practices. We successfully demonstrated our ability to adapt content to this template for a range of pharmacogenomics scenarios and information resources in this study. This task, however, did not come without challenges. Given we kept the language general for a broad range of genomic medicine scenarios, we found that the hints and content sections did not always appear directly relevant for pharmacogenomics scenarios (e.g., "genetic condition" implies a "*disease-causing* genetic condition"). This finding is not surprising given the DISCERN-genetics questionnaire was evaluated previously with a sample of information on cystic fibrosis, Down's syndrome, familial breast cancer, familial colon cancer, hemochromatosis, Huntington's disease, sickle cell disease and thalassemia.[18] To these authors knowledge, however, the DISCERN-genetics criteria is the only criteria that has been assessed with such a broad range of genetic conditions that represent different populations, disease pathways and treatment decisions, and that has been evaluated with a diverse audience including health information consumers, producers and providers.

When assessing the coverage of content topics among information resources developed by eMERGE institutions we found that many existing resources have sections or sub-sections that map directly to the content topics we defined in our template. These findings reinforce the appropriateness of our decision to use the DISCERN-genetics criteria

as the basis for our master template, given the criteria focus on information content, rather than the way information is packaged, presented and made accessible. For example, MyResults.org and AskMayoExpert both have structured templates for content relevant for drug-gene pairs of interest to eMERGE. The MyResults.org template is organized into tabs that allow patients to explore answers to common questions and resources (e.g., the video titled "Does Everyone Respond to Statins in the Same Way?"[39] under the "Media and Recommended" tab). Alternatively, the AskMayoExpert template provides content on a single document organized into major sections including "FAQs", "Key Facts", "Guidelines", "Publications and Resources", and "Patient Education". Even though the templates are quite different from each other, they both include sections or sub-sections that align with the content topics listed in **Box 1** (see **Table 4** e.g., "Pub/Resources" and "Patient Education" sections of AskMayoExpert and the "Media and Recommended" tab of MyResults.org map to the "Additional sources of support and information" eMERGE template content topic).

We also identified important aspects of genetic testing that are not addressed well by existing information resources in their current form. For example, "Shared decision making," and "Potential risks (psychosocial consequences, implications of discrimination, potential consequences for others)," were covered by fewer than half of the information resource/drug-gene pair combinations we reviewed. In addition, we found that few resources captured content on "Date of the information," which directly impacts our ability to define formal processes for updating materials. We also identified aspects of genetic testing that are covered very well by the resources we analyzed. For example, content relevant for "Clinical scenario/Overview", "Background and effects of the condition", "Treatment and management choices for the condition", and "Additional sources of support and information" template content topics were available in all of the resources we evaluated. These findings help guide areas of focus for developers of genomic medicine content. Toward improving the coverage of important content areas and achieving consistency across eMERGE informational projects, the MyResults team has already made revisions to their template to align with the 13 content topics included in the master template. At the time of our analysis, MyResults targeted a patient audience, and is now being considered for expansion to a healthcare provider audience.

Conclusions and Future Directions

Overall, we gathered genomic medicine information resources in preparation for a network-wide infobutton implementation across eMERGE institutions. Given that a standard implementation does not exist and sites relied on a diversity of information resources, there is a need for methods and approaches to help institutions efficiently produce sharable genomic medicine resources. Our findings highlight two potential areas for developing tools as part of the eMERGE infobutton project: (a) collaborative authoring and (b) adapting existing information resources. Exploring both areas, in turn, there are several considerations and opportunities to collaborate with existing projects.

First, our finding that teams of individuals often author and review information resource content motivates future work to design a collaborative writing application. We also suspect that the primary literature, clinical guidelines, and systematic reviews that authors draw from to prepare materials are similar among eMERGE institutions. It may therefore be useful to provide access to these resources in a common authoring environment. We hope to draw from the experiences of others developing software (e.g., the Librarian Infobutton Tailoring Environment, LITE[9]) to provide content for the Infobutton Manager knowledge base that creates a set of context-specific links to information resources. As an important note for designing collaborative writing applications, we will also need to address open questions about the safety, reliability, divergence from traditional authoring approaches and legal implications for decision-making.[40]

Second, our finding that many resources already have sub-sections that map to our master template motivates the need for a tool to assist with adapting existing resources. Given the challenges we encountered in interpreting content-topics for pharmacogenomics scenarios, we will also need to incorporate flexibility to tailor language to the genomic medicine scenario of focus (e.g., the option to substitute "genetic condition" with "genomic predisposition" for pharmacogenomics scenarios). We expect to encounter organizational and technical challenges in our pursuits. From an organization point of view there may be many barriers that exist such as a lack of rewards to motivate sharing, little communication about the benefits and values of sharing knowledge, and a shortage of appropriate infrastructure to support sharing practices. Collaborative projects such as eMERGE provide opportunities to identify and develop models and approaches to overcome such challenges to sharing genomic medicine knowledge. From a technical standpoint, free-text is not ideal for implementing clinical decision support. We are therefore collaborating with the OpenInfobutton development team that has released the Infobutton Responder[41] to enable healthcare organizations to index their local clinical content so that it is compliant with the HL7 infobutton standard[12, 42]. Such tools could help institutions to efficiently produce sharable genomic medicine resources in a form that can be

leveraged by infobuttons in the EHR that link to specific content topics. Exploration of open source content management systems that might be customized for these purposes is underway within the eMERGE Network.

Acknowledgments

We are grateful for valuable input from Dr. Guilherme Del Fiol (University of Utah), Dr. James Cimino (NIH Clinical Center), Dr. Roberta A. Pagon (University of Washington), and Dr. Mary Relling (St. Jude Children's Research Research Hospital). The authors would also like to thank Ms. Sarah Stallings (Vanderbilt University), Vivian Pan (Northwestern University) and the PREDICT Internal Development Team (Vanderbilt University) for their contributions.

This research was supported in part by the Columbia Training in Biomedical Informatics (NIH/NLM #T15 LM007079), the University of Maryland Program for Personalized and Genomic Medicine, NIH/NIGMS (U19GM61388; the Pharmacogenomics Research Network), NIH/NHLBI PAPI (U01HL105198), UW NEXT grant (U01HG006507), UW CSER (U01HG006507), UW CTSA (UL1TR000423), and the eMERGE network [U01HG006828 (Cincinnati Children's Hospital Medical Center/Harvard); U01HG006830 (Children's Hospital of Philadelphia); U01HG006389 (Essentia Institute of Rural Health); U01HG006382 (Geisinger Clinic and University of Maryland, Baltimore); U01HG006375 (Group Health Cooperative and the University of Washington); U01HG006379 (Mayo Clinic).); U01HG006380 (Mount Sinai School of Medicine); U01HG006388 (Northwestern University); U01HG006378 (Vanderbilt University); and U01HG006385 (Vanderbilt University serving as the Coordinating Center]. Information resources we cover are supported in part by Mayo Clinic (AskMayoExpert), Vanderbilt University Medical Center (MyDrugGenome.org), Children's Hospital of Philadelphia (MyResults.org), and Northwestern University (Northwestern Patient Handout and Northwestern Clopidogrel Fact Sheet).

Abstract

Secure messaging (SM) allows patients to communicate with their providers for non-urgent health issues. Like other health information technologies, the design and implementation of SM should account for workflow to avoid suboptimal outcomes. SM may present unique workflow challenges because patients add a layer of complexity, as they are also direct users of the system. This study explores SM implementation at two Veterans Health Administration facilities. We interviewed twenty-nine members of eight primary care teams using semi-structured interviews. Questions addressed staff opinions about the integration of SM with daily practice, and team members' attitudes and experiences with SM. We describe the clinical workflow for SM, examining complexity and variability. We identified eight workflow issues directly related to efficiency and patient satisfaction, based on an exploration of the technology fit with multilevel factors. These findings inform organizational interventions that will accommodate SM implementation and lead to more patient-centered care.

Introduction

Secure messaging (SM) is increasingly available as a component of patient portals and allows patients to communicate online with their providers about non-urgent issues through a secure website. SM allows healthcare organizations to provide personal service in an effective and efficient manner, and provides patients with an additional communication channel that is complementary to existing channels (i.e. phone calls and walk-in clinics). The use of SM is positively associated with health outcomes[1–3], patient satisfaction[2,4], perceived improved patient knowledge and self-care[5], adherence[6], efficiency[7] and cost of care[1,8]. However, there are also various challenges regarding SM. For example, SM adoption rates among patients are still low[9].

Integrating SM into existing practice is of widespread interest, given its inclusion in meaningful use criteria (http://www.healthit.gov/providers-professionals/achieve-meaningful-use/core-measures-2/use-secure-electronic-messaging, Last accessed on 08/03/2014), yet it poses significant challenges for clinicians[10,11]. Heyworth et al[10] reported that providers' inability to access the SM system easily was an important challenge possibly leading to less enthusiastic system adoption. Wakefield et al.[11] developed a seven-step SM implementation framework. A critical step of the framework was integration with workflow. Organizations that implement SM need to determine who will be involved in SM, who will be responsible for responding to patient messages, and what policies should be in place regarding patient access rights and staff responsibilities. These decisions, specific to organizational context, can lead to either better or worse integration of SM in workflow[12,13]. These decisions can be carefully planned, but they can also result in unintended consequences if there is a lack of fit between the technology and the work being done[11].

The importance of the fit between information technologies and workflow has been discussed in the context of a variety of health information technologies such as electronic health records (EHR)[14], barcoding[15] and computerized provider order entry (CPOE)[16]. The boundaries of these technologies are limited to clinical settings and the active users are clinicians and staff. However, workflow considerations for SM are more complex because the system boundaries extend into daily living settings, with patients being active users as well. The design of SM systems should consider these broader boundaries and wider range of users. Clinical workflow for SM (i.e., the component of overall workflow occurring in the clinic) should be sensitive to the workflow in the daily living environment.

Conceptual models that address the design and integration of technology for a work system stress the need to assess the fit between the new technology and workflow at multiple levels. The Technology Acceptance Model (TAM) and its variations mainly focus on individual factors such as perceived usefulness and ease of use[17]. Organizational

theories such as sociotechnical systems theory highlight the importance of the joint optimization of social (e.g. policies) and technical systems for effective functioning of organizations[18]. The broader cultural, political, and economic environment in which organizations operate also affect technology implementation[19]. SM implementation may also be affected by factors at each of these levels. However, successful implementation is challenged by requiring attention to all factors simultaneously[20].

The purpose of this study is to describe clinical workflows associated with the use of SM, and to identify issues (at multiple levels such as individual, task, organizational and environment) that affect clinical efficiency and effectiveness in primary care settings. Although several studies have demonstrated the positive contribution of SM, workflow challenges may limit the full benefit from SM from being achieved, particularly if adoption rates and use increase. This study examined the research question "What challenges arise when integrating SM use with workflows at different organizational levels?". Based on our data, many challenges were related to technology fit, and we then explored these challenges using a multilevel framework[21] to inform system design and organizational interventions that can lead to more effective SM use and more patient centered care.

Methods

The Veterans Health Administration (VHA) began broad enterprise implementation of SM in 2011, after a pilot implementation at several sites. Clinical staff members used an integrated EHR called the Computerized Patient Record System (CPRS). The SM application is tethered to, but not fully integrated into CPRS. Patients who were in-person authenticated for the VHA's patient portal and personal health record (My Health***e***Vet) were able to opt-in to use SM. In the VHA, patients can use SM to contact their primary care providers (and more recently specialists) about non-urgent matters by logging into their My Health***e***Vet accounts. They are told that a response from the clinical team will occur within three business days. Teams at two study locations, four teams each in New England and the Pacific Northwest, initiated SM use in 2008 as part of a pilot implementation conducted prior to national rollout. While not all providers at these locations participated in SM until the full rollout in 2011, because of their participation as pilot sites, the early adopters had more experience with SM than those at other facilities. This experience allowed us to evaluate how they had incorporated SM into their workflow, defined in this study from an operations perspective, focused on processes and allocated resources. Specifically we defined workflow as a sequence of activities by multiple individuals related to SM utilization[22]. We conducted twenty-nine individual interviews with the members of eight primary care teams. The eight teams were selected based on variation in the volume of secure messages received during the six months prior to selection for the study and the proportion of messages completed by the provider (physician or nurse practitioner) versus other team members (Table 1).

Data was collected by MO and BAP from the New England teams in March-June 2013 and by MO, SS, BAP, ES and SW from the Northwest teams in April 2013. Interviews were guided by a semi-structured interview protocol. Interview questions addressed general information about each interviewee's role on the healthcare team, how SM was used, the integration of SM with daily practice, and team members' attitudes towards and experiences with SM. Interviews took place in private rooms at each interviewee's clinic. Each interview lasted approximately 30-45 minutes. All interviews were audiotaped, except for one, and transcribed verbatim. All data collection methods were approved by the VHA Central Institutional Review Board.

Data were qualitatively analyzed in two steps. In the first step, all interviews for a team were read by two of the authors, and each author separately created a summary describing the team's use of SM. The summary was completed using a semi-structured template, focused around the elements of workflow. The sections of the template included who was interviewed, their roles and responsibilities with respect to secure messages, their impressions of the types of messages received, their description of major process steps in handling secure messages, perceptions of the value of SM, comments about organizational decisions and factors that affected SM workflow, and any technology-related issues that arose. A third author synthesized the other two researchers' notes to create an overall site summary. In the second step, the authors worked from the site summaries to develop a general workflow diagram. The researchers who analyzed data have backgrounds in medical informatics, industrial engineering, management information systems, health administration, qualitative research and primary care medicine.

Table 1. Description of the study sample

Team No	Location	Incoming Message Volume in 6 Months	Provider Completion Rate*	Roles of the Interviewees
1	New England	303	0%	Physician, licensed practical nurse (LPN), registered nurse (RN), Pharmacist**
2	New England	197	0%	Physician, LPN, Pharmacist**
3	New England	283	20%	Nurse Practitioner, LPN, RN
4	New England	329	58%	Physician, LPN, RN, Pharmacist
5	Northwest	385	0%	Physician, LPN, RN, Pharmacist
6	Northwest	491	0%	Physician, RN, Medical assistant
7	Northwest	503	73%	Physician, LPN, RN, Social worker
8	Northwest	539	32%	Physician, LPN, RN, Medical Assistant

* Provider completion rate is the percentage of the secure messages completed by provider (physician or nurse practitioner) by clicking the "***Complete***" button in the SM system.

** The same pharmacist serves both Teams 1 and 2.

Results

Secure Messaging Workflow

The clinical workflow for SM as described by interviewees and synthesized across the eight teams is illustrated in Figure 1. Figure 1 shows the main activities, the order of these activities and information flow at a high level once a team receives a message from a patient. Messages are usually focused on one request and can be addressed by one staff member. However, some messages included multiple requests and were handled by multiple people.

Once a message is opened, the team member reviews the content of the message and identifies the staff member who can best respond to the message based on their scope of practice. The team member who first opened the message often collects additional information (e.g. reviewing patient data in the CPRS system or contacting the patient for further details) and takes necessary action (e.g., request an appointment or refill a prescription). Alternatively, the message might be triaged or assigned through the SM system to another team member. In some cases, the issue was handled outside of SM by notifying another staff in person or via an electronic alert in CPRS.

If a patient requested more than one item for action (e.g. scheduling a new appointment and also providing information about physical therapy resources), then the message was first be handled by one of the team members appropriate to the request (e.g. scheduling clerk) and then reassigned to another team member (e.g. physician).

Once necessary actions were taken, a response was sent to the patient, typically either via SM or by phone. Based on the team member's judgment, the secure message was copied into CPRS as a clinical note and signed by the team member. All secure messages were required to be completed. This was accomplished by clicking the "***Complete***" button in the SM system. Replying to a message also automatically generated the option to simultaneously complete the message. Completing a message was designed to signal that the issue raised by the patient was resolved, and the message no longer appeared in the team member's Inbox. VHA policy requires completing messages within three business days; otherwise, the message is flagged as "***Escalated***".

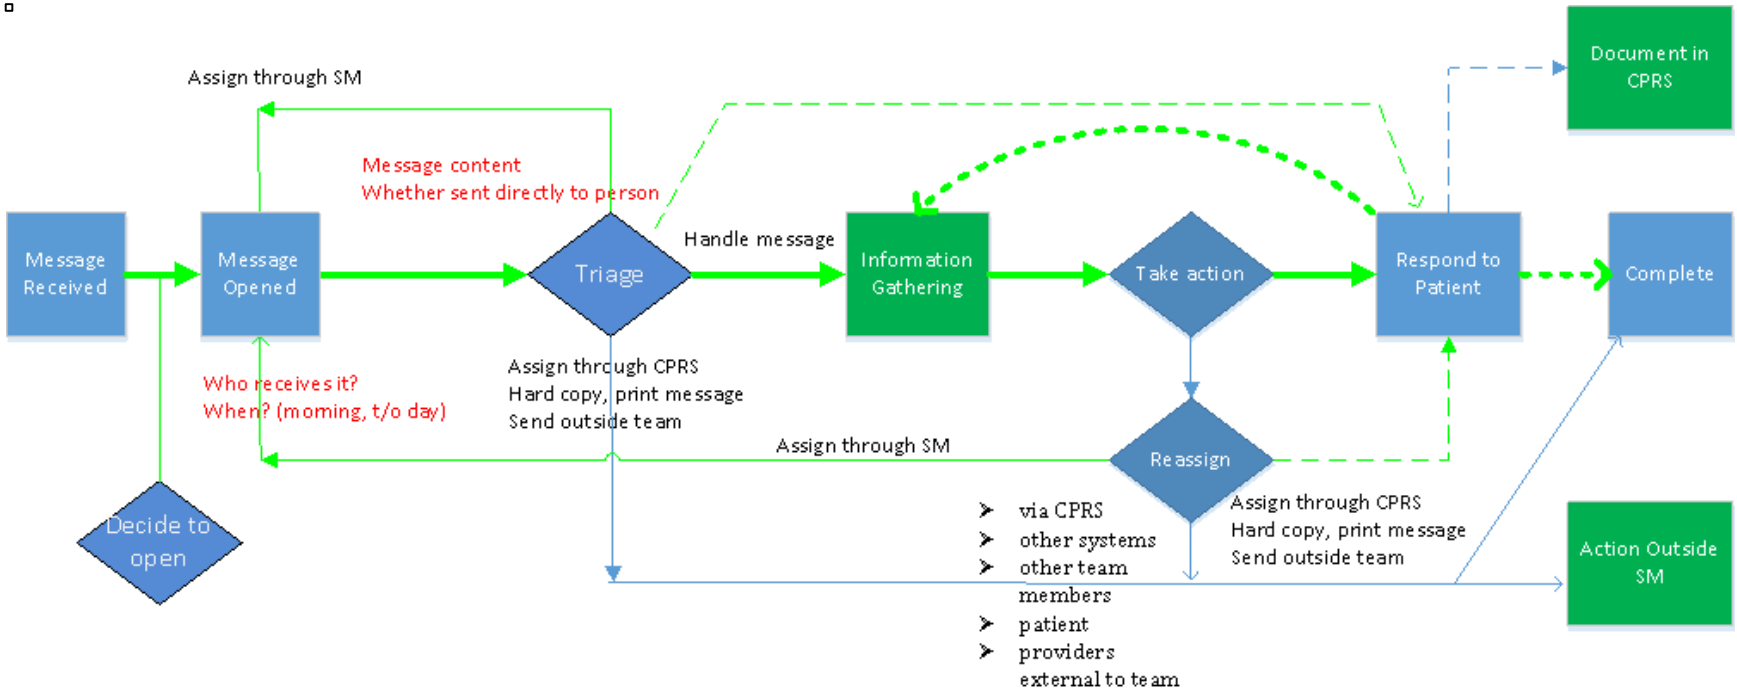

Figure 1. Overview of SM workflow across teams

The clinical workflow for SM can be complex because it includes various decision points, requires the cooperation of clinical team members, and exists in tandem with other workflows focused on responding to patients (e.g., telephone calls, walk-ins). On occasion, it was necessary to reach the patient for further information and clarification in order to proceed. If the patient's question was multifaceted, interviewees noted that it was often more expeditious to follow up with patients directly by phone, although patients were not always available to ensure timely contact. While the SM platform was the same across sites, clinics varied in terms of size, locale, patient demographics, physical layout, and organizational structure. In addition, each clinic and the teams within these clinics made local organizational decisions about how to embed SM into their existing workflows. These differences and decisions led to variability in the clinical workflow for SM across the care delivery teams. Our analysis revealed two major workflow variations across teams. Variations occurred in how team members used the SM system, and how teams communicated with other staff members and patients outside of the SM system.

Differences were found both in how messages were received and how team members responded to messages. Depending on the team and situation, there was significant variation in which team member was responsible for opening messages. For example, on one team an LPN was the first to open all incoming messages. On another, registered nurses and LPNs shared the responsibility of opening messages. In yet other settings, physicians opened messages first. In four of the teams, the providers did not personally use the SM system, relying on team members to relay the information. (Note that these team members were intentionally selected to be interviewed based on their low provider completion rate.) In other teams, physicians acted on and directly responded to patient messages using the SM system

In part because of differences in how roles and responsibilities were defined with respect to SM, message resolution was handled using a variety of means of communication. For example, providers who did not use the SM application accessed information through in-person consultations with staff, via printed copies of messages, or through CPRS notifications. Other team members called patients to respond to the issues raised in a secure message, rather than replying within the application. Although the use of multiple channels provides convenience and facilitates communication, it can also affect the team's ability to track message handling via the SM application. For example, if the staff member who opened the message forwards the message verbally and then closes the message, reviewing a secure message thread within the system may not reveal when or whether the issue was actually resolved.

Workflow Issues

Most interviewees believed the SM system was of value to patients, providing an alternate access channel and a potentially richer way to communicate. However, they were more mixed in their assessment of how well the system worked. We examined several workflow issues raised by interviewees and conceptualized the source of these issues as a lack of fit between the technology and multiple levels of work. Karsh et al.[21] discussed technology-work misfit at four interrelated levels: user, task, organization and environmental levels. In Table 2, we describe technology-work fit at different levels from Karsh et al.'s model, and identify specific workflow issues from our findings.

User-technology fit: At the user level, we observed two workflow issues related to technology fit. First, some nurses and providers preferred not to use the SM system while others were enthusiastic users. Some team members were not comfortable with computers, while others found the system burdensome (i.e. using SM required them to log in to another system and to keep several applications open simultaneously). Enthusiastic users often took on a greater role within the SM workflow (e.g. opening all messages), while others used alternative communication channels, such as telephones to respond to patients. Second, several types of messages described by interviewees suggested patients may use the system inappropriately, thereby impacting workflow. We identified two broad areas of inappropriate use by patients: 1. sending a message for an urgent issue such as chest pain, and 2. sending long messages that also included personal information not directly relevant to their health condition and request.

Task-technology fit: At the VHA, SM is not integrated with the primary existing clinical information system, CPRS. Use of the SM system therefore requires opening an additional window in the computer screen and an additional login. Moreover, because SM is not integrated into CPRS, clinicians juggle between windows to locate pertinent information such as test results to copy and paste to the SM screen. This not only is additional work, but also presents potential safety and privacy concerns[23,24]. Several interviewees also raised the issue of the inconvenience of not being able to send information (e.g. lab results) from CPRS. Other aspects of the technology also interfere with workflow tasks. For example, for privacy and security reasons, the SM software automatically times out when not in use.

Table 2. Levels of technology fit, description of levels and findings related to workflow issues at different work levels

Level	Description of the Level from Karsh et al.	Workflow Issues Identified
User-technology fit	"Fit between technology and user characteristics (e.g., values, attitudes, abilities)"	1. Use among team members varies due to their abilities, attitudes and values 2. Inappropriate use of messaging by patients
Task-technology fit	"Fit between technology and health care task characteristics (e.g., complexity, time constraints) "	3. SM was tethered, but not integrated, into the electronic record 4. Technology-related issues (e.g., frequent log offs, time required to log onto second system)
Organization-technology fit	"Fit between technology and organizational characteristics (e.g., policies, practices, social climate, resources)"	5. Need for additional policies (e.g. access by family members, identification of surrogates) 6. Additional workload 7. Despite the significant impact on workload, there was no workload credit for SM.
Environment-technology fit	"Fit between technology and the external (e.g. politics, culture) or internal (e.g., lighting, layout, noise) environment"	8. Patient expectations of early response

Organization-technology fit: Three workflow issues were identified. First, because SM is a new communication channel between patients and providers, new situations arise that require additional policies. For example, SM accounts might be used by family members (i.e., informal caregivers) on behalf of patients. This situation has not been officially addressed by organizational policies, and staff members used their judgment in how to handle confidentiality when they communicated about with family members about patients. Another example was ensuring timely response to SM when a provider was off duty. Although CPRS enables identification of surrogates for CPRS alerts, a duplicate, separate arrangement must be made in the SM system. Second, some organizational practices create additional workload. Some sites had decided that every secure message should be copied by the team user into CPRS – a task requiring manual intervention. Finally, the use of SM was not formally counted as a part of workload credit. Several interviewees saw this as a significant barrier to use, particularly as the volume of messages has grown.

Environment-technology fit: At the level of the environment, we identified one workflow issue. VHA expects clinical teams to respond and complete patient messages within three business days. On the other hand, patients may expect a same-day or faster response. The expectations of patients for quick responses has also been documented in previous studies[25]. Patients who do not get a response on the same day may be upset, and they may send additional messages or follow up by telephone to repeat their requests and reflect their frustration.

Discussion

We studied the implementation of SM in eight primary care delivery teams within the VHA. The complexity of the clinical workflow for SM, shown in Figure 1, makes it challenging to develop a SM system that fits with existing work at all levels, across many sites. Across sites, variation occurred at the user, task, organization, and environmental levels, both before and in response to implementation. Based on our data, we examined the issue of fit between the technology and four levels of work, and categorized workflow issues described by interviewees in terms of these levels. A limitation of our work is that it is based on a single organization, and a study sample of eight teams, which may limit the range of workflow challenges.

The value of using a multi-level framework to examine technology fit is that it underscores the need for strategies to mitigate issues in both the technical and organizational spheres, and at different organizational levels. Design and implementation strategies for health information technologies should recognize these levels, and the relationships between them.

Implementation strategies should seek to determine where lack of fit between technology and workflow is occurring, then develop responses to improve the fit. Responses can include both changes in technology design as well as organizational practices. In terms of technology design, in the context of this study, several refinements to the SM system would improve task-technology fit, eliminating what interviewees' perceived as difficulties or time-wasting workarounds. For example, a key improvement from the interviewees' perspective would be integrating the SM system with existing information systems. Such a change might increase the engagement of providers with the system, reduce total workload in the clinic and potentially reduce variability across sites. In terms of user-technology fit focused on patients, systems might be developed that flag key words in messages – such as chest pain – that direct the patient to call rather than to send a secure message.

To increase fit, implementation can also address organizational practices at multiple levels. For example, in our context, user-technology fit might be improved by more effective training of clinicians and patients. Effective training may increase adoption among staff members and decrease inappropriate use of the SM by patients. Organization-technology fit can be improved by developing policies or guidance to address areas of uncertainty, such as when a secure message should be copied to the EHR or who will open messages first. As the number of patients using SM and message volume increase, a policy to address workload is particularly important. Environment-technology fit can be improved by providing guidance to patients about the best use of the system, with personalized training to patients when needed.

Conclusion

The clinical workflow for SM is complex and includes variations as an SM system is implemented in different clinic settings. The direct involvement of patients as users also contributes to its complexity. Based on interview data, we identified eight workflow issues that emerged in an SM implementation, and used a multi-level technology-fit framework to examine them. To improve fit, design and implementation strategies should encompass both technical improvements and organizational practices, and be sufficiently comprehensive to address workflow issues at different levels. While this study was based on data from a single organization and SM system, which influenced to some extent the issues identified, the multi-level framework and analysis of fit are applicable for any system and organization. With the emphasis on SM in meaningful use criteria, which is likely to increase the number of patients using SM and the overall volume of messages, organizations need insights about how to implement SM systems to ensure that SM increases access to providers, improves communication and eventually leads to more effective, timely, patient centered and safe care.

Workflow issues have been explored in other technology studies (e.g. EHR, CPOE), but SM workflow differs because patients are also active users. We identified two workflow issues related to patient use, including inappropriate use of messaging by patients and patients' expectation of quick (often 24 hour or sooner) response. Both issues relate directly to patient satisfaction and influenced staff workflow. Because the study design focused on staff interviews, our results emphasize the importance of effective communication between patients and staff, to provide relevant information without requiring additional rounds of messages or phone calls. Our future research includes an analysis of messages between the patients and clinics to better understand communication patterns. From a system design perspective, templates that can structure patient interactions have been shown to be effective[26]. Examining SM use from the patients' perspective, in daily living environments, is also likely to be a fruitful area for additional research.

Acknowledgement

This study was funded by the Veterans Health Administration (QUERI RRP 11-409, PI: Woods), with additional support from the New England Veterans Engineering Resource Center. We would like to thank the members of the eight PACT teams who agreed to be interviewed.

Visualization of Patient Prescription History Data in Emergency Care

Selcuk Ozturk, MS, Mehmet Kayaalp, MD, PhD, Clement J McDonald, MD
Lister Hill National Center for Biomedical Communications,
U.S. National Library of Medicine, National Institutes of Health, Bethesda, MD

Abstract

Interpreting patient's medication history from long textual data can be unwieldy especially in emergency care. We developed a real-time software application that converts one-year-long patient prescription history data into a visually appealing and information-rich timeline chart. The chart can be digested by healthcare providers quickly; hence, it could be an invaluable clinical tool when the rapid response time is crucial as in stroke or severe trauma cases. Furthermore, the visual clarity of the displayed information may help providers minimize medication errors. The tool has been deployed at the emergency department of a trauma center. Due to its popularity, we developed another version of this tool. It provides more granular drug dispensation information, which clinical pharmacists find very useful in their routine medication-reconciliation efforts.

Introduction

Preventing Medication Errors, a report published by Institute of Medicine, drew the attention of the healthcare community, policy makers, and the general public to the gravity of serious clinical mistakes due to preventable medication errors.[1] As recognized by the Joint Commission, taking an accurate and current medication history can be difficult to accomplish, especially when patients are severely ill, injured, disabled, extremely young, or unable to articulate themselves in English.[2] These conditions occur more frequently in emergency rooms. In the case of a disaster, even a well-prepared emergency department can become overwhelmed.

We developed a software system that aims at helping clinicians obtain necessary patient medication history quickly and accurately both in disaster and in routine emergency care. Our effort is part of a joint enterprise called Bethesda Hospitals' Emergency Preparedness Partnership (BHEPP).[3] Other members of BHEPP include Clinical Center at National Institutes of Health (NIH), Suburban Hospital Johns Hopkins Medicine and Walter Reed National Military Medical Center. We developed and deployed our system at the Emergency Department (ED) of Suburban Hospital.

The system first receives patient registration information from the hospital's Health Level 7 (HL7) messaging system and then queries the prescription history of the registered patient at Surescripts. Surescripts, in turn, searches that patient's prescription history in the databases of its network of pharmacy benefit managers (PBMs).[4] If the patient is found, we receive the full-year of prescription history of the patient. Our software system parses the list of prescription fulfillment activity, converts it into a visual timeline chart, and sends it to a printer in the ED. The entire process takes approximately 4 seconds.

Surescripts usually provides a short summary of the report, which lists each drug's fulfillment count and the first and last fulfillment dates within the last twelve month period. However, some pharmacy benefit managers do not deliver NDC (National Drug Code) numbers with each drug name. In those cases, the summary reports become long lists of individual drug dispensations. In a high polypharmacy case of an elderly patient, drug history data can easily be 15- to 20-pages long. Such a long list of medication dispensation data is difficult to read and interpret. When quick emergency care response is required, decoding such a document can become a burden. Our system ameliorates this situation by grouping the drugs with the same name and dose together, making it an easily interpretable summary as it is done by Surescripts when drug NDC numbers are available.

Emergency care providers usually do not have time to read long drug lists containing various doses, dates, dispensation amounts and so on. Our system creates a timeline chart (see Figure 1). On the right column, drugs grouped by name and dose are ordered from the most to the least recent. The drugs that are currently in use are printed in boldface. The time flows from left to right as indicated with the dates on the horizontal axis at the top of the chart. With this chart, care providers can glean a year-long prescription history of the patient very quickly The example presented in Figure 1 was produced from a de-identified two-page, more than 100-line-long summary of drugs without NDC numbers.

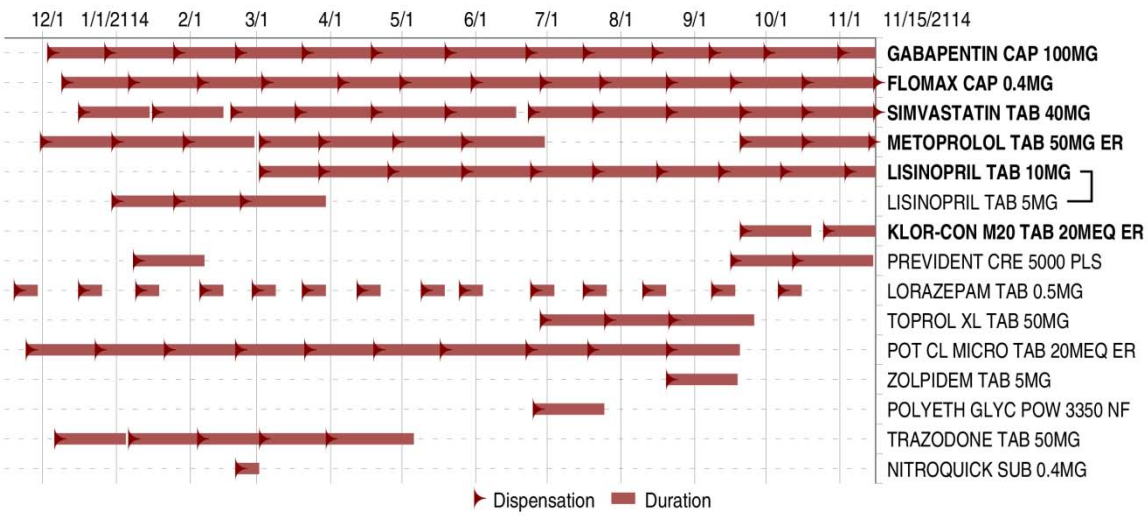

Figure 1. Patient Prescription History Data on a Timeline Chart

Methods

Surescripts' feed provides two types of HL7 message information: An RDS, pharmacy dispense message, and an ORU, unsolicited transmission of observation message.[5] Our system processes the observation message to create the graphical timeline chart. In the input, each dispensation is represented in three subsequent OBX HL7 segments (see Figure 2). These segments contain tabular information about drug names, dosage forms, dispense dates, dispense units, prescription durations, prescribers, dispensing pharmacies, data entry types and information sources.

```
OBX|45|TX|MEDS^DRUG||IBUPROFEN 800 MG TABLET (IBUPROFEN)||||||F
OBX|46|TX|MEDS^DRUG||Fill Date    Qty         Days   Prescriber  Pharmacy   Type    Source||||||F
OBX|47|TX|MEDS^DRUG||01/01/2020   12          3                  7          Claim    CMX||||||F
```

Figure 2. A Small Portion of De-identified Observation Message Representing a Single Dispensation

In addition to this detailed dispensation information, we receive a summary textual report that includes patient identifiers, including the name, the zip code, the date of birth, and the gender of the patient. This text also includes providers and pharmacy lists related to the dispensations.

We parse both sets of information using Perl scripts and compute the "drug use" intervals by adding the prescription duration days to the dispensation date of the drug. We truncate all intervals of recently dispensed drugs to the current date if they pass beyond the current date of information. We order the list of the drugs according to the "last drug use date," i.e. the end date of the most recent interval for each drug. This way all medications currently in use come at the top of the list. The secondary ordering among equals is the total duration of use. If the secondary ordering does not break the tie for some, we order them alphabetically.

We also group medications with the same name but in different dosages (see LISINOPRIL TAB in Figure 1) and connect them together with a bracket emphasizing their relation to each other. Although the medications listed at the top are the current ones, we further emphasize the current medication by printing their labels in boldface.

After all information is parsed from input and the necessary computations are made, our Perl script translates this information into Postscript. Since Postscript is both a representation language of graphical information and a specialized programming language, it is capable of computing and adjusting a number of graphical parameters automatically. We first calculate the maximum width of the right-most column, where we list the medications, and then divide the remaining at the left into 365 (day) logical units. Postscript scales the width of the chart as well as all other visual elements accordingly.

Unfortunately, the input is not always clean or simple. For example, a refill usually does not occur on the same day that the patient is out of the current supply of medication. It is expected that the patient gets his/her refills a few days

before the end of use day. However, what we frequently observe is multiple refills of the same drug within a couple of days. There may be different reasons for this type of noise, but apparently, the same dispensation information is passed to Surescripts from different sources, for example both by the pharmacy and by the pharmacy benefit managers, separately.

If the same label in the same form and dosage had been refilled within a couple of days with the same amount, and the duration of the medication is not short (e.g., 15-day or longer), we could assume that the second refill was a duplicate and draw the chart accordingly. Although we believe that our heuristic was quite good, we could not validate it for an extended period due to the lack of resources. In order not to take the associated liability, we decided not to continue with our heuristic plan. Instead, we decided to develop a visual representation of the data that reflects the incoming information as closely as possible.

Our problem was how to present to the provider overlapping dispensation information with clarity. We came up with a new version of the chart (see Figure 3). In this chart, each drug has a band allocated for printing the "drug use interval" lines. Now, we draw these intervals as a thin line through the mid-height of this band unless two or more intervals overlap. In that case, we shift the overlapping interval lines up and down by a few pixels in an alternating up and down pattern until the bound of the band is reached. Our implementation allows up to 9 concurrent intervals. When that level of multiplicity is reached, we put a footnote above the line, indicating that there are too many overlapping dispensations to plot. This way, each dispensation interval has a distinct beginning and end point and all overlaps are clearly visible.

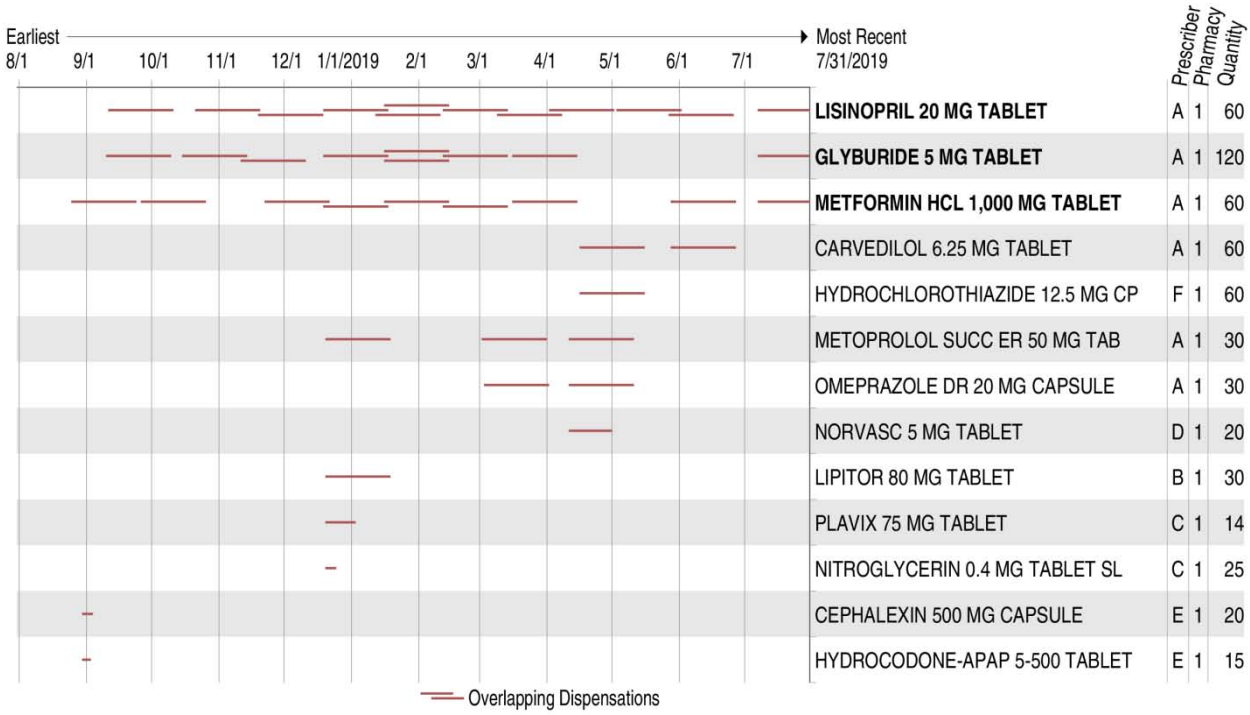

Figure 3. Patient History Data with Overlapping Dispensation Information on a Timeline Chart

In this version, we also decided to include the prescriber and pharmacy information when available along with the dispensed quantity in the chart: The last three columns on the right in Figure 3 above. The letters and numbers in the prescriber and pharmacy column refer to the lists printed later in the report. In the course of a one-year history, the same drug may be prescribed by different physicians, dispensed by different pharmacies, and/or prescribed in different amounts. The columns located on the far right display only the most recent information about that particular prescription and dispensation.

Results

By using Perl and Postscript languages, we created information-rich visual timeline displays, which can be absorbed by a clinician almost at a glance saving time and facilitating care. A sample copy of a de-identified printout that the providers receive is displayed in its entirety in Figure 4.

On the top of this page, we provide the timestamp of the information, patient name (redacted with Xs in Figure 4) and page number followed by a table containing patient identifiers, including name, address, gender, and date of birth. Before printing the standard disclaimer text, we provide a medication history date range. In this example, it ranges from 08/01/2018 to 07/31/2019. Due to the de-identification, the surrogate dates of this example lie in the future.

Starting about one-third of the way down the page, we draw a timeline corresponding to the date range. The direction of time from left to right is denoted by an arrow. At the tip of the arrow, the current full date (i.e., the date when the information is acquired) is provided. The timeline is divided into monthly portions and each tick mark is labeled with the first day of the corresponding month (Month/Day). Only the label of the New Year day tick mark contains the year information (i.e., 1/1/2019) to aid the provider for a quick temporal orientation in the chart.

Every other row is highlighted with a band for an easy read. To the right of medication labels, we inserted three columns. Both the prescriber and pharmacy columns are narrow, holding only one letter key to denote the prescriber reference or one digit key to denote the pharmacy reference. The last column is wider, to hold up to 3 digits denoting the most recently dispensed quantity. The pharmacy and prescriber tables with proper cross-reference keys are located below the chart.

The disclaimer at the top of the page could be moved to the end of the report since it does not convey any new information for the experienced provider; however, mostly for legal reasons, we had to place it where it currently is. We placed another set of standard remarks at the bottom of the page.

Discussion

Prescription data is an essential part of the medical history of the patient, but it can be quite voluminous. In emergency care, when rapid response is necessary, providers may not have time to sort through 15-page long prescription fulfillment report. The problem would be exacerbated during a disaster, as emergency departments would at that time become triage centers as well. Our project started with this kind of scenario in mind and we adhered to that perspective in all design decisions.

In order to provide all necessary information with utmost clarity, we attempted to follow best practices in visual display design.[6] We tried to avoid any superfluous text and visual design elements. We strived to strike a balance between the proportions designated to the visual timeline and to the textual information, i.e. drug label, dose, quantity, prescriber, and pharmacy information. Our top-down order of drugs has a narrative quality by itself, capturing part of a medical story of the patient.[6]

These design principles guided us in both versions of the timeline chart. We believe the first version is most suitable for emergency care providers, since it does not contain any unnecessary information or noise such as duplications. On the other hand, the second version seems very useful for pharmacists who need to conduct medication reconciliation and need every bit of information about the dispensation detail.

The three columns of prescriber, pharmacy, and quantity cross-references also helped us to eliminate all other textual data, since per consultation with the pharmacists at the trauma center, the current layout constitutes the necessary and sufficient information needed for medication reconciliation.

In addition to its valuable use in routine emergency care and in medication reconciliation, the visualization of the prescription history data help healthcare providers to quickly spot drug abuse and drug seeking behavior. We also believe that due to simple physical proximities of the currently used drugs, providers have a better chance of spotting pairs of medications with adverse drug event potentials. Note however that the efficacy and utility of our design and its effect on the patient outcome need to be measured and evaluated by future studies.

As one of our reviewers rightly pointed out, our design would benefit from a mapping between brand name drugs and their generic counterparts. If such a mapping were in place, we could move up Toprol XL tab 50mg (brand) and clamp it with its generic version Metorprolol tab 50mg ER (generic) in Figure 1. This way the clinician could immediately see that there was no discontinuity of the drug use.

RxHub Patient Medication History

Patient Id: XXXXXXX

Figure 4. Patient Prescription History Report

Our approach can be extended to a visual interactive display on tablets or monitors. In such an interactive environment, one could allow for drilling down and zooming in for more detailed information, allow for selectively narrowing the report to certain drug classes to focus on critical elements in the report. Even, automatic drug interaction warnings could be implemented.

Locating Relevant Patient Information in Electronic Health Record Data Using Representations of Clinical Concepts and Database Structures

Xuequn Pan, PhD[1, 2], James J. Cimino, MD[1, 2]
[1]Lister Hill National Center for Biomedical Communications, National Library of Medicine;
[2]Laboratory for Informatics Development, NIH Clinical Center; Bethesda, MD

Abstract

Clinicians and clinical researchers often seek information in electronic health records (EHRs) that are relevant to some concept of interest, such as a disease or finding. The heterogeneous nature of EHRs can complicate retrieval, risking incomplete results. We frame this problem as the presence of two gaps: 1) a gap between clinical concepts and their representations in EHR data and 2) a gap between data representations and their locations within EHR data structures. We bridge these gaps with a knowledge structure that comprises relationships among clinical concepts (including concepts of interest and concepts that may be instantiated in EHR data) and relationships between clinical concepts and the database structures. We make use of available knowledge resources to develop a reproducible, scalable process for creating a knowledge base that can support automated query expansion from a clinical concept to all relevant EHR data.

Introduction

The retrieval of clinical data from electronic health records (EHRs) for whatever reason, including care of a particular patient or broader inquires to support research, can be thought of as starting with some concept of interest and then expanding to include the concepts, and their representations, that actually appear in EHR data. For example, a clinician looking for evidence that a patient has had a particular disease or a researcher seeking records of all patients with a particular disease will naturally search record documents for codes and text that correspond to the disease in question. However, in order to improve recall, they will likely need to expand their inquiries to include such things as test results or medication orders that imply the presence of the disease. [1]

Once the set of concepts has been selected, there still remains the challenge of finding them in the EHR documents. Diagnoses might appear with some unobvious code (e.g., "Diagnosis not Elsewhere Classified") or synonym. Relevant laboratory results might be easy to find, based on test names, but they might require interpretation of complex results, or they might be buried in a laboratory test comment or even an image of a document obtained from an outside laboratory.

We are developing a set of methods to help overcome these challenges by the creation of an ontology that includes representations of concepts of interest, related concepts that appear in EHR data, and concepts corresponding to EHR database structures. Using Lyme disease as an example concept of interest, we demonstrate the construction and use this ontology through four steps: 1) identify terms related to Lyme disease in available knowledge resources, 2) add these concepts and their relationships to a dictionary of coded terms found in EHR data, 3) connect relevant EHR data concepts identified in the previous step with concepts that correspond to EHR data structures, and 4) identify pathways through the ontology that ultimately relate concepts of interest to database structures to support automated, comprehensive data queries.

Background

Lyme Disease

We selected Lyme disease, the most common tickborne infectious disease in the US, as our concept of interest. Lyme disease is diagnosed based on its typical symptoms (e.g., erythema migrans) and detailed medical history of possible exposure to infected ticks. Serologic testing is important for the diagnosis by looking for evidence of antibodies (IgG or IgM) to the causative agent, Borrelia (B.) burgdorferi. To support the diagnosis of Lyme disease, the Centers for Disease Control and Prevention (CDC) recommends a two-step process: a screening test that uses sensitive enzyme immunoassay (EIA)/enzyme-linked immunosorbent assay (ELISA) or indirect immunofluorescence assay (IFA); after a positive result, a specific immunoblot (Western blot) test should be conducted. [2, 3] The diagnosis is considered confirmed if there is a positive result on both tests.

The Systematized Nomenclature of Medicine – Clinical Terms (SNOMED-CT)

SNOMED-CT is a clinical terminology that represents a wide variety of clinical information that appears in EHRs. SNOMED-CT is composed of concepts, descriptions, and relationships. Each concept contains a unique fully specified name (FSN), a preferred term (PT), and synonyms that are additional terms and phrases about the concept. SNOMED-CT contains 344,000 concepts and a rich set of hierarchical or non-hierarchical relationships. Non-hierarchical semantic relationships connect concepts to relevant concepts from other domains and semantic categories to represent definitional information about the concept. [4]

The Biomedical Translational Research Information System (BTRIS)

BTRIS is a clinical research data repository at the National Institutes of Health (NIH) that collects data from over 35 NIH sources with 477,000 human subjects since 1976. BTRIS's major data sets include patient demographics, research study enrollment information, laboratory results, medication orders and administration records, and notes and reports from EHR systems. [5] All data in BTRIS are coded with the NIH's Research Entities Dictionary (RED), a terminology resource that comprises the controlled terminologies used by systems that supply data to BTRIS. Each source term is associated with a specific RED concept; knowledge about the terms is represented as literal-valued properties or through semantic relationships between concepts, including hierarchical relationships organized in a directed acyclic graph. The RED includes concepts that correspond to terms actually found in BTRIS ("data concepts"), database structure concepts that correspond to database structure ("database concepts"), and general biomedical concepts that are not actually present in EHR data ("knowledge concepts").

Methods

The ultimate goal of the project is to facilitate the matching of patient data in EHRs to a user's concepts of interest. For example, if a clinician is interested in finding evidence that a particular patient has Lyme disease, or a researcher is interested in identifying all records of patients with Lyme disease, comprehensive retrieval would at least need to examine problem lists, clinician notes and diagnostic test results. We therefore developed a method to expand the RED to include the knowledge necessary to support queries of these disparate data sources in BTRIS, based on an initial concept of interest. For this initial work, we focused on the knowledge related to Lyme disease.

General Knowledge Relating Concepts of Interest to Clinical Data

We reviewed clinical information about Lyme disease from authoritative sources and identified relevant key terms. This approach applied general knowledge to identify ways in which terms interrelate, such as "diseases are caused by organisms", "organisms produce antigens", "antibodies are produced in response to antigens", "laboratory tests detect organisms and substances", etc.

Identifying Specific Concept Relationships in Knowledge Resources

We examined the ways in which SNOMED CT and the RED represent general knowledge about diseases and their related concepts. We then explored and identified specific concepts and relationships in knowledge resources, such as Lyme disease and its associated terms. We generated a list of concepts based on parent-child relationships among the retrieved concepts. We then expanded our list to include concepts from other domains related through non-hierarchical relationships, such as "Borrelia (organism) is the causative agent of Lyme disease (disease)".

Adding the Concepts and their Relationships to RED

After review by domain experts, we added concepts and relationships discovered in the previous step into the RED through the usual maintenance process. We selected the concepts to be added and linked the concept of interest to EHR data concepts through their associations defined.

Linking EHR Data Concepts to BTRIS Database Structures

Finally, we linked EHR data concepts to database concepts that correspond to the BTRIS database structures, based on the BTRIS data.[5] For example, EHR data concept, Lyme disease (RED Code C114654) is linked to the specific database concept (C2179248) that represents the Observation_Value_Text column in the Observation_General table where diagnosis information was stored.

Results

General Knowledge Relating Concepts of Interest to Clinical Data

We reviewed clinical information about Lyme disease from CDC and NIH Web sites. The terms identified included "Lyme disease", "Borrrelia burgdorferi", "erythema migrans", and various antigens of and antibodies to B. burgdorferi, as well as terms for polymerase chain reaction (PCR) tests for B. burgdorferi DNA, serologic tests, antibody screens, and Western blot to measure those antibodies. Based on these findings, we therefore generated a general knowledge structure (Figure 1) in which the concept of interest is connected to terms from clinical domains of disease, organism, substances, and laboratory tests.

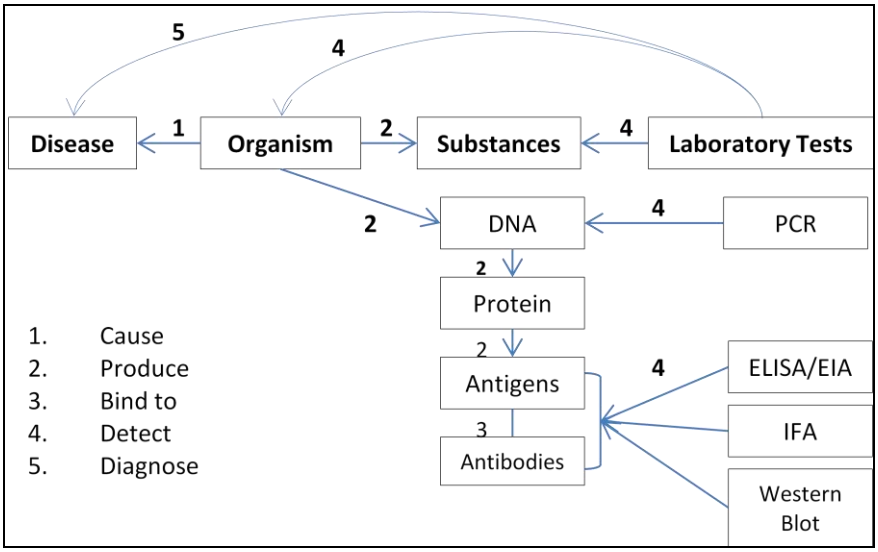

Figure 1. General knowledge structure for Lyme disease

Identifying Specific Concept Relationships in Knowledge Resources

In SNOMED CT, we retrieved a total of 64 SNOMED CT concepts related to Lyme disease including terms for 27 procedures, 21 substances, disorders, and 1 organism. The three non-hierarchical relationships we found are shown in Table 1. Figure 2 depicts for examples of concepts related to Lyme disease in SNOMED CT.

Table 1. Non-hierarchical relationships between Lyme disease and other terms in SNOMED CT

Non-hierarchical Relationship	Examples
disorder|causative agent|organism	Lyme disease|Caustive Agent|Borrelia
procedure|component|substance	Measurement of Borrelia burgdorferi antibody | Component | Borrelia burgdorferi antibody Measurement of Borrelia burgdorferi 29 kDa antibody | Component | Borrelia burgdorferi 29 kDa antibody Borrelia burgdorferi band pattern dectected|Component| Borrelia burgdorferi antibody Borrelia burgdorferi DNA Assary|Component| Borrelia burgdorferi DNA
finding|interpret|procedure	Lyme ELISA equivocal|Interpret|Lyme ELISA test

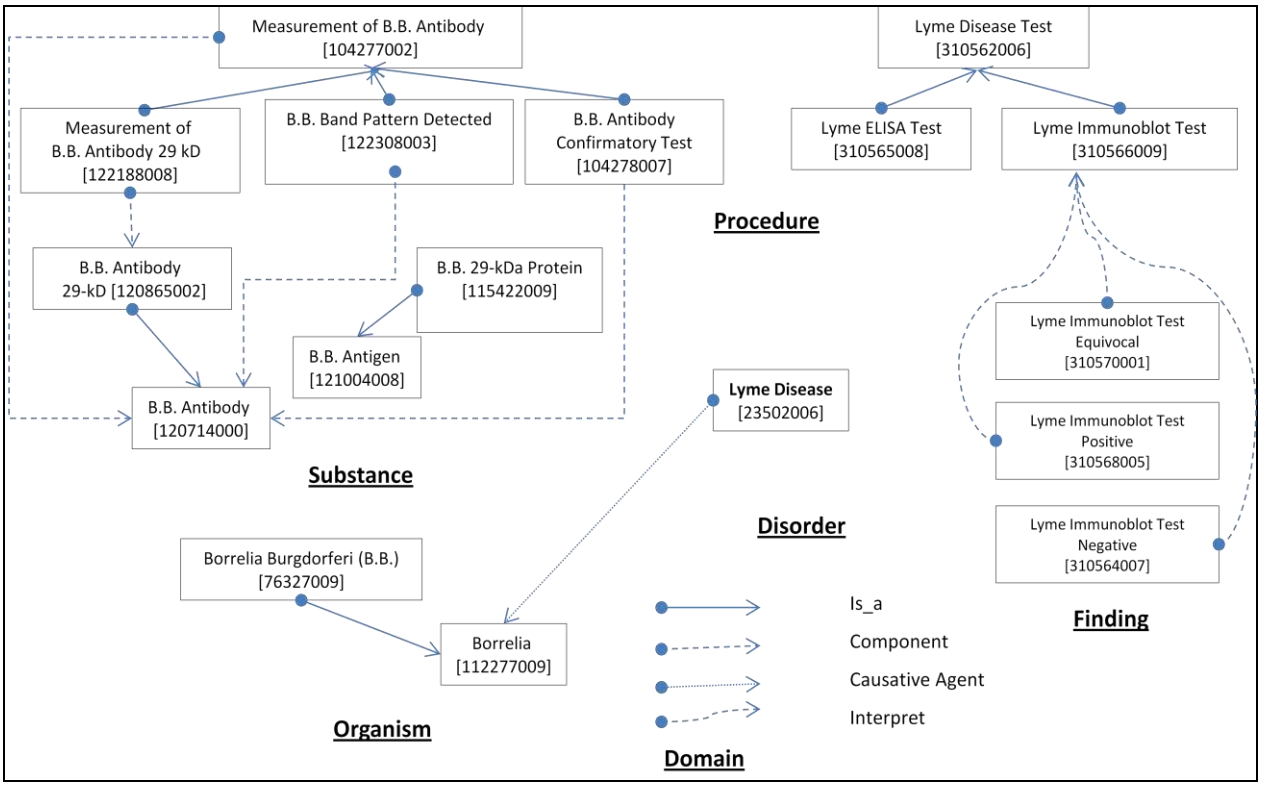

Figure 2. Examples of concepts related to Lyme disease in SNOMED CT. Numbers in brackets are SNOMED CT identifiers.

We retrieved one diagnosis concept from the RED (Lyme disease), 101 laboratory procedure concepts (tests and panels), and one organism concept (Borrelia burgdorferi). A total of 57 test and panel concepts are actually used to code EHR data. RED relationships found in these concepts included "procedure has component", "diagnostic procedure has targeted infectious organism", and "procedure has measured gene product". Figure 3 illustrates the example of the Lyme Disease Cerebrospinal Fluid (CSF) Antibody Panel (C1163227) and its two components: an antibody screen test (C116326) and a confirmation panel (C119063). The confirmation panel, in turn, includes Western blot IgG and IgM tests. The Lyme Disease CSF Antibody Panel targeted the bacterium B. burgdorferi and measured the antibodies.

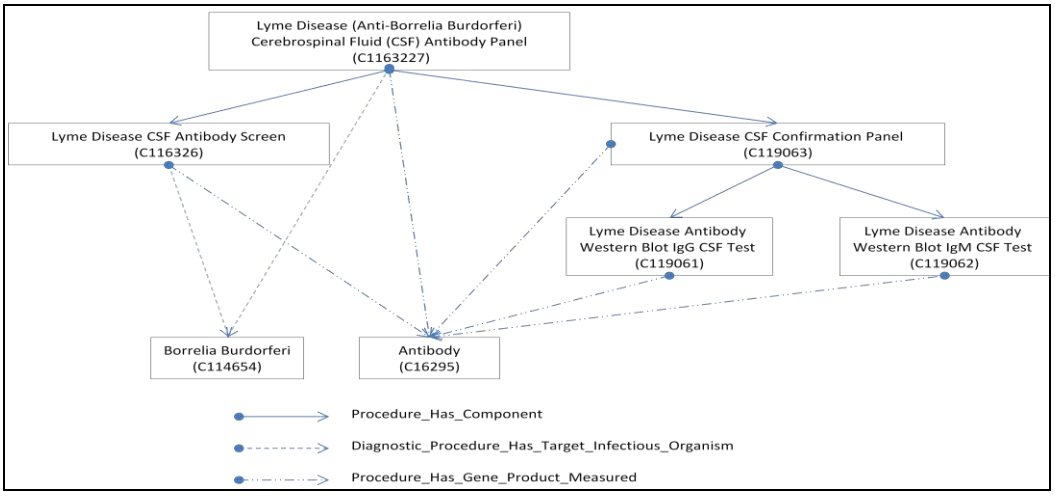

Figure 3. Examples of concepts related to Lyme disease in the RED. Numbers in brackets are RED codes.

Adding Concepts and Relationships to the RED

The RED substance concepts were expanded to include B. burgdorferi gene products, antigens, antibodies, IgG and IgM, and IgG and IgM to specific antigens. We did not add additional laboratory terms because the RED laboratory terms already cover the available EHR data. Terms for findings were not included in the current stage of the project.

Instances of the "Substance measured" relationship were added between the substance and laboratory test terms. Figure 4 illustrates examples of added concepts and links. A "has causative agent" relationship was created and an instance of that relationship was added between Lyme disease and Borrelia burgdorferi.

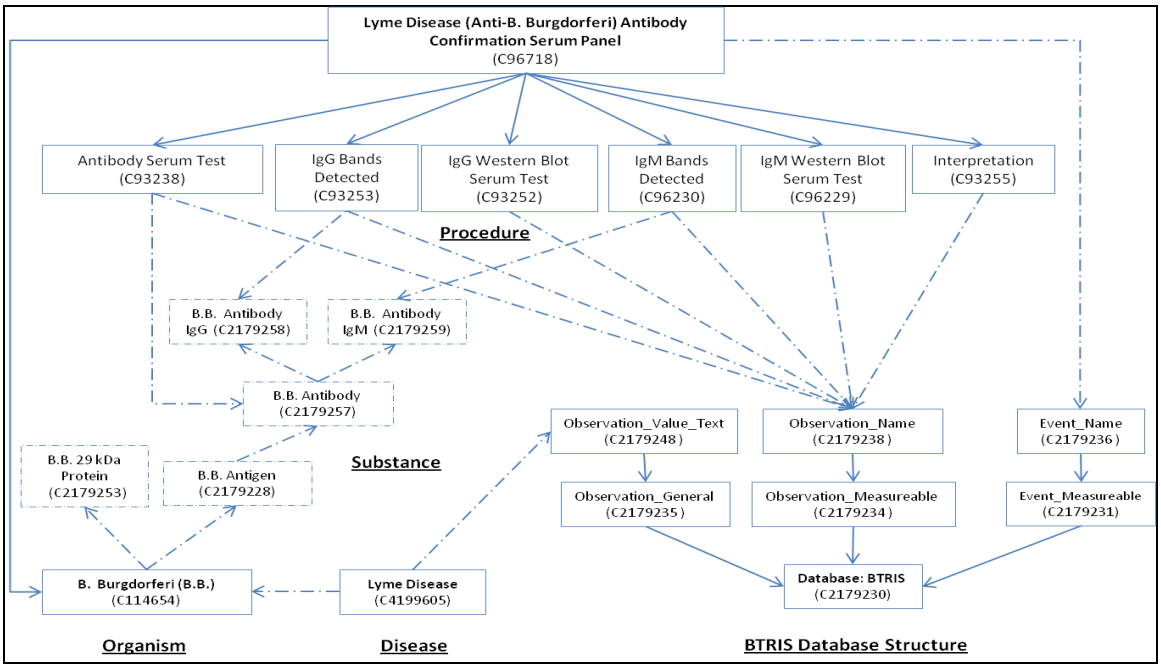

Figure 4. Concepts and relationships added to RED to represent EHR database concepts and relate them to EHR data concepts.

Linking EHR Data Concepts to BTRIS Database Structures

We related domains of EHR data concepts to specific database concept as follows. Diagnostic terms were related to the Observation_General table. Laboratory test order terms (panels) were related to the Event_Measurable table. The terms that were both tests and orders (basically, panels containing only one test) were related to both Event_Measurable and Observation_Measurable tables.

We defined the database column associated with laboratory test results (not shown in Figure 4). A specific organism's RED code appears in the Observation_Value_CONCEPT column, and its name appears in the Observation_Name. Table rows associated with laboratory tests of particular interest included those for which the RED concepts were "Specimen" and "Culture Comment" in the Observation_Name column.

In BTRIS, laboratory finding values are in Observation_Value_Text or Observation_Value_Numeric columns, depending on the format of the value. When a RED concept was available (such as for B. burgdorferi), the code was recorded in the Observation_Value_Concept column. Additional textual information is stored in Observation_Note and Observation_Value_Name columns.

Identify Pathways that ultimately Relate concepts of interest to Data Structure

The general knowledge structure supports the semantic expansion of the concept of interest to EHR data concepts that connected with database concepts. The expansion allows us to follow the concept of interest to its associated concepts from different data domains to identify patients. In the following example, we demonstrate how starting from Lyme disease, to generate SQL queries and retrieve patients who had diagnostic (confirmatory) laboratory tests. We looked up Lyme disease and related EHR data concepts which led to B. burgdorferi, the causative

organism, and then B. burgdorferi Antibody IgG and IgM, the measureable substances (step 1). We set concepts association value as where the concepts are these two substances and the association is substance measured (step 2). We used this list of B. burgdorferi Western blot tests to obtain patient data from BTRIS (step 3).

Step 2: To obtain the list of concepts representing tests measured B. burgdorferi Antibody IgG and IgM

```
"SELECT Distinct [Concept_ID] , [Database_Concept_Column], [Database_Concept_Table]
  FROM [BTRIS].[RED_Knowledge_Structure]
  WHERE Substance_Measured in (' B. burgdorferi Antibody IgG ',' B. burgdorferi Antibody IgM')
```

The list of tests includes C92569, C93238, C93253, C96230, C93416, C96770, C96713, C119061, C119062, and they are associated with the Observation_Measurable table, and the Observation_Name_CONCEPT column.

Step 3: To identify patients with laboratory results of B. burgdorferi Antibody Western blot IgM and IgG tests

```
"SELECT *
  FROM [BTRIS].[Observation_Measurable][Database_Concept_Table]
  WHERE Observation_Name_CONCEPT [Database_Concept_Column] in (<List of tests>)
```

Discussion

In this study, we added knowledge of an external clinical terminology and relational database structures to a repository terminology for semantically enhanced EHR data retrieval. Although we only focused on Lyme disease; our specific approach can be applied to any infectious diseases (looking for organisms that cause disease) and this general approach of identifying concept relationships should be applicable to any domain. The knowledge sources used, SNOMED CT and RED may currently be incomplete, but they are expandable and growing. We also consider other knowledge sources such as LOINC or co-associations of terms in PubMed citations [6, 7].

Our approach for knowledge extraction is based on established and validated methods in ontology development. For efficient query evaluation, we can measure patient data retrieval performance. We need to work with human raters to construct a gold standard from our EHR data sets. We can then test the retrieval results based on queries generated against the gold standard to calculate recall and precision. The actual validation work is beyond the scope of this paper.

All the work was done manually. Automated steps can be considered in the process of knowledge extraction from knowledge resources and mapping database structure concepts. Since the locations of concepts in tables and columns have been specified, SQL statements can be generated programmatically [8]. Currently our knowledge model does not handle the assessment of results (for example, to determine if a test result is positive or negative). Additional steps in the SQL query can assist with this or results could be processed through some other means if this is desirable. A richer knowledge model can open more fields in the EHR systems and support dynamic SQL for users.

This study only focuses on coded EHR data. The queries can be expanded to text searches. For example, some lab tests' names are too general without specific clinical meaning, such as "Other Laboratory Test" so that a further linking process is needed to connect text data stored in the results or notes. The names of all related concepts and their synonyms are the key terms to identify patient information from textual clinical data. Natural language processing (NLP) techniques can be applied and help the connection of the concept of interest to relevant clinical data hidden in the text.

This knowledge model can be applied to other EHR system. We consider the use of HL7 RIM as the intermediary, with the FHIR mapping [9] as the key to connect our knowledge model with local coding systems used in other system. Through mappings, the knowledge model can be replicable, and relevant concepts related to concepts of interest will be connected to their local EHR data concepts. The work left is to add and link database structure concepts of their own databases.

Conclusion

We constructed a simple general knowledge structure and used it to relate a concept of interest, Lyme disease, to EHR data concepts and their database concepts with specified values of identifiers (table and column) corresponding to BTRIS data structures. This method could be applied to any EHR database in which coded data are stored in specific structures based on their classification.

Does Query Expansion Limit Our Learning? A Comparison of Social-Based Expansion to Content-Based Expansion for Medical Queries on the Internet

Christopher Pentoney[1], Jeff Harwell[1], Gondy Leroy PhD[1,2]
[1]Claremont Graduate University, Claremont, CA; [2]University of Arizona, Tucson, AZ

Abstract

Searching for medical information online is a common activity. While it has been shown that forming good queries is difficult, Google's query suggestion tool, a type of query expansion, aims to facilitate query formation. However, it is unknown how this expansion, which is based on what others searched for, affects the information gathering of the online community. To measure the impact of social-based query expansion, this study compared it with content-based expansion, i.e., what is really in the text. We used 138,906 medical queries from the AOL User Session Collection and expanded them using Google's Autocomplete method (social-based) and the content of the Google Web Corpus (content-based). We evaluated the specificity and ambiguity of the expansion terms for trigram queries. We also looked at the impact on the actual results using domain diversity and expansion edit distance. Results showed that the social-based method provided more precise expansion terms as well as terms that were less ambiguous. Expanded queries do not differ significantly in diversity when expanded using the social-based method (6.72 different domains returned in the first ten results, on average) vs. content-based method (6.73 different domains, on average).

Introduction

Searching for medical and healthcare information is the third most popular online activity[1]. However, it poses several difficulties to online health information consumers: composing good queries, identifying objective information, and understanding the content. The second and third problems have been the topic of much research. Evaluating the quality of websites automatically and manually has been shown not only to be possible, but also effective[2], and there exist tools and frameworks for evaluating health information online specifically[3,4]. Improving understanding has relied on readability formulas, and more recently, evidence-based corpus-driven simplification. The readability formulas are applied to a variety of text, e.g., for patient education materials[5,6], bereavement materials[7], informed consent forms[8],and even survey instruments[9]. The formulas are recommended to help evaluate text[10] suggested by government instances and in IRB training courses. More recent corpus-based approaches use semi-automated simplification and have demonstrated that using more familiar terms, grammar structures, or shorter noun phrases is associated with both perceived and actual text difficulty[11,12].

The first problem is less frequently addressed or placed as the goal of information systems development in the medical field. This is an issue because knowing what type of information is best to present to a user can be difficult. Especially with complex medical terms and conceptual relationships, naïve users may not have enough knowledge to even form an effective search query. A current, popular solution of generic search engines, e.g., Google, is to automatically offer additional terms to a user that might help better define their search. Relevant terms are typically appended to the user's search based upon popularity of similar searches conducted by other users[13]. While query formation has also been subject of considerable research, it only became a common tool when Google provided their automatic query completion.

This study compares Google's method of query expansion to another method that focuses on the information within the documents being searched. Our goal is to evaluate the effect of using the different query expansion terms on the query and the query results. Since the social-based queries rely on other people's queries, they may make searching less diverse. At the population level, this may lead to less information being read and digested. If this limited information happens to be biased or untrue, the longitudinal effects may affect the general population. To evaluate social-based expansion, we compare it with an objective, text-based query expansion baseline that uses the existing text on the Internet as the basis for query expansion. In order to explore information, it may be more useful to expand based on what exists in the documents rather than what other people are searching. If searchers are already naïve, using their queries would seem to be a somewhat misguided way to finding reliable health information online.

Background and Significant Information

Online Medical Search

With 72% of internet users in the U.S. responding that they have searched online for health information in 2013[14], there is a clear need to deliver this knowledge in a way that presents internet users with reliable information. Furthermore, 77% of people who searched online for information about health said that they began the search with a common search engine (i.e. Google, Bing, Yahoo), and 52% of smartphone owners say that they have even used their phones to search for medical information[14]. People are constantly looking for health information, even on-the-go, and it needs to not only be reliable, but accessible. It is important for search engines to return medical knowledge that is useful and trustworthy. One way to make this information accessible is to guide people to useful information through the use of query expansion. By helping them form their searches, a search engine can provide relevant information.

Query Expansion

Returning relevant and reliable information can be difficult. Natural language itself is often very ambiguous, and health language is no exception; it is further complicated by medical jargon. Query expansion helps guide a user in generating a query by suggesting search terms that may be relevant to their search. Historically, these additional terms have been generated through methods such as relevance feedback, co-occurrence, and ontologies[15]. This is not a trivial problem since words can have multiple meanings and different words can share similar meanings. Many expansion techniques were evaluated at the Text Retrieval Conferences (http://trec.nist.gov/) with varying results. However, regardless of technique, most expansion methods showed improved search results. Today, query expansion as offered by Google is based on overall popularity of search queries already submitted by others[13]. While it has been shown that successive querying (more queries) leads to looking for increasingly serious conditions[16], the effect of query expansion (more terms) is unknown. For the individual, seeing alternate query options may lead to more diverse searching or a different search than originally intended. For the population of all searching individuals, reusing queries may lead to less diverse search and even more limited medical domain knowledge.

While other research has explored different methods to expanding queries in medical text, none has used the actual document text to suggest additional terms. Knowledge-based types of query expansion that leveraged the Unified Medical Language System (UMLS) as a related information source for expanding queries led to increases in precision-recall[17]. Expansion methods that employ the UMLS Metathesaurus for expansion with synonyms or hierarchically related terms[18] showed similar improvements. Using these content-based or knowledge based methods of query expansion have advantages over the social-based methods, and they should be compared.

Research Interests

Our overall interest was to determine the differences between two different methods of expanding medical queries. It is possible that the social-based expansions will not offer diverse enough results, which may result in a misleading picture of the results. This particular project addressed a comparison between the status quo (Google's social-based expansion) and a content-based expansion method that can sometimes present results more clearly. Given these two types of expansion methods, we were able to conduct a study that explored two questions: (1) how do the expansion terms for medical queries differ based on expansion type, and (2) how do results differ based upon expansion type? Google searches were conducted using each of the methods on 1% of the queries that were identified as being medically relevant.

Using existing knowledge, as found in text, to expand medical queries may provide some benefit over socially popular expansion types. Current social-based methods may help to spread common misunderstandings or misinformation, while content-based methods will show term relationships that exist in text already. Furthermore, as popularity of a term increases, it may become easier for people to come across information that is only popularly searched, and much more difficult to find new knowledge. This study investigates both content-based and social-based expansion types.

Social and Content-based Query Expansion

Nearly a quarter (24.2%) of all queries in the AOL User Search Collection was identified as trigrams, whereas only 19.9% were bigrams and 17.4% were unigrams. Since trigrams were so frequent, we decided to limit the study to all three keyword searches.

Social-based expansion i.e., Google's Auto-complete function, involves appending the search with terms that have been popularly used by other individuals who have searched with similar queries. In order to do this type of expansion, we programmatically submitted queries to Google. Google's suggestions were obtained using Google's Autocomplete API[19] and a Python 2.7 script that sent each search with its expansions to the Google Search (URL: https://ajax.googleapis.com/ajax/services/search/web?v=1.0&rsz=8&q=). The returned set contains 10 queries. We use all of these top 10 suggestions to expand upon, although it is unclear what the order is based on. Each suggested term is added to the initial query to provide a more precise search.

Content-based expansion depends upon the text in online documents themselves. We used the 2006 Google Web Corpus[20], which reflects the index of all sites available to Google. Since we used trigram queries, the four-gram data contained in the corpus (approximately 1.3 million) was needed to suggest the additional terms: the original trigram and one extra term. Punctuation and symbols were filtered out before matching the queries to the Web Corpus in order to find text matches.

Table 1 below shows how the two types of expansion yielded different searches. Typically, the content-based expansion led to broader expansion terms, which have more Google results overall. Even though terms may have been related between the expansion types (i.e. "seroconversion" and "labor"; "figures" and "info"), the content-based ones were often times more broad and returned a larger number of results from Google.

Table 1. Examples of social-based and content-based query expansions with the number of results returned by Google.

Original Search	Social-Based Expansion	Content-Based Expansion
HIV testing during	HIV testing during seroconversion (122,000 results)	HIV testing during labor (2,200,000 results)
Obesity and blood pressure	Obesity and blood pressure cuff (1,050,000 results)	Obesity and blood pressure baby (15,900,000 results)
Diabetes Facts and	Diabetes facts and figures (1,690,000 results)	Diabetes facts and info (21,900,000 results)

Study Design

Stimuli

Medical Queries: Queries were obtained from the AOL 500k User Session Collection, which is a set of approximately 20M queries from 650K AOL users gathered during a three-month period in 2006. We selected queries that matched terms from the UMLS that were associated with the following UMLS semantic types: antibiotic, disease or syndrome, injury or poisoning, or body substance. We choose these semantic types because they are related to top medical concerns as described on Health.gov. The fourth gram of a four-gram was used to expand the base three-gram queries for content-based For each query, we collected up to ten expansion terms using both methods. This results in a total of 346,145 expanded queries. However, since each query is submitted to Google for the results evaluation and to complete the project in a reasonable time frame, we extracted a random 1% sample

for the analysis. This provided 1,731 expanded searches for social-based expansions, and 1,731 expanded searches for corpus-based expansions.

Variables

There was one independent variable used in the study: query expansion type. All medical queries were expanded in two fashions: using social query expansion and using content query expansion.

We evaluated the effect of expansion on the query itself using *specificity* and *ambiguity* and on the results by using *domain diversity* and *expansion edit distance*. These metrics were chosen because they provide an objective, if not complete, evaluation of queries and because they can be used for large sets of queries in an automated fashion. The first two dependent variables (ambiguity and specificity) help evaluate the effect of expansion on the queries. They are of interest because they measure how easily understood a word might be. Words that are more ambiguous have more possible meanings and would be expected to lead to more diverse results. Words that are more specific are further down a conceptual hierarchy (i.e. German Shepard is more specific than dog) and would be expected to result in a more focused results set (even though that set of results can be large). Both are calculated using WordNet 3.0 through the NLTK for Python 2.7.

Ambiguity was calculated as the number of synsets for a specific term, or how many different concepts that word can have. For example, the word "dog" has eight synsets or cognitive synonyms in WordNet, while the word "beagle" only has 1. This is an indication of how many different concepts each word might have, suggesting that "dog" is more ambiguous than "beagle."

Specificity was as the depth in the hypernym path of the first synset for each word. In this case, "dog" is found at the ninth level in WordNet's tree (top term is simply: "entity"), while "beagle" has 12, indicating that "beagle" is a more specific term conceptually than "dog."

The effect of expansion on the results themselves was measured by the *diversity* of domains in the results. Similarly, this measure was chosen because it is a straightforward way to evaluate the number of different domains returned by a search. This was measured using the Google Search API, which returns results as a JSON object given a query. Results returned show the base URL of each result as seen in Table 2.

Table 2. Example of the top three domains returned by a content expanded query and social expanded query.

Query	Top Three Domains
HIV testing during seroconversion (Social-based expansion)	www.healthline.com www.aidsmap.com www.jhsph.edu
HIV testing during labor (Content-based expansion)	www.aids.gov www.cdc.gov www.jiasociety.org

Finally, the *expansion edit distance* was calculated to compare the effect of an expanded query to the original (unexpanded) query. This was done in both a ranked and unranked manner. In the unranked method, the order of results was not taken into account, only the domains themselves. Searches that returned one different result when the expansion was included compared to when it wasn't would have a distance of 1. For example, in the results above, if the query "HIV testing during seroconversion" had returned "www.thebody.com" instead of "www.jhsph.edu," but the other two returned domains had been the same, the unranked edit distance would be 1. For the ranked edit distance, order was taken into account. For example, if the query had this time returned had returned

"www.thebody.com" instead of "www.jhsph.edu," and "www.healthline.com" and "www.aidsmap.com" had been switched in order, the edit distance would be 2.

Results

Searching the 3462 expanded queries required approximately 38.2 hours to complete using a Python script with the Google Search API previously described.

Table 3 shows the details of expansion type on ambiguity and specificity of queries. We provided the numbers for the entire set, and for the subset that were used to evaluate the results. Since the original query did not change, only the expansion terms, these numbers were averages of the expansion terms only.

Overall, the social-based expansion terms were almost an entire level more specific in the WordNet 3.0 hierarchy. The difference in ambiguity was larger. On average, there was an extra meaning (sense) for content-based expansion terms versus social-based expansion terms. A similar trend is seen for the 1% sample, although the differences are smaller.

Table 3. Query Evaluation: Average specificity and ambiguity for different query expansion types.

Complete Set (N = 346,145)	Specificity	Ambiguity
Social-based (N = 277,319)	7.89	6.37
Content-based (N = 68,826)	7.01	7.68
1% Sample (N = 3462)		
Social-based (N = 1731)	7.16	7.37
Content-based (N = 1731)	7.10	7.50

This means that for each individual using this query expansion method, the social-based method adds a term that narrows the search term to a subcategory of the original search. These words also tend to have fewer different meanings.

Table 3 also shows the results of social-based and content-based expansion the results of the search. The number of unique domains did not vary depending upon the type of expansion used. For content-based expansion, an average of 6.73 (SD = 1.53) unique domains were returned, for social-based expansions an average of 6.72 (SD = 1.55). A Welch's t-test showed no significant difference in domain diversity for the two expansion types ($t = .04$, $p = 0.96$, $d < 0.01$).

Table 4 shows the expansion edit distance (steps needed to go from unexpanded to expanded result set) for the two expansion types. There was a statistically significant difference between ranked social-based and content-based expansion. The social-based expansion had a slightly higher edit distance (M = 6.67, SD = 1.57) than content-based expansion (M = 6.44, SD = 1.73) $t(3,460) = 4.07$, $p < .001$. This means that, on average, social-based expansion resulted in more different results before and after expansion than the results from the content-based expansion. It is important to note, however, that the mean difference was small (0.23), and may not be a meaningful difference although it is statistically significant. The difference between the unranked edit distance was also significant in the same direction, such that social-based queries had a slightly higher unranked edit distance (M = 4.61, SD = 2.00) than content-based queries (M = 4.38, SD = 2.20), $t(3,460) = 3.22$, $p < .01$. In other words, query expansions matters: expanding the queries by a single term caused four of the ten results to change, on average.

Table 4. Average edit distances for top ten results from content-based and social-based expanded queries.

	Ranked	Unranked
Content-based (n = 1731)	M=6.44 SD=1.73	M=4.38 SD=2.20
Social-based (n = 1731)	M=6.67 SD=1.59	M=4.61 SD=2.00

Discussion

Two main findings stand out from this study. First, there is an interesting difference in specificity and ambiguity in the content-based expansion and social-based expansion. Terms generated through social-based expansion tended to be less ambiguous (have fewer different meanings) and more specific (further down the concept hierarchy) than terms created through content-based expansion. Since social-based expansion takes into account the popularity of searched phrases, it is likely that people use much more specific terms when they are searching information than actually exist in the text online. Information that exists on the web is written to express a certain point or relationship an author wants to express.

Secondly, although the findings above show that the two types of expansions resulted in different types of terms on average, there was almost zero difference in diversity of domains returned. However, since the starting queries in the 1% were less different based on expansion method, the results have most likely been affected. There is the possibility that Google purposely places a similar number of domains for every query in order to keep results diverse. In addition, a limitation of our work is that we could not directly compare the domains returned by social-based to content-based queries. On an individual query basis there was no good way to pair queries for a matched comparison. That is, a social-based expansion "hiv during seroconversion" is asking for different, more specific information than "hiv during pregnancy," and would obviously return different domains. Because of this, we only were able to compare the *number* of different domains returned by each expansion type, on average.

Edit distances provided some interesting information. Although the small difference in edit distance between the two expansion types was statistically significant, the raw difference was small. It is worth noting, however, that the addition of the terms from their base query did change results by quite a bit. Not only was the order of existing results changed, but nearly half of the results completely changed depending upon whether the query was expanded or not. At the very least, it can be argued that expanding does matter, but the method of expansion may not matter as much. It is unclear how much the expansion would affect user behavior, and subjective evaluation from human raters is necessary to further investigate the results here. Furthermore, there may be some impact of Google's AdWords on results in a real user setting. Certain search results will actually be from paid advertisements that are a function of the keywords searched. These were not collected in this study, but would likely have some influence on actual search behavior nonetheless. It may be hypothesized that users form subsequent queries based on the text of initial results. As such, paid advertisements within the results may influence what is being searched.

Overall, the small size of these effects is surprising, but there is the possibility that there may still be an impact on the diversity of information people read. More studies are needed evaluate the effects of the current query expansion on health information consumption. A further limitation is that this study represents only the effects on one query followed by an expanded query. The effect may be much more pronounced when 3 or 4 searches on one topic (as would be common for someone searching online) are combined. An engaged user is very likely to have interest in a topic beyond a single query. The effect could be such that results end up converging, or diverge even further. The effect could be such that search results converge or diverge even further. The actual impact of the human behavioral process of searching is a complex question that requires further study. Current directions in this work involve exploring how an individual user forms multiple queries upon the same search topic.

A final limitation of this study was the sole use of objective measures, so there was no direct human interaction with the search process. Subjective evaluations from human raters will be added to fully evaluate the results and look at the quality of information and the ability of readers to form a comprehensive picture.

Conclusion

Queries can be expanded using content from the documents being searched to provide queries that are broader on average than terms used by popular social-based expansion methods. Both social-based and content-based methods of expansion do not lead to differences in diversity of information returned on the internet, but whether or not the results differ in other ways is unknown. It is possible that one of the two methods returns *better* results depending on different criteria. Further research is needed to explore this possibility.

Future work will include subjective ratings of results and expansion terms in addition to analysis of temporal trends and human interaction studies with concrete search tasks. Specifically, the effects of multiple queries on a search topic need to be investigated to provide a more complete picture of how different types of search expansion affect the results returned. It is unlikely that an interested individual would conduct a search on a topic using a single query. In addition to research on the process of searching, evaluation of the search results needs to be refined and measured using broader criteria, such as subjective ratings of the quality and diversity of webpages. Ultimately, human raters and searchers will be a crucial part of next steps in this research, including the formation of queries and multiple search process, as well as the subjective evaluation of search results. Subjective ratings will give insight into human understanding and initial response to results returned by the different expansion types. Exploring results from search engines (i.e. Bing or DuckDuckGo) may also provide different results, but it is unclear what direction those results might go. Ultimately, more interaction from human raters is needed to draw strong conclusions about the different expansion types.

ARX - A Comprehensive Tool for Anonymizing Biomedical Data

Fabian Prasser[12], Florian Kohlmayer[12], Ronald Lautenschläger[1], Klaus A. Kuhn[1]
[1] Technische Universität München, München, Germany, [2] Equal contributors

Abstract

Collaboration and data sharing have become core elements of biomedical research. Especially when sensitive data from distributed sources are linked, privacy threats have to be considered. Statistical disclosure control allows the protection of sensitive data by introducing fuzziness. Reduction of data quality, however, needs to be balanced against gains in protection. Therefore, tools are needed which provide a good overview of the anonymization process to those responsible for data sharing. These tools require graphical interfaces and the use of intuitive and replicable methods. In addition, extensive testing, documentation and openness to reviews by the community are important. Existing publicly available software is limited in functionality, and often active support is lacking. We present ARX, an anonymization tool that i) implements a wide variety of privacy methods in a highly efficient manner, ii) provides an intuitive cross-platform graphical interface, iii) offers a programming interface for integration into other software systems, and iv) is well documented and actively supported.

Introduction

Collaboration and data sharing have become core elements of biomedical research; see, e.g., the joint statement on sharing research data[1] and the guidelines for access to research data of the *Organization for Economic Co-operation and Development* (OECD)[2]. For clinical data, and increasingly for genetic data as well as for combinations of these data, there is a growing understanding of related privacy threats. Disclosure of data may lead to harm for individuals, especially when different data sources are available for linkage[3]. From the legal perspective, national laws, e.g., the *Health Insurance Portability and Accountability Act* (HIPAA)[4] *Privacy Rule*, and international regulations, e.g., the *European Directive on Data Protection*[5], mandate stringent protection of personal data.

The HIPAA Privacy Rule[6] defines two basic methods for de-identifying datasets. The first requires the removal of a pre-defined set of attributes from the dataset. This procedure significantly reduces re-identification risks[7], but it can *1)* obstruct data use if the involved attributes are essential[8], and *2)* under certain circumstances not prevent re-identification[9]. The second method is "expert determination": A professional "determines that the risk is very small that the information could be used […] to identify an individual"[6]. In this context, *statistical disclosure control* (SDC) allows balancing privacy risks with data quality[8]. Examples include methods focusing on data extracts, such as *differential privacy*[10], and methods for microdata release, such as *k-anonymity*[11].

In the biomedical domain, methods for microdata release are currently preferred[12]. The primary reason for this is that they can be implemented with non-pertubative methods that preserve the truthfulness of data[12]. They have been included in guidelines of best-practices for de-identifying health data[13], and they have been successfully applied to research data[14]. Moreover, many approaches for microdata release have been developed specifically for the biomedical domain[15,16,17].

Objectives

Although anonymization is an important method for privacy protection, there is a lack of tools which are both comprehensive and readily available to informatics researchers and also to non-IT experts, e.g., researchers responsible for the sharing of data. As protection has to be balanced against losses in data utility, responsible researchers should be able to keep an overview of the anonymization process and the trade-offs chosen. This requires powerful but easy to use tools which can be integrated in research workflows. *Graphical user interfaces* (GUIs) and the option of using a wide variety of intuitive and replicable methods are needed. Tools have to offer interfaces allowing their integration into pipelines comprising further data processing modules. Moreover, extensive testing, documentation and openness to reviews by the community are of high importance. Informatics researchers who want to use or evaluate existing anonymization methods or to develop novel methods will benefit from well-documented, open-source software libraries. The lack of such a framework is illustrated by the fact that, although data anonymization has been researched for a long period of time already, only recently efforts have started to systematically evaluate and compare existing methods[18,19].

The landscape of existing tools is heterogeneous. *PARAT*[20] is the leading commercial de-identification software. It is a closed-source tool for which only limited information is available to the public. We will focus on

non-commercial tools in the remainder of this article. The *UTD Anonymization Toolbox*[21] and the *Cornell Anonymization Toolkit* (CAT)[22] are research prototypes that have mainly been developed for demonstration purposes. Problems with these tools include scalability issues when handling large datasets, complex configuration requiring IT-expertise, and incomplete support of privacy criteria and methods of data transformation. *sdcMirco*[23] is a package for the *R* statistics software, which implements many primitives required for data anonymization but offers only a limited support for using them to find data transformations that are suitable for a specific context. *μ-Argus*[24] is a closed-source application that implements a broad spectrum of techniques, but it is no longer under active development. A comparison of our work with these tools is presented in the *Discussion* section.

To overcome these limitations we present ARX, a comprehensive open-source data anonymization framework that implements a simple three-step process. It provides support for all common privacy criteria, as well as for arbitrary combinations. It utilizes a well-known and highly efficient anonymization algorithm. Moreover, it implements a carefully chosen set of techniques that can handle a broad spectrum of data anonymization tasks, while being efficient, intuitive and easy to understand. Our tool features a cross-platform user interface that is oriented towards non-IT experts. Additionally, it provides a stand-alone software library with an easy-to-use public *application programming interface* (API) for integration into other systems. Our code base is extensible, well-tested and extensively documented. As such, it provides a solid basis for developing novel privacy methods.

Background and Terminology

In the context of SDC, data is organized in a tabular structure, where each *record* represents the data about one individual. Basically, *identifiers* within a dataset are modified in such a way that linkage is prevented[25]: Firstly, highly distinguishing attributes that can be used for re-identification and that are not required for analyses are removed. Examples for such *direct identifiers* include *Social Security numbers* or names. Secondly, *quasi-identifiers*, i.e., attributes which are required for analyses while being potentially identifying are *recoded* to make sure that the data fulfills well-known *privacy criteria*[25]. Examples include the age or sex of data subjects. Data recoding is typically performed with *generalization hierarchies*[11], which can be built for categorical and continuous attributes (see Figure 1). To increase the utility of resulting datasets, this method is often combined with *tuple suppression*: data records that violate the privacy criteria (so called *outliers*) are automatically removed from the dataset, while the total number of suppressed records is kept under a given threshold[11]. As a result, less generalization is required to ensure that the remaining records fulfill the privacy criteria.

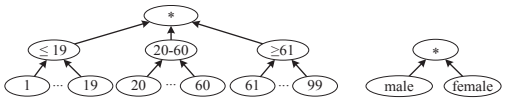

Figure 1. Hierarchies for attributes "*age*" and "*sex*"

k-Anonymity[11] is the most wide-spread privacy criterion. It ensures that each data record cannot be distinguished from at least k-1 other data records regarding the quasi-identifiers. It aims at protecting datasets against *identity disclosure*, i.e., from linking an individual to a specific data record by an attacker[26]. *ℓ-Diversity*[27] and *t-closeness*[28] aim at protecting datasets against *attribute disclosure*, where an attacker can infer information about an individual without necessarily linking it to a specific record in the dataset[26]. As an example, linkage to a set of records allows inferring information if all records share a certain attribute value. The attributes in which an attacker might be interested and which, if disclosed, could cause harm to the data subject are called *sensitive attributes*. Different variants exist for both criteria, which offer different privacy guarantees by enforcing different properties on the distributions of sensitive attribute values within a set of indistinguishable data records. *δ-Presence*[29] aims at protecting datasets against *membership disclosure*, which means that an attacker is able to determine whether or not data about an individual is contained in a dataset[26]. For an overview of further privacy criteria we refer to the work by Fung et al.[25].

Different types of algorithms can be used to transform datasets so that they fulfill a given set of privacy criteria. For the biomedical domain, the use of *globally-optimal full-domain anonymization* algorithms using *multi-dimensional global recoding* has been recommended[30]. These algorithms construct a search space, which consists of all possible combinations of generalization levels for all quasi-identifying attributes. This space of possible generalizations is then traversed to find a transformation that fulfills all privacy criteria while resulting in optimal data quality. To this end, utility is measured with *metrics* for information loss[25].

Methods

Our work aims at making data anonymization available to a wide variety of end users. We therefore decided to implement a type of algorithm that is intuitive to non-IT experts: a globally-optimal full-domain anonymization algorithm that uses multi-dimensional global recoding[17]. On the upside, such algorithms implement anonymization

procedures that can easily be configured by users, e.g., by altering generalization hierarchies or choosing a suitable transformation from the solution space, and result in datasets that are well suited for biomedical analyses[30]. On the downside, the underlying coding model is strict and potentially results in low data utility. To attenuate this, our framework combines the method with local tuple suppression. It increases data quality, but can also significantly increase execution times. Consequently, our tool is also able to approximate the result in much less time. Approximated results are guaranteed to fulfill the given criteria but might not be optimal in terms of data quality, because only some transformations in the solution space are classified with absolute certainty.

In order to cover a broad spectrum of privacy problems, our tool comes with implementations of all commonly used privacy methods: k-anonymity, all variants of ℓ-diversity, two variants of t-closeness, and δ-presence. A querying interface allows selecting a research subset, which is a subset of the data records that are to be included in the final anonymized dataset. Moreover, δ-presence can be enforced on the subset, i.e., attackers that know the overall dataset can be prevented from determining whether a specific tuple is included in the subset. In contrast to previous approaches our tool is the first to support classifying the complete solution space for arbitrary combinations of privacy criteria while using generalization *and* suppression. For assessing data utility, we included a large set of metrics for information loss, including simple methods, such as *height* and *precision* as well as more sophisticated approaches, such as *discernibility*[31] and *non-uniform entropy*[30].

Data and generalization hierarchies can be imported from many different types of sources in order to provide compatibility with a wide range of data processing tools. ARX currently features interfaces for importing data from *character-separated values* (CSV) files, *MS Excel* spreadsheets and *relational database management systems* (RDBMSs), such as *PostgreSQL* or *MySQL*. Data imported into ARX is immutable and cannot be changed. ARX implements several methods that can be used for identifying data quality issues: *1)* data can be sorted, compared and analyzed regarding statistical properties, and *2)* the query interface can be used to search for records with quality issues. For handling such issues, ARX supports the automated and manual removal of records. If more complex data cleansing tasks must be performed, data can be exported to other software systems. ARX safely handles missing values by treating them similar to all other values (i.e., missing values match other missing values)[32]. This scheme allows for truthful and non-truthful handling of missing values, depending on how they are generalized, without introducing privacy issues[32].

ARX offers methods for manual and semi-automatic creation of generalization hierarchies. Semi-automatic creation is supported for all common types of attributes, such as numerical (discrete or continuous) and categorical variables. Hierarchies can be generated by grouping values based on a natural or user-defined ordering, by mapping them into user-defined or automatically created intervals or by data redaction. Hierarchies are represented in a tabular manner, which is an intuitive representation that enables compatibility with third-party applications, such as spreadsheet programs.

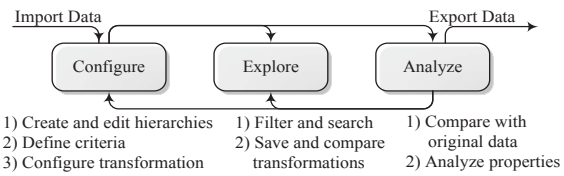

Figure 2. Implemented de-identification workflow

ARX supports all major aspects of data anonymization. These different aspects are combined in a multi-step process that allows users to iteratively adjust parameters, until the result matches their requirements. As depicted in Figure 2, the basic steps consist of *1)* configuring the anonymization process, *2)* exploring the solution space and *3)* analyzing the transformed data. In the configuration phase, the input data is loaded, generalization hierarchies are imported or created and all further parameters, such as privacy criteria, are specified. When the solution space has been characterized by executing the anonymization algorithm, the exploration phase allows searching the solution space for privacy-preserving data transformations that fulfill the user's requirements. To assess suitability, the analysis phase allows comparing transformed datasets to the original input dataset. Based on this analysis, further solution candidates might be considered and analyzed, or the configuration of the anonymization process might be altered. Our tool features a cross-platform graphical interface for non-IT experts. All methods implemented in ARX are accessible via the API and the GUI.

An important goal of our efforts is to make the anonymization framework, consisting of the graphical application and the software library, available to software developers and informatics researchers. To this end, we chose to implement it in the *Java* ecosystem, which offers one of the most popular cross-platform development environments. We chose to implement the GUI with the *Standard Widget Toolkit* (SWT) and the *JFace* library, which provide support for the native *look and feels* of the three most common platforms: *OS X*, *Windows* and

Linux/GTK. We spent extensive time on documenting our code as well as the public API and on adding a large set of examples to our code base. Our project has a high test coverage, featuring hundreds of unit tests with different configurations and a broad spectrum of input datasets, including a large set of tests for which the results were validated manually. Our website provides users with background information and extensive documentation[33].

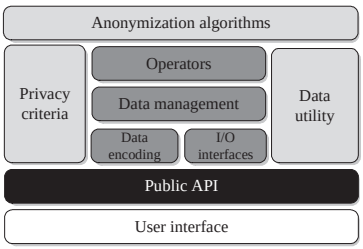

Figure 3. High-level architecture

A high-level overview of the architecture of ARX is shown in Figure 3. We carefully designed the framework, to prevent tight coupling of subsystems and ensure extensibility. The core modules (dark gray), which normally need not be modified, provide the basis for our framework. The *I/O module* provides methods for reading data from and writing data to external storage, while the *data encoding module* transforms the data into the format and memory layout required by the framework. The *data management module* deals with this internal representation and implements several optimizations (e.g., caching). Problem-specific *operators* are built on top of this representation and allow grouping of data records and computing of frequency distributions over sensitive attribute values. This provides the basis for extensible modules (light gray), which implement *privacy criteria* and metrics for measuring *data utility*. Analogously, anonymization algorithms can be plugged into the framework. Currently our tool features several variants of the *Flash* algorithm but the framework can be used to implement a large set of methods[18]. The public API is based on both the extensible and the core modules. It is also used by the graphical interface, which is completely decoupled from the internals of the framework.

Our three-step process poses considerable challenges in terms of efficiency. Firstly, ARX automatically classifies the complete solution space to support users in finding a transformation suitable for their application scenario. Secondly, the iterative character of the process potentially requires this classification to be performed repeatedly. It is thus very important that classification can be carried out in near real-time. For this purpose, our framework features a highly efficient algorithm[17]. Moreover, instead of using existing database systems, we implemented a runtime environment that is tailored to the problem domain. In previous work we have shown that our method significantly outperforms comparable algorithms within our highly optimized framework[18].

Results

In this section, we present an overview of the graphical interface for end-users which illustrates ARX's functionality. We then address the public API for researchers and software developers. Finally, we shortly analyze the scalability of our tool in terms of execution time and memory requirements.

Importing data and configuring the de-identification process

The graphical interface of ARX is divided into three perspectives that follow the workflow outlined in the previous section. In the first perspective, a dataset can be imported and the anonymization process can be configured.

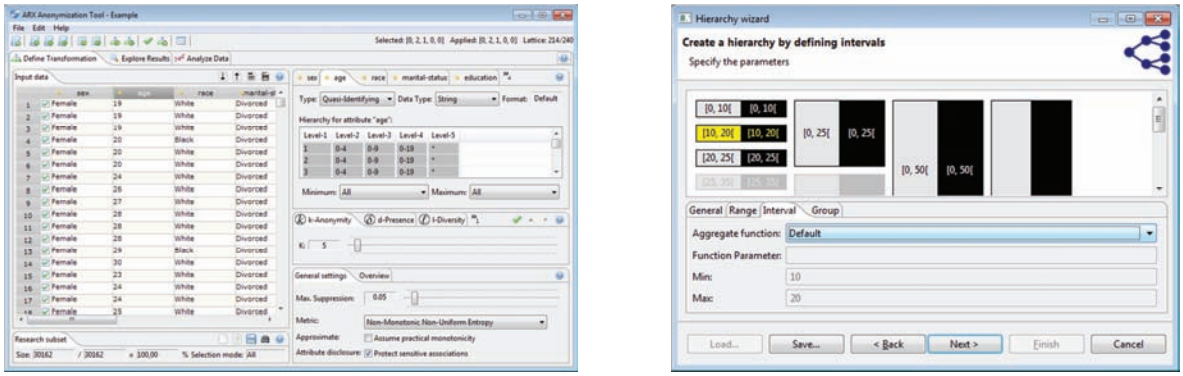

Figure 4. Interfaces for configuring the de-identification process and creating generalization hierarchies

A screenshot is presented in Figure 4. On the left-hand side, the imported dataset is displayed. Individual records can be included or excluded via checkboxes to define a research subset. An overview of the current subset is presented in the lower left area of the perspective. The header of the table showing the dataset also indicates the attribute type associated to each column in terms of a color scheme. These attribute types can be defined in the upper right area of the perspective: directly identifying attributes are removed from the dataset, quasi-identifiers are transformed by

applying the provided hierarchies, while sensitive attributes are not transformed but can be used to derive t-close or ℓ-diverse transformations. *Insensitive* attributes are simply kept unchanged. The area also displays a tabular representation of the generalization hierarchies associated to the attributes. Hierarchies can be edited manually, e.g., by adding and removing generalization levels or altering labels. The lower right area of the perspective allows for defining privacy criteria and for configuring the transformation and classification process. Important aspects include selecting the metric that is to be used for assessing data utility and defining an upper bound on the number of records that can be suppressed. When all parameters have been configured, the solution space can be classified.

ARX offers several wizards for semi-automatically creating generalization hierarchies. The wizard for interval-based hierarchies is shown on the right side of Figure 4. Intervals are a natural means of generalization for variables with a ratio scale, such as integers, decimals or dates and timestamps. Each level of the hierarchy is represented by one column, with the lowest level being defined by a sequence of intervals (leftmost column). Subsequent levels can be added by grouping any given number of elements from the previous level. Any sequence of intervals or groups is automatically repeated to cover a predefined range. For values outside of this range, *top and bottom coding* can be applied. Automatically created repetitions of intervals and groups are indicated visually.

Exploring the solution space

When the solution space has been classified, the exploration perspective allows users to browse the set of all possible transformations. The aim of the perspective, a screenshot of which is presented on the left-hand side in Figure 5, is to select a set of interesting transformations for analysis.

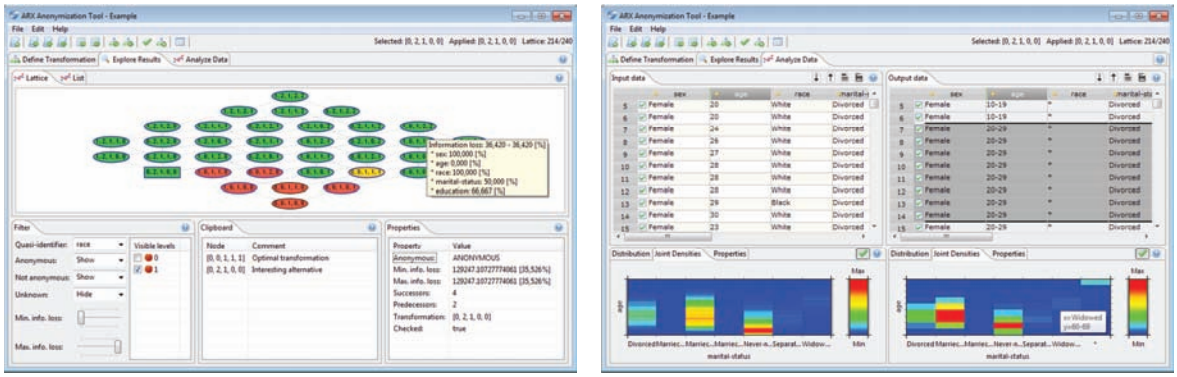

Figure 5. Interfaces for exploring the solution space and analyzing the results of data transformations

In the center of the screen, the view displays a subset of the solution space. Each node represents one transformation, which is identified by the generalization levels that it defines for the quasi-identifiers in the input dataset. Transformations are characterized by four different background colors: green denotes that the transformation results in an anonymous dataset, red denotes that the transformation does not result in an anonymous dataset, orange denotes that the transformation is the global optimum and gray denotes that the anonymity property of the transformations is unknown (only applies when approximating the result). The view supports zooming and moving the visualization of the solution space. Interesting transformations can be added to a clipboard, where they can be organized. Applying a transformation to the dataset allows exporting the resulting dataset or analyzing it in the view presented in the next section. A filter allows selecting a subset of the solution space by defining that only transformations with certain generalization levels, certain anonymity properties or with their information loss being within a defined interval should be visible. In case of an approximated result, this also includes transformations which are probably anonymous or probably non-anonymous. If such a transformation is applied, its actual anonymity property will be computed in the background and the state of the solution space will be updated.

Analyzing transformed data

A given privacy problem can often be solved with several different transformations. Although ARX is able to automatically find a solution which is optimal regarding the selected metric for data utility, automatically choosing an appropriate solution for a given usage scenario is often difficult. The aim of this perspective, which is shown on the right-hand side in Figure 5, therefore is to support users in assessing the utility of a transformed dataset for a specific application scenario. For this purpose, it allows comparing transformed data to the original dataset.

The perspective displays the input dataset on the left and the output dataset on the right. The tables are synchronized when scrolling, allowing an easy comparison of different parts of the data. The data can be sorted according to selected attributes. It is possible to toggle between showing the whole dataset or only the research subset. Moreover, the resulting equivalence classes can be highlighted. For comparing the statistical properties of two data representations, the view also shows the frequency distributions of values of a selected attribute in both tables. Moreover, a graphical representation of contingency tables for two selected attributes is included. This feature allows for visually comparing the combined occurrence of values from two different attributes. In the example, the number of values of the attribute "marital-status" remains the same, while the number of values of the attribute "age" is reduced from 100 to 10. Additionally, some values of the attribute "age" and exactly one value of the attribute "marital-status" have been suppressed. This is reflected by the heat map on the right-hand side, which shows a slightly shifted generalization of the contingency from the input dataset.

Programmatic access via the API

All features that are accessible via the graphical interface are also accessible via the public API. However, the aim of the programming interface is to provide de-identification methods to other software systems and we note that interaction with the software library provided by ARX will often be simpler than interaction with the graphical tool. Programmatic access will usually rely on ARX's ability to automatically determine a solution to a privacy problem.

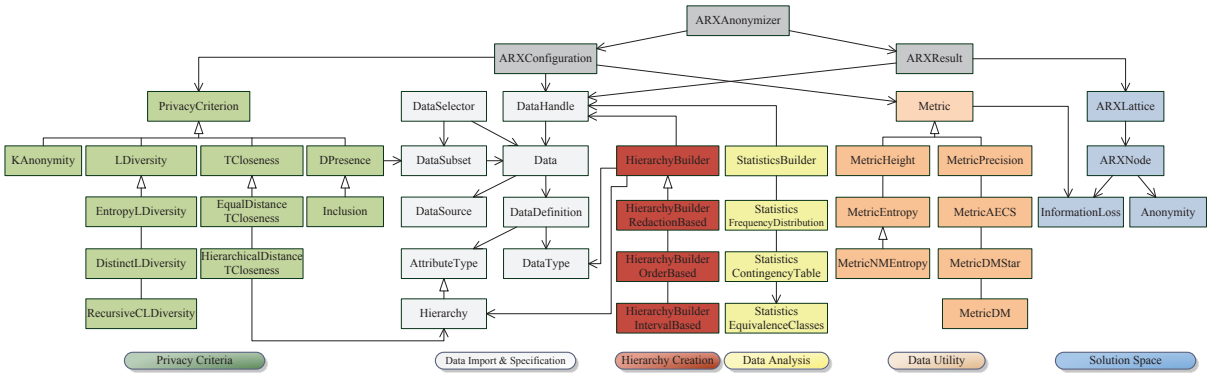

Figure 6. UML diagram of the most important classes in the public API

A *Unified Modeling Language* (UML) diagram of the most important classes of our API is shown in Figure 6. It can be seen that the API consists of a set of packages for *1) data import and specification*, *2) hierarchy generation*, *3) privacy criteria*, *4)* measuring *data utility*, *5) data analysis*, and *6)* representing the *solution space*. The classes `ARXConfiguration`, `ARXAnonymizer` and `ARXResult` provide the main interfaces to ARX's functionalities.

Data and attribute types are provided as static variables from the `DataType` and `AttributeType` classes respectively. The class `DataHandle` allows users to interact with the data (read-only), by performing operations such as sorting, swapping rows or reading cell values. Handles can be obtained for input data, output data and research subsets of such data. Data handles representing input and derived output data are linked with each other, meaning that operations performed on one representation are transparently performed on all other representations as well. For example, sorting the input data sorts the output data analogously. The class `ARXLattice` offers several methods for exploring the solution space and for obtaining information about the properties of transformations

```
/* Load data from SQLite database*/
DataSource source = DataSource.createJDBCSource("jdbc:sqlite:test.db", "test");
source.addColumn("zipcode", DataType.STRING);
source.addColumn("age", DataType.INTEGER);
source.addColumn("diagnosis", DataType.STRING);
Data data = Data.create(source);

/* Create hierarchy with redaction*/
data.getDefinition().setAttributeType("zipcode", HierarchyBuilderRedactionBased.create(Order.RIGHT_TO_LEFT, Order.RIGHT_TO_LEFT, ' ', '*'));

/* Load hierarchies*/
data.getDefinition().setAttributeType("age", Hierarchy.create("age.csv", ';'));

/* Define sensitive attribute*/
data.getDefinition().setAttributeType("diagnosis", AttributeType.SENSITIVE_ATTRIBUTE);
```

Figure 7. Importing data and creating hierarchies with the API

(represented by the class `ARXNode`). The class `Inclusion` implements a dummy criterion that can be used to exclude tuples from the input dataset by defining a research subset.

In the remainder of this section, we will present an example for deriving an optimally anonymized transformation from a dataset loaded from an RDBMS. The process of importing data and of loading as well as creating generalization hierarchies is outlined in Figure 7. Firstly, a `DataSource` is created, which encapsulates all information required to access a database as well as the schematic properties of the data to be imported. The dataset is loaded by creating an instance of the class `Data`. Secondly, a generalization hierarchy for the attribute "zipcode" is created automatically by applying redaction. Finally, attribute types are specified. Quasi-identifiers are defined by associating a hierarchy, which is loaded from a CSV file for the attribute "age".

```
/* Configure the anonymization process*/
ARXConfiguration config = ARXConfiguration.create();
config.addCriterion(new KAnonymity(5));
config.addCriterion(new HierarchicalDistanceTCloseness("diagnosis", 0.6d, Hierarchy.create("diagnosis.csv", ';')));
config.setMaxOutliers(0d);
config.setMetric(Metric.createEntropyMetric());

/* Perform classification of the solution space*/
ARXAnonymizer anonymizer = new ARXAnonymizer();
ARXResult result = anonymizer.anonymize(data, config);

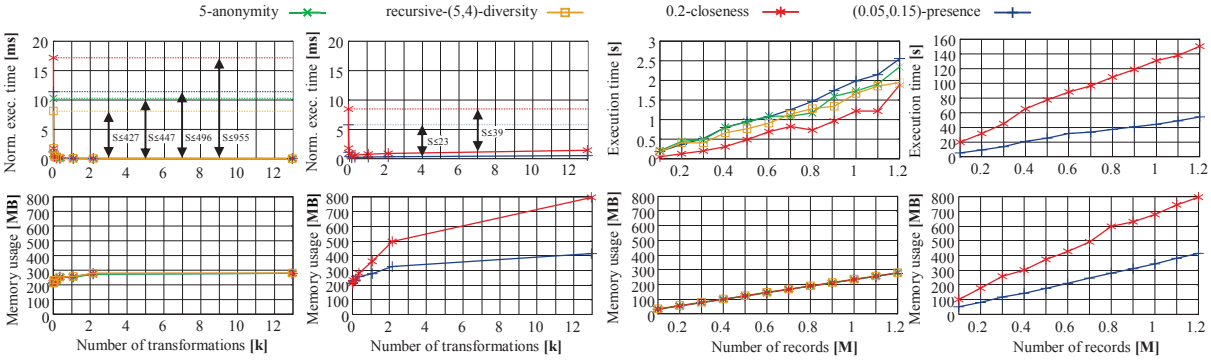
/* Write result of applying the optimal transformation*/
result.getOutput(result.getGlobalOptimum()).save("output.csv", ';');
```

Figure 8. Anonymizing and exporting data with the API

In Figure 8, the process of defining privacy requirements, configuring the transformation process, classifying the solution space, applying the globally-optimal transformation to the dataset and writing the result to a CSV file is sketched. The example configuration features 5-anonymity and 0.6-closeness for the sensitive attribute "diagnosis". The distance between distributions of the sensitive attribute is computed using a generalization hierarchy[28]. Tuple suppression is disabled and information loss is measured with non-uniform entropy[30].

Scalability of ARX

As already highlighted in the previous section, it is crucial that the process of classifying the search space is highly efficient. Most optimal anonymization algorithms are built on the assumption of monotonicity, meaning that generalizations of anonymous datasets are also anonymous and that specializations of non-anonymous datasets are also non-anonymous. This is, e.g., not true for ℓ-diversity and t-closeness combined with tuple suppression. ARX is the first tool to support such configurations, too, thus offering full support for tuple suppression. Our algorithm dynamically leverages any form of monotonicity. It can already prune parts of the search space if only some privacy criteria from a combination of several criteria are monotonic or if only the metric for assessing data utility is monotonic. In the context of utility metrics, monotonicity means that data quality decreases monotonically with generalization. This, again, is not always the case when tuple suppression is utilized.



(a) Scalability for monotonic configurations depending on the size of the search space

(b) Scalability for non-monotonic configurations depending on the size of the search space

(c) Scalability for monotonic configurations depending on the number of records

(d) Scalability for non-monotonic configurations depending on the number of records

Figure 9. Scalability of ARX for the *Integrated Health Interview Series* (IHIS) dataset

For our experiments we used a dataset from the *Integrated Health Interview Series* (IHIS)[34]. We have chosen this dataset, as it is publicly available and large, containing records about nearly 1.2 million individuals. From its

attributes, we have chosen eight quasi-identifiers (QIs) and one sensitive attribute[18], resulting in a solution space consisting of 12,960 transformations. To assess scalability, we evaluated our tool with two different types of privacy problems: scenarios with 0% suppression in which criteria and metrics are monotonic (leading to best-case performance) and scenarios with 5% suppression in which neither criteria nor metrics are monotonic (resulting in worst-case performance). Additionally, we scaled the size of the dataset and the size of the solution space. The latter has been realized by incrementally increasing the number of QIs. In this case it has to be considered that adding a QI to a dataset multiplies the size of the solution space by the number of levels in the associated hierarchy and leads to the need to transform one additional column. To exclude this effect and derive comparable numbers for different scales, we report a *normalized execution time*, which is defined as the execution time divided by the number of transformations in the solution space and divided by the number of QIs.

The results are summarized in Figure 9. The normalized execution times for the monotonic case show that the optimizations implemented in ARX (including pruning based on monotonicity) lead to a speedup of up to a factor of 955 compared to the baseline execution time. The baseline is defined by the configuration with only one QI, as, in this case, almost no optimizations can be leveraged. In the non-monotonic scenario, the entire solution space must be searched. Still, ARX is able to leverage its optimized runtime environment to achieve speedups of up to a factor of 39 compared to its baseline performance. The factor between best-case execution times (~2.5s) and worst-case execution times (~150s) is roughly 60. The results of our experiments with increasing dataset size and a non-monotonic configuration show that our tool can evaluate 12,960 transformations in about 150s. This means that in an average of roughly 12ms, ARX is able *1)* to generalize and suppress values in a dataset consisting of 1.2 million records, with eight QIs each, *2)* to group the transformed records according to the QIs, *3)* to compute frequency distributions for the sensitive attribute values in each group, *4)* to check whether each frequency distribution fulfills t-closeness measured with the *Earth Mover's Distance* (EMD) based on a generalization hierarchy, and *5)* to compute the overall utility of the dataset in terms of non-uniform entropy. We note that our experiments were performed on cheap commodity hardware[18]. Performance increases further when no frequency distributions are required, e.g., for k-anonymity or δ-presence. In terms of memory requirements, our tool uses up to 300MB for monotonic and up to 800MB for non-monotonic configurations. We note that ARX implements a space-time trade-off that allows reducing its memory consumption, if required[17].

Discussion

Principal Results

We have presented a comprehensive open-source data anonymization framework. It is under active development, well-tested, and available for many platforms. We have given an overview of the core design of our system, the graphical user interface, and the public API for external software. Our tool implements a three-step data anonymization process, and it supports arbitrary combinations of privacy criteria and the use of tuple suppression for finding optimal transformations regarding t-closeness, ℓ-diversity or δ-presence.

ARX is still under development and constantly being updated with new features; we have just released version 2.2.0 which fully supports the anonymization workflow described in this paper. While this workflow and the implemented methods are motivated by usage scenarios of the biomedical domain, the tool can also handle other types of data. Through feedback from users and researchers we have learned that there is indeed a strong demand for data anonymization tools such as ARX. We constantly update our online documentation to provide answers to common questions and extend our tool to cover functionalities required by our users.

Tests and Experiences

We have successfully tested and evaluated the current version of ARX with multiple real-world benchmark datasets[18], including publicly available biomedical data, such as IHIS[34]. We plan to add a formal study with real-world use cases. From a scientific perspective, we have used our framework as a basis for several informatics research projects[17,18,35,36]. The hypothesis that our efforts have made data anonymization technologies available to a broader audience is supported by access statistics to our project website. In one year (2013/7-2014/7), our website had more than 2000 unique visitors, hundreds of whom have downloaded our tool. Visitors from India, the USA, Germany and Japan account for over 50% of all traffic.

Comparison to Prior Work

The UTD Anonymization Toolbox[21] supports three different privacy criteria (k-anonymity, ℓ-diversity and t-closeness) and uses a *SQLite* database backend. In our experiments, we encountered problems with larger datasets.

It further lacks a graphical interface and requires configuration to be performed via an XML file. It does not support combining tuple suppression with ℓ-diversity or t-closeness, which can lead to low data quality.

Table 1. Comparison to previous approaches

		UTD-AT	CAT	sdcMicro	μ-Argus	ARX
Developer Support	Open source	Yes	Yes	Yes	No	Yes
	Active	No	No	Yes	No	Yes
	Public API	No	No	Yes	No	Yes
	Extensibility	Low	Low	Low	No	High
	Cross-platform	Yes	Yes	Yes	No	Yes

	Hierarchy format	Proprietary	Proprietary	Proprietary	Proprietary	CSV
	Standalone	No	Yes	No	Yes	Yes
Anonymity Methods	Automatic solution	Yes	Yes	Partial	No	Yes
	Privacy criteria	k, ℓ, t	ℓ, t	k, ℓ	None	k, ℓ, t, δ
	Generalization	Yes	Yes	Yes	Yes	Yes
	Tuple suppression	Partial	No	Yes	Yes	Yes
	Risk assessment	No	Limited	Yes	Yes	Limited

The Cornell Anonymization Toolkit (CAT)[22] supports ℓ-diversity and t-closeness. It was developed for demonstration purposes and is no longer under active development. It lacks support for tuple suppression and requires input data to be in a tool-specific format. sdcMicro[23] is a package for the R statistics software and as such not meant to be a standalone application. It provides a graphical user interface, but only implements limited methods for automatically solving privacy problems or classifying the solution space. It supports k-anonymity and ℓ-diversity and is still being actively developed. μ-Argus[24] is a project which is no longer under active development. It is a closed-source Windows application that is not intended to act as a software library. It provides a broad spectrum of recoding techniques, including global recoding with local suppression as well as top and bottom coding and multiple methods for risk estimation. De-identification must be performed manually. SECRETA[19] is a tool that allows comparing different anonymization algorithms for relational and transactional data, but it is not available to the public. Many related tools include methods for evaluating re-identification risks, e.g., sdcMicro or μ-Argus. A simple but often used measure for the *prosecutor re-identification risk*[37] is the minimum, maximum and average size of equivalence classes, which is also available in our tool. If users need to use further risk assessment methods, data can be exported into other applications. The results of our comparison have been summarized in Table 1.

Future Work

In future work, we plan to enhance ARX with several additional features. We already implemented multiple risk estimators, e.g., the approach by Dankar et al.[38], but integrating the results into our tool will require further work. Additionally, we plan to combine our method with less restrictive coding models (e.g., local recoding) and to provide a set of typically needed hierarchies. We are also actively working on support for transactional attributes as well as methods for secure continuous data publishing. Currently, ARX focusses on methods for privacy-preserving release of microdata. In future work, we plan to integrate non-interactive variants of differential-privacy, which provide provable privacy guarantees that are independent of an attacker's background knowledge[12].

Extending the HL7/LOINC Document Ontology Settings of Care

Sripriya Rajamani, MBBS, PhD, MPH[1, 2], Elizabeth S. Chen, PhD[4, 5, 6], Yan Wang, MS[2], Genevieve B. Melton, MD, MA[2, 3]

[1]Public Health Informatics Program, [2]Institute for Health Informatics, [3]Department of Surgery, University of Minnesota, Minneapolis, MN; [4]Center for Clinical & Translational Science, [5]Department of Medicine, [6]Department of Computer Science, University of Vermont, Burlington, VT

Abstract

Given federal mandates recommending document standards, increasing numbers of electronic clinical documents being created, and local initiatives/projects using clinical documents, there is a growing need to better represent clinical document metadata. The HL7/LOINC Document Ontology (DO) was developed to provide a standard representation of clinical document attributes with a multi-axis structure. Prior studies have demonstrated the need for extension of DO axes values and proposed new values for some axes, but significant gaps remain for representing the DO "Setting" axis. This study aimed to extend the "Setting" axis by combining the current values in the DO with values from 5 other sources. Evaluation and refinement by subject matter experts over a series of four iterative sessions resulted in a reorganized hierarchy with 254 additional values from a baseline of 20. Incorporating a comprehensive set of "Settings" in DO provides better representation of clinical information across the healthcare ecosystem.

Introduction

Federal initiatives like the Centers for Medicare & Medicaid Services (CMS) Electronic Health Record (EHR) Incentive Program along with standards and certification efforts led by the Office of the National Coordinator for Health Information Technology (ONC) have propelled the adoption and use of EHR systems[1]. These efforts have also led to dramatic increases in usage of electronic clinical documents, some of which are associated with requirements to use document standards for exchange of particular types of clinical information and for certain public health reporting use cases. With continuous increasing volumes of clinical documents, there is a need for better document metadata representation to promote standardization and reduce local customization. Availability of a comprehensive representation schema is critical to fit the needs of providers and the full set of inter-professional partners and sites in health care and also to facilitate their future retrieval and use for clinical care and research.

The HL7/LOINC Document Ontology (DO) is an ontology for the representation and standardization of clinical documents in a hierarchical structure comprising of five axes: *Kind of Document (KOD)*, *Type of Service* (*TOS*), *Setting*, *Subject Matter Domain* (*SMD*) and *Role*. The purpose of the DO is to support exchange of clinical documents across organizations, systems, and other stakeholders and to facilitate retrieval and reuse of documents for research and other secondary uses. Each DO axis is comprised of a set of values. A valid document specification with the DO consists of specification of the KOD axis and at least one additional DO axis. A select combination of valid DO specifications that have been precoordinated have assigned LOINC codes.

Several researchers have explored the application of DO and have proposed extensions to value sets, which have been incorporated by the LOINC Committee. A recent study that attempted mapping of data items from a large clinical repository to DO concluded that document attributes do not always link consistently with DO axes and recommended that additional values for certain axes, particularly for *Setting* and *Role* are needed[2]. This study addresses that recommendation and focuses on one axis of DO – the *Setting* axis.

The objective of this study was to create a comprehensive representation of care settings that combines the current values in DO with values from other representative sources. As emphasis shifts from traditional care in hospitals and office visits to care coordination, care management, and care within home and other nontraditional healthcare settings, healthcare is being offered in places that have been typically outside the scope of traditional health delivery which likely requires better representation in DO. As an additional potential benefit, this study is poised to benefit a wide range of secondary uses of documents for research, quality initiatives and population health management.

Background

Meaningful Use recommendations for document standards specify the HL7 Clinical Document Architecture (CDA) and HL7 Consolidated CDA (C-CDA)[3]. Both structure and semantics of a clinical document are guided by CDA, which is an XML-based standard[4]. C-CDA is a consolidation of various CDA templates to facilitate implementation[3].

The implementation guide for C-CDA that contains a library of CDA templates is available from HL7[5]. A companion guide was created by the ONC Standards and Interoperability Framework Initiative to offer guidance on implementation of certification criteria which required HL7 C-CDA[6].

The HL7 CDA header contains the context of a clinical document and facilitates exchange across and within institutions as well as retrieval for various purposes. The CDA body holds the actual facts pertaining to the document. The CDA header comprises of document information, encounter data, service actors and service targets. Document information includes a unique identifier that is drawn from the realm of clinical LOINC codes, which are guided by the HL7/LOINC Document Ontology[7]. Figure 1 includes a sample XML showing a portion of a C-CDA header that includes the LOINC code "34133-9" for "summarization of episode note" (the value for the LOINC System axis is "{Setting}" indicating that a particular setting is not designated).

Figure 1: Sample XML for C-CDA with Select Header Portion and Document Code[8]

```
<code
    codeSystem="2.16.840.1.113883.6.1"
    codeSystemName="LOINC"
    code="34133-9"
    displayName="Summarization of Episode Note"/>
```

The current model of DO was started by the HL7 Document Ontology Task Force (DOTF) and later continued through a joint effort with the LOINC Committee. The current DO is available as part of the LOINC User's Guide, which is updated biannually[9]. LOINC codes in the Document Ontology class (DOC.CLINRPT) and values from various axes can be downloaded as part of the LOINC Document Ontology file, which has been publicly available since the LOINC 2.44 release[10]. An implementation guide for HL7/LOINC Clinical Document Ontology has been released as of September 2013 as a Draft Standard for Trial Use (DSTU)[8]. As mentioned, this 5 axis model uses multiple classes under each axis requiring specification of the *KOD* axis and at least one of the other four axes. Though *Setting* is not a required component for a valid document specification, it is often included in clinical document names to help distinguish between important classes of documents. Initial development of DO with relevant background is described by Frazier *et al.*[11].

In related work, detailed analysis of the *Subject Matter Domain* (*SMD*) axis was conducted by Shapiro *et al.*[12] who mapped a set of inpatient document titles and showed that 56% of documents were classified as "not specified" with respect to values on the DO SMD list. This study created a new polyhierarchical *SMD* structure by combining the values from the DO SMD axis with values from American Board of Medical Specialties (ABMS), thereby increasing the coverage of SMD significantly. Veterans Administration (VA) has also contributed to expansion of the *Type of Service (TOS)* axis, which characterizes the kind of service or activity provided to the patient or subject of the service where sub-classes under this axis include evaluations, consultations, and summaries. More specifically, the VA work expanded the Compensation and Pension Examination value set that is under Disability Examination and part of the Evaluation and Management sub-class, and these are now available as part of DO[9].

Other pertinent studies have focused on mapping of document names from inpatient settings to DO and attempted to understand DO in depth and precoordination of its axes with LOINC. Document names from two large institutions were mapped to DO, and LOINC codes were identified based on mapping by Chen *et al.*[13]. This study showed that a majority of document names could be assigned a LOINC code, but granularity was often lost. The work highlighted strengths and limitations of DO and LOINC codes for representation of documents.

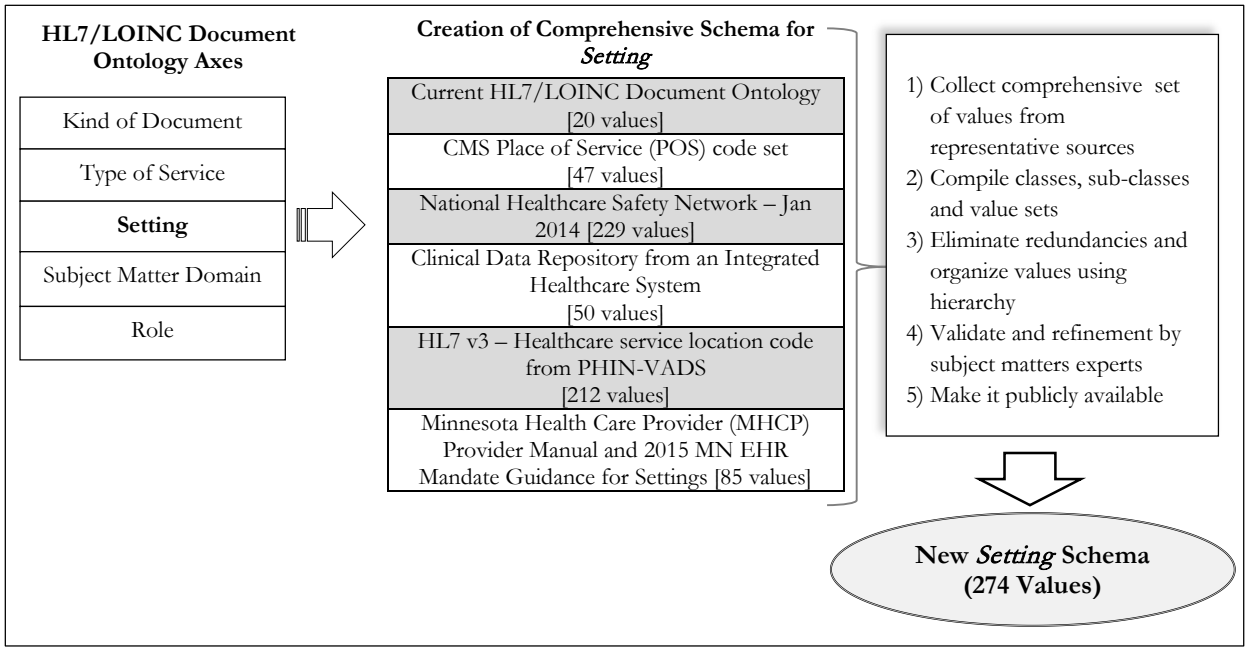
Comparison of the three versions of DO in their adequacy to represent document names in an inpatient setting was done by Hyun *et al.*[14]. Dugas *et al.*[15] examined 86 document types from an inpatient information system and their coverage using LOINC codes. Usage of LOINC codes for document exchange across inpatient settings of two campuses of a hospital was explored and coverage of DO on clinical document titles was evaluated as part of process by Li *et al.*[16]. Hyun and Bakken[17] extracted section headings from nursing documents and then identified DO components and mapped them to LOINC as a potential model for representing this class of texts. Most recently, Wang *et al.*[2] evaluated the adequacy of DO for representing clinical documents in a data repository from an integrated health delivery system which contained data from legacy and current EHR systems and is used for multiple purposes including research. A common theme across these studies was the need for extension of attribute values of the LOINC

semantic model, more specific LOINC codes and limitations with precoordination, and the recommendation to expand the value sets for certain DO axes, particularly for *Setting* and *Role*.

Methods

This study involved creation of a comprehensive representation of the *Setting* axis in the HL7/LOINC Document Ontology (DO). The methodology comprises of five main components: (1) collection of a comprehensive set of values from representative sources; (2) compilation of classes, sub-classes, and value sets for the *Setting* axis; (3) elimination of redundancies and organization of values into an extended hierarchy; (4) validation and refinement by subject matters experts; and (5) a resulting publicly available hierarchy for sharing the resultant value set with the broader community. Figure 2 details the methodology for the proposed expansion.

Figure 2: Methodology for Creation of Comprehensive Schema for *Setting* in Document Ontology



The current value set for *Setting* in DO[9] is comprised of 20 values that are organized into 12 classes with 8 sub-classes for two of the classes, leading to 20 overall values for document representation. The first step in the process was to examine the value sets for *Setting* in the secure local research-oriented clinical data repository, including large numbers of clinical documents, which was established in a partnership between the University of Minnesota and its affiliated integrated healthcare system, Fairview Health Services. Prior work of the authors examined the representation of documents in this repository and demonstrated inadequacy of the *Setting* axis in DO[2]. Next, other valid sources were identified that could contribute to representation of *Setting* values. The Place of Service (POS) code set[18] from CMS was identified and selected, as CMS is the largest insurer and provider of healthcare services in the US. In order to find corresponding value sets for a Medicaid source, values were obtained from the Minnesota Health Care Plans (MHCP) provider manual[19] and the 2015 Minnesota Electronic Health Record mandate guidance[20] on settings. Other sources incorporated in this study were the HL7 version 3 (v3) code set[21] for representation of settings, which was retrieved from the Public Health Information Network (PHIN) Vocabulary Access and Distribution System (PHIN-VADS). Since the HL7 codes were based off of the National Healthcare Safety Network (NHSN), the current version of NHSN codes (Jan 2014 release)[22] was also incorporated. Compilation of all these values resulted in classes and sub-classes of 327 values.

Once all value sets from the six sources including DO were obtained, redundancies were identified and eliminated. Table 1 shows some examples of values across sources and consensus arrived by subject matter experts as part of an iterative review process.

Table 1. Mapping Examples of Different Classes Across Sources

Current HL7/LOINC Document Ontology (LOINC User's Guide – Dec 2013)	CMS Place of Service (POS) code set – Nov 2012 version	Clinical Data Repository from an Integrated Healthcare System – June 2013	National Healthcare Safety Network (NHSN) – Jan 2014 release	HL7 v3 – Healthcare service location code set from PHIN-VADS (2010 version)	Minnesota Health Care Provider (MHCP) Provider Manual and 2015 MN EHR Mandate Guidance for Settings (2013)	Subject Matter Expert (SME) Consensus
Office	Office	Office				Office
			Physician's Office	Physician's Office		
Hospital						Inpatient setting
	Inpatient Hospital	Inpatient Hospital			Inpatient Hospital	
			Inpatient location			
Ambulatory Surgical Center	Ambulatory Surgical Center	Ambulatory Surgical Center	Ambulatory Surgical Center	Ambulatory Surgical Center	Ambulatory Surgical Center	Ambulatory Surgical Center
Urgent Care Center			Urgent Care Center	Urgent Care Center		Urgent Care Center
	Urgent Care Facility	Urgent Care Facility				
					Urgent Care Clinic	
						Public Health - Public Health Clinic - State Agency: Health - Prison Infirmary - Mass Immunization Center
	Public Health Clinic	Public Health Clinic				
					State Agency – Health	
			School or Prison Infirmary	School or Prison Infirmary		
	Mass Immunization Center	Mass Immunization Center				

As shown in Table 1, this process also included identifying synonyms and the need for "preferred terms." For example, "office" is used currently in the DO, CMS POS, and MHCP; however, "physician's office" is used in HL7 v3 and NHSN, which were meant to represent the same setting. From this, a consensus decision was made by the subject matter experts to keep the current "office" value and eliminate "physician's office" in light of the variety of inter-professional office settings, including non-physician provider offices. Also, some settings in NHSN were deemed irrelevant to this study which focuses on document representation. This phase of selection and redundant value harmonization reduced the total number of values to 274, which were then organized into a hierarchy.

A series of iterative sessions with 4 subject matter experts (2 providers, 1 public health provider, and 4 informaticians) was held where the hierarchy was constructed, refined, and validated. In particular, three of experts were experienced with the DO and biomedical standards evaluation. The reviewers looked at the following aspects of the sources and value sets in placing them into the hierarchy, including: (1) relative granularity of values, (2) representation of current content, and (3) need for additional layers in the hierarchy. Experts reviewed the value sets independently and also together to compare proposed revisions. This process was repeated iteratively four times until there was consensus amongst the experts. As a final step, the proposed final list was made available publicly for use by the larger community.

Results

The processes resulted in the creation of a comprehensive *Setting* value set with compilation of values from relevant and representative sources which included: current HL7/LOINC Document Ontology [20 values], CMS Place of Service (POS) code set [47 values], National Healthcare Safety Network [229 values], clinical data repository setting value set from an integrated healthcare system [50 values], HL7 v3 – healthcare service location code from PHIN-VADS [212 values] and Minnesota Health Care Provider (MHCP) provider manual and 2015 MN EHR mandate guidance for settings [85 values]. Using the methodology described, this resulted in the creation of a final proposed list of 274 values. Table 2 provides a comparison of the current hierarchy in DO for *Setting* with proposed extended hierarchy.

Table 2: Comparison of Values across Current and Proposed HL7/LOINC Document Ontology for Settings

Current HL7/LOINC Document Ontology Values [includes all classes and sub-classes]	***Proposed Extended Hierarchy for Settings of Care [displays main classes only]***
Ambulance	Inpatient setting
Birthing center	Critical care unit
Emergency department	Step down unit
Hospital	Mixed acuity unit
Intensive care unit	Operating room
Long term care facility	Ward
Custodial care facility	Inpatient psychiatric facility
Nursing facility	Hospice
Skilled nursing facility	24 hour observation area
Unskilled nursing facility	Hyperbaric oxygen center
Outpatient	Emergency department
Ambulatory surgical center	Outpatient setting
Office	Acute setting
Outpatient hospital	Clinic (non-acute) setting
Urgent care center	Other outpatient setting
Patient's home	Long term care facility
Pharmacy	Skilled nursing facility
Rehabilitation hospital	Unskilled nursing facility/Custodial care facility
Telehealth	Intermediate care facility
Telephone encounter	Behavioral health facility
	Rehabilitation center
	Birthing center
	Telehealth
	Telephone encounter
	Mobile
	Transport
	Pharmacy
	Laboratory
	Public Health
	Community
	Home

The current DO axis has 12 main classes and 8 sub-classes, whereas the study's proposed axis has 14 main classes and 17 sub-classes and also includes additional value sets. The representation of 274 values with the extended hierarchy comprises of Inpatient setting [n=97], Emergency department [n=2], Outpatient setting [n=93], Long term care facility [n=17], Behavioral health facility [n=5], Rehabilitation center [n=4], Birthing center [n=3], Telehealth [n=1], Telephone encounter [n=1], Mobile [n=8], Pharmacy [n=1], Laboratory [n=11], Public Health [n=21] and Community [n=10].

Table 3 offers a snapshot of the proposed values and their hierarchical organization for three of the 14 main classes: Public Health, Community, and Mobile. The entire structure comprising of 274 values is available publicly (http://www.bmhi.umn.edu/ihi/research/nlpie/) for dissemination to the broader community (e.g., for sharing with the LOINC Committee and other interested stakeholders).

Table 3: Snapshot of Proposed Extensions to the HL7/LOINC Document Ontology for *Setting*

Proposed Values in Select Classes		
Public Health	**Community**	**Mobile**
City/county agencies: Jails	**Home**	Mobile unit
City/county agencies: Human services	Home-based hospice	Mobile blood collection center
City/county agencies: Local health departments	Home hemodialysis	Mobile MRI/CT
Community mental health center	Group home	**Transport service**
Federally qualified health center (FQHC)	Assisted living facility	Mobile emergency services/EMS
Indian health service free-standing facility	Place of employment - worksite	Ambulance – air or water
Indian health service provider-based facility	Homeless shelter	Ambulance – land
Mass immunization center	Temporary lodging	
Migrant health clinic	Other place of service	
Military treatment facility		
Prison – Correctional facility		
Prison Infirmary		
Public health clinic		
State agency – corrections		
State agency – health		
State agency – human services		
State or local health clinic		
Tribal 638 free-standing facility		
Tribal 638 provider-based facility		
Veterans Affairs (VA)		

Discussion

In this study, we have described an effort to construct a comprehensive value set for representation of *Setting* for the HL7/LOINC Document Ontology. The methodology involved identifying additional representative and valid sources for *Setting* values, integrating these value sets to eliminate redundancies and combine synonyms, extending the existing DO hierarchy for *Setting* and organizing the values into this hierarchy, validating with subject matter experts in multiple sessions, and disseminating the results. One of the challenges encountered in this work was the effort and decisions around optimal hierarchical representation of value sets. The sessions with subject matter experts revealed the complexity of this task due to numerous places in which care is delivered across inpatient, outpatient, home, and community locations, as some of the major settings of care, and the variation in care delivery by organizational structure. Also, there were numerous redundancies and synonyms to deal with across the value sets from various sources. Expert review revealed that there are a multitude of ways to organize the setting values, depending on the specification of higher classes and the granularity of terms. One consensus was that the *Setting* axis in the current HL7/LOINC Document Ontology needs inclusion of additional settings of care to truly reflect the changing healthcare delivery landscape to accurately capture information on settings of care and facilitate representation and reuse of documents for research.

Guidelines were also developed for systematic review and organization of settings in a hierarchy. Criteria which were discussed included: (1) inclusion of specialty locations separately in a particular setting or roll them up as part of over-arching settings of care such as inpatient and outpatient, (2) potential need for poly-hierarchy with a class to be included as a sub-class of various categories, (3) validity of sources for inclusion, (4) addition of other reliable sources, and (5) identification of main classes in settings of care. Multiple rounds of expert review, including both independent and combined sessions revealed the complexity in organization of the setting concept. These assessments also revealed inconsistencies in representation across sources, redundancies, and synonyms, all of which had to be addressed.

One of the limitations of this work is the difficulty in obtaining data on internal validity. Although we did have multiple rounds and exposed the data hierarchy to multiple expert stakeholders, because of the large number of values and need to leverage group wisdom about care settings, separate and independent assessments of the value sets was found to be difficult for applying inter-rater reliability measures, which are often applied to terminology coding tasks. An ongoing challenge is balancing the comprehensiveness of information in the hierarchy and associated granularity with the

practical aspects of implementation and mapping burden. This study proposes an over 10-fold extension of the *Setting* axis values from a current list of 20 to a proposed set of 274 values. More coverage in the Setting axis is needed, but further efforts are needed to determine the optimal set of values and their organization for uses ranging from clinical care to research.

Next steps for this study would be submission of the value sets to the LOINC Committee for a formal review as outlined in the LOINC User's guide[9]. This is a critical next step in the generalizability of this work and its applicability to *Setting* axis extension. Other ongoing work involves studying the representation of *Role* in DO as a recent study recommended the need for additional values in the *Role* axis[2]. Ultimately, these findings need to be promoted and value sets shared as a form of external validation by other interested stakeholders, including those from the standards community. Both informal feedback and also the formal LOINC submission and review process would decide the extent of *Setting* axis expansion. As this study group and others continue to promote better representation of clinical information across providers and partners in healthcare ecosystem, the extension of DO value sets is needed to incorporate a comprehensive and reflective set of values for settings of care.

Differences in Nationwide Cohorts of Acupuncture Users Identified Using Structured and Free Text Medical Records

Doug Redd, MS[1,2], Jinqiu Kuang, MS[1], Qing Zeng-Treitler, PhD[1,2]

[1]VA Salt Lake City Health Care System; [2]Department of Biomedical Informatics, University of Utah, Salt Lake City, Utah

Abstract

Integrative medicine including complementary and alternative medicine (CAM) has become more available through mainstream health providers. Acupuncture is one of the most widely used CAM therapies, though its efficacy for treating various conditions requires further investigation. To assist with such investigations, we set out to identify acupuncture patient cohorts using a nationwide clinical data repository. Acupuncture patients were identified using both structured data and unstructured free text notes: 44,960 acupuncture patients were identified using structured data consisting of CPT codes;. Using unstructured free text clinical notes, we trained a support vector classifier with 86% accuracy and was able to identify an additional 101,628 acupuncture patients not identified through structured data (a 226% increase). In addition, characteristics of the patients identified through structured and unstructured data were compared, which show differences in geographic locations and medical service usage patterns. Patients identified with structured data displayed a consistently higher use of the Veterans Health Administration (VHA) medical system.

Introduction

Over the past decade, integrative medicine has gained increasing attention from providers and researchers. Compared to traditional healthcare, integrative medicine's emphasis on a partnership between patients and clinicians takes a holistic view of patients' health and well being, and incorporates complementary and alternative medicine (CAM) approaches such as acupuncture and massage into treatment options. Many large hospitals now provide some form of integrative health services to their patients.

At the same time, the safety and effectiveness of many CAM treatments are not sufficiently understood. For instance, acupuncture is widely practiced to relieve pain and treat certain health problems, but debate on its effectiveness continues in the literature. Witt et al evaluated clinical and economical effectiveness of acupuncture on chronic low back pain in a large randomized controlled trial (RCT).(1) They demonstrated that acupuncture in addition to routine care considerably improved clinical outcomes and was relatively cost-effective. A systematic review of RCTs looking at acupuncture for pain was published by Linde et.al. It included thirteen trials (3,025 patients) with a variety of pain conditions and found a small analgesic effect from acupuncture, hardly distinguishable from bias.(2) Another systematic review of 23 RCTs on the effectiveness of acupuncture for nonspecific lower back pain by Yuan et al showed moderate evidence that acupuncture is more effective than no treatment, and strong evidence of no significant difference between acupuncture and sham acupuncture, for short-term pain relief.(3) This review concluded that acupuncture can be a useful supplement to other forms of conventional therapy for nonspecific lower back pain, but the effectiveness of acupuncture compared with conventional therapies requires further investigation. Considering acupuncture is one of the most studied CAM modalities, these uncertain results indicate that more research is needed to ascertain the efficacy of CAM practices.

Secondary analysis of electronic medical records (EMR) is a powerful approach to study treatment safety and effectiveness. At the Veterans Health Administration (VHA), we have begun leveraging its nationwide EMR repository to study the use of acupuncture to manage pain and control other symptoms like nausea. A critical step in EMR secondary analysis is cohort identification.

In this paper, we describe our effort to identify a cohort of patients who had undergone acupuncture treatments while receiving care from the VHA. Both structured data and unstructured data were used. To understand the impact of data source on the resultant cohorts, cohorts identified from the two methods were compared in terms of size of patient characteristics.

Materials and Methods

Data Source

Data for this study was procured through the Veterans Informatics and Computing Infrastructure (VINCI), VHA. The VHA comprises 152 medical facilities in addition to 1,400 clinics that are community-based and tailored to serve individuals on an outpatient basis, Vet Centers, community living centers, and Domiciles. In total, these facilities employ over 53,000 healthcare professionals who provide their services to over 8.3 million veterans on an annual basis. VINCI is a collaboration between the Office of Research and Development and the Office of Information and Technology in the U.S. Department of Veterans Affairs (VA), providing data and infrastructure needs of the VHA research community. VINCI provides access to structured and unstructured health information originating from the VISTA electronic health record system, and includes data for over 17 million patients. We identified patients receiving acupuncture treatments through structured as well as unstructured data using the process outlined in Figure 1.

Cohort Identification Using Structured Data

VHA offers many forms of CAM treatments from acupuncture to sweat lodge. Patients receiving specific treatments within the VHA system can be identified through Current Procedural Terminology (CPT) codes identifying specific patient procedures. Acupuncture treatments are represented by CPT codes 97780, 97781, 97810, 97811, 97813, and 97814.

Many non-standard treatments can be identified through the locations of patient visits. In the VHA, clinic "Stop Codes" are included in the outpatient visit records to indicate the clinic or work group providing specific services. We were, however, only able to identify a single location for acupuncture services using the "Stop Code". Since acupuncture services are widespread in the VHA system, we resorted to CPT codes for their identification.

Cohort Identification Using Free Text Data

Structured data has been shown to be insufficient for cohort identification in many cases (4). Some patients receiving acupuncture will not have corresponding CPT codes assigned for various reasons. For example, many patients obtain treatment from non-VHA providers, particularly when VHA clinics offering a specific therapy are not available in the geographic area of the patient. In some cases, their VHA clinicians do not prescribe or authorize the treatments. Although they may not be recorded by CPT codes, many VHA healthcare providers do ask Veterans about the non-VHA treatments they are receiving and document them in narrative clinical notes. Thus, we searched unstructured, free text clinical notes for mentions of acupuncture.

Free text clinical notes have been shown to be rich in medical information that can be accessed using natural language processing techniques (5-7). Searching of the unstructured notes was accomplished using the Voogo search engine, which was developed specifically for searching structured and unstructured data within VINCI. Using Voogo, patients with clinical documents containing the string "acupuncture" were identified. Snippets of text containing acupuncture, including surrounding context, were extracted and manually annotated to identify if the snippets were positive, negative, or prescribed (if the snippet described a recommendation) for use of acupuncture treatment by the patient. A support vector machine (SVM) was trained for automated acupuncture text classification. Using text classification results, patients were classified as positive for acupuncture treatment use if they had at least one positive snippet; prescribed if they had no positive snippets but at least one prescribed snippet; or negative if they had only negative snippets.
Patients with a positive history of acupuncture use identified through unstructured data is referred to as UD.

Comparing Cohorts from Structured and Free Text Data

We compared the two cohorts (UD and SD) to determine the distribution of patients identifiable only from SD, only from UD, or both. The UD and SD patients were then compared and contrasted for geographic location, gender, age, and most frequent medical procedures, diagnoses, and prescriptions.

A list of the 25 most common procedures was constructed by combining the 21 most frequent Current Procedural Terminology (CPT) codes from UD patients and the 21 most frequent CPT codes from SD patients (the number of codes from UD and SD patients was chosen by trial and error to obtain a combined number of 25). Similarly, a list of the 25 most common diagnoses was constructed by combining the 23 most frequent International Classification of Diseases version 9 (ICD-9) codes from UD and SD patients. And again with prescriptions, the 24 most frequent drug names from UD and SD patients were determined, for a combined set of 25 unique drug names. We then determined the proportions of UD and SD patients receiving these most frequent procedures, diagnoses, and prescriptions..

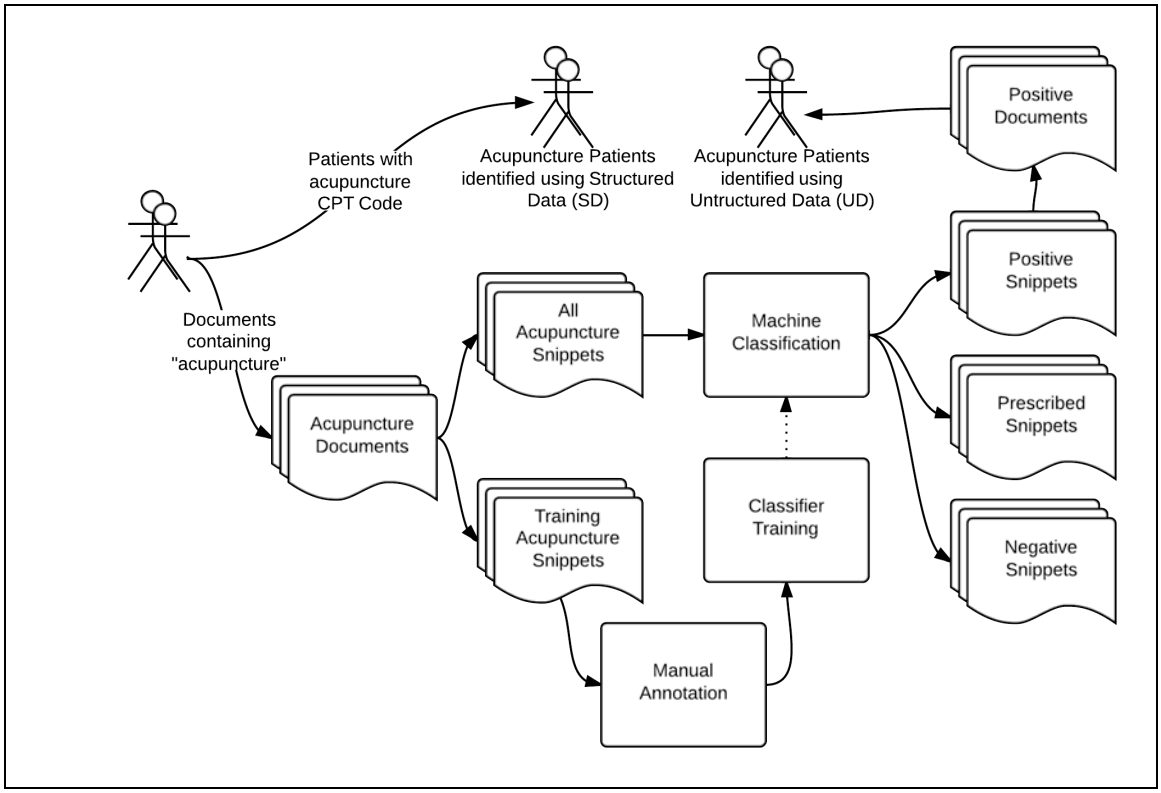

Figure 1. Acupuncture Patient Cohort Identification from Structured Data (SD) and Unstructured Data (UD)

Results

Using CPT codes, 44,960 patients were identified as receiving acupuncture treatment using structured For identification of acupuncture using unstructured data (UD), 1,245,753 documents mentioning identified representing 400,350 patients. 297 snippets were classified as positive, prescribed, or annotators with an inter-rater reliability kappa score of 0.74. Since the kappa is relatively low, reached through discussion to create the reference standard. A support vector machine (SVM) using these snippets and validated with 10-fold cross validation. This resulted in the ability to identify text with an overall accuracy of 0.862 (precision 0.883, recall 0.743, and f_1-measure 0.785) (Table 1). Using the SVM classification model, 140,525 patients were identified as positive for acupuncture use. SD and UD identified patients were compared to determine an intersection of 38,897 patients, so that an additional 101,628 (226%) patients were identified using UD that were not identifiable using SD (Figure 2).

Table 1. Confusion matrix for acupuncture classifier.

		Reference Standard			
		Yes	No		
Acupuncture Classifier	Yes	77	13	Precision	88.3%
	No	24	183	Recall	74.3%
				F1 Measure	78.5%
				Accuracy	86.2%

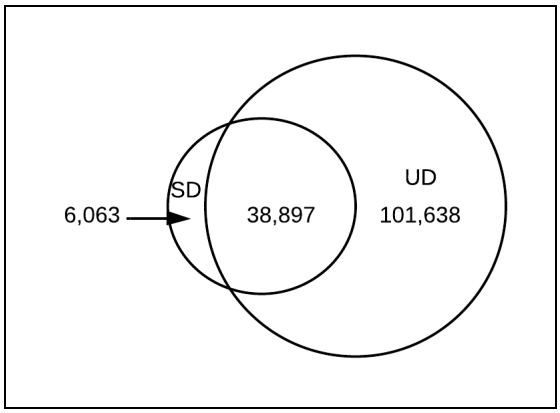

Figure 2. Distribution of patients between groups identifiable by structured data (SD), unstructured data (UD), or both (SD + UD).

We compared the geographic locations of UD and SD patients. Overall, patients congregated around major population centers. There were some differences in the distributions, however. There was a much higher proportion of UD patients in the northwest region of Oregon, and a higher proportion of SD patients in the New York City metropolitan region. (Figure 3).

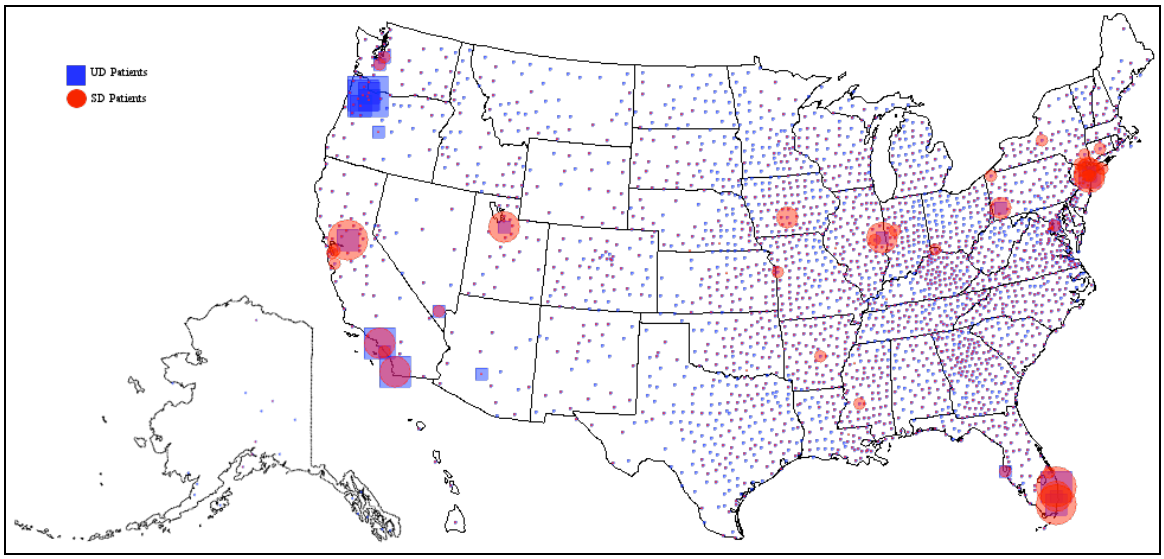

Figure 3. Geographic distribution of acupuncture patients identified from structured data (SD) and unstructured data (UD).

The age distribution of UD and SD patients were essentially similar (Figure 4). The mean age was 56.4 (stdev. 15.2) for UD patients and 56.1 (stdev. 14.6) for SD patients. The difference was statistically significant ($p < 0.00$ by student t-test) due to the large sample size, however this small difference is not clinically meaningful.

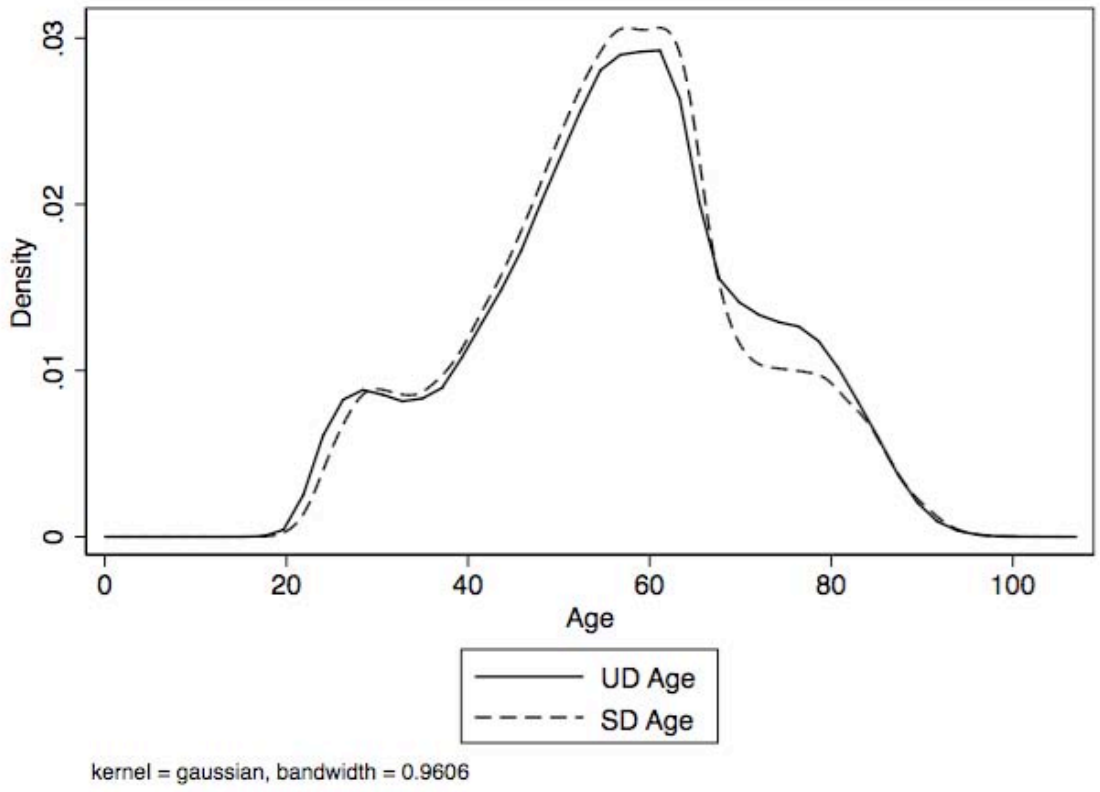

Figure 4. Density of age distribution for acupuncture patients identified from unstructured data (UD) and structured data (SD).

We compared the percent of UD and SD patients receiving the most common procedures, diagnoses, and prescriptions (Figure 5). Although the percentages are somewhat similar, overall a higher percent of SD patients received the measured procedures, diagnoses, and prescriptions. There are some procedures where SD patients show a higher percent that is more pronounced, i.e. metabolic panel total calcium, patient evaluation, therapeutic exercises, and comprehensive metabolic panels. Alternatively, UD patients show a higher percent of assays for quantitative blood glucose, alanine aminotransferase, and assay of urea nitrogen. For diagnoses SD patients also have a higher percentage in most cases, exceptions including unspecified reason for consultation and unspecified tobacco use disorder. Prescriptions continue the trend of higher SD percentages, with SD having higher percentages in all cases. We also examined the per-patient average number of all procedures, diagnoses, prescriptions, and visits between the two groups. This analysis confirmed that SD patients had a higher rate of use in all cases (Table 2).

Overall, both diagnoses and prescriptions indicate the presence of pain and pain management. Diagnoses of lumbago (low back pain), unspecified back pain, and cervicalgia (neck pain) are frequent, as are pain medications such as hydrocodone, gabapentin, cyclobenzaprine, naproxen, tramadol, oxycodone, codeine, etc.

We also compared the gender distribution (Figure 5). There was a higher percent of females in SD patients (14%) as opposed to UD patients (12%), both of which reflect the expected minority of females in the veteran population.

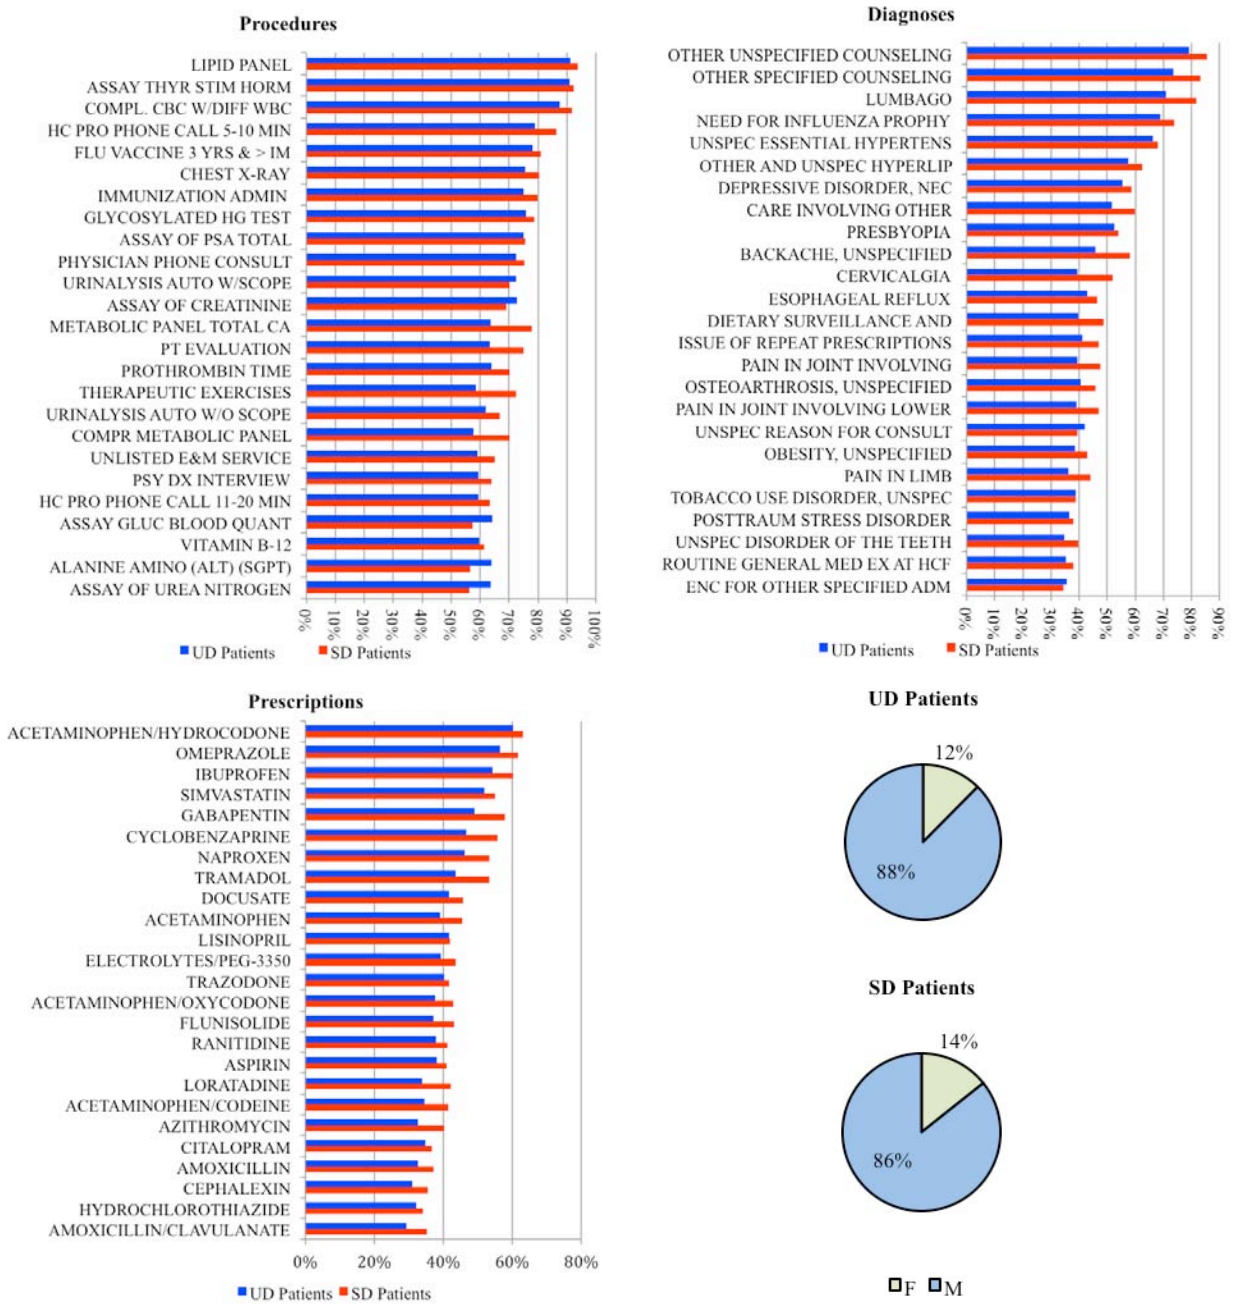

Figure 5. Percent of UD and SD patients with the most frequent procedures (by CPT code), diagnoses (by ICD9 code), and prescriptions, and gender distribution of UD and SD patients.

Table 2. Average per-patient procedure, diagnosis, prescription, and outpatient visit rates for UD and SD patients.

	Procedures per Patient	Diagnoses per Patient	Prescriptions per Patient	Visits per Patient
UD Patients	634	473	202	483
SD Patients	724	568	232	562

Discussion

In this study we identified patients in the VHA system being treated with acupuncture. We identified the cohorts using structured data and unstructured full-text data. We used CPT codes to identify patients for the structured data cohort, and SVM classification of unstructured free-text clinical notes to identify patients in the unstructured data cohort. There was a large overlap in the two sets, with only 13% of structured data patients not also being present in the unstructured data set. However, 72% of the unstructured data patients were not present in the structured data set, demonstrating the ability to significantly enlarge the set of identified acupuncture patients by using unstructured data. Our study shows that while it is feasible to identify acupuncture cohorts through structured and unstructured data independently, combining the two approaches can maximize the cohort size. This finding is consistent with findings reported by prior studies (8-11), but we show a more dramatic increase due to this medical domain not being traditionally included in electronic health records.

Aside from increasing the cohort size, combining structured and unstructured data can lead to a more representative patient population. Some prior studies compared sensitivity and specificity of different cohort identification methods, while we compared the cohorts. In comparing the cohort characteristics, we found a high degree of similarity but also some meaningful differences. Geographically, large acupuncture patient populations tend to locate in or near large metropolitan centers. The unstructured data cohort had a much higher proportion in the northwest region of Oregon, and those in the structured data cohort were proportionally more highly represented in the New York City metropolitan area. Some large metropolitan centers showed low acupuncture populations from either method. This suggests a variance in practice and/or documentation, although there are many other possibilities that will require further study to identify.

The distribution of ages in the two cohorts showed no significant difference, with the mean patient age at the time of treatment being about 56 years old in both groups. The gender representation in the two cohorts was also very similar. The rankings of the most frequent medical procedures, diagnoses, and prescriptions were very similar between the two cohorts, however there were consistently higher percentages of patients in the structured data cohort that received each procedure, diagnosis, and prescription. A frequent application of acupuncture treatment is for pain management (12), which is reflected in the frequent use of pain management prescriptions and diagnoses related to pain conditions in both cohorts.

Our data suggest that the patients in the structured data cohort had consistently higher rates of procedures, diagnoses, and prescriptions in general, not only in the most frequent sets. Patients in the structured data set also had a higher average outpatient visit rate. This indicates a difference in medical resource usage pattern between the two cohorts, with those in the structured data cohort consistently displaying higher use of VHA resources. This may indicate that patients identified only through unstructured data are relatively healthy or relying less on VHA as the sole provider.

Abstract

Mechanical ventilation provides an important, life-saving therapy for severely ill patients, but ventilated patients are at an increased risk for complications, poor outcomes, and death during hospitalization.[1] The timely measurement of negative outcomes is important in order to identify potential issues and to minimize the risk to patients. The Centers for Disease Control and Prevention (CDC) created an algorithm for identifying Ventilator-Associated Events (VAE) in adult patients for reporting to the National Healthcare Safety Network (NHSN). Currently, the primarily manual surveillance tools require a significant amount of time from hospital infection prevention (IP) staff to apply and interpret. This paper describes the implementation of an electronic VAE tool using an internal clinical data repository and an internally developed electronic surveillance system that resulted in a reduction of labor efforts involved in identifying VAE at Barnes Jewish Hospital (BJH).

Introduction

The use of mechanical ventilation can be an important, life-saving treatment for severely ill patients. The Centers for Disease Control and Prevention (CDC) estimate as many as 300,000 patients receive mechanical ventilation each year, but also notes that this can lead to additional complications, poor outcomes, and death during hospitalization.[1] Because of the increased risk to patients, it is important that hospitals monitor for adverse events associated with the use of mechanical ventilation.

Prior to 2013, the BJC HealthCare (BJC) Infection Prevention (IP) staff performed surveillance for ventilator-associated pneumonia (VAP). VAP is among the most common hospital-acquired infections, but accurate surveillance for VAP was difficult because of the lack of universally accepted objective definitions. VAP surveillance was time consuming, potentially less accurate than clinical/microbiologic criteria, and the use of quantitative lower respiratory tract cultures for the establishment of VAP is not universally performed.[2-3]

The CDC's National Healthcare Safety Network (NHSN) Working Group developed a new and more objective approach for surveillance that focuses on Ventilator-Associated Events (VAE). These include Ventilator-Associated Conditions (VAC), Infection-related Ventilator-Associated Complications (IVAC), possible VAP and probable VAP.[1] The new methodology was developed with the goals of: limiting the VAP definition's subjectivity and inaccuracy; using readily available and objective clinical data; making inter-facility comparisons more meaningful; and encouraging broader prevention strategies. It was also designed to allow electronic data collection, given the availability of a hospital-wide electronic health record (EHR) system with exportable data. The new definition still requires daily monitoring of patients, and would be time intensive to complete manually in large institutions. In order to decrease the burden of manual surveillance for VAE, BJC developed an electronic surveillance process for gathering relevant data elements. The approach used a combination of new interfaces and the incorporation of a new electronic algorithm with an existing, intranet-based surveillance system called Surveillance Assistant (SA) that was internally developed and deployed at BJC in 2009.

Hospital Setting

BJC is a large, nonprofit healthcare organization affiliated with Washington University School of Medicine (WUSM) that delivers services to the greater Saint Louis metropolitan region. The 12 BJC hospitals provide adult and pediatric care at locations ranging from rural and community hospitals to large, academic institutions.

Barnes Jewish Hospital (BJH) is a 1250 bed, tertiary care academic facility associated with WUSM. There are six intensive care units (ICUs) at BJH with 121 total beds, including medical, surgical, cardiac, cardiothoracic and neurological specialties. Ventilated patients can also be cared for on a bone marrow transplant unit, which is staffed to have up to 8 ventilated patients at a time, a step-down long term vent unit with 10 beds and an advanced heart failure unit with 6 beds. On average, there are a little over 1,500 ventilator days each month at BJH.

Methods

The first step in developing the electronic algorithm for VAE surveillance was to analyze the NHSN specification. Based on CDC's NHSN VAE protocol, a VAC represents an episode of sustained respiratory deterioration, caused by both infectious and non-infectious conditions and complications occurring in mechanically-ventilated patients. A VAC is defined by a sustained period of worsening oxygenation that immediately follows a baseline period of stability or improvement on the ventilator. To meet the VAC definition, a mechanically-ventilated patient must have at least two calendar days of stable or decreasing daily minimum positive end-expiratory pressure (PEEP) or fraction of inspired oxygen (FiO2) followed by at least 2 days of increased daily minimum PEEP or FiO2. The increase in the daily minimum PEEP must be ≥ 3cm H2O or an increase in the daily minimum FiO2 of ≥ 0.20 (20 percentage points in oxygen concentration) than the daily minimums during the baseline period.

An IVAC is defined as a VAC in which the patient has either a temperature or white blood cell count outside the expected ranges provided by NHSN and a new, eligible antimicrobial agent started and continued for four or more calendar days. Both of these triggers have to happen within the window period defined as on or after the third day of mechanical ventilation and within 2 days before or after the onset of worsening oxygenation.

Possible VAP is defined by the presence of purulent secretions or a positive lower respiratory tract culture. Probable VAP is defined by the presence of purulent secretions in addition to a positive lower respiratory tract culture meeting certain quantitative or semi-quantitative thresholds of pathogen growth (endotracheal aspirate [ETA], >105 CFU/ml; BAL, >104 CFU/ml; tissue, >104 CFU/g; protected specimen brush [PSB], >103 CFU/ml). The probable VAP definition could also be met based upon the presence of a positive pleural fluid culture, lung tissue with histopathological evidence of infection, or positive diagnostic tests for Legionella or selected respiratory tract viruses, without the concomitant requirement for purulent secretions.

This implementation project was focused on getting the needed data for BJH due to the surveillance burden at that facility. Analysis of VAE rates over the study period were evaluated using linear regression (SPSS V 21.0, IBM SPSS Inc, Armonk, NY).

Development and Implementation Processes

BJC previously developed an enterprise clinical decision support system and repository (CDS) for surveillance and real-time alerting.[4] The Pharmacy Expert Systems database (PES) has been in use since 1994 and receives registration, lab, vital sign, pharmacy, microbiology, and select nursing assessment data through a combination of some real-time and nightly batch interfaces. This data allows for the generation of batched alerts, some real-time alerts, and both prospective and retrospective surveillance monitoring for a wide range of hospital initiatives.

Prior to starting the VAE project, the implementation team did a gap analysis between the current database and the requirements of the NHSN algorithm. The analysis showed that the current CDS contained all of the necessary data for calculating the VAC and IVAC candidates, with the exception of some of the ventilator settings. In late 2012, BJC initiated a new data acquisition project to capture the ventilator settings data documented within the hospital EHR.[5]

In an effort to bring the ventilator settings data into CDS, we expanded a nightly data extract from the source clinical documentation system at BJH to include of all data elements needed for accurate determination of VAC and IVAC cases according to the NHSN specifications. Using the ventilator setting data along with existing data available in CDS (including antibiotics, vital signs, and microbiology results), we were able to implement electronic surveillance for the respiratory status (VAC) and the infection and inflammation components (IVAC) of VAE.

Due to data limitations, the electronic algorithm can only identify patients as having a VAC or an IVAC. For example, while microbiology data is available within the clinical data repository, the specific quantitative results required for the purulent respiratory secretions are not reliably available in a discrete format. It would be possible to detect a positive endotracheal aspirate culture, but it would not be possible to apply the requirement of $\geq 10^5$ CFU/ml

with the existing interface. As a result, the final determination for possible or probable VAP requires clinical review of IVAC patients by IP staff.

The manual and electronic surveillance were performed in parallel for 6 intensive care units, 1 step-down long term ventilation unit, 1 oncology unit and 1 advanced heart failure unit at BJH for 8 months, between January and August 2013. The performance of the electronic algorithm for VAC and IVAC surveillance was manually verified by IP staff. In an automated fashion, the electronic algorithm gathered and summarized daily data for every ventilated patient.

During the assessment period, an Excel report with patient identifiers, mechanical ventilator (MV) data, PEEP (minimum), FiO2 (minimum), temperature (minimum and maximum), WBC (minimum and maximum), and antibiotics was provided to IP for review on an ad-hoc basis. IP staff was blinded to the electronic algorithm's decision of VAC or IVAC status. Every patient was reviewed independently by the two sources for 8 months. The electronic algorithm went through several iterations of refinements to ensure the NHSN definitions were correctly applied. After the initial 8 months of validation were completed, the electronic algorithm was incorporated into the daily work of SA for BJH.

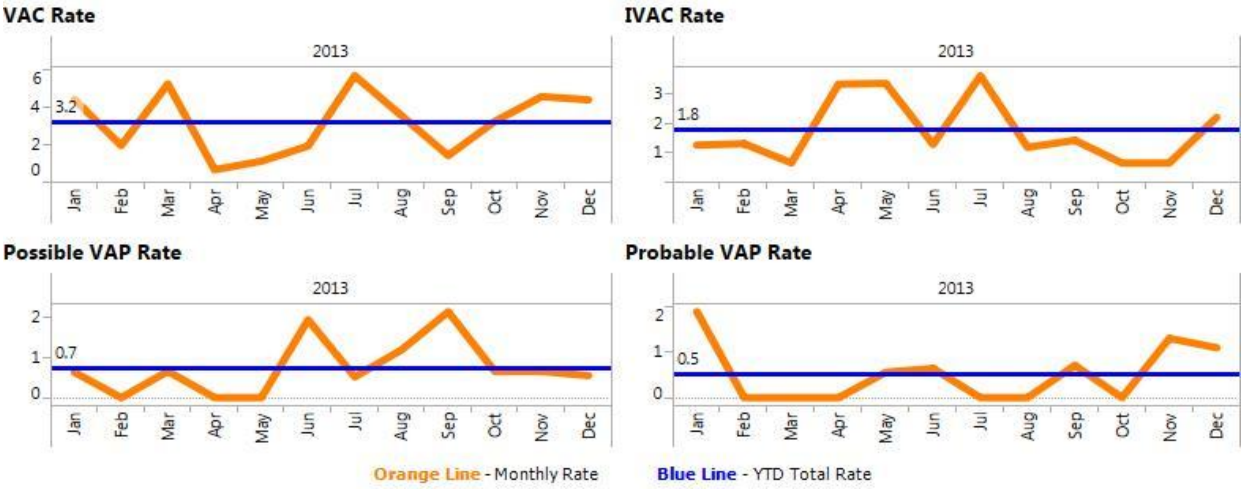
Results

In 2013, there were 3,691 ventilated patient visits, accounting for 19,105 ventilator days at BJH. Of the 3,691 patient visits, 121 were identified with 1 or more VAE events: 62 were VAC (3.2/1,000 ventilator days), 35 were IVAC (1.8/1,000 ventilator days), 14 were possible VAP (0.7/1,000 ventilator days) and 10 were probable VAP (0.5/1,000 ventilator days). VAE rates showed no increasing or decreasing trends over the study period ($p = 0.32$, Figure 1).

Figure 1

Ventilator Associated Event (VAE)

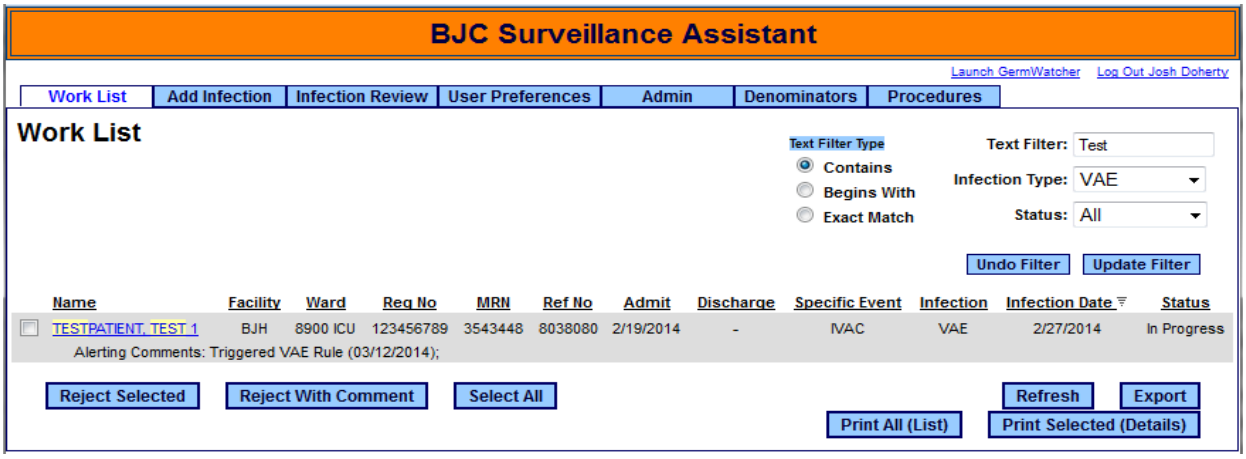
	2013				YTD
	Q1	Q2	Q3	Q4	
All VAE Events:	27	24	37	33	121
VAC	17	6	19	20	62
VAC Rate	3.7	1.3	3.8	4.2	3.2
IVAC	5	13	11	6	35
IVAC Rate	1.1	2.8	2.2	1.2	1.8
Possible VAP	2	3	6	3	14
Possible VAP Rate	0.4	0.6	1.2	0.6	0.7
Probable VAP	3	2	1	4	10
Probable VAP Rate	0.6	0.4	0.2	0.8	0.5
Vent Days	4,645	4,713	4,942	4,805	19,105
Vent Utilization	34%	36%	38%	37%	36%



The electronic algorithm required about 600 hours from an informatics intern to develop, and about 80 hours from a senior informatics analyst to complete. The senior informatics analyst was primarily responsible for a final code review and the logic to incorporate the data into the existing electronic surveillance application. About 175 hours of IP staff time was spent working with developers and validating results. The initial develop time could have been reduced by using a more experienced resource, but the overall cost would have been equivalent given the higher resource cost of a senior informatics analyst compared to an intern.

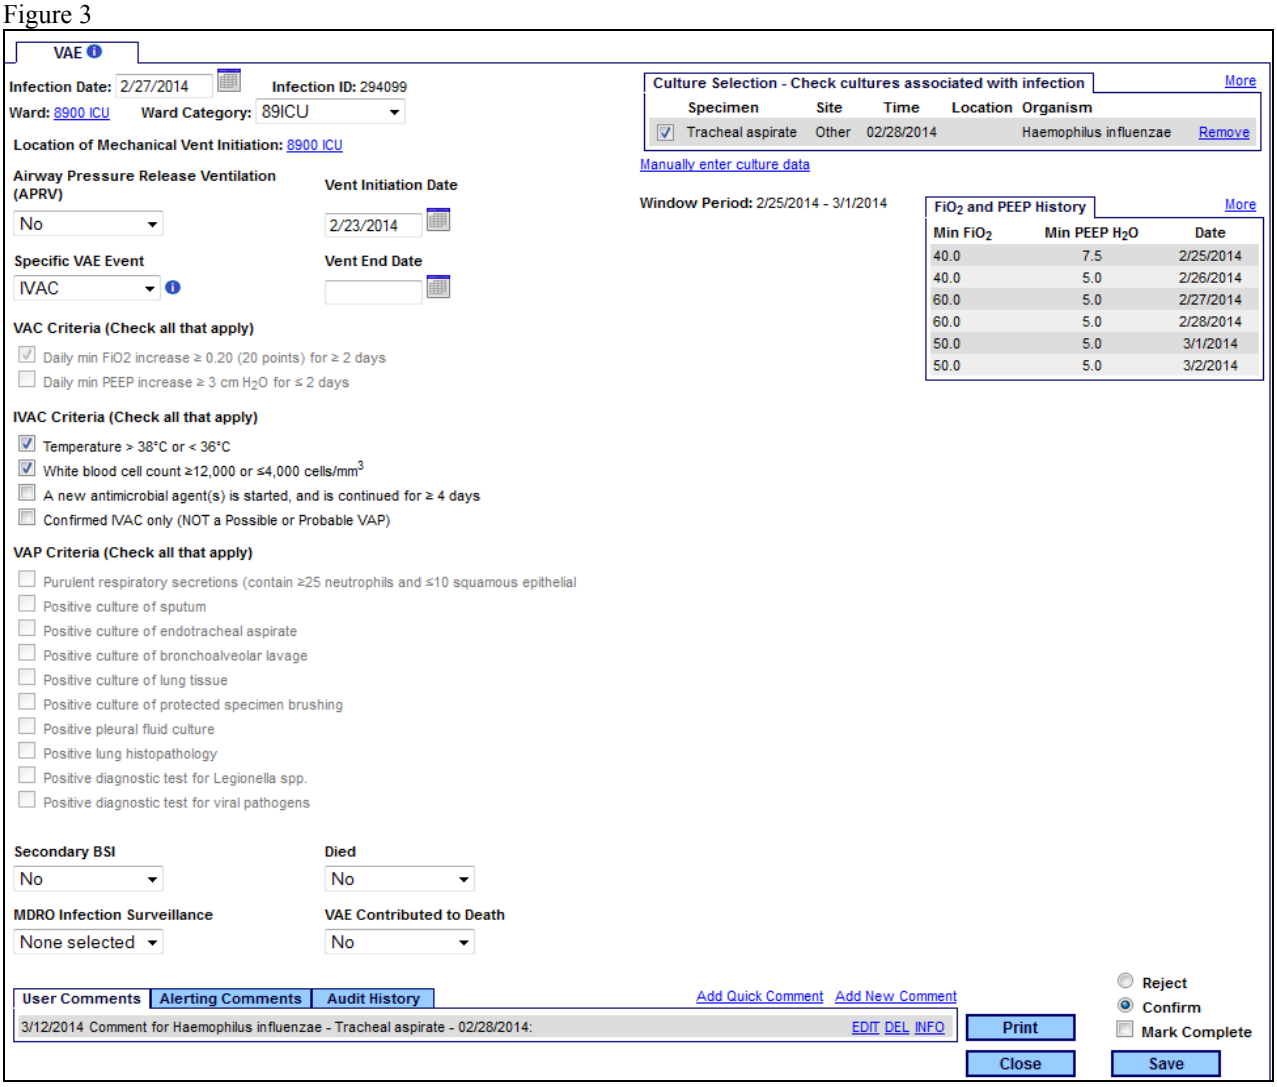
In the 8 months of duplicative review, many tweaks were made to the electronic algorithm to account for intricacies of the process. In the end, the electronic algorithm was able to correctly identify all cases of VAC and IVAC allowing IP staff to then identify possible or probable VAP. After the initial period of reviewing the VAE candidates using a daily report, work was done to incorporate the results of the query into SA that provides the IP staff with a line list that they can review on daily basis (Figure 2).

Figure 2



Initially all new events are loaded into the SA application as either VAC or IVAC. VAC cases are not displayed on the line list since they are not candidates for further classification. IVAC cases must be opened to a detail screen where a workflow module will help the user assess the IVAC case against the possible and probable VAP definitions (Figure 3). The detail page provides the IP staff with as much data as is available in the clinical repository, including microbiology data, room assignments, antibiotics, etc. It also determines the window period, which can change depending on the dates of mechanical ventilation and symptom development.

Figure 3



If the patient meets possible or probable VAP criteria, IP makes the appropriate selections and fills in details marking the case as possible or probable VAP. New VAC and IVAC cases are posted once a day on the SA web interface and IP staff can pull all previously identified cases as well as the new cases. At the time of identification, case information is given to the unit staff where the patient was located. On a monthly basis, rates of each type of VAE are fed back to all areas in a standardized format. All areas are monitored for trends in VAE.

The automated line list report reduced the IP labor efforts for surveillance. The former VAP definition surveillance took approximately 10 hours per ICU per month, equating to about 60 IP hours per month to complete ICU surveillance at BJH. The remaining 3 non-ICU units with ventilated patients generally have low census and surveillance time committed to those unit was not considered in this calculation. It is estimated that completely manual surveillance of the new VAE definition would require the same amount of time (60 hours/month). By manually using the Excel report of components of the VAE definition, that time was reduced to about 2 hours per ICU per month (12 hours/months). The complete automation of the VAE definitions in SA decreased IP time to about 30 minutes per unit per month (3 hours/month), an overall time savings of 57 hours/month.

Discussion

While the electronic VAE surveillance module was successfully deployed at BJH in November 2013, the overall effort represented a significant investment of resources from both the clinical and technical sides of the organization.

The greatest implementation cost was the development and testing of the electronic algorithm. This was in large part due to the complexity of the specifications and the lack of prior experience with the definition. At the time the electronic algorithm was being developed, there was no easy way to validate results outside of a manual review. The development process was very iterative, and questions had to be addressed either by reviewing the specifications or working with our NHSN technical contacts. While the initial investment spent on developing the electronic VAE algorithm and building an infrastructure to accommodate data collection from different hospital systems was significant, BJC is planning to leverage the investment and increase cost savings by implementing the algorithm enterprise wide and rolling it out to the other 9 adult hospitals.

It is important to note that NHSN now offers a web-based interface that takes relevant patient level data (mechanical ventilation dates, FiO2, PEEP values, etc.) and applies the VAC or IVAC criteria. This VAE Calculator provides a quick way to validate the algorithm logic and test out different rule scenarios against a standard. Having this available a year ago would have dramatically reduced the development time, and it has already provided an easier way to perform regression testing when bugs or issues have been uncovered. Furthermore, NHSN has announced that a new web service will be developed that receives de-identified patient data via an XML message. The web service returns an XML result set with the VAC/IVAC classification. While this does replace some of the functionality we have developed, the advantage to hospitals and vendors with the capacity to interact with the web service is clear in terms of development time and future maintenance as definitions change. At the time this paper was written, a prototype of the NHSN's web service was available, but no clear timeline was provided for a production version. Hospitals and vendors still have to do the work to build the required XML message and there has to be some infrastructure for storing the data that is returned. In the case of BJC HealthCare, the results of the web service would be used to populate the same infection tables that populate the detail screens from Figures 2 and 3.

Another significant challenge with the implementation involved getting access to the necessary ventilator data. The pilot hospital involved in the algorithm development already had a daily interface of ventilator data in place prior to the start of the project. This reduced the effort required to capture the additional fields required for the algorithm. In addition, the hospital had a clear champion who worked with the application team to modify the extract with the additional data fields. The interfaces for the other system hospitals require an entirely new interface to be developed. The project team had to meet with subject matter experts at the hospitals to make sure the necessary fields were included in the extract request, and Meaningful Use and other regulatory initiatives have limited access to key technical resources.

The remaining project resource investment was associated with creating the new detail web page in the SA application. The developers worked closely with the IP staff to design the screens with the goal of making it easy to apply the correct definitions. The workflow was considered, and dynamic content was added to reduce the chance of data entry errors. For example, an IVAC cannot be marked as complete unless the specific checkbox is selected that indicates no evidence of a possible or probable VAP.

There have been some concerns raised by those involved in developing and testing these new definitions. One is that healthcare workers may be able to learn to "game the system" by making small, short changes in ventilator settings daily to skew the true picture of a patient's progress. As the team has access to all ventilator setting changes for the patient population, this can be analyzed. One next step for the group is to trend patient-specific ventilator settings, looking for daily outliers.

This development project was strengthened by the fact that the validation included many patients from various medical backgrounds, including several types of intensive care and other critical care units and the oncology population. Due to this fact, and the extensive 8 month period of manual validation of the electronic algorithm, the group hypothesizes that the electronic algorithm is robustly built to correctly identify VAE in a variety of patient populations. However, as this study was completed in a large academic institution, it may not be generalizable to all populations. The application will be applied to the community hospitals that are members of BJC Healthcare, with additional manual validation of the electronic algorithm to ensure generalizability.

To date, the numbers of VAC, IVAC, possible VAP, and probable VAP have been small, and within anticipated ranges. No interventions have been specifically developed in response to this data, however there are ongoing efforts in these units to decrease adverse events associated with ventilator use. As we continue to perform surveillance and gather data, we will be able to better analyze and interpret them for use in intervention development.

Conclusion

BJC HealthCare was able to successfully implement an electronic VAE surveillance algorithm based on the CDC VAE definition and incorporate it into an existing electronic surveillance system at BJH. This saves an estimated 57 hours of IP staff work per month at just one hospital by providing decision support for identification of VAC and IVAC cases and reducing the burden of data collection. The VAE module also helps provide the additional data required to classify an IVAC case as possible or probable VAP cases. The data is stored in a local repository where it can be queried or eventually uploaded to NHSN.

The costs involved in the development and implementation must be carefully weighed against the savings obtained. Even with a robust data infrastructure, there was significant development cost in getting access to the necessary data, creating the electronic algorithm, and modifying the existing web application. In the case of a large multi-hospital system the cost can be easier to justify due to the volume of patients receiving mechanical ventilation and the ability to leverage the initial investment by implementing the electronic algorithm enterprise wide as BJC is planning on doing.

For a smaller hospital without a strong IT and data infrastructure, the costs might well outweigh the benefit. This is especially true when taking into account the new tools that NHSN is providing for hospitals and vendors to use in the classification of the VAC and IVAC cases.

Automatically Classifying Question Types for Consumer Health Questions

Kirk Roberts, PhD, Halil Kilicoglu, PhD, Marcelo Fiszman, MD, PhD,
Dina Demner-Fushman, MD, PhD
U.S. National Library of Medicine, Bethesda, MD

Abstract

We present a method for automatically classifying consumer health questions. Our thirteen question types are designed to aid in the automatic retrieval of medical answers from consumer health resources. To our knowledge, this is the first machine learning-based method specifically for classifying consumer health questions. We demonstrate how previous approaches to medical question classification are insufficient to achieve high accuracy on this task. Additionally, we describe, manually annotate, and automatically classify three important question elements that improve question classification over previous techniques. Our results and analysis illustrate the difficulty of the task and the future directions that are necessary to achieve high-performing consumer health question classification.

Introduction

Questions posed in natural language are an intuitive method for retrieving medical knowledge. This is especially true for consumers, who may both lack medical background knowledge and be untrained in clinical problem solving techniques. The types of questions consumers ask differ as well. Medical question answering systems targeted to professionals often utilize the PICO structure,[1,2] which is particularly useful for comparative treatment questions. Conversely, consumers often ask for general information about a disease they have been diagnosed with, potential diseases associated with their symptoms, the range of potential treatment options, the typical prognosis, and how they might have acquired the disease.[3] Additionally, the most appropriate type of answer for a consumer is qualitatively different than that for a medical professional. The PICO-based methods typically draw answers from the latest medical research, such as that available in Medline®. Since consumers often lack the necessary medical background knowledge, providing them with the latest research may not aid their understanding. Instead, answers should be taken from consumer-oriented resources such as MedlinePlus® and other medical encyclopedias. Because of the differing nature in the type of questions and the most appropriate answers, consumer health question answering systems necessarily diverge from approaches that target medical professionals. In this work, we tackle a critical aspect of consumer question answering: automatically classifying the type of question asked by the consumer. The question type can then be used to identify the most appropriate resource to retrieve answers.

The National Library of Medicine® (NLM®) provides a medical information service, largely targeted toward consumers, as part of its library operations. Confirming the findings of Zhang,[3] the requests NLM receives from consumers contain questions that are different in nature from those posed by medical professionals. The consumer health questions concentrate less on the technical details, and more on general information, such as prognosis, treatment, and symptom information for diseases. Furthermore, consumer health requests often contain multiple questions, with significant amounts of co-reference and ellipses. For example:

- *I have recently been diagnosed with antisynthetase syndrome. Could you please provide me with information on antisynthetase syndrome? I am also interested in learning about prognosis, treatment, and clinical trials.*
- *Although I have not been diagnosed with trimethylaminuria, I have been having a foul odor for about 2 years. Can you tell me more about this condition? How can I be tested? Is there a cure for trimethylaminuria?*

This work is part of a larger project to automatically provide feedback to consumers with appropriate resources for their medical questions. Currently, NLM answers these questions manually, which means that a consumer question might not be answered for several days. By performing this process automatically, consumers can have their questions answered immediately. The process of extracting and representing individual questions from the larger request has already been discussed,[4,5] as well as the handling of co-reference and ellipses,[6] but the difficult problem of accurately classifying the individual consumer health questions has, to our knowledge, not yet been studied.

In this work, we discuss our initial attempt to automatically classify consumer health questions. While many of the questions are not strictly "factoid" questions in the style of the TREC question answering competitions,[7] in

this paper we focus on identifying the structural question elements typically found in factoid questions. Our results demonstrate that recognizing these elements with high accuracy can indeed aid in automatic question classification, but further work is necessary to make significant improvements in classifying consumer health questions. In summary, the primary contributions of this work are:

(i) presenting methods for automatically classifying consumer health questions,
(ii) demonstrating the importance of understanding the key semantic elements of each question, and
(iii) discussing what further work is needed to achieve high accuracy classification of consumer health questions.

Methods

We begin by describing our question types and the data they are annotated on. Next, we describe previous approaches to question classification to provide useful baseline methods. Finally, we describe additional annotations and features proposed in this work for consumer health question classification.

A. Question Types

We classify questions using the following question types. In many respects, the question types are generalizable to non-consumer medical questions. A more complete description of each question type, along with annotation rules and many more examples, can be found in Roberts et al.[8] To illustrate how the question types correspond to encyclopedic sections, for each question type we list the sections of MedlinePlus where answers are most likely to be found (though our system uses several other sources as well).

(1) ANATOMY: Identifies questions asking about a particular part of the body, such as the location affected by a disease. (Answers to ANATOMY questions are typically found in the "Anatomy/Physiology" section.)
   – *Does IP affect any areas inside the body, such as internal organs?*

(2) CAUSE: Identifies questions asking about the cause of a disease. This includes both direct and indirect causes, such as factors that might increase the susceptibility to a disease. ("Common Causes")
   – *Can pregnancy trigger such an issue?*

(3) COMPLICATION: Identifies questions asking about the problems a particular disease causes. This primarily focuses on the risks faced by patients with the disease and does not include the signs/symptoms of a disease. ("Related Issues")
   – *Are carriers of cystic fibrosis at a higher risk for other health conditions?*

(4) DIAGNOSIS: Identifies questions asking for help making a diagnosis. Our question answering system is not designed to provide a direct diagnosis. However, the DIAGNOSIS type does include questions asking about diagnostic tests, or methods for determining the difference between possible diagnoses (differential diagnosis). ("Diagnosis", "Testing")
   – *Can Bloom syndrome be detected before symptoms appear?*

(5) INFORMATION: Identifies questions asking for general information about a disease. This includes type information about diseases, e.g., whether two disease names represent the same disease, or if one disease is a type of another disease. ("Definition", "Description")
   – *Can you please provide me with general information about hyper IgD syndrome?*

(6) MANAGEMENT: Identifies questions asking about the management, treatment, cure, or prevention of a disease. ("Treatment", "Prevention")
   – *Are there new therapies for treatment of pili torti?*

(7) MANIFESTATION: Identifies questions asking about signs or symptoms of a disease. ("Symptoms")
   – *Are there any physical characteristics associated with the disorder?*

(8) OTHEREFFECT: Identifies questions asking about the effects of a disease, excluding signs/symptoms (MANIFESTATION) or risk factors (COMPLICATION). When the question requires medical knowledge to understand a given effect is actually a MANIFESTATION or COMPLICATION, it is instead classified as an OTHEREFFECT. ("Symptoms", "Related Issues")
   – *Can tuberous sclerosis affect eye closure?*

Request:
I have been recently diagnosed with antisynthetase syndrome. Could you please provide me with information on antisynthetase syndrome? I am also interested in learning about prognosis, treatment, and clinical trials.
Decomposed Questions:
Q1) Could you please provide me with information on antisynthetase syndrome?
Q2) I am also interested in learning about prognosis.
Q3) I am also interested in learning about treatment.
Q4) I am also interested in learning about clinical trials.

Table 1: Question Decomposition Example.

(9) PERSONORG: Identifies any question asking for a person or organization involved with a disease. This can include medical specialists, hospitals, research teams, or support groups for a particular disease. Answers to PERSONORG questions are typically not found in MedlinePlus articles, but may be found in links on MedlinePlus pages (especially for support groups).
   – *I would like information about which doctors could treat me.*

(10) PROGNOSIS: Identifies questions asking about life expectancy, quality of life, or the probability of success of a given treatment. ("Expectations")
   – *I would like to know what the life expectancy is for people with this syndrome.*

(11) SUSCEPTIBILITY: Identifies questions asking how a disease is spread or distributed in a population. This includes inheritance patterns for genetic diseases and transmission patterns for infectious diseases. ("Mode of Inheritance", "Prevalence")
   – *Are people of certain religious backgrounds more likely to develop this syndrome?*

(12) OTHER: Identifies disease questions that do not belong to the above types. This includes non-medical questions about a disease, such as requests for financial assistance or the history of a disease. Answers to OTHER questions are typically found in the "Definition" and "Description" sections, though by definition these answers may be found anywhere in the encyclopedic entry.
   – *How did Zellweger Syndrome get its name?*

(13) NOTDISEASE: Identifies questions that are not handled by our question answering system.
   – *Is there any information about what genes are on chromosome 20q12?*

B. Data

As a source for consumer health questions about diseases, we used 1,467 publicly available requests on the Genetic and Rare Diseases Information Center (GARD) website. It may be argued that, since these requests are about rare diseases, they do not constitute a representative sample of disease questions. While this may be true, GARD requests are still appropriate for this task because the aspects of diseases (treatment, prognosis, etc.) that the requests are concerned with are shared between all diseases. Additionally, since there are far fewer online resources for rare diseases, these questions may be more reflective of the types of questions consumers actually ask than other disease question sources.

The GARD requests contain multiple question sentences, and many of the question sentences contain requests for different types of information, thus the questions were annotated for syntactic decomposition as described in Roberts et al.[4] Table 1 illustrates an example of question decomposition. This decomposition process results in 2,937 questions from the 1,467 GARD requests. Additionally, these requests are annotated with a FOCUS, typically one per request, the disease the consumer is interested in learning more about. In Table 1, the FOCUS is *antisynthetase syndrome*. Since our question answering approach primarily utilizes medical encyclopedias, the FOCUS is often the encyclopedic entry, while the question type is the section of the entry in which the answer is found. For cause-and-effect questions, for example, if the FOCUS is the cause, the answer is likely to be found in the effect section, and vice versa.

The process of annotating the thirteen question types on the GARD data is described more thoroughly in Roberts et al.[8] In this paper, we describe the first automatic classification methods on this data. Additionally, we have manually annotated additional elements, described below, not discussed in any of our previous work.

C. Previous Question Classification Approaches

To investigate how classifying consumer health questions differs from previous forms of question classification, we present four previous machine learning-based methods and their corresponding features. These methods provide solid baseline approaches as well as a reliable set of features from which to choose for consumer health question classification. In some cases, as described below, we slightly alter features from their original versions due to either resource availability or appropriateness. In other cases, the original feature description might not have been completely clear, and thus we chose the best interpretation based on our data.

Li and Roth[9] presented the first machine learning method for classifying questions by their answer type. Answer types specify the semantic class of the answer, as opposed to our question types which specify the search strategy (typically, the section of an encyclopedic entry). In many cases, the answer type and question type are identical.

- f_{LR1}: Words. This is the classic "bag-of-words"feature. We use the caseless form of each token
- f_{LR2}: Part-of-speech tags
- f_{LR3}: Phrase chunks
- f_{LR4}: Head chunks. The first noun phrase chunk and the first verb phrase chunk in the question
- f_{LR5}: Named entities. Li and Roth used named entity types such as PERSON and LOCATION, which make less sense for our data. Instead, we use UMLS semantic types
- f_{LR6}: Semantically related words. Here Li and Roth utilized lexicons that would capture similar words such as *actor* and *politician* for the HUMAN:INDIVIDUAL type. Instead, we approximate this feature using the cue phrases from Kilicoglu et al.[6]

Yu and Cao[10] presented a method for classifying into a similar set of classes to our own, but tailored for questions posed by physicians instead of consumers.

- f_{YC1}: Words, the same as f_{LR1}
- f_{YC2}: Stemmed (lemmatized) words
- f_{YC3}: Bigrams
- f_{YC4}: Part-of-speech tags, the same as f_{LR2}
- f_{YC5}: UMLS concepts. This feature is useful to recognize UMLS synonyms
- f_{YC6}: UMLS semantic types, the same as f_{LR5}

Liu et al.[11] presented a method for distinguishing consumer health questions from professional questions. Their features are designed more to capture the lexical tendencies of consumers and professionals against all types of questions, but we utilize them here because their work is one of the first studies in automatically classifying consumer questions.

- f_{LAY1}: Words, the same as f_{LR1}
- f_{LAY2} - f_{LAY4}: Minimum, maximum, and mean word length in the question
- f_{LAY5}: The question length in words
- f_{LAY6} - f_{LAY8}: Minimum, maximum, and mean inverse document frequency from Medline 2010. Instead, we use a 2013 version of Pubmed Central

Patrick and Li[12] presented a method for classifying clinical questions about information within an EHR. The questions in their data were posed by medical staff in an ICU. They classify clinical questions into a taxonomy and a set of template questions to facilitate answer retrieval within an EHR system. Patrick and Li used SNOMED-CT, while we use all of UMLS.

- f_{PL1}: Unigrams, same as f_{LR1}
- f_{PL2}: Lemmatized unigrams, same as f_{YC2}
- f_{PL3}: Bigrams, same as f_{YC3}
- f_{PL4}: Lemmatized bigrams
- f_{PL5}: Interrogative word. Typically, a WH-word (e.g., `what`, `how`) or verb (`is`, `could`)
- f_{PL6}: Interrogative word + next token

- f_{PL7}: UMLS semantic types, same as f_{LR5}. Patrick and Li also use a version of this feature limited to the SNOMED category "observable entity". We do not include this specific feature as it has no clear analogue nor recognizable need in our data
- f_{PL8} + f_{PL9}: verb-subject relations in both the original (f_{PL8}) and lemmatized (f_{PL9}) form. While Patrick and Li use the Enju parser, we use the Stanford dependency parser[13] In the question, "*What treatments have you recommended?*", f_{PL8} would be `nsubj(recommended,you)`, f_{PL9} would be `nsubj(recommend,you)`
- f_{PL10} + f_{PL11}: verb-object relations in both the original (f_{PL10}) and lemmatized (f_{PL11}) form, again using the Stanford dependency parser. From the question above, f_{PL10} would be `dobj(recommended,treatments)`, f_{PL11} would be `dobj(recommend,treatment)`
- f_{PL12} - f_{PL15}: Features f_{PL8} - f_{PL11}, but with the subject/object being replaced by `UMLS` if it is a UMLS concept
- f_{PL16} - f_{PL19}: Features f_{PL8} - f_{PL11}, but with the subject/object being replaced by its semantic type if it is a UMLS concept
- f_{PL20}: WordNet synonyms and antonyms of key terms found by analyzing the data. We approximate this by using a WordNet-expanded version of f_{LR6}

Patrick and Li employ three classifiers that each utilize a sub-set of these features. Their unanswerable question classifier (UQC) uses f_{PL2}, f_{PL13}, and f_{PL15}. Their answerable question taxonomy classifier (QTC) uses f_{PL2}, f_{PL13}, f_{PL15}, and f_{PL20}. Their genetic template classifier (GTC) uses f_{PL2}, f_{PL5}, f_{PL6}, f_{PL7}, and f_{PL8}.

D. Question Stems

The *question stem* is the span of text that introduces the question. It is often referred to as the WH-word or interrogative word, though it need not be a classic WH-word (e.g., "*Are the treatments effective?*") or even a single word. It provides a useful signal for indicating the question structure, while also indicating distributional differences in the question types. For example, a *where* question is far more likely to have a PERSONORG or ANATOMY type than a PROGNOSIS or CAUSE type. Examples of question stems are:

- **What** *may be the underlying cause?*
- *At* **what** *age progressive hemifacial atrophy typically present?*
- *If she needs hormonal treatment,* **which** *medication may be the safest choice?*
- **Could** *you please let me know the name of the blood test used to diagnose a vitiligo carrier?*

Not all WH-words are question stems, however, as it depends upon their syntactic function:

- **Are** *there any other recommended treatments other than what my doctor has already tried for this condition?*
- **Have** *any side effects been reported in patients who use these medications?*

We annotated all 2,937 questions with a single-token question stem. 99.2% of questions were judged to have a question stem, and in 76.6% of these the question stem was the first word. The ten most common question stems in the GARD data are *what*, *is*, *how*, *can*, *are*, *if*, *does*, *do*, *looking*, and *could*.

We use a two-step machine learning method for automatically recognizing question stems. First, a question-level SVM determines whether or not a question has a question stem using a bag-of-words model where the first word is intentionally cased and other words are lower-cased. Second, a token-level SVM is used to rank the words in the sentence, with the top-ranked word being chosen as the question stem. This ranker uses the current word (cased as before), lemma, part-of-speech, previous word, and next word as features.

Once recognized, the question stem allows for several useful features during question classification.

- f_{QS1}: Uncased Question stem
- f_{QS2}: Uncased question stem plus the next token
- f_{QS3}: Uncased question stem plus the next two tokens
- f_{QS4}: Uncased question stem plus the next three tokens
- f_{QS5}: Whether or not the question stem is in a pre-defined set of boolean stems
- f_{QS6} + f_{QS7}: Question tokens (uncased + stemmed) ignoring those tokens before the question stem

- f_{QS8} + f_{QS9}: Versions of f_{QS6} and f_{QS7}, respectively, that account for word order after the question stem
- f_{QS10} + f_{QS11}: Similar to f_{QS6} and f_{QS7}, but only over the range of the WHNP in the syntactic parse tree
- f_{QS12} + f_{QS13}: Similar to f_{QS6} and f_{QS7}, but only over the range of the clause in the syntactic parse tree

E. Answer Type Terms

The *answer type term* is the noun phrase that specifies the expected answer type. Due to its importance, a significant amount of question answering research has focused on describing and automatically identifying answer type terms.[14,15] In the traditional TREC-style factoid questions, it is typically found immediately after the question stem *what* in one of several predictable syntactic positions:

- *What* **disease** *does she have?*
- *What* **symptoms** *usually occur?*
- *What is the* **prognosis** *for this disease?*

In our data, however, answer type terms may occur in less predictable locations, or be syntactically dominated by a more general word:

- *Could you tell me some of the* **symptoms** *of cardiomyopathy hypogonadism collagenoma syndrome?*
- *How can I obtain information about* **treatment options** *for FIBGC?*

Additionally, since our interest is in question types instead of answer types, we relax the definition from an *explicit* answer type term to an *implicit* answer type term. For instance:

- *Can women have* **symptoms** *of glucose 6 phosphate dehydrogenase (G6PD) deficiency?*
- *Where can I get information on the official* **recommendations** *for pregnant women?*

Neither question above has an explicit answer type term, as their question stems convey the answer type (boolean for *Can*, location for *Where*). However, implicitly these questions are asking for symptoms and recommendations, respectively. This indirect question style is a major characteristic of our data, and reflects a less formal querying style. We thus use implicit answer type terms for classifying questions, which are more semantic in nature than the syntactically predictable explicit answer type terms. Thus our answer type term annotations resemble something closer to our question types and further from Li and Roth's answer types.

We annotated all 2,937 questions with a single-token answer type term. 62.4% of questions were judged to have an answer type term. The ten most common answer type terms in the GARD data are *information*, *treatment*, *symptoms*, *prognosis*, *more*, *treatments*, *chances*, *testing*, *risk*, and *expectancy*.

We use the same two-step process to identify answer type terms as we do question stems. Once recognized, the answer type term allows for many useful features:

- f_{ATT1}: Whether or not an answer type term is present
- f_{ATT2} + f_{ATT3}: The uncased and lemmatized answer type term token
- f_{ATT4}: The WordNet hypernyms of the answer type term token
- f_{ATT5} + f_{ATT6}: The uncased and lemmatized words in the answer type term's noun phrase
- f_{ATT7}: The WordNet hypernyms of the words in the answer type term's noun phrase
- f_{ATT8}: The full noun phrase of the answer type term

F. Answer Type Predicates

Not all questions specify their answer type with a question stem or nominal answer type term. Especially in our data, often the answer type is specified with a verb or adjective. To differentiate these from answer type terms, we refer to the verb or modifier span as the *answer type predicate*. Examples of answer type predicates are:

- *How is this condition* **treated***?*
- *If so, what is the likelihood he could* **pass** *it on to his next child?*
- *Is this a* **genetic** *disorder?*

The first two examples above illustrate verbal answer type predicates, while the third illustrates and adjective answer type predicate. The second example also shows a case where an answer type term (underlined) and an answer type

predicate both exist in the same question. In this case, the answer type predicate is more useful in determining a question type of SUSCEPTIBILITY, but often both are necessary to make a proper decision.

We annotated all 2,937 questions with a single-token answer type predicate. 54.2% of questions were judged to have an answer type predicate. The ten most common answer type predicates in the GARD data are *treated*, *have*, *is*, *diagnosed*, *causes*, *affect*, *genetic*, *cause*, *tested*, and *help*.

We use the same two-step process to identify answer type predicates as question stems and answer type terms. The feature that utilize answer type predicates (f_{ATP1} - f_{ATP7}) correspond exactly with the answer type term features. The only exception is that adjectives in WordNet, unlike verbs and nouns, cannot have hypernyms.

Collectively, we refer to the question stem, answer type term, and answer type predicate as the *key question elements*.

G. Classifier

To automatically classify question types, we utilize a multi-class SVM[16]. Due to the wide variety of features described in this paper, we use an automatic feature selection technique[17] to choose the best sub-set of features. Because many of these features convey redundant information, using every feature would not only be slower, but would result in over-training and a drop in accuracy of 3-4%. Ideally, we would have sufficient annotated data to perform these experiments on a development set and provide a final evaluation on a held-out test set. The main goal of this paper, however, is to explore the utility of various machine learning features on this problem. The feature selection technique relies on a 5-fold cross validation on the full data set using a different view (a shuffled split) of the data from that used in the Results section to ensure more generalizable results. Furthermore, since the key question elements are trained on the same data, we utilize stacking to ensure the relevant features are representative of the automatic output.

In addition to replicating the existing feature sets above, we propose three additional feature sets chosen with automatic feature selection:

- CQT_1: The best features without key question element features: f_{LR1}, f_{PL6}, f_{LR5}, f_{LAY7}, f_{LAY8}, f_{LAY4}
- CQT_2: The best features using the automatic key question elements: f_{QS4}, f_{QS7}, f_{QS10}, f_{ATT4}, f_{ATP3}, f_{ATP8}, f_{LR6}
- CQT_3: The same features as CQT_2 using the *gold* key question elements

Feature set CQT_1 allows us to determine a baseline without any key question element involvement. Feature set CQT_2 provides an expectation of how well our overall method would perform in practice. Finally, feature set CQT_3 allows us to establish a ceiling for the utility of key question elements based on the gold annotations.

Results

The results for our key question element classifiers on a 5-fold cross validation are shown in Table 2(a). Question stem recognition is the easiest task with an F_1-measure of 96.16, largely due to the limited vocabulary and the frequency of the first word acting as the question stem. The answer type term recognizer was the next best at 84.08, likely because the answer type terms are nouns that often occur in specific contexts. Finally, the answer type predicate recognizer has the most difficulty with an F_1-measure of 76.81. The fact that only around half of questions have an answer type predicate, while almost every question has at least one verb or adjective, likely leads to the lower score. While it is certainly possible to improve the automatic recognition of these question elements, below we discuss why dramatic improvements to the accuracy of these methods might not result in similar improvements to the overall question type classifier.

The results for question classification are shown in Table 2(c). The baseline bag-of-words model performs at 76.9%. The previous question classification techniques barely out-perform the baseline, with one system even under-performing this baseline. Feature set CQT_1 demonstrates slight improvements (an increase of 0.6 points) can be made over Yu and Cao's feature set by automatic feature selection. The key question element features (CQT_2), however, show a larger improvement of 2 percentage points. When gold question elements are used (CQT_3), this improves to 4 points over Yu and Cao's method and 5.5 points over the bag-of-words baseline. This ceiling, however, appears fairly low considering we used gold question elements. Originally this was thought to be a result of annotation inconsistency, but upon further analysis several interesting sources of error emerge, discussed below. Finally, Table 2(b) provides details of how well CQT_3 classifies each question type. The F_1 scores are largely reflective of the imbalances in the

	Precision	Recall	F_1
Question Stems	95.97	96.36	96.16
Answer Type Terms	84.47	83.69	84.08
Answer Type Predicates	76.90	76.71	76.81

PersonOrg	128	87.1	78.9	82.8
Prognosis	313	78.9	79.9	79.4
Susceptibility	420	78.0	86.0	81.8

(b) Detailed question classification results by question type using CQT_3 feature set.

	Accuracy
Bag-of-words	76.89%
Li and Roth (2002)	77.45%
Yu and Cao (2008)	78.43%
Liu et al. (2011)	76.37%
Patrick and Li (2012) – UQC	77.41%
Patrick and Li (2012) – QTC	77.76%
Patrick and Li (2012) – GTC	77.76%
CQT_1	79.01%
CQT_2	80.40%
CQT_3	82.42%

(c) Results for automatic classification of question types.

Min # Elements	# Questions	Accuracy
1	2,814	82.16
2	2,606	84.92
3	2,481	86.50
4	2,353	87.46
5	2,286	88.15
10	1,919	90.20
25	1,538	92.39

(d) Sparsity Experiment. Demonstrates how accuracy of CQT_3 model increases as questions with uncommon question elements are removed.

Table 2: Experiments

data, though OTHEREFFECT appears particularly difficult while PERSONORG, CAUSE, and MANIFESTATION appear particularly simple relative to their relative frequencies in the data.

Discussion

The fact that using gold question elements only raised the score slightly is somewhat surprising. These are the elements of a question that humans intuitively look for while annotating. The semantic gap between answer types and question types does not fully explain the 17.6% error rate when using gold elements. We performed a detailed error analysis to understand the major types of errors made when using gold elements.

The first major type of error involves word sense ambiguity, where a question element could have multiple possible interpretations. For instance:

- *My lower back doesn't seem to work, and I wonder if I will ever be able to* **run**. PROGNOSIS
- *Does CREST syndrome* **run** *in families?* SUSCEPTIBILITY
- *Can you send me a* **link** *concerning hereditary fructose intolerance?* INFORMATION
- *Is there a* **link** *between MELAS and a person who is not really strong?* OTHEREFFECT

In the first two examples, different senses of the answer type predicate *run* are used. In the first, *run* corresponds to the WordNet sense defined as "move fast by using one's feet". This corresponds to inquiring about a disease's impact on a part of one's lifestyle, which we define as PROGNOSIS. In the second case, *run* corresponds to the WordNet sense meaning "occur persistently". The question is therefore asking whether the disease is passed genetically and is thus a SUSCEPTIBILITY question. In our data, the answer type predicate *run* corresponds more with SUSCEPTIBILITY and thus the first question was mis-classified. The next two examples illustrate different senses of the answer type term *link*. The first *link* refers to a website and should be classified INFORMATION. The second *link* is referring to a causal connection between a disease and a possible effect. This question was annotated as OTHEREFFECT. In our data, the answer type term *link* corresponds more with OTHEREFFECT, and so the first *link* was mis-classified. Clearly, some form of word sense disambiguation (WSD) might prove helpful, but WSD has been shown to be a very difficult and highly domain-dependent task[18]. We therefore leave the task of WSD in consumer health questions to future work.

The word sense problem illustrates a key insight into how consumer health questions differ from professional questions. Consumers often lack the terminological familiarity to pose questions in an unambiguous manner. For example, a health professional might have written the second and fourth questions above as:

Answer Type Terms	information, treatment, symptoms, prognosis, more, treatments, chances, testing, risk, expectancy, research, chance, options, cure, test, people, studies
Answer Type Predicates	treated, have, is, diagnosed, causes, affect, genetic, cause, tested, help, treat, associated, having, rare, inherited

Table 3: Answer type terms and answer type predicates with at least 25 instances in our data.

- *Is CREST syndrome* **hereditary***?*
- *Is physical weakness a* **manifestation** *of MELAS?*

In these questions, the key question elements are entirely unambiguous, and should be easily recognized by automatic classifiers. Instead, ambiguous words like *run* and *link* are sufficiently common in the training data to result in misclassification of questions where those words might have actually been the best choice of terminology. Note that this is a different terminological problem from that discussed by McCray et al.[19] In their work, terminology issues arose from the way diseases were specified. For question classification, the disease itself is largely unimportant since we are trying to classify which aspect of the disease the user is interested in.

A second important type of error when using gold question elements has to do with data sparsity: if a question element only appears once or twice, there is not sufficient evidence for its proper question type. For instance:

- *I'm looking for a* **dermatologist** *in my area who has experience with this condition.* PERSONORG
- *What is the* **remedy** *of mixed connective tissue disorder?* MANAGEMENT

While clearly unambiguous, *dermatologist* and *remedy* each only appear once in our data. Resources like WordNet can be utilized to recognize a *dermatologist* is a *doctor*, and a *remedy* is a *cure*, and indeed f_{ATT4} does just this. Yet hypernym features also introduce a good deal of noise, and often aren't highly trusted by the classifier. We can explore the impact of sparsity on question classification by simply removing questions with uncommon elements. Table 2(d) shows this experiment. It is relatively safe to say that having at least 10 occurrences of a question element in the data removes the effects of sparsity, in which case the error rate is reduced by almost half.

Finally, the sparsity experiment provides a useful mechanism for exploring the role of the semantic gap between an answer type (the form or class of an answer) and the question type (which is more related to the topic). Table 3 lists the elements that occur at least 25 times in the data. Clearly, some are ambiguous (e.g., *have*, *options*), but many of the seemingly unambiguous words do not correspond to one specific question type. This is due to the semantic difference between answer types and question types. For example, the answer type predicate *tested* is used in 18 DIAGNOSIS, 12 SUSCEPTIBILITY, and 2 PERSONORG questions. In each case *tested* is being used in the same sense. Furthermore, the answer type term *people* is used in 11 SUSCEPTIBILITY, 9 OTHEREFFECT, 6 PERSONORG, 2 MANAGEMENT, and 2 PROGNOSIS questions. For instance:

- *How can I be* **tested** *for this condition?* DIAGNOSIS
- *Who in the family needs to be* **tested** *for the carrier gene for MLD?* SUSCEPTIBILITY
- *How many* **people** *are affected by Alexander disease?* SUSCEPTIBILITY
- *I would like to contact other* **people** *with epidermolysis bullosa acquisita.* PERSONORG

The first use of *tested* is in a question asking for a diagnostic test, and thus a DIAGNOSIS question. The second question asks *who* requires testing because they are genetically susceptible. In the third question, *people* is being used as a unit of measure for prevalence (SUSCEPTIBILITY), while the fourth question uses *people* to imply other sufferers (PERSONORG). As could be seen in these examples, in order to recognize question types with much higher accuracy than the systems presented here, methods will need to be developed to understand the role an answer type plays in determining the consumer health question's class.

Conclusion

We have presented a method to automatically classify consumer health questions into one of thirteen question types for the purpose of supporting automatic retrieval of medical answers. We have demonstrated that previous question classification methods are insufficient to achieve high accuracy on this task. Additionally, we described, annotated, and classified three important question elements that improve question classification over previous techniques. Our results showed small improvements on a difficult task. We concluded by motivating importance of overcoming word sense ambiguity, data sparsity, and the answer type/question type semantic gap for future work.

Abstract

Condition-specific registries are essential resources for supporting epidemiological, quality improvement, and clinical trial studies. The identification of potentially eligible patients for a given registry often involves a manual process or use of ad hoc software tools. With the increased availability of electronic health data, such as within Electronic Health Record (EHR) systems, there is potential to develop healthcare standards based approaches for interacting with these data. Arden Syntax, which has traditionally been used to represent medical knowledge for clinical decision support, is one such standard that may be adapted for the purpose of registry eligibility determination. In this feasibility study, Arden Syntax was explored for its ability to represent eligibility criteria for a registry of very low birth weight neonates. The promising performance (100% recall; 97% precision) of the Arden Syntax approach at a single institution suggests that a standards-based methodology could be used to robustly identify registry-eligible patients from EHRs.

Introduction

The increased adoption of Electronic Health Record (EHR) systems for the management of patient data has largely been touted for the ability to improve health care outcomes[1-4] as well as to support research endeavors[5-7]. An essential first step in the enablement of EHR data to support research is the identification of patient cohorts that match a specified set of criteria[8,9]. Myriad approaches that leverage healthcare standards have been described for identifying such types of patient cohorts within EHR systems to serve as subjects of prospective clinical trials[8,10]. By contrast, there has been limited description of such types of vendor-agnostic approaches that may also be used to populate condition-specific registries from EHR systems.

Condition-specific registries provide a population-level view of retrospective data that may originate from clinical encounters[11,12]. Approaches that may be used for identification of eligible patients for clinical trials could potentially be used for identifying patients that fit a specified set of criteria for inclusion in a registry. Previous work has demonstrated the potential to develop automated approaches for identifying patients eligible for clinical trials based on data that are available in an EHR system[13]. The success of such approaches may also support the development of systems that can further automate the process of populating registries, taking advantage of data that are available within contemporary EHR systems.

Arden Syntax, which dates back to 1989, is a Health Level 7 (HL7) maintained standard for representing clinical knowledge such that it may be used to support clinical decision-making[14]. As an HL7 standard, it is regularly updated and supported by a formal working group that oversees the advancement of the standard in accordance with HL7 processes[15,16]. By maintaining algorithms in self-contained Medical Logic Modules (MLMs), Arden Syntax provides a means to share decision-making rules independent from technical implementation across institutions or environments[17,18]. MLMs are organized into three major categories (*maintenance*, *library*, and *knowledge*) that store information into "slots."[18] The *maintenance* and *library* categories have slots for metadata associated with the management (*maintenance* category) and categorization (*library* category) of a given MLM. The *knowledge* category contains slots that are used for representing the actual clinical knowledge. For example, the *data* and *logic* slots within the *knowledge* category define the variables that will be used within the MLM (*data* slot) and the procedural logic that is required for representing the clinical knowledge for the MLM (*logic* slot).

For an MLM written in Arden Syntax to function, it requires that the source data conform to a usable format. This has historically required custom interfaces for accessing EHR-based data[17,19-21]. By contrast, the secondary use of EHR-based data for research purposes commonly involves the extraction of data into research data repositories. Perhaps the most successful system demonstrating the value of EHR extracted data for secondary use is the Informatics for Integrating Biology and the Bedside (i2b2) platform, which provides a standard and portable interface for browsing health data that may have originated from an EHR[22]. The use of external frameworks, such as

i2b2, therefore helps position research-motivated clinical enterprises to utilize health data for secondary uses[5]. There remain other contexts, however, where the incorporation of such external systems into the health data ecosystem of a clinical enterprise is not feasible or perhaps even permissible. To address this challenge, many EHR vendors provide a "reporting database" that enables one to query data from the EHR using Structured Query Language (SQL). Similar to how previous studies have demonstrated the potential to leverage Arden Syntax for identifying clinical trial patient cohorts from EHR data[23], there may be an opportunity to use similar techniques to identify registry-eligible patient populations.

The Vermont Oxford Network (VON) is a non-profit collaboration that gathers and enables the study of neonatology data from over 900 Neonatal Intensive Care Units (NICUs) that span the globe[24,25]. The data are gathered for neonates from VON members that meet specified eligibility criteria into de-identified registries that have been used to support a range of activities, including quality improvement projects, clinical trials, and outcomes research[25]. VON members each develop a process for identifying eligible neonates according to specified VON criteria and provide data systematically using common formats or interfaces that are maintained by VON. The source systems increasingly include healthcare enterprises that utilize an EHR for primary clinical data gathering and analysis. Due to the potential range of EHR options, including both vendor and homegrown systems, there is motivation to develop a systematic and uniform process to identify eligible neonates whose data may be contributed into the VON registries.

This study explored the potential to leverage Arden Syntax for identifying eligible patients from the EHR at an academic health center EHR. Here, the process for adapting Arden Syntax to be used for identifying cohorts of eligible records from contemporary EHR systems with reporting interfaces is described. The performance of the approach is quantified based on an evaluation relative to a reference standard that included previously identified records for a VON registry. The promising results provide the motivation for developing a comprehensive data abstraction tool that can help automate the process of populating condition-specific registries.

Materials and Methods

The overall goal of this study was to explore the potential of using Arden Syntax for representing eligibility criteria to identify patients whose data might be included in a condition-specific registry. The system and approach were developed and evaluated in accordance with a human subjects protocol that was reviewed and approved by the Committee of Human Research in the Medical Sciences at the University of Vermont. The proposed approach was implemented using Java, making use of the ANother Tool for Language Recognition (ANTLR[26,27]) parser generator to enable the processing of Arden Syntax. The evaluation of the system was carried out using data from Fletcher Allen Health Care (FAHC), the clinical affiliate of the College of Medicine at the University of Vermont.

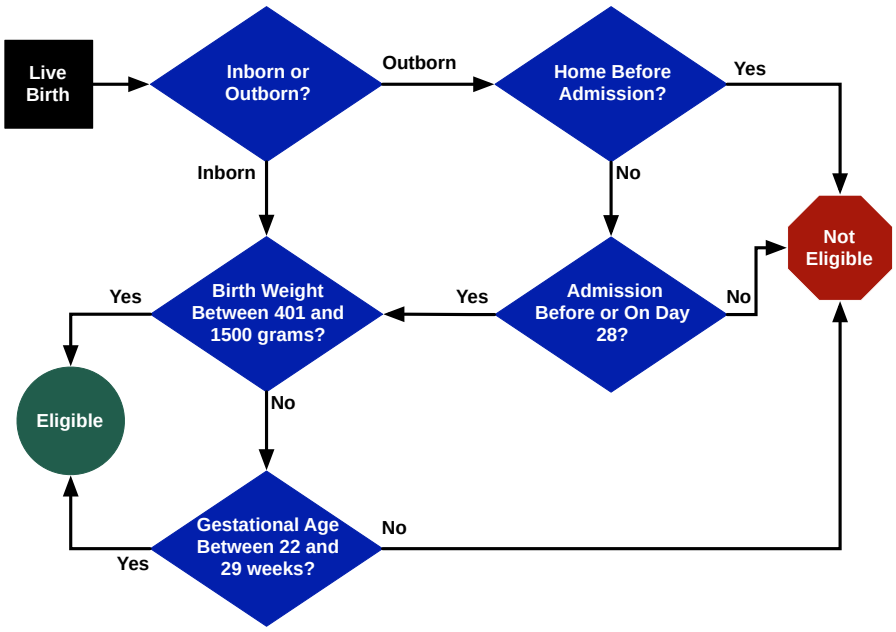

Figure 1: VON VLBW Eligibility Criteria.

VON VLBW Eligibility Criteria. This study focused on the VON Very Low Birth Weight (VLBW) registry, which gathers information on approximately 85% of all VLBW infants born in the US each year. The VON VLBW criteria for eligibility are graphically depicted in Figure 1. Briefly, the registry is focused on gathering data for live-born infants, where status of life is defined as a neonate who breathes or has any evidence for living (e.g., heart beating, umbilical cord pulsation, or definite voluntary muscle movement). Neonates are then categorized into two groups: (1) *inborn* (where the birth occurs within a particular hospital) and (2) *outborn* (where the birth occurs outside this hospital but is admitted within 28 days of birth without first having gone home). Additional criteria for inclusion into the VON VLBW registry are defined by birth weight (between 401 and 1500 grams) or gestational age (between 22 and 29 weeks).

Identifying Eligibility Data Fields in the EHR. The framework for the approach developed in this study utilized a reporting database that contains data extracted from the EHR. First, all the data elements required for determining eligibility within the MLM were manually identified from within the reporting database (i.e., date of birth, hospital name, gestational age, birth weight, admission date/time, and admission source). The chosen data fields were determined based on a manual review of the available data fields in the EHR and a validation of the chosen data fields relative to the FAHC obstetric and neonatology workflows that have been in place for more than a decade. A SQL statement was then created that retrieved all the data elements in a single query from the FAHC EHR reporting database (equivalent to generating a 'report' that included the required data elements).

Representing VON VLBW Eligibility Criteria in Arden Syntax. Within the VLBW MLM *data* slot, a patient record object was created for storing the eligibility data elements needed as well as links to other data needed for retrieving additional information about the patient (i.e., patient identifier). The object was then populated using the aforementioned SQL statement. The eligibility logic as represented by the flow diagram shown in Figure 1 was then encoded into the *logic* slot of the VLBW MLM using Arden Syntax. Conversions between local system units to those used in the eligibility criteria were also done within the *logic* slot (e.g., conversion of the birth weight from imperial ounces to metric grams). To ensure processing of all records retrieved from the EHR, a default categorization of "unknown" was added for patients for whom inborn/outborn status could not be determined (the first step in the eligibility determination as shown in Figure 1 after birth); these patients were automatically deemed not eligible.

Developing a System to Process the VLBW MLM. After eligibility criteria were encoded into the MLM, a Java-based system was developed to interact with the FAHC EHR reporting database using the jTDS[28] Java database connectivity application programming interface. Eligibility status for records subjected to the VLBW MLM was then stored into an eligibility database (either "pass"[eligible], "fail"[not eligible], or "unknown"[requires manual review]). For records deemed eligible, an additional Java routine was used to gather electronically available data from the FAHC EHR reporting database using another set of SQL queries. The resulting records were then transformed into a format that could be transmitted to the VON VLBW registry. The overall approach is shown in Figure 2.

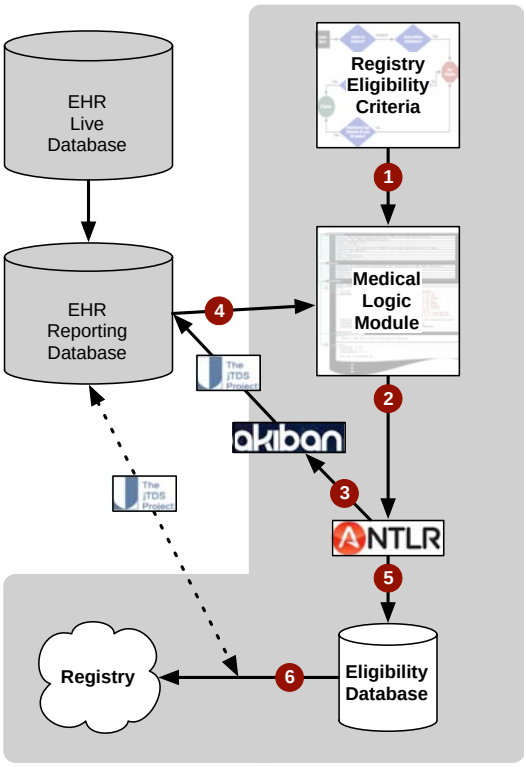

Figure 2: Overview of Approach. (1) Eligibility criteria are manually encoded into an Medical Logic Module (MLM); (2) an ANTLR parser is used to interpret the Arden Syntax; (3) SQL statements are parsed by the Akiban SQL parser and used to send queries to an SQL-92 compliant database using the jTDS Application Program Interface (API), such as an EHR reporting database that uses a relational database model (which is populated from the live EHR database that uses a hierarchical database model); (4) the returned results of the SQL query are then used by the MLM to determine eligibility; (5) eligible records are recorded in a Eligibility Database; (6) the records in the Eligibility Database are enhanced with additional data needed for the registry by additional SQL queries using the jTDS API.

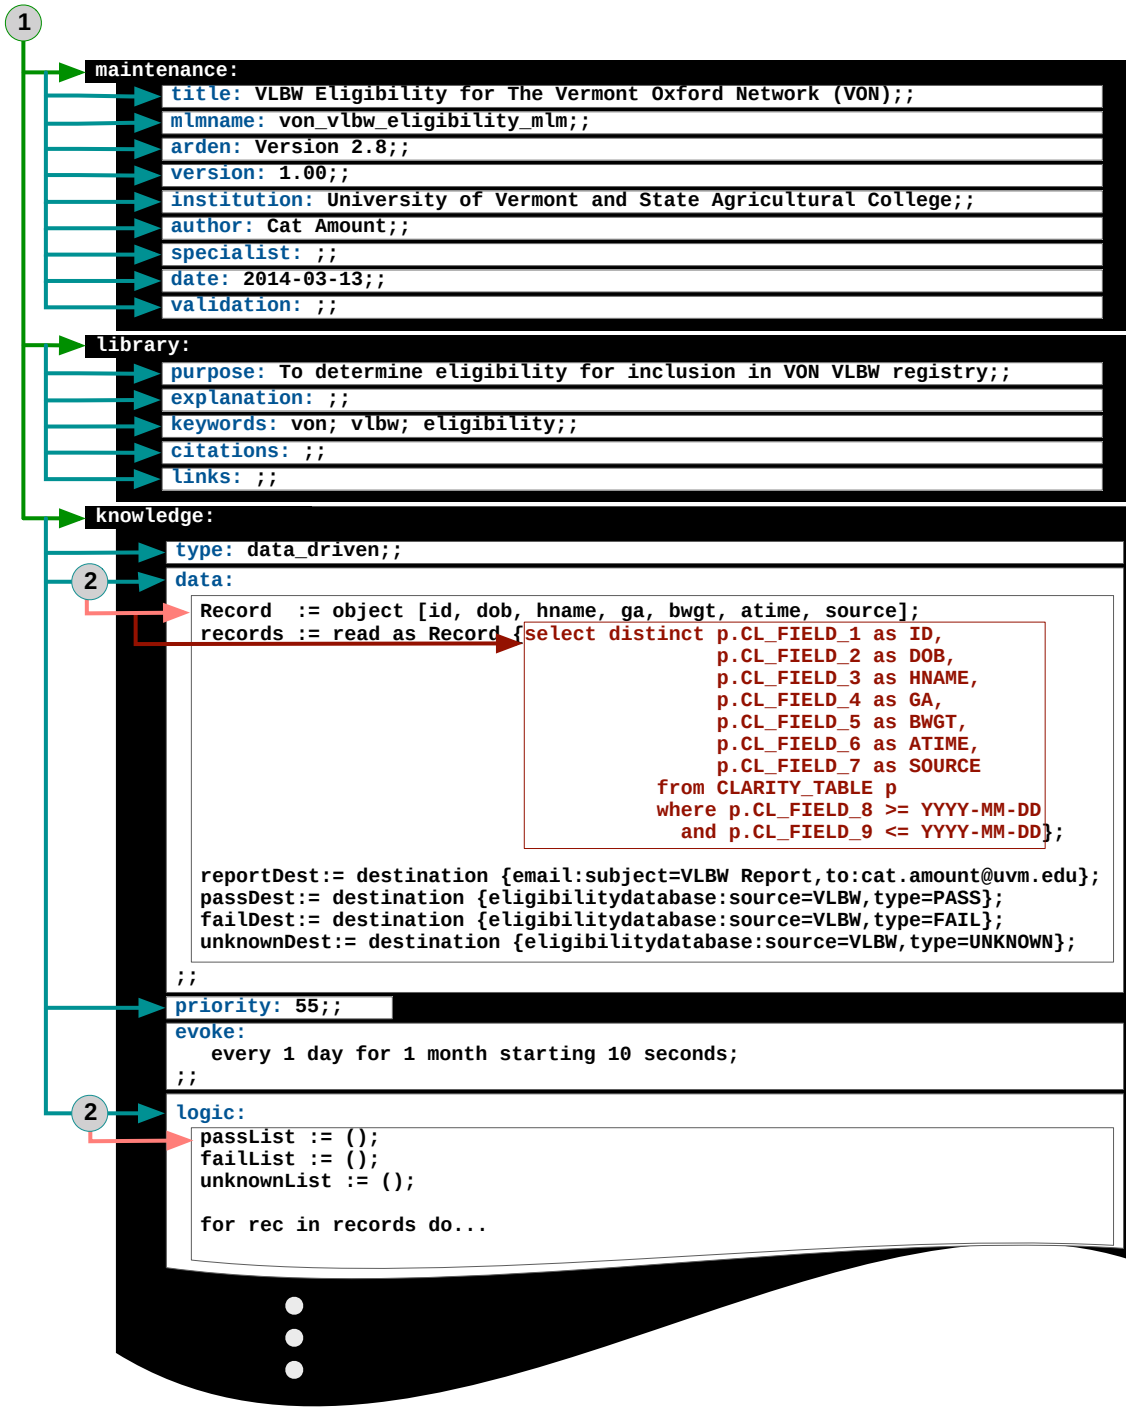

Figure 3: MLM Parsing. A system was developed that (1) used an ANTLR parser generator to identify the MLM categories (maintenance, library, and knowledge) and their contained slots; and (2) used an additional ANTLR parser generator to process the slots and leveraged the Akiban SQL Parser to process SQL statements embedded within the data slot. For this feasibility study, a SQL statement was used to retrieve data from the FAHC EHR reporting database that were used for eligibility determination (ID = Patient identifier; DOB = patient date of birth; HNAME = hospital name; GA = gestational age; BWGT = birth weight; ATIME = admission time; and SOURCE = admission source) according to the criteria depicted in Figure 1.

The actual processing of the VLBW MLM was done in a two-phased process, as depicted in Figure 3. First, an ANTLR parser generator was used to extract the MLM categories and associated slots. ANTLR uses a context-free grammar (expressed in Extended Backus-Naur Form) to recognize language, generate syntax trees, and process those trees to create machine-interpretable actions[26]. An additional ANTLR parser was then used to process the syntax embedded within specific slots (e.g., the data and logic slots). For this study, version 2.8 of Arden Syntax was used as the basis for the parsing grammar. Additionally, the Akiban SQL parser[29] was used to interpret embedded SQL-92 compliant SQL statements. The MLM parsing resulted in a parse tree for which a Java routine was developed to interpret the retrieved data from the source database and apply the encoded eligibility rules.

System Evaluation. A reference standard was generated from VON VLBW registry records associated with eligible records from the time that the Epic EHR at FAHC was fully deployed (2010) to a full complete calendar year prior to the time of this study (2012). The records contained within the VON VLBW registry for this time period were based on manual chart review and guided by a process workflow that has been in place for over a decade. The VLBW MLM was then configured to determine the eligibility of infants born between January 1, 2010 and December 31, 2012. True Positives (TP) were defined as patients who were deemed eligible by the VLBW MLM and in the reference standard; False Positives (FP) were defined as patients who were deemed eligible by the VLBW MLM but not in the reference standard; and False Negatives (FN) were defined as those patients who were in the reference standard but not deemed eligible by the VLBW MLM. The metrics of precision (TP/TP+FP) and recall (TP/TP+FN) were then used to assess the overall performance of the approach.

Results

All of the necessary fields for determining neonate eligibility for inclusion in the VON VLBW registry were identified within the relational data schema used for the FAHC EHR reporting database. The SQL statement that was used to identify the data for all neonates was then embedded within the Arden Syntax within the *data* slot of the *knowledge* category of an MLM. The VON VLBW eligibility criteria were then manually encoded into the MLM (within the *logic* slot of the *knowledge* category). Finally, the instructions for writing the status of a given processed record were defined within the *action* slot of the *knowledge* category.

A Java-based system was developed to interpret MLMs written in Arden Syntax (version 2.8) as well as embedded SQL-92 compliant SQL statements, utilizing a combination of the ANTLR parsing generator and Akiban SQL parser. The developed VLBW MLM was then used to determine the eligibility of patients born between January 1, 2010 and December 31, 2012. In total, the system processed 12,025 neonates who were either born at or transferred to FAHC for that period, of whom the VLBW MLM deemed 192 to be eligible for inclusion into the VON VLBW registry. The evaluation was done relative to the reference standard, which contained 187 neonates that were manually identified and entered in the VON VLBW registry. The total processing time used for the system to determine the eligibility for all newborn records spanning the three-year period was less than five minutes. Of the eligible patients, 187 were in agreement with the reference standard (TP), five were not found in the reference standard (FP), and no patients in the reference standard were missing from the predicted eligible patient list (FN). The overall precision and recall of the system was thus determined to be 97.4% and 100.0%, respectively.

Discussion

The primary motivation for use of Arden Syntax has historically been described in the context of clinical decision support systems[14]. Previous studies have explored other potential applications for Arden Syntax, such as for clinical trial eligibility[23] and facilitating clinical quality studies[30]; however, the majority of systems developed to date for processing Arden Syntax have been done within the context of clinical decision support[31-34]. This study thus reflects a first application of Arden Syntax for the identification of patient cohorts for inclusion in population registries. A recent survey suggests complex clinical trial eligibility representation may require a combination of multiple available formal standards[8]. In this study, the potential to leverage Arden Syntax for identifying registry-eligible patients was explored, where the eligibility rules could be expressed through procedural statements. The promising results suggest that the proposed approach can be used in place of time-consuming and manual processes to identify registry-eligible patients using eligibility criteria that are compatible with machine-encoded logic (e.g., as can be represented in Arden Syntax).

The use of an algorithm-based approach may provide a means to uniformly apply eligibility criteria for reliable data gathering as required for population-level registries that support public health initiatives. Such uniform application of eligibility algorithms may also be used to identify potential challenges in the use of applications. For example, in the evaluation performed for this study, there were five patients identified by the VLBW MLM but not reported as

eligible to the VON VLBW registry (classified in the evaluation as "False Positives"). On closer examination of the data associated with these patients, it was determined that the strict definition of the VON VLBW criteria should have included these individuals. These patients may have been excluded from the registry due to difficult situations (e.g., how are stillborns or planned terminations registered?). While each institution may establish a culture around certain criteria, it can be difficult to ensure consistency when gathering data across many sites. An MLM-driven registry eligibility approach may provide a foundation for high-quality and consistent data acquisition. An interesting future study might be to use the developed VLBW MLM across VON data providers and quantify any possible effect of inclusion/exclusion of certain patient types based on hospital culture. Such a study may help to refine the inclusion/exclusion criteria used in the algorithm to better reflect accepted and consistent practices for a given patient population.

A major potential challenge that has been noted in general deployment of MLMs is the difficulty in accommodating the heterogenic nature of EHR implementations across institutions. The ability to use MLMs is often challenged by the difficulty in completely representing all the local variables needed for the execution. As Arden Syntax specifies that local data variables are to be referenced between a set of curly braces ("{}"), which has led to an referred to as the "curly-brace problem"[35,36]. Amidst some description of systems that are able to directly interact with transactional database systems[37], the majority of previous implementations of MLM driven decision support systems leveraged local relational databases that contained information from EHR systems[36]. Contemporary solutions have also included the translation of Arden Syntax MLMs into intermediate formalisms (e.g., Drools[38]). In the approach presented here, EHR data was mapped through the use of SQL-92 compliant statements to acquire data from an EHR reporting database. This SQL statement, as well as the system-specific databases for tracking pass/fail/unknown records, was the major "curly brace" aspect of the developed approach. The increasing availability of SQL-compliant reporting databases with contemporary EHR systems (in many cases to facilitate the ability to meet Meaningful Use requirements) provides a common interface that allows for the development of an MLM that is built around the processing of a set of records that could be generated as part of an EHR report. Still, the approach described here requires database experience with the local EHR reporting database and the ability to generate a SQL statement that contains mappings to the required elements for determining eligibility. Additionally, the same challenges that one might have within a reporting context (e.g., identifying which fields are the relevant ones to retrieve) remain the same in the context of the approach developed here. It is also important to underscore that because the context for which Arden Syntax was used here is for the population of a registry that is based on information that is commonly captured within a clinical chart, it was conceivable that many of the requisite data elements would be available within a reporting interface that is updated nightly. This is in contrast to more typical scenarios where MLMs are used for more real-time clinical decision support, and would thus need to interface directly with the live EHR system. Nonetheless, the promising results demonstrate the application of Arden Syntax for retrospective patient eligibility determination and the potential utility for other contexts, such as retrospective determination of patient cohorts that may be eligible for clinical trials or who may need to be systematically alerted about a potential adverse event.

It must be acknowledged that other formalisms may be able to represent the logic for cohort identification using procedural logic. However, a significant reason for exploring the potential utility of Arden Syntax over other possible (generally more business analytic centric solutions, such as Pentaho) formalisms is because it is a maintained HL7 healthcare standard. As an established and maintained healthcare standard, Arden Syntax is likely to be more readily accepted for integration into healthcare environments. Furthermore, it is likely that one could embody the logic for cohort identification using a set of boutique SQL statements that encode the eligibility criteria, but the portability to another institution would likely be challenged by the need to modify a possibly lengthy SQL script to address variations in schema design. This could be especially difficult when considering that different reporting databases may have very different data structures and implementations of SQL dialects that may not necessarily be able to handle the full logic required for eligibility determination. The variation of SQL implementations and customization could then challenge the ability to centrally manage the process for consistent eligibility determination, since each institution will be required to maintain local customizations of the criteria to meet their data structure and SQL environment. In the context of international registries, such as the VON VLBW registry, these technical considerations are important in light of the range of technical capabilities across data contributors. Nonetheless, the minimal technical requirement that the solution presented here does require is the ability to generate a SQL statement that gathers the fields required to determine eligibility. Future studies that directly benchmark standards based (e.g., Arden Syntax) approaches against alternative approaches for patient cohort identification are needed.

The intent of the system described here was two fold: (1) identify eligible patients for inclusion in a registry; and (2) gather electronically available data from the EHR to transmit for eligible patients to the registry. In this study, the primary focus was on exploring the feasibility of developing a system that was able to identify eligible patients. The evaluation was thus focused on the ability to use the VLBW MLM to reliably identify potentially eligible patients for the VON VLBW registry. While not described here, the system is also able to gather additional data beyond the information needed for determining eligibility using SQL statements and export the full set of gathered data into a number of consumable formats (e.g., as eXtensible Markup Language or a Comma-Separated Value file). However, it should be noted that a remaining major challenge is the identification of the needed data elements from within an EHR system that should be targeted for inclusion into a registry. This requires study of the workflow at a given institution for data gathering from the respective EHR and developing appropriate data transformation techniques. One must also consider that many elements within a registry may not be available as discrete elements (e.g., they may be in natural language form) and thus advanced processing (e.g., using natural language processing [NLP]) may be required before data can be appropriately formatted into the requisite format for the target registry. Currently, if a data element required for eligibility is either inaccessible or not interpretable through simple processing (e.g., regular expressions), a record will be labeled as "unknown" and require manual review to override the status. As such, a user interface is being developed that enables manual review and override of the MLM based eligibility determination that also fits the workflow currently used to populate the VON VLBW registry. A major intent of developing the system described in this study in Java was thus to enable the potential leveraging of Java-based resources that are available for such processing (e.g., NLP could be integrated into the system using the Unstructured Information Management Architecture framework[39]).

The positive results of the performed evaluation for the VON VLBW registry using the VLBW MLM support the intention to deploy the developed system into production. It is anticipated that the system can be run in production (and set to run on a defined periodic basis through the *evoke* slot of the *knowledge* category) parallel to the current method for populating the registry. Additional evaluations will be done to compare differentials in patient classifications, and it is anticipated that if similar performance benchmarks as presented here are achieved for a defined period that the system will be used as the primary mode for identification of eligible patients for inclusion in the VON VLBW registry. While it is conceivable that the approach described here could lead to a fully automated system, it is expected that the system in practice will remain semi-automated; that is, the eligibility status of patients will be presented to users through a curation interface that allows for manual override of status before submission to the registry. Further evaluations are also being planned at other institutions that have a similar SQL-compliant reporting environment as leveraged in this study. As part of the process of deploying the process at other institutions, it is expected that a version of the system described here will be made available for other applications. In the meantime, the corresponding author (INS) may be contacted for the most recent version of the system.

Conclusion

Standards traditionally used for clinical decision support may be utilized to support the population of condition-specific registries. In this study, Arden Syntax was explored as a possible health standard for representing eligibility criteria for a neonatology registry. Based on a system developed to interact with the reporting framework associated with a reporting database that is based on data from an EHR, it was found that a Medical Logic Module written in Arden Syntax was able to perform well relative to a reference standard representing three years of registry-eligible patients. The promising results suggest that Arden Syntax may used to represent eligibility criteria and thus provide a mechanism to leverage electronically available health data (e.g., as encapsulated within an EHR) for supporting the population of patient cohort databases such as condition-specific registries.

Abstract

Mobile health (mHealth) technology presents opportunities to enhance chronic illness management, which is especially relevant for persons living with HIV (PLWH). Since mHealth technology comprises evolving and adaptable hardware and software, it provides many challenging design problems. To address this challenge, our methods were guided by the Information System Research (ISR) framework. This paper focuses on the Design Cycle of the ISR framework in which we used user-centered distributed information design methods and participatory action research methods to inform the design of a mobile application (app) for PLWH. In the first design session, participants (N=5) identified features that are optimal for meeting the treatment and management needs of PLWH. In the second design session, participants (N=6) were presented with findings from the first design session and pictures of existing apps. Findings from the Design Cycle will be evaluated with usability inspection methods. Using a systematic approach has the potential to improve mHealth functionality and use and subsequent impact.

Introduction

Despite advances, The United States (US) Human Immunodeficiency Virus (HIV) epidemic continues to take a heavy toll, which is evidenced by the 1.2 million Americans who are currently living with the disease. New York City, the setting of our study, is the epicenter of the US HIV/AIDS epidemic, accounting for 17.9% of the estimated number of persons living with HIV (PLWH) in the US [1]. The burden of HIV/AIDS is borne disproportionately by a growing number of racial and ethnic minorities[2]. Forty eight percent (48.7%) of new HIV diagnoses are among African Americans and 31.3% were among Latinos [3].

Mobile health (mHealth)

Mobile health (mHealth) is focused on the use of mobile information and communication technologies for healthcare purposes. mHealth aims to support care delivery through meeting information, communication, and documentation needs of patients, clinicians, and other healthcare workers, as well as facilitating health resource monitoring and management [4]. The development and use of mobile technologies to rapidly and accurately assess and modify health-related behavior and biological states has great potential for improving healthcare delivery. Advancements in current mobile technology allow for more memory and data storage, full color graphical interfaces with video capability, wireless access, location awareness, and integration with other computer-mediated technologies. Specifically, the use of mobile technology affords numerous advantages, including reduced memory bias, the ability to capture time-stamped data, and the potential for personalizing and tailoring information in real-time. The ubiquitous nature of mobile technologies in daily life has created opportunities for applications (apps) that were not previously possible. Thus, mHealth presents opportunities to enhance chronic illness management in real-time [5]. In fact, the use of mobile apps and technology has the potential to reduce costs, reduce geographical and economic disparities, and personalize healthcare.

Of particular relevance to this work, the use of mHealth has made a huge impact on communication, access, and information/resource delivery especially among racial and ethnic minority groups [6-8] and offers an ideal venue for meeting targeted healthcare needs for racial and ethnic minorities, as well as youth, who are the fastest growing age group affected by HIV [9]. As the HIV epidemic continues to grow among adolescents and young adults, mHealth technology can address many of the healthcare needs of PLWH including: adherence to HIV medications, prevention with positives, retention in care and self-management, all critical needs for this population. mHealth technology can bridge a divide in healthcare delivery in underserved minority groups, since ownership of a mobile

device is more common among African Americans than among Whites (87% vs. 80%) [7]. African Americans are also among the most active users of the mobile Internet and take advantage of a much greater range of their phones' features than do Whites [10]. This grants the potential to ameliorate health disparities, since in the case of HIV, health disparities are inextricably linked to age, race and ethnicity. Due to the high incidence of HIV among minorities, adolescents and underserved young adults, and their reliance on mobile technology, it is appropriate to develop health information technology (HIT) tools tailored to the needs of this population.

Theoretical Framework

Design science is the development, implementation, evaluation, and adaptation of artifacts for problem solving [11,12] and attempts to focus human creativity into the design and construction of artifacts that have utility for mobile apps. Design activities are central to most applied disciplines, including health informatics, and are particularly relevant and necessary for the development of mHealth technology that is safe, useful, and effective for end-users [13]. mHealth technology is composed of mutable and adaptable hardware, software, and human interfaces and so it provides many unique and challenging design problems that call for new and creative ideas. The design science research paradigm is highly relevant to mHealth research and supports the creation of innovative artifacts to solve real-world problems.

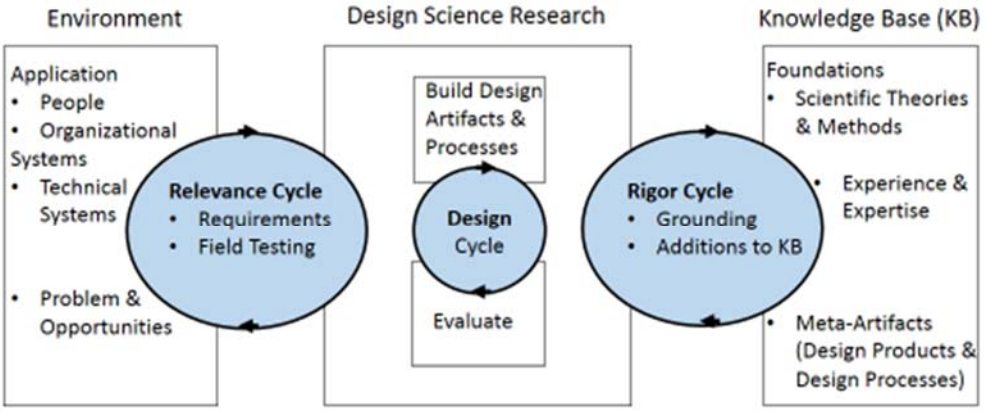

Figure 1: The Information System Research (ISR) Framework

Our study activities were guided by the Information System Research (ISR) Framework, which uses design science to inform the development of information systems [11]. The design and development cycle is repeated iteratively until a desired final product is achieved. Using the ISR Framework (shown in Figure 1), we employed three research cycles: I) the Relevance Cycle in which we seek to understand the environment of the end-user by determining requirements through a series of interactions (e.g., focus groups, interviews) with stakeholders; II) the Rigor Cycle, in which evaluation of theories and artifacts contribute to the design science and application domain knowledge base; and III) the Design Cycle in which artifacts are produced and evaluated [11]. The result of HIT-related research activities informed by the ISR framework is the purposeful creation of artifacts developed to address an important health problem.

Research Context

The activities reported here reflect a single cycle that was part of a larger research project to inform the development of two mobile apps for: 1) HIV treatment and care for PLWH and 2) HIV prevention for high-risk Men who have sex with Men (MSM). Research activities reported here focus on the development of a mobile app for PLWH. To guide this work, we used user-centered information design methods [14] and participatory action research methods [15] to ensure that the app met end-user needs. The overall goal of this two year project was to create a Design Document for the Centers for Disease Control and Prevention (CDC) to inform the development of two mobile apps for dissemination. Prior to the design sessions, we conducted study activities related to the Rigor and Relevance Cycles. The project activities discussed in this manuscript focus on Cycle III: The Design Cycle: Develop/ Build activities

for the mobile app for PLWH only.

Cycle I: The Relevance Cycle: For this cycle, we conducted six focus group sessions with PLWH (N=50) ages 18-59 and three focus group sessions with HIV care providers (N=30) to identify the desired content, features, and function of a mobile app for PLWH. Results of this work are reported elsewhere[16]. Thematic analysis of the focus group session revealed five categories of functional requirements: My Information Management, Managing My Medication, Staying Healthy, Communication (divided into provider communication and peer communication) and Resources. Participants suggested some of the following tools and functionalities for inclusion in a mobile app for meeting their health needs: reminders/alerts, lab tracking, notes, chat boxes/forums, testimonials of lived experiences, personal outreach, games/virtual rewards, coding of health tasks, and simulation on how to disclose their HIV status.

Cycle II: The Rigor Cycle: The rigor cycle guided our selection of theories and methods for designing and evaluating the Design Document [17]. We conducted a systematic review of existing studies, which used mobile technology and e-Health applications for HIV treatment and care. In addition, we did an ecological scan of the existing mobile applications that are already frequently used by many in our study population.

Cycle III: The Design Cycle: Develop/Build: The goal of this cycle is to improve the design and to increase the likelihood of technology acceptance. The design cycle is sub-divided into two phases: Develop/Build and Evaluate. Our activities reported in this paper focus on the Develop/Build phase, which centers on the creation of a highly usable artifact. To achieve the goals of this cycle, we incorporated findings from the earlier parts of our study. These include a list of content, features, and functions from the focus groups, as well as findings from the literature review. We used user-centered distributed information design methods [14] and participatory action research methods [15] for the development of our user-centered participatory design session activities. We conducted two design sessions; each successive design session was developed based on the information gathered in the previous design session.

Methods

Design Session I:

Sample

For our first design session, we recruited five PLWH who had previously participated in our focus group sessions. We had two male and three female participants whose ages ranged from 39-59 years. Two participants reported their ethnicity as being Latino and three participants reported their race as African American. One participant had never used a smartphone. For their participation, study subjects were given $25 and provided lunch as a token of appreciation for their time.

Procedures

The first design session was audio recorded and lasted approximately two hours. Study team members were present during the session and took notes. The goal of this session was to identify optimal features for improving HIV treatment and management needs of PLWH. Using the findings from the focus group sessions we developed an initial list of content, features and functions. During this session, participants discussed topics and did not look at existing apps or prototypes. For this session, we did not benchmark with other apps so as not to remove the creativity out of the intended purpose of the design session.

We asked participants to imagine each of the broad categories, identified from our focus group analysis, as a separate screen on a mobile app. We presented this information in a PowerPoint as a starting point as we sought to identify the functional requirements for a prototype of a mobile app. We presented the categories derived from our focus group sessions to the participants and asked them to discuss the content and features that would be included as functionality in a mobile app. Participants were encouraged to revise the information presented and discussion was stimulated by a set of probing questions, including: What information do you need from a mobile app related to your treatment regimen? What would make some of the current apps that you use better?

The study team met and coded the transcripts and notes from the design session to inform the content (What) and features (How) of the mobile app.

Results

Results from the first design session are categorized by topic area, derived from the Cycle I focus group sessions, and reported in Table 1. In addition to the content and features, participants also identified usability factors which would make it more likely for them to use this app. Participants mentioned it would be important not to have too many screens to access information. In addition, participants noted the user interface as well as the information presented should be "simple and straightforward." Finally, participants stressed the importance of confidentiality and privacy, reinforcing the critical need of passwords to ensure the information in the app was secure.

Table 1. Results from Design Session I

Topic Area	What	How
My Information Management	Lab results HIV and all lab work	Lab tracker
	Information on non HIV medications	Quick search feature for medications
		Health-related to-do list for HIV positives
Managing Your Medications	Medication information	Information on which medications need to be taken with or without food, and specify the type of foods
		Provide generic and brand names of medications
		Medication Interactions
		Visuals of medications with information on why to take it
	Medication reminders	Provide specific times, not just twice a day; the specific hours one dosage should be from the next
		Medication refills
	Medication tracker	Missing doses chart; how it would affect the efficacy of the medication, and the risk of not staying undetectable
Staying Healthy	Diet/Nutrition	Food log/diary
		Calorie tracker
	Exercise	Measure physical activity
	Harm reduction	Pre-Exposure Prophylaxis (PrEP)
	Measuring risk	Risk calculator
	Mental health	Stress reduction measures
	Condom information	Information about types and sizes of condoms
	STD information	Games must be sensitive to users - i.e., brain or light bulb with big eyes and bubble pop ups with information
Communication	Provider-patient communication	Virtual lectures given by providers
		Face-to-face communication with provider
		Able to share/send information with provider
		Virtual support groups with providers
		Digital audio recorder
	Peer communication	Role playing videos
		Social networking links
Resources	Support group locations	Voice activated "siri"
		GPS mapping
	Condom distribution locations	GPS mapping and information on distribution sites
	Latest HIV news	Newsfeeds

Design Session II:

Sample

For our second design session, we had six participants, all of whom participated in the earlier focus group sessions. However, only three had participated in the first design session. We had 3 male and 3 female participants whose ages ranged from 39-59 years. Two participants self-identified as Latino and four participants identified as African

American. Five of the participants were smartphone users. Of those participants who used a smartphone, social networking apps were the most frequently used applications.

Procedures

We audio recorded this session, which lasted approximately 100 minutes. The goal of the second design session was to gain information about the user interface so that prototypes could be created at the end of this design session. The investigator who ran the design session helped the end-user participants sketch a user interface of the desired mobile app. In this session, we presented the findings from the first design session as categories along with pictures of existing apps. Sticky post-it boards, size 25”x30”, were posted on the walls of the room. Each post-it board was designated for one of the topic areas listed in Table 1.

Participants were asked to identify the components to include under each topic area. The same broad categories were used as in the first design session, reported above. Once again, participants were reminded that each of the categories would be a screen on the app and were asked to describe the content, features and interface they would want to see in an app.

After participants shared their ideas, we asked probing questions to stimulate discussion about the existing apps and the need for refined content, features, and interface design. The questions were: What information do you need from a mobile app related to your treatment regimen? Which information from your healthcare visits should be viewable on your app? Participants were asked to identify app preferences including platform and design requirements, navigational features, and marketing preferences.

Figure 2: Sample Apps for Medication Reminders and Tracking

Following these questions pictures of existing apps were presented. Sample apps are in Figures 2 and 3. Participants were asked to comment on the features and interface of the existing apps.

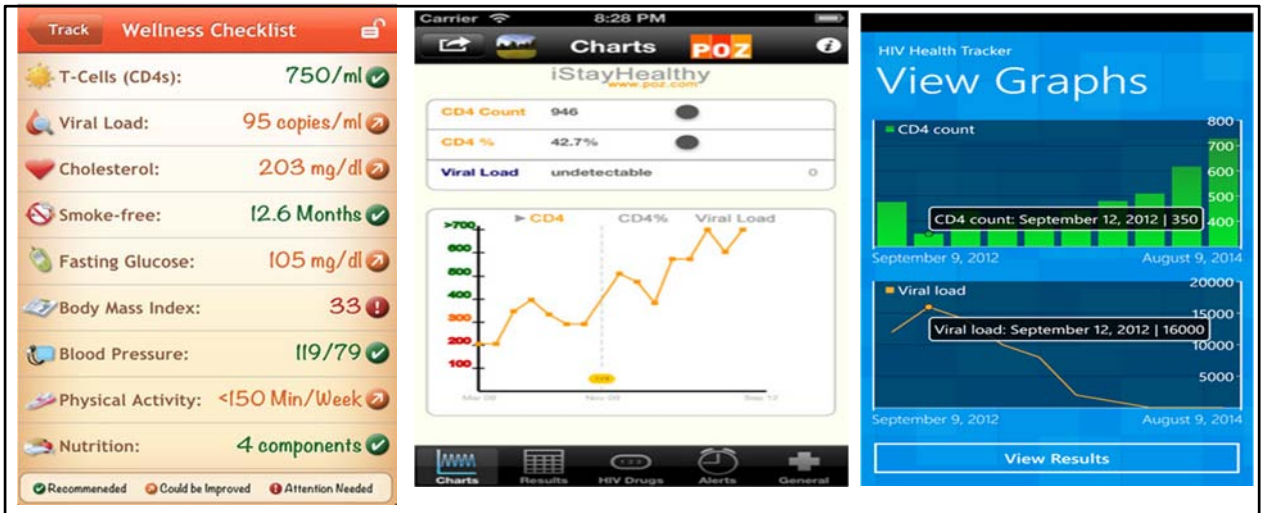

Figure 3: Sample Apps for My Information Management

Results

Participants made suggestions on the content as well as the interface of their desired app. Participants commented on the existing apps and described which features have the potential to work well for them. Moreover, participants identified features and interfaces, which were confusing and would not meet their needs. Importantly, participants had mixed views on whether they would want their app to be used as a communication tool with providers. Most participants said that they would want to be able to communicate with peers for support as well as share HIV information and other resources.

While the participants reviewed and commented on the existing apps, the design session leader sketched designs of the app on post-it boards so the participants could visualize the app. For each of the broad categories, a user interface was sketched. Sample sketches are in Figure 4.

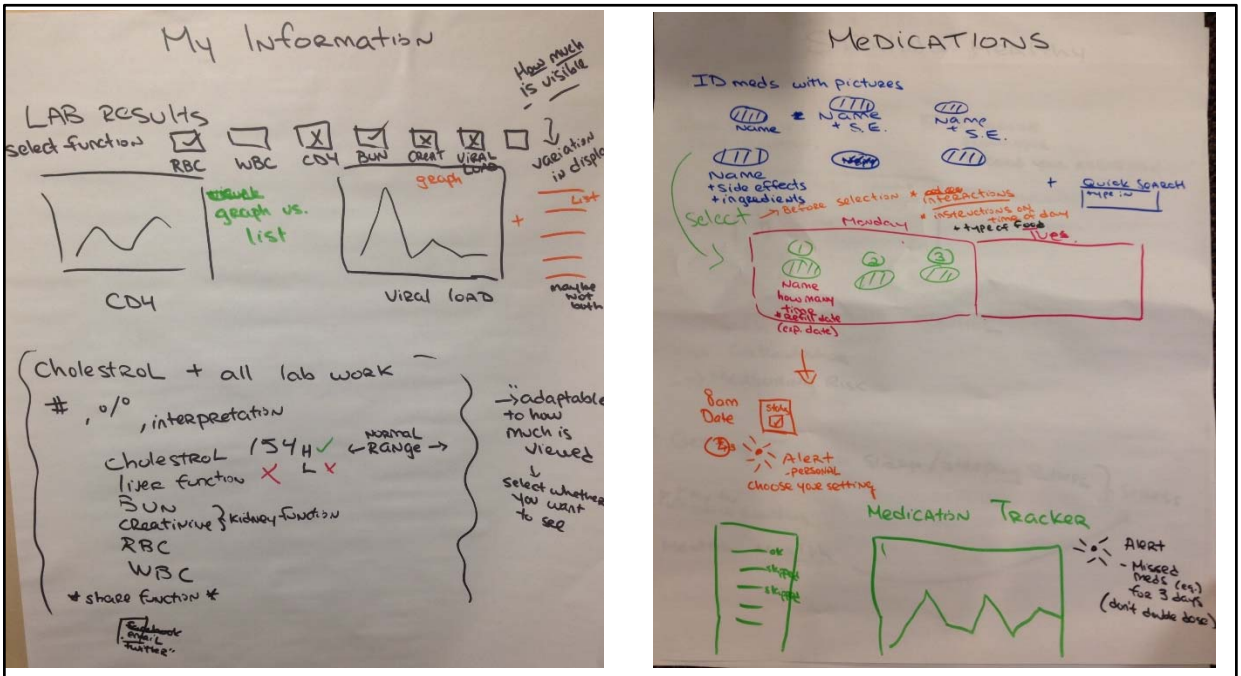

Figure 4: Sketches of Managing Your Medications and My Information Management Screens

Findings from the design sessions informed Cycle III: The Design Cycle: Build. Based on the results of the white board design, a final user interface for the prototype system was developed. We developed a low-fidelity prototype of user interface screens using a Web development tool based upon the results of the design sessions. The design sessions' findings provided information for drafting formal functional requirements, which will be refined during prototype evaluation prior to inclusion in the Design Document. The prototypes of two screens in our build phase can be found in Figure 5. These prototypes mirror the sketches presented in Figure 4. In addition, findings from our design sessions informed the creation of a map of the screen order of the mobile app. Use of a low-fidelity prototype will enable us to explore and understand our potential end-user's preferences related to content functionality (e.g. a calendar to record an appointment for HIV testing), as well as their ability to achieve tasks associated with the prototype content (e.g., scheduling a reminder in a calendar).

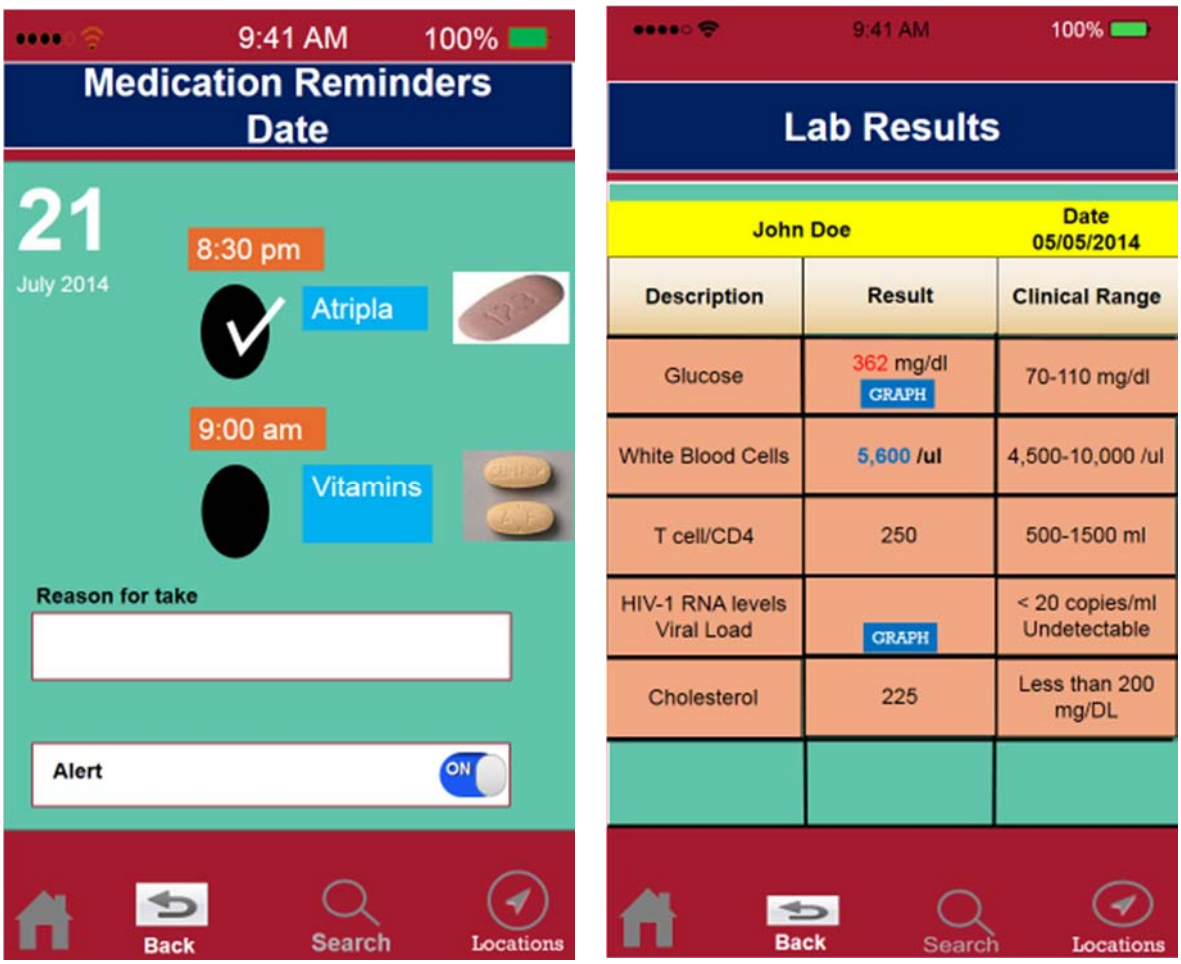

Figure 5: Mock-Ups of Medication Reminder and Lab Results Screens

The goal of Cycle III: The Design Cycle: Evaluate in order to improve the design, and to increase the likelihood of technology acceptance. To achieve this goal we will evaluate the user interface and system functions of the prototype and assess whether they are consistent with the end-users' needs. We plan to conduct two types of usability assessments: 1) a heuristic evaluation using informaticians with experience in interface design, 2) and end-user usability testing with PLWH.

Discussion

To achieve the goal of designing a mobile app for meeting the healthcare needs of PLWH, we used the ISR Framework to inform our design processes in order to build an artifact for further testing. [18] The design sessions

were an iterative process whereby study participants were considered the experts and teachers, and the investigators were the learners. The study participants contributed to the design ideas, provided feedback regarding effective interfaces, and explained which aspects of mobile interfaces, functions, and tasks they found appealing.

With increasing evidence related to the use of mHealth for improving and managing health conditions, there is recognition that scientific methods are needed to help determine how best to use mobile platforms for delivering health information. In this paper a detailed description of a novel user-centered methodology integrated with a rigorous theoretical framework is provided. Frequent interactions between developers and end-users have been noted to result in positive project outcomes. Therefore, rigorous development with end-user input is critical for the development of mHealth tools [19].

Using the ISR framework to guide our study design, we used qualitative methods, focus groups followed by end-user design sessions, which allowed us to develop an end-user perspective and not rely on the researchers' assumptions about what is important. Based on the premise that an app designed from an end-user perspective is more likely to support user needs, we applied user-centered approaches to design the content, features, and interface for a mobile app for PLWH.

Limitations

Our research focused on a single geographic area with a small sample of PLWH. Additionally, the age of those who participated in the design session activities (ages 39-59) was higher than the identified target group, adolescents and young adults. Even so, our design session activities were informed by our findings from the focus group sessions, which included a representative sample of adolescents and young adults.

This paper focuses on the process for designing a mHealth app. Further evaluation is necessary to determine whether adopting this theoretical framework for system design will improve usability and patient outcomes. The next steps for this work include a rigorous usability evaluation. Future work should also focus on the impact of a mHealth app designed through rigorous user-centered designed methods as compared to many currently available patient support apps which were not developed using a rigorous user-centered design approach.

The findings from our design session must be considered in context of the limitations of our study. Nonetheless, this work introduces a framework of system development that is perhaps more systematic and comprehensive than the development process adopted for many existing health systems. The methods that we developed and refined may be useful to others who are designing mHealth technology tools and developing HIT tools for chronically ill patients.

Conclusions

For this work, we used user-centered distributed information design methods and participatory action research methods to identify the mobile app design preferences of PLWH. Our novel approach of integrating design science and user-centered qualitative methods is unique to the design and evaluation of mHealth applications. Given our focus on design specifications from the end-user perspective, findings from this work have the potential to result in sustained use and long-term appeal for PLWH.

Analysis of Medication and Indication Occurrences in Clinical Notes

Sunghwan Sohn, PhD[1], Hongfang Liu, PhD[1]
[1]Department of Health Sciences Research, Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN

Abstract

A medication indication is a valid reason to use medication. Comprehensive information on medication and its intended indications has valuable potential applications for patient treatments, quality improvements, and clinical decision support. Though there are some publicly available medication resources, this medication and indication information is comprised primarily of labeled uses approved by the FDA. Additionally, linking those medications and the corresponding indications is not easy to accomplish. Furthermore, research that analyzes actual medication and indication occurrences used in real clinical practice is limited. In this study, we compiled clinician-asserted medication and indication pairs from a large cohort of Mayo Clinic electronic medical records (EMRs) and normalized them to the standard forms (ie, medication to the RxNorm ingredient and indication to SNOMED-CT). We then analyzed medication and indication occurrences and compared them with the public resource in various ways, including off-label statistics.

Introduction

A medication indication is a valid reason—most often for medical issues such as signs/symptoms or diseases/disorders—to use medication. The patients' medication history and intended indications are critical information for future medical treatment, improvements in the quality of clinical care and better clinical decision support. The linkage of medication and its intended indications and normalizing them to standard terminologies aid in clinical knowledge management [1, 2] and play an important role in enabling the secondary use of electronic medical records (EMRs) for clinical and translational research [3, 4].

A comprehensive medication and indication linkage is not straightforwardly obtained, although some freely available medication resources exist. Those medication indications are primarily labeled indications provided by manufacturers, which are later approved by the FDA. However, off-label medication use (ie, not approved by the FDA) is common in clinical practice. One in five prescribed medications in the U.S. is off-label and is most often employed as for psychiatric medication, and off-label use represents up to 31% of prescribed psychiatric medication[5].

There have been studies to aggregate indication information for prescribed medication from the data recorded by clinicians. Bashford et al. [6] observed the relation between new prescriptions for proton pump inhibitors and upper gastrointestinal morbidity in a general practitioner database and showed that new prescriptions did not necessarily reflect changes in licensed indications. Walton et al. [7] assessed a clinical decision support system based on computerized physician order entry to obtain medication indications and to record medical problems. They examined three medications to alert off-label uses and observed that the system produced less than optimal accuracy. They claimed that this result demonstrated the challenge in obtaining accurate indication information during the prescription process and suggested potential mandates for indication based prescription.

There also have been research efforts to establish a relationship between medication and indication using EMRs and public medication information resources. Burton et al. [8] processed 1.6 million EMRs from the Regenstrief Medical Record System to extract medications and diagnoses. They then linked medications and indications using RxNorm, VA National Drug File Reference Terminology (NDF-RT), and SNOMED-CT and produced 24,398 medication-indication pairs. They achieved overall sensitivity of 67.5% and specificity of 86%. Wei et al. [9] create a computable resource of medication and indication pairs, called MEDI, compiled from four publicly available medication resources, such as RxNorm, Side Effect Resource 2, MedlinePlus, and Wikipedia. They apply natural language processing and ontologies to extract indications for prescribable medication. They map medications to RxNorm ingredients and indications to the Unified Medical Language System (UMLS) and ICD9 codes. MEDI contains 63,343 medication and indication pairs. The estimated precision and recall are 56% to 94% and 20% to 51%, respectively depending on the resources. However, it should be noted that those medication-indication linkages from

the above studies are not based on the clinician-asserted data in EMRs, but, rather, are derived from using known publicly available medication information resources.

Jung et al. [10] developed the method to automatically detect off-label medication uses using a machine learner based on various features including drug and disease similarities, known medication usages, and medication-indication co-occurrence statistics in EMRs. They achieved a precision of 0.945, recall of 0.778 and F- score of 0.853 and produced 10,765 potential novel drug-indication pairs with a probability estimate cut-off of 0.95. Li et al. [11] determined the reasons for medication uses based on medical conditions in outpatient notes. They first generated the medication indication knowledge database compiled from MicroMedex, NDF-RT and Adverse Event Reporting System, and ranked indications based on the established and frequent uses. Then, they obtained an overlap between medication conditions in EMRs and the medication indication knowledge database, and selected the highest-rank medication-condition pair as the most likely reason for prescribing medication. They achieve an F-measure of 0.739 in the pilot study.

A large-scale study that analyzed diverse medication and indication pairs used in real clinical practice was limited due to technical difficulties in extracting these medications and indications from EMRs and limited access to a large amount of appropriate clinical data. In this study, we compiled medication and indication occurrences from a cohort consisting of 140K patients whose medical home is at Mayo Clinic and normalized them to the standard terminologies (ie, medication to the RxNorm ingredient (IN) and indication to SNOMED-CT). We then analyzed the medication and indication occurrences in various ways, including off-label statistics and also compared them with the public medication indication resource, MEDI.

Backgrounds

This study utilized the medical terminology and ontology to normalize medications and their indications, and the existing tools to extract them. We briefly describe them as follows:

RxNorm

RxNorm is a terminology for normalized medication names developed by the U.S. National Library of Medicine (NLM). It contains the prescription medications and many nonprescription formulations approved for human use. RxNorm uses term types to describe generic and branded names at different levels of specificity and conceptually unique medication descriptions are assigned by a concept unique identifier (RxCUI). RxNorm provides normalized medication names that link to medication variants frequently used in pharmacy management such as First Databank [12], Micromedex [13], MediSpan [14], Gold Standard [15], Multum [16], and NDF-RT [17]. Hence, RxNorm enables various systems using different medication terminologies to share and exchange data. RxNorm is becoming part of Meaningful Use to support the expanding functionality of health record technology [18].

SNOMED-CT

SNOMED-CT (Systematized Nomenclature of Medicine-Clinical Terms) is a systematically organized collection of medical terminology providing codes, terms, synonyms and definitions used in clinical documentation. SNOMED-CT provides the core general terminology for EMRs. SNOMED CT is one of the standard uses in U.S. Federal Government systems for the electronic exchange of clinical health information. It covers clinical findings, symptoms, diagnoses, procedures, body structures, organisms and other etiologies, substances, pharmaceuticals, devices and specimen (http://www.ihtsdo.org/snomed-ct). It also supports in organizing EMRs by mapping and encoding various medical concepts to the standard for clinical care and research [19].

MedXN

MedXN (Medication eXtraction and Normalization) is a UIMA (Unstructured Information Management Architecture) based pipeline to extract medication information and map it to the most specific RxNorm concept [20] (http://sourceforge.net/projects/ohnlp/files/MedXN/). MedXN focuses on medication normalization by mapping the comprehensive medication description to the best matching RxCUI using flexible matching, abbreviation expansion, inference, etc. MedXN uses externalized resources (ie, medication dictionary, attribute definitions, and regular expression attribute patterns) to allow a simple customization process for the needs of end users. For medication RxCUI assignment, MedXN produced an F-measure of 0.932. In this study, we used MedXN for normalizing medications (ie, mapping medications to RxNorm).

MedTagger

MedTagger is the open-source pipeline (http://sourceforge.net/projects/ohnlp/files/MedTagger/) that contains a suite of programs including three major components: indexing based on dictionaries, information extraction based on patterns, and machine learning-based named entity recognition [21, 22]. In this study, we used MedTagger's indexing functionality to map medication indications to SNOMED-CT.

MEDI

MEDI (MEDication Indication) is an open-source computable medication indication resource that is compiled from four publicly available medication resources, such as RxNorm, Side Effect Resource 2, MedlinePlus, and Wikipedia (http://knowledgemap.mc.vanderbilt.edu/research/content/MEDI). In this study, we compared Mayo medication-indication pairs with MEDI (MEDI_01212013_UMLS.csv) that contains 3,112 medications, 4,396 indications, and 53,106 medication-indication pairs. MEDI also contains a maker, 'possible label use,' which denotes whether a given indication is highly likely on-label or not. We utilized this information to analyze potential off-label uses in Mayo medication-indication pairs.

Materials and Methods

Data

We use all clinical notes of a cohort consisting of 140K patients whose medical home is at Mayo Clinic. The clinical notes consist of a variety of sections, such as Impression/Report/Plan, Current Medications, History of Present Illness etc., and each section contains specific content. Medication information appears in numerous ways across sections. However, most medication mentions are found in the Current Medication section, which contains medications currently being taken by patients. Therefore, it is the most important section regarding to medication information for patient care. The format of the Current Medication section is much like a grocery list. However, it contains the most diverse medication description patterns [23]. Some medication entries in the Current Medication section also occur with clinician-asserted indications, followed by "Indication:" or "Indication, Site, Instruction:" (See the example in Figure 1). In this study, we investigated the clinician-asserted medication and indication pairs extracted from the Current Medication section in clinical notes.

Aspirin 325-mg tablet enteric-coated 1 tablet by mouth one-time daily.
Indication: stroke prevention.
Bactrim-DS 160-800 mg tablet 1 tablet by mouth one-time daily.
Ativan 1-mg tablet 1 tablet by mouth once-a-month.
Indication, Site, Instruction: anxiety. take 1-mg one-hour every month.
Azopt 1 % drop suspension 1 drop ophthalmic two times a day.
Site: Both eyes.
Indication: glaucoma.

Figure 1. Medication and indication descriptions in the Current Medication section

Medication-indication pair extraction

The MedXN system was employed to extract medications and map them to RxNorm. An indication was extracted using regular expressions in the following ways: (1) extracted strings after 'Indication:' and (2) extracted strings after 'Indication, Site, Instruction:' In (1) we treated all extracted strings as an indication, but in (2) we selected only the concept classified as 'disease' and 'finding' in UMLS as an indication because there might be non-indication mentions, such as 'site' or 'instruction' that are generally not a disease or disorder.

The medication name extracted from MedXN is a generic (ie, ingredient, precise ingredients, multiple ingredients) or brand name (ie, trade name), and an indication is free-text signs/symptoms and disease/disorder expressed in various ways. In order to properly analyze overall medication-indication occurrence statistics, the synonyms of medication names and indications need to be normalized to the standard terminologies.

After we compiled all medication and indication pairs, each medication was mapped to an RxNorm ingredient (IN), and an indication was mapped to a SNOMED-CT concept. A medication name that is not an ingredient (ie, brand name) was mapped to an ingredient using RxNorm relationship (ie, "tradename_of" "has_precise_ingredient" in

RXNREL.rrf). We used MedTagger to process free-text indication strings and map them to SNOMED-CT with UMLS CUI.

Finally, we aggregated all normalized indications (SNOMED-CT with UMLS CUI) along with their frequency for a given normalized medication (RxNorm IN with RxCUI) to obtain medication and indication pairs—ie, each indication for a given medication is counted across all clinical notes to obtain the global number of occurrences. Figure 2 shows the overall process employed to obtain medication and indication pairs from clinical notes.

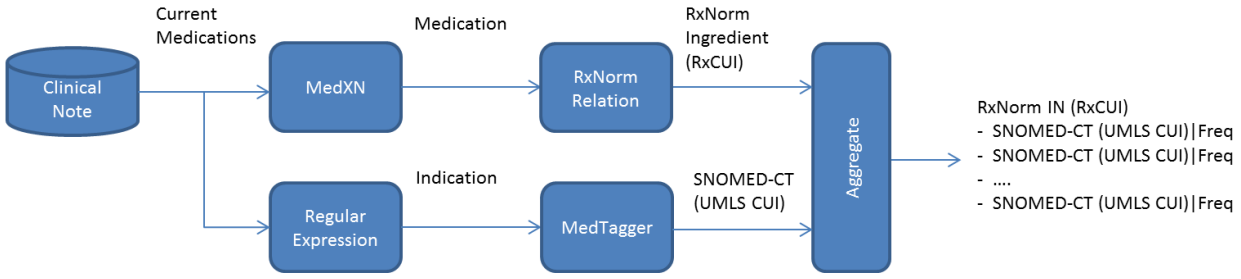

Figure 2. A workflow to extract medication and indication pairs.

Comparison of Mayo medication-indication with MEDI

We compared the normalized Mayo medication-indication pairs with MEDI (MEDI_01212013_UMLS.csv) to determine to what extent they share the same medication-indication pairs. In MEDI, medication and indication are normalized to RxNorm IN and UMLS CUI, respectively. The normalized indications of the Mayo data are SNOMED-CT concepts that are a part of UMLS and that also have UMLS CUI assigned. Hence, we first found medications that have the same RxNorm IN (ie, RxCUI) and we then checked to see if they shared the same UMLS CUI for an indication.

Medication-indication pair assessment

Various statistics, including numbers of medications/indications/medication-indication pairs, comparisons (ie, match and mismatch) with MEDI, and potential off-label medication indications, have been analyzed. For comparison with MEDI, we used two types of matches—ie, 'Exact match' and 'Flexible match.' In exact match, if both Mayo's medication (RxCUI) and the corresponding indication (UMLS CUI) appear in MEDI, we treat them as a 'match,' otherwise, we treat them as a 'mismatch.' In flexible match, a 'match' means that two of indications each in Mayo and MEDI for the same medication are within two steps of navigation in the network where the nodes are the FIND and DISO concepts in the UMLS and the edges are concept relations defined in the UMLS concept relation table (ie, MRREL), otherwise, it is a 'mismatch.'

For the normalization of indication, we used SNOMED-CT in the UMLS. SNOMED-CT is known to have a fine granularity—ie, the detailed classifications for similar medical concepts although they are semantically the same in general. Since indications in clinical notes generally are not described in such detail or precise manner, this fine granularity classification may cause mismatches when compared with the data that are built from different sources. For this reason, we also investigated the flexible match that may represent more reasonable match statistics.

Results

Mayo medication-indication statistics

Table 1 contains basic statistics delineating Mayo's medication and indication occurrences. Each column represents the unique number of medications, indications, and medication-indication pairs, respectively. The term 'Original' denotes the medication and indication descriptions as they appear in clinical notes. In 'Normalized,' medications were mapped to RxNorm ingredients, and indications were mapped to SNOMED-CT. In the normalization process, 434 medications out of 5,128 original medications did not have the ingredient relationship in RxNorm's RXNREL.rrf and 7,769 indications out of 88,522 original indications were not able to map to SNOMED-CT using our dictionary lookup algorithm. After the normalization process (without considering mismatches), the number of medication, indications, and medication-indication pairs were decreased significantly (to approximately 29%, 6%, and 21% of the original size, respectively)

Table 1. Mayo medication and indication statistics

	# medications	# indications	# medication-indication pairs
Original	5,128	88,522	140,499
Normalized	1,494	5,066	29,823

Mayo vs. MEDI medication-indication occurrences

We compared Mayo's normalized medication and indication occurrences with those of MEDI (MEDI_01212013_UMLS.csv). Since MEDI's normalization is the same as Mayo's (ie, MEDI's medications are normalized to RxNorm ingredient and indications are normalized to UMLS CUI), we were able to identify matches between Mayo's and MEDI's medication and indication pairs. Table 2 shows overall matched and mismatched medication-indication pairs between Mayo and MEDI. Mayo's medication-indication pairs are stratified by the log of the patient-level occurrences. Each row represents the cases that have greater or equal to the log of the number of patients who have a given medication-indication pairs.

Table 2. Mayo's medication-indication pairs compared with MEDI.

		Exact match		Flexible match	
$\log_2$(#pts)	# total	# matches (%)	# mismatches (%)	# matches (%)	# mismatches (%)
0 (1)	29823	4347 (15%)	25476 (85%)	17285 (58%)	12538 (42%)
1 (2)	15677	3244 (21%)	12433 (79%)	9482 (60%)	6195 (40%)
2 (4)	8095	2262 (28%)	5833 (72%)	5101 (63%)	2994 (37%)
3 (8)	4715	1601 (34%)	3114 (66%)	3084 (65%)	1631 (35%)
4 (16)	2850	1108 (39%)	1742 (61%)	1911 (67%)	939 (33%)
5 (32)	1710	712 (42%)	998 (58%)	1159 (68%)	551 (32%)
6 (64)	997	452 (45%)	545 (55%)	675 (68%)	322 (32%)
7 (128)	608	291 (48%)	317 (52%)	412 (68%)	196 (32%)
8 (256)	331	171 (52%)	160 (48%)	226 (68%)	105 (32%)

(%) denotes a percentage of the given case out of # total.

Table 3. Statistics of potential off-label indications in Mayo.

		Exact match		Flexible match	
$\log_2$(#pts)	# total	# potential off-labels in matches (%)	# potential off-labels in mismatches (%)	# potential off-labels in matches (%)	# potential off-labels in mismatches (%)
0 (1)	29823	1901 (6%)	23905 (80%)	9733 (33%)	10967 (37%)
1 (2)	15677	1349 (9%)	11706 (75%)	5106 (33%)	5468 (35%)
2 (4)	8095	897 (11%)	5498 (68%)	2643 (33%)	2659 (33%)
3 (8)	4715	613 (13%)	2917 (62%)	1516 (32%)	1434 (30%)
4 (16)	2850	387 (14%)	1619 (57%)	886 (31%)	816 (29%)
5 (32)	1710	236 (14%)	928 (54%)	510 (30%)	481 (28%)
6 (64)	997	144 (14%)	501 (50%)	267 (27%)	278 (28%)
7 (128)	608	82 (13%)	285 (47%)	150 (25%)	164 (27%)
8 (256)	331	38 (11%)	146 (44%)	70 (21%)	91 (27%)

(%) denotes a percentage of the given case out of # total.

Mayo's medication indications that appear in a low number of patients might be incorrect or simply noise, because of human mistakes or the system error in extracting or normalizing indications. Hence, we investigated statistics at a

different level based on patient volume, as shown in Table 2. The higher the number of patients who have the given medication indication—ie, the higher the number in $\log_2$(#pts)—the greater the reliability of the given medication-indication pairs. We can also assume that the portion of the number of matches between Mayo and MEDI would be increased as the given medication indications occur in the higher number of patients. As expected, the match ratio of Mayo's medication-indication pairs with MEDI increases when the given medication indications appear in a higher number of patients (see Figure 3 and 4). This phenomenon is more significant in the original match than the flexible match.

In MEDI, there exists a marker that denotes 'possible label use' whether the given indication can be considered as a labeled use or not. In Table 3, the column '# potential off-labels in matches' denotes the number of matched Mayo medication-indication pairs with MEDI, but their indications are not considered as a 'possible label use' in MEDI. The column '# potential off-labels in mismatches' denotes the number of the mismatched Mayo medication-indication pairs, in that the Mayo medication is in MEDI but its corresponding indication is not in MEDI. In light of these facts, we may consider those two cases above (ie, '# potential off-labels in matches' and '# potential off-labels in mismatches') as the potential off-label candidates. However, those indications should be further reviewed and validated thoroughly to determine true off-label uses.

Figures 5 and 6 show the portions of potential off-label candidates from Mayo's medication-indication pairs when $\log_2$(#pts) is 5 when using the exact match and flexible match, respectively. For the exact match, the ratio of potential off-label candidates is 68% (= 54% in mismatch + 14% in match, Figure 5). Whereas for the flexible match, the ratio of potential off-label candidates is 58% (= 30% in mismatch + 28% in match, Figure 6).

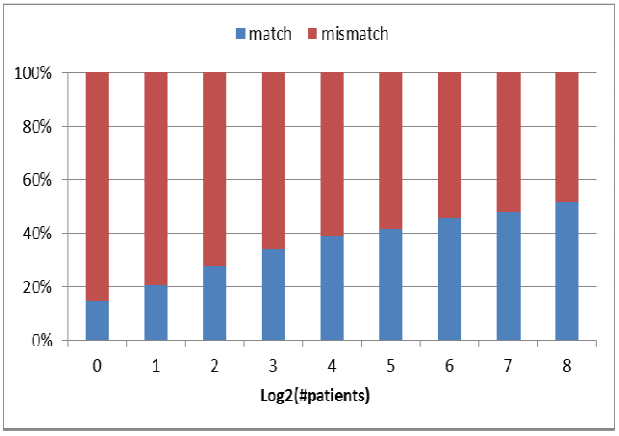

Figure 3. A ratio of match and mismatch Mayo's medication-indication with MEDI (Exact match)

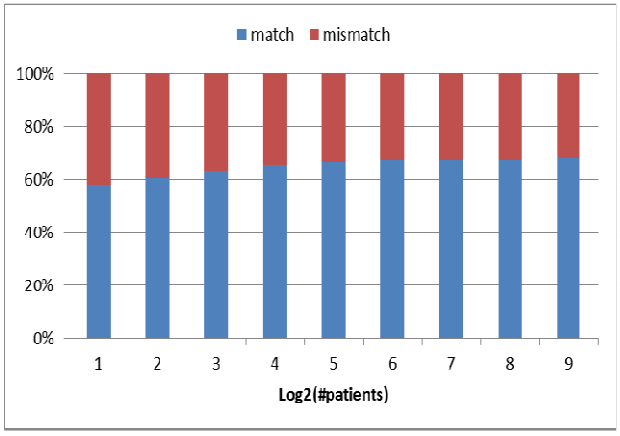

Figure 4. A ratio of match and mismatch Mayo's medication-indication with MEDI (Flexible match)

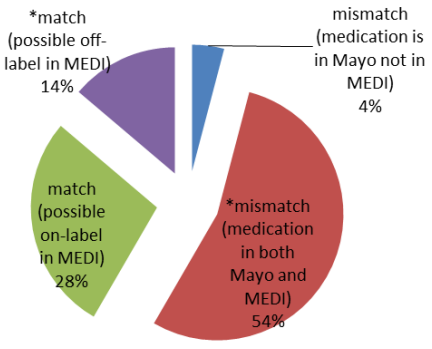

Figure 5. Off-label candidates (starts with *) in Mayo ($\log_2$(#pts)=5, Exact match)

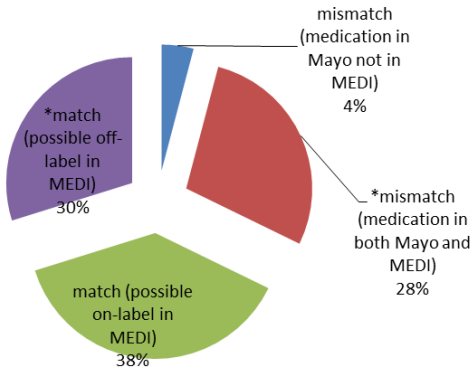

Figure 6. Off-label candidates (starts with *) in Mayo ($\log_2$(#pts)=5, Flexible match)

Table 4. Manual match of mismatched indications between Mayo and MEDI in flexible match.

$\log_2$(#pts)	Medication	Mayo indication	MEDI indication (close to Mayo)
0 ~ 1	lidocaine	vertebral compression fractures	-
	clobetasol	insect bite	-
	codeine	pain in right breast	chest pain, generalized pain
	gabapentin	PTSD	-
	hydrocortisone	nose sore	-
1 ~ 2	omeprazole	pregnancy nausea	Nausea alone
	amoxicillin	foot wound	-
	hyoscyamine	stomach cramps	unspecified disorder of stomach
	insulin lispro	dms	diabetes mellitus
2 ~ 3	nabumetone	ankle pain	generalized pain
	prednisone	facial swelling	-
	mupirocin	skin irritation	unspecified disorder of skin
	rifaximin	small bowel bacterial overgrowth	irritable bowel syndrome
	topiramate	chronic daily headache	cluster headache syndrome
	neomycin	conjunctivitis	other ill-defined disorders of eye
3 ~ 4	prednisone	urinary tract infection	-
	etodolac	back pain	acute pain, generalized pain
	amlodipine	vasospasm	-
	levalbuterol	cough	-
	digoxin	heart rate control	congestive heart failure (CHF)
4 ~ 5	glyburide	gestational diabetes	type II diabetes mellitus
	tramadol	arthritis pain	acute pain, chronic pain, generalized pain
	lidocaine	blood draw	-
	loratadine	asthmatic	-
	benzocaine	mouth sores	candidiasis of mouth
	clobetasol	scalp dermatitis	contact dermatitis and other eczema
5 ~ 6	fluticasone	sinus congestion	-
	docusate	hard stools	constipation
	bupropion	anxiety depression	major depressive disorder
	prednisone	poison ivy	-
	methylphenidate	idiopathic hypersomnia	ADHD
6 ~ 7	oxycodone	knee pain	chest pain, chronic pain, generalized pain
	fluticasone	vasomotor rhinitis	chronic rhinitis, allergic rhinitis
	tacrolimus	psoriasis	Other atopic dermatitis
	triamterene	hypertensive	hypertension
7 ~ 8	quetiapine	panic attacks	schizophrenia, bipolar
	ketorolac	headaches	generalized pain
	polymyxin b	pink eye	other ill-defined disorders of eye
	varenicline	quit smoking	unspecified drug dependence
	epinephrine	bee stings	-
8 ~	lorazepam	panic attacks	panic disorder without agoraphobia
	citalopram	anxiety depression	anxiety state unspecified
	albuterol	SOB	shortness of breath
	diphenhydramine	sleep	persistent disorder of sleep
	acetaminophen	cold symptoms	acute nasopharyngitis (common cold)

Table 4 shows some examples from the mismatch indications where medications are in both Mayo and MEDI but Mayo's indications were not found in MEDI in flexible match. We manually examined MEDI's indications for a given medication to see if there exist any similar indications to those of Mayo in a broad sense. If we found any similar indications, we place them into the column 'MEDI indication close to Mayo,' otherwise, we place '-' in this column. As can be seen in Table 4, manually identified MEDI's indications share common high-level indications with Mayo (eg, 'back pain' vs. 'general pain'; 'pink eye' vs. 'other ill-defined disorders of eye'). However, there are still some indications that were not able to be matched with MEDI in this manual process (ie, the cells with '-'). Most of these cases seem to be specific medical problems asserted by clinicians rather than general indications, which more likely appear in the low number of patient frequency. For example, Lidocaine's general use is 'numbness or loss of feeling' but Mayo's indication is 'vertebral compression fractures,' Clobetasol's general use is 'itching, redness' but Mayo's indication is 'insect bite.'

Based on the previous comparison between Mayo and MEDI, we investigated actual examples of potential off-label candidates from Mayo's medication-indication data. Tables 5 and 6 show potential off-label indications (the second column) and actual labeled indications (the third column). Table 5 contains examples of medication indications that appear in Mayo but not in MEDI, which are regarded as potential off-label uses. Table 6 contains examples of medication indications that appear in both Mayo and MEDI but which MEDI indicates not 'possible label use.' Since these indications are not marked as a possible label by MEDI, we might also assume them to be potential off-label uses.

We have examined these potential off-label indications through Wikipedia and Internet searches and have verified that they are treated as off-label uses. Through this investigation, we also found many psychiatric medications are prescribed for off-label uses.

Table 5. Examples of potential off-label indications (exist in Mayo but not in MEDI)

Medication	**Indication in Mayo (off-label)**	**On-label Indication**
Brimonidine	photophobia	glaucoma
Bupropion	smoking cessation assistance	depression
Albuterol	cough	asthma
Doxepin	allergies, hives	depression, anxiety, sleep disorders
Modafinil	wakefulness, alertness	narcolepsy
Sertraline	bipolar disorder	depression

Table 6. Examples of potential off-label indications (exist in Mayo and MEDI's possible off-label)

Medication	**Indication in Mayo and MEDI (off-label)**	**On-label Indication**
Azithromycin	traveler's diarrhea	certain bacterial infections
Gabapentin	hot flashes	certain types of seizures
Trazodone	difficulty sleeping	antidepressant
Methylphenidate	depression	ADHD, narcolepsy
Duloxetine	anxiety	depression

Discussion

A large volume of medication and indication occurrences from Mayo clinical notes have been analyzed and compared with MEDI that compiled from four public medication resources. Unlike previous studies, we used actual medication-indication pairs asserted by clinicians in real clinical practice. For exact and flexible matches (Table 2),

Mayo's medication-indication pairs match MEDI approximately 15% to 52% and 58% to 68% of the time, depending on the number of patients with the given indication, respectively.

Mayo's medication-indication pairs demonstrate that they have both off- and on-label medication uses. The ratio of potential off-label candidates when considering the indications that occurs in greater than or equal to 32 patients ($\log_2$(#pts)=5) is approximately 68% and 58% for exact and flexible matches, respectively. However, these represent rough 'potential candidates' that may be off-label indications which require further validation.

It should also be noted that the overall ratio of potential off-label indications found in our results does not represent the actual ratio of off-label uses in Mayo as a whole, because we only investigated the medication descriptions that include indications, but these are only a small portion of the total medication descriptions. Also, we do not know when the clinicians actually add indications to in the Current Medication section of our clinical notes.

Instead of medication information in clinical narratives, which is often described with intended indications, we used medication information in a specific section—ie, Current Medication—that contains a majority of patient-intake medications in a list format (as shown in Figure 1). This provides us with a relatively straightforward method of extracting medication-indication pairs. Using current medications may provide another benefit. Current medications may infer active diagnoses of patients and therefore support the compilation of the patient's comprehensive problem list, which is often difficult to maintain and manage in clinical practice. If we were able to obtain missing indications in the Current Medication section through examining other portions of clinical narratives, we would be able to compile comprehensive patient medication-indication lists, which would aid in better clinical care and decision support.

Off-label medication use is common in clinical practice, but most of these off-label uses lack rigorous evidence or studies to support them. However, off-label medication use is legal and often useful. Table 5 and 6 show good examples of potential off-label use as they show that clinicians use them differently from the original pharmaceutical use. Analyzing actual clinical practice of off-label use through a well-managed database would likely prove beneficial to patient treatments, patient safety, and quality improvements. Our study may serve as a foundation for further investigation and the eventual development of such a database.

There are some limitations to this study. Our analysis was based on medication-indication pairs automatically extracted by the system. We believe that most are correct, because medication indication descriptions in our clinical notes are relatively straightforward for extraction purposes. However, there exists the possibility that some medications and their indications could be incorrectly linked. We used normalized Mayo medication-indication pairs to compare with those of MEDI but this normalization has not been thoroughly evaluated in this study. Although we employed flexible matches between Mayo and MEDI, some mismatches may occur because of normalization differences between the two data sets. Also, false matches may occur because of over-generalization (ie, within two steps of navigation in the UMLS network). One-step distance or using certain types of relationship would be alternative ways to investigate. The appropriate medical-concept normalization would be necessary to better match indications between different medication resources.

Abstract
Wrong patient selection errors are a major issue for patient safety; from ordering medication to performing surgery, the stakes are high. Widespread adoption of Electronic Health Record (EHR) and Computerized Provider Order Entry (CPOE) systems makes patient selection using a computer screen a frequent task for clinicians. Careful design of the user interface can help mitigate the problem by helping providers recall their patients' identities, accurately select their names, and spot errors before orders are submitted. We propose a catalog of twenty seven distinct user interface techniques, organized according to a task analysis. An associated video demonstrates eighteen of those techniques. EHR designers who consider a wider range of human-computer interaction techniques could reduce selection errors, but verification of efficacy is still needed.

Project webpage with video demonstration: http://www.cs.umd.edu/hcil/WPE/

Introduction

Patient selection errors can be defined as actions (orders or documentation) which are performed for one patient that were intended for another patient[1]. Such wasteful and potentially life-threatening errors are a well-documented problem. Koppel et al. categorized 22 types of scenarios where CPOE increased the probability of prescription errors, including wrong patient selection[2]. The wrong patient can be selected when referring to patient profiles, lab results, or medication administration records[3.] According to a study by Hyman et al., placing orders in the incorrect patients chart comprised 24% of the reported errors[4]. Case-reports from the Veterans Health Administration showed that 39% of their "laboratory medicine adverse events" were caused by wrong patient order entry and 8% of these were due to reporting back the results to the wrong patient medical record[5]. Lambert et al. [6] projected that 14247 cases of wrong drug errors happen every day in USA, and many of them were caused by a wrong patient selection error. Two studies[7,8] estimated that about 50 per 100,000 electronic notes are entered in the wrong patient record. We believe that providing cognitive support though interface design for patient selection can reduce the frequency of harmful outcomes, thereby improving performance and safety.

Method

We reviewed sources of user interface selection errors from academic literature, interviews with clinicians, and inspection of existing EHR interfaces. Then, guided by a task analysis (ranging from recall of patient identity to error recovery or reporting of errors), we propose 27 user interface techniques. Eighteen techniques are illustrated in a prototype and available on video. Finally the techniques were tagged with an estimated level of implementation difficulty and estimated payoff, based on past findings of Human-Computer Interaction research[9.] Verification of efficacy is clinical environments is still needed.

Prior Work

Sengstack[10] provides a 46-item checklist for CPOE system designers to follow, categorized into clinical decision support, order form configuration, human factor configuration, and work flow configuration. Like Sengstack we found many descriptions of the safety problems associated with patient selection but very little prior work describing empirical evaluation of user interface design guidelines. The scope of the suggested techniques was limited and many proposed solutions had shortcomings. For example Adelman et al.[7] showed that ID-reentry (i.e. keying the

patient information twice) could reduce wrong patient selection errors, but this technique takes a substantial amount of additional time and therefore is likely to cause significant user frustration.
Lane et al.[11] list 'Wrong Selection' as a type of error in their taxonomy of errors in hospital environments, with wrong patient selection being only one of the errors mentioned. Most of those errors were attributed to poorly designed systems for patient selection[7]. More general work by Reason[12] categorized human errors as violations, mistakes and slips. Norman[13] asserts that the dividing line is the intention: it is a slip when the intention is correct but mechanical factors lead to error, while it is a mistake when the intention itself is wrong. Wrong patient selection can be a result of either a slip or a mistake. It is a slip if the clinician accidentally selects the patient in an adjacent row or hits the wrong number key when entering a patient ID number[14]. Slips are more frequent when the text is hard to read or small buttons are hard to select. Mistakes are more frequent when two patients are listed with the same first and last name[15] or inconsistent Medical Record Numbers (from different data sources).

Various human factors such as visual perception or short-term memory can lead to confused intentions. For example when names are sorted alphabetically similar names can coalesce visually and lead to intentional selection of the wrong one. Hospitals often have shared computers where clinicians need to log in to work and then to log off. Failure to log off can leave then next clinician's memory being cued by the wrong list. To minimize confusion between patients, it is possible to display other identifier such as date of birth, room number, gender, admission date, or attending physician name[3]. Clinicians often identify their patient by room number / location[16]. The Joint Commission now mandates that at least two patient identifiers be used[17]. Unfortunately, clinicians do not routinely verify patient identity after selection[18, 19]. They may be interrupted in the midst of selecting a patient or toggle between the records of two patients[15].

The general literature on errors can also inform better design of EHR systems[13.] Slips can be reduced by providing feedback (e.g. highlighting the item before the selection occurs). Mistakes can be reduced providing memory aids (e.g. providing pictures to remind the clinician of the patient) especially when interruptions / distractions between the time of the intent and the time to perform the task. Visual attention guidelines can also be useful. For example animation, if used appropriately, can focus users attention[20, 21]. Schlienger et al.[22] presented empirical evidence that use of animation and sound improves perception and comprehension of a change. One recent example of the use of animation is TwinList, that was designed to assist the medication reconciliation process[23].

Task Analysis

While a detailed clinician task analysis depends on a particular system and its user interface, we focus on general steps for CPOE, namely patient selection, verification, order entry and confirmation (Figure 1). In an ideal hospital, order entry would occur at the patient's bedside assuring identity confirmation, or if not at the bedside using proper documentation. Unfortunately, in reality, interruptions are frequent, documentation incomplete, and human nature tends to shortcuts. Inevitably, recall will be used[16], so it seems prudent to engineer EHR interactions to maximize odds of correct patient selection from recall. We therefore include the following tasks:

1. *Recall patient:* Clinicians must first recall the patient's identity (e.g. John Smith, or the heart failure patient in Room 201, or the patient whose ID# is on this sheet of paper). They may not recall the correct patient name.
2. *Select patient:* This is done either by typing a name or record ID number or by selecting in a list of patients.
3. *Verify selection:* After selecting a patient, clinicians may or may not verify whether they selected the correct patient. Unfortunately the patient name may be invisible (e.g. scrolled away from view). To verify may require checking the age, chief complaint, or room number, all of which may not be displayed at that time. They may not recognize the error, and continue working with the wrong patient's record.
4. *Place order:* One or more orders are entered for the patient. This can be a long and complex task which can be interrupted multiple times, sometimes to work on other patient records.
5. *Confirm order:* A confirmation dialogue may be displayed before or after order submission. This is likely to be the last chance to stop a wrong patient order.
6. *Report error:* If clinicians realize later on (minutes or days later) that they made an error after submitting an order, they should be able to cancel the wrong order and then place the same order for the correct patient. They should also be able to report the error and notify stakeholders.

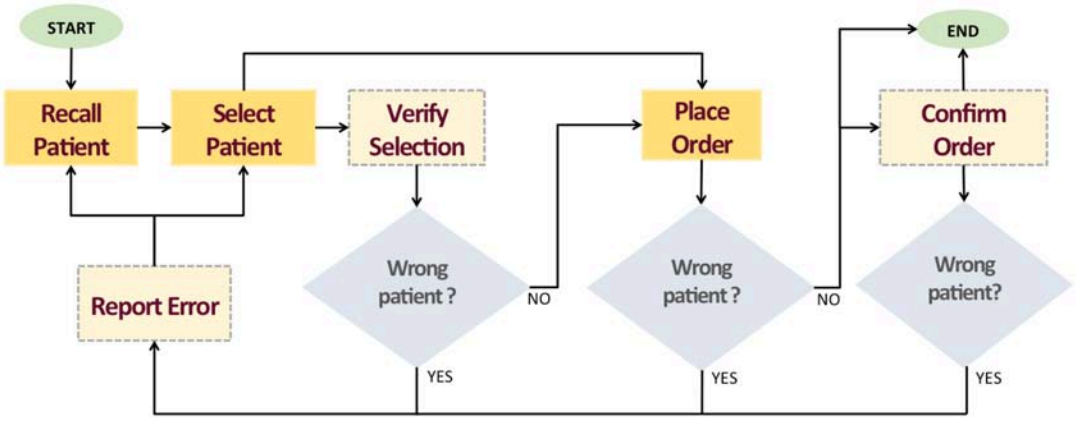

Figure 1: Task analysis of the selecting a patient and placing an order, shown as a flow-diagram. Lighter colored dotted rectangles represent tasks that may not be taken.

Proposed User Interface Techniques to Reduce Wrong Patient Selection Errors

Based on the error types reported in the prior work and the task analysis, we provide a design space of 27 potentially helpful user interface techniques (see Table 2). We grouped the techniques by the task for which they would be most useful. Some of the techniques have been successfully implemented, either in some EHR systems or in other non medical applications, but most have not. Eighteen techniques with comparatively higher pay-offs and lower implementation cost were implemented in a prototype, refined based on clinician feedback, and recorded on video (see http://www.cs.umd.edu/hcil/WPE). The prototype has a control panel that allows designers to combine techniques or check them individually. The prototype was developed in JavaScript and HTML. The animated features use the JavaScript library D3 and jQuery. For user interface and layout, we used the Bootstrap library from Twitter and jQueryUI. Source code is available.

During Task 1: Recall patient

* *Use patients' photos and other information.* Patients' photos can be used along with the patients' information both in the patient list and in the header of the order screen. Photos likely aid the recall and verification step[28]. More contextual information, like the location, admission date, attending clinician's name, chief complaint, etc. may also help clinicians recall the patient correctly. Color coding patient age and using visual clues indicating how long each patient has been in the hospital can also help clinicians identify the correct patient. Providing more information helps resolve confounding cases where two patients have similar names. Usually room number is shown in the patient selection list. But if the room numbers do not provide any contextual information, they will not be helpful.
* *Show the floor plan.* Patients are often recalled by the location where they were seen. Clinicians dealing with a new patient and unable to remember the patient name after returning to their desk should be allowed to select from a floor plan to narrow the list of patients to only see the patients at that location. In small facilities the patient information might appear directly on the map, while in large facilities the map can be used to filter patients by ward or room (Figure 2).

Other techniques can be used to facilitate recall as well as selection by narrowing the list of patients, so when clinicians only recall that a patient had a French name they can more easily scan the list to recall the exact name. In general users find their targets faster in smaller lists, and are more likely to miss a target in a large list[24].

* *Provide a personalized list of patients.* Showing only the patients assigned to the currently logged-in clinician is preferable. Different clinicians may use the same computer to log in so showing the clinician's name in the selection screen is critical. Further visual differentiation is likely to be needed to help clinicians recognize that someone else is logged in – especially when they do not expect it, or have been interrupted. Overlaying the clinicians' name in large characters over the screen after a brief period of inactivity might be useful. A distinct background color or border style could be recommended to each user during initial setup, which could then be applied to all their screens.
* *Allow sorting.* Sorting patient lists by attributes such as date of birth, date of admission, name of provider, etc. can help match the list to the clinician's mental organization of their care, for example clinicians often think of young

and elderly patients.

* *Allow filtering.* Repetitively scanning long lists takes time, and clinicians also need to be able to recall patients' identity based on other attributes than name. They should be able to use filters to narrow down the list of patients. For example, if clinicians remember that a patient was in cardiology, they can filter the list to see only the patients from that department. Our prototype provides three examples of filters (Figure 3): by patient name or ID, room number, and attending clinician name (which may be relevant for a nursing station). Filters need to be rapid, incremental and reversible. For example typing a string of letters should progressively filter down the list to only show names that include the string. Menus and controls should be optimized for rapid selection[9].

* *Allow categorical grouping.* Meaningful groups also reduce search time[25]. The patient list can be grouped into smaller lists based on categories, such as gender, floor, room number, service, department, attending physician name, etc. We show three examples of grouping in our prototype: gender, clinician and ward.

Task	User Interface Technique	Estimated Effort	Estimated Safety impact	In demo?
Recall patient	Use patients' photos and other information	**HIGH**	**HIGH**	x
	Show the floor plan	**medium**	**medium**	x
	Provide a personalized list of patients	low	**medium**	
	Allow sorting	low	low	x
	Allow filtering	low	low	x
	Allow categorical grouping	low	low	x
Select patient	Provide clues that similar names exist	**HIGH**	**HIGH**	x
	Use RFID technology	**HIGH**	**HIGH**	
	Always show patient's full name	low	**HIGH**	x
	Consider ID reentry	low	**medium**	
	Include buffer space between rows	low	**medium**	x
	Increase row height	low	**medium**	x
	Highlight row under cursor	low	**HIGH**	x
	Consider using a 2D grid instead of a list	**medium**	low	
Verify selection	**Highlight on departure**	low	**HIGH**	x
	Highlight on arrival	low	**medium**	x
	Use animated transition	low	**medium**	x
	Use a visual summary of the patient history	**medium**	TBD	
Place order	Keep the patient header visible at all times	low	**medium**	x
	Maintain consistency between screens	low	low	x
	Use clinical decision support	**HIGH**	**HIGH**	
	Consider side-by-side display of detailed patient information and order information	**medium**	TBD	
Confirm order	**Include the identity of the patient in Submit button**	low	**HIGH**	x
	Consider placing the submit button near the patient information	low	**medium**	x
Report error	Report errors with proper feedback	**medium**	TBD	
	Speed up placing the same order for the correct patient	**HIGH**	Low	

Table 2: Techniques to reduce wrong patient selection, with our estimates of the level of effort and safety impact (TBD = to be determined). Techniques with high estimated safety impact and low estimated effort are highlighted with bold text. The In-demo checkmarks (x) indicate which techniques are demonstrated in the prototype or video.

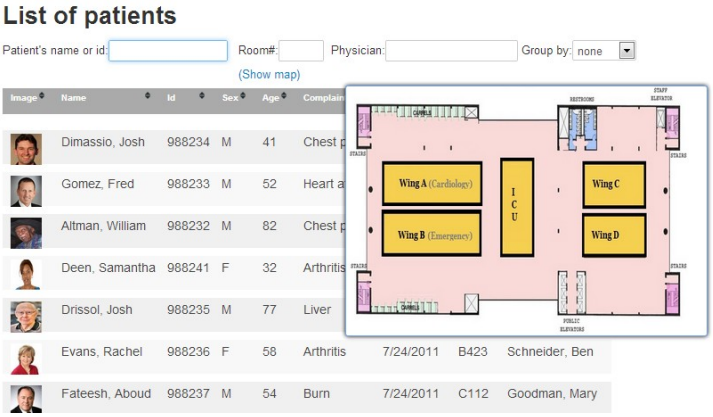

Figure 2: As clinicians click on a section of the map, the patient list is filtered to show only patients in that section. In small facilities individual rooms might be selected.

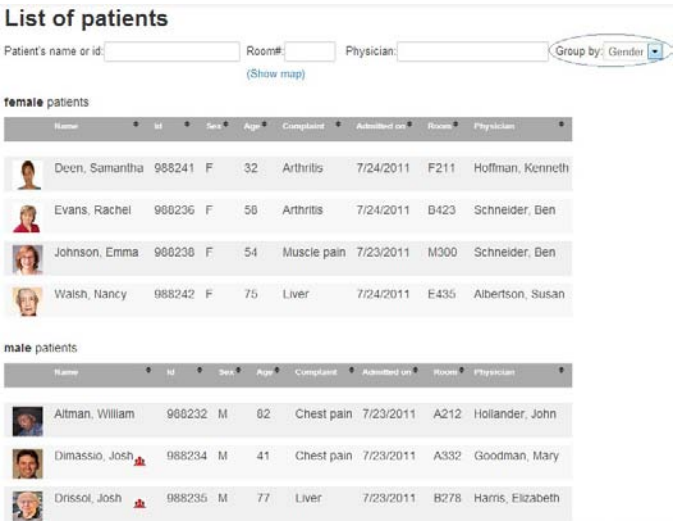

Figure 3: A list of patients with pictures and examples of controls for searching (by name, ID, room or physician) and grouping (here by gender). Each row includes a patient's photo, room number, date of birth, gender and the name of the attending clinician.

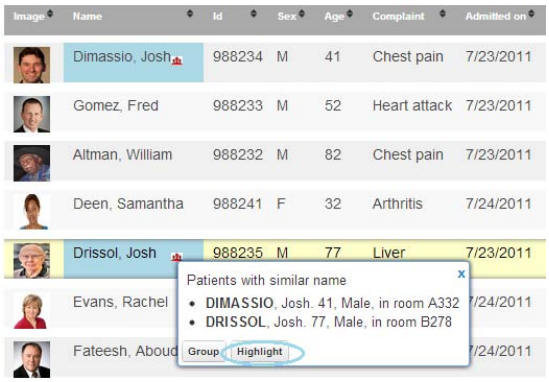

Figure 4: Notification about similar names: here, a red little icon is placed next to names that are similar to other names. The cursor is hovering over Josh Drissol, showing that the name was found similar to Josh Dimassio.

During Task 2: Select patient
After clinicians have recalled the identity of the patient whose record they want, they need to easily select that record. Several user interface techniques can help reduce errors.

* *Provide clues that similar names exist.* The system can alert clinicians of the existence of similar names. Imagine that a clinician recalls the name Adam Davis, then see David Adams at the top of the list. Those names will not sort together. Clinicians may never realize that there are two patients with similar names. Both orthographic (similar spelling) and phonological (similar sounding) similarity are detectable. Our prototype and video illustrates an example technique to notify clinicians about this similarity. It shows a small icon next to the name if there are other patients with similar names. Hovering the cursor over the icon reveals the list of similar names and additional information about those patients. The prototype also allows users to highlight the similar names in the list, or to group the rows of the patients with a similar name close together to facilitate comparison (Figure 4).
* *Use RFID technology*. Some hospitals give wristbands with their ID and demographic information. An RFID (radio frequency identification) scanner can be used to read the information. Although the technology is still costly and has its technical limitation, it has the potential to help reduce patient misidentification. RFID tags might also be used to read the location of the patient (e.g. a room) or the clinician ID.
* *Always show patient's full name.* Some tabular lists crop patients' names to fit it in the limited horizontal space. This will lead to confusion among similar names. The row displaying the patient names should be automatically resized to be large enough to show the entire names. Even omitting titles or suffixes can lead to a wrong selection. If a name in the list is abnormally long (to the point of not leaving room for the other columns) it should be wrapped inside the cell using a double height row.
* *Consider ID reentr*y. Re-entering the patient's ID a second time on the order screen has been shown to helpful[7]. Nevertheless we believe that the additional time it takes is likely to produce a lot of user frustration.

Other design techniques can be used to facilitate the mechanical aspects of target selection in lists:
* *Include buffer space between rows.* If there is "dead" space between the rows and the mouse click occur, nothing will be selected. This reduces the chance of selecting the wrong row by mistake. This could be accomplished by added white space between rows (e.g. in figure 2-4) or by only accepting clicks in the center of the row. A proper balance should be found: when the spacing becomes too large, more scrolling will become needed, and if the click-able area is too small selection becomes more difficult
***** *Increase row height.* If the row height is big enough, there is less chance of clicking the adjacent rows as we tend to click in the middle of a target. In general target selection performance follow Fitts' law, i.e. speed and accuracy decreases proportionally with the smallest dimension of the target area[26] (i.e. in this case the height of the selectable area). Again, if each row takes more vertical space, the screen can contain fewer number of rows.
***** *Increase font size.* Readability can be an issue while working under pressure and older or tired users with even mild vision impairments may have trouble. Users should be allowed to increase the font size easily so that the text is always clearly readable. In our prototype, users can use a keyboard shortcut to customize the font-size.
* *Highlight row under cursor*. This is a standard technique for list selection which is sometime omitted. Highlighting the row under the cursor draws attention to the impending selection. It also makes more apparent an inadvertent slip to an adjacent row. In our prototype, the row under the cursor is highlighted by changing the background color to yellow and changing the font to a darker gray (see Figure 4).
