The goal of this study was to evaluate a Virtual Pointer system in terms of how the added visual information affects trainee’s cognitive load, i.e. the effort needed for trainees to process instruction and task related information. Our hypothesis was that although the Virtual Pointer would add more visual information, it could improve communication efficiency between trainer and trainee, thereby allowing more space for cognitive processing.

Overall, we found no additional cognitive load was associated with the Virtual Pointer after trainees became accustomed to the system despite the indication of prior work. There was a slight non-significant increase to the trainees’ cognitive load in the first experience of the Virtual Pointer condition compared to Standard condition. However, despite the addition of a visual source of information, i.e., a component seen to have the potential of causing increased cognitive load on trainees in a CSCL environment, it in fact does not impose more cognitive load on...
trainees. In fact, once the trainees gained additional experience with the Virtual Pointer-based instruction, it was less cognitively demanding 20,21,50. This result is also in line with our previous findings that the benefits of a virtual pointer in improving the trainees’ performance become evident after initial knowledge is gained 37.

Our further analysis shows the Virtual Pointer could improve communication efficiency between trainer and trainee. Trainees were able to perform more dual tasks – the laparoscopic task itself and watching/listening to the trainer’s instruction – with the Virtual Pointer without being cognitively overloaded. Moreover, an increase in dual task instances in the Virtual Pointer condition did not lead to higher cognitive load. This is especially interesting considering previous research has demonstrated that performing two tasks simultaneously is more cognitively demanding 44. Our findings that increased dual-tasks did not increase cognitive load suggests that the Virtual Pointer actually improves the communication efficiency between the trainee and the trainer, allowing the trainees to have further cognitive processing as suggested by Lim 18. According to the modality effect in Cognitive Load Theory, receiving both verbal and visual instruction leaves more cognitive capacity for trainees to perform more cognitive processing. Thus, the combined visual and audio instruction provided with the Virtual Pointer may open more cognitive processing space enabling the trainees to listen to instruction and perform the surgical task simultaneously. This contrasts with the Standard condition in which less efficient communication, i.e only audio guided instruction, requires greater mental effort to visualize the instruction and perform the laparoscopic task simultaneously. Being able to perform two tasks simultaneously – the laparoscopic task in addition to watching and listening to the trainer’s instruction - may contribute to better comprehension and thus better performance as was indicated in 37 due to benefits of embodied learning 51. The embodied learning theory states that learning and consolidating mastery occurs better by physically practicing the task than by mentally simulating it. Therefore, the better performance of trainees while using a Virtual Pointer 37 might be the result of embodied cognition which is gained through performing and listening to the instruction at the same time.

Limitations

This study was conducted in a simulated training environment. However, the Virtual Pointer is intended for instructing trainees while they are performing laparoscopic surgical tasks on real patients in the operating room - a more complex, stress-inducing, and cognitively demanding condition. In the operating room, even a slightly higher cognitive load may result in poorer performance which could be detrimental to real patients. Thus, further studies need to be conducted to evaluate the use of the Virtual Pointer and possible unintended consequences to workflow in a real life operating room environment. In addition, while EDA has been recognized as the most precise physiological signal for measuring cognitive load 52, it is still affected by other factors, such as activity and movement. Although we removed the segments of EDA data identified to be influenced by factors other than cognitive load, there is still a risk that some of the observed changes in EDA may have other underlying origins not associated with cognitive load. One concern is distinguishing stress from cognitive load in EDA-based measurement methods. However, results from 49 on discriminating between stress and cognitive load demonstrate that SCR interval rate is a predictor of stress, while the number of SCRs present, used as our measure, is a predictor of cognitive load. Additionally, use of the non-dominant wrist for collecting EDA data, although recommended by the Empatica E4 user manual, might miss some relevant information related to cognitive load from the dominant hand.

Abstract

This paper describes a novel technique for annotating logical forms and answers for clinical questions by utilizing Fast Healthcare Interoperability Resources (FHIR). Such annotations are widely used in building the semantic parsing models (which aim at understanding the precise meaning of natural language questions by converting them to machine-understandable logical forms). These systems focus on reducing the time it takes for a user to get to information present in electronic health records (EHRs). Directly annotating questions with logical forms is a challenging task and involves a time-consuming step of concept normalization annotation. We aim to automate this step using the normalized codes present in a FHIR resource. Using the proposed approach, two annotators curated an annotated dataset of 1000 questions in less than 1 week. To assess the quality of these annotations, we trained a semantic parsing model which achieved an accuracy of 94.2% on this corpus.

Introduction

Fast Healthcare Interoperability Resources (FHIR)1 is an emerging standard developed by Health Level Seven International for storing and sharing information between different electronic health systems. Because of its RESTful architecture (adherence to REpresentational State Transfer style), it can be effectively used to view the data in different settings such as mobile and web applications. However, accessing some required information in electronic health records (EHRs) is still a cumbersome task2. Efficient query mechanisms such as question answering (QA) from medical records have the potential to reduce the delay between stored information and its prospective users.

EHRs contain information in both structured and unstructured format. Information extraction from unstructured data present in EHR (such as clinical notes and diagnostic reports) is well-researched and holds a promise to convert the free text data into structured format3,4. Efficient techniques to surface information from such structured EHR data have the potential to make the overall information access faster and reduce burdens related to system complexity.

Systems for QA from structured databases rely on unambiguous interpretation of natural language questions, often represented as machine-understandable logical forms. This process of converting natural language questions to their logical representations is called semantic parsing. Training semantic parsers usually requires a set of questions along with their annotated logical forms and/or answers5,6. Such corpora are widely available for the general domain but there is a scarcity of such datasets for EHR QA, mainly because of privacy issues and the complexity of EHR data.

Though annotating the questions with answers seems to be an easier task, one of the main difficulties involved in training a semantic parser using such dataset is ambiguity related to the realization of logical forms. Multiple logical forms can produce the correct answer but it becomes challenging for the semantic parser to separate the correct logical forms from the incorrect ones in such a scenario. Moreover, constructing a dataset of question-logical form pairs require annotating concept normalizations where medical concepts are recognized and mapped to a standard ontology. This is one of the hardest and time-consuming parts of creating a dataset for semantic parsing7.

Concept normalization alone is a challenging task as the same basic concept may legitimately map to multiple clinical codes and/or be stored in separate FHIR resources, even with the interoperability standards in place. For instance, the information that a patient has abdominal tenderness can be stored using FHIR Observation resource in at least the following ways8:

i. code: C4321457 (Examination), value: Abdomen tender
ii. code: C0562238 (Examination of abdomen), value: Tenderness
iii. code: C0232498 (Abdominal tenderness), value: found or true
iv. code: C0232498 (Abdominal tenderness), value: no value

1207
Moreover, a Condition resource can also be used to store this information if the symptoms are lasting\(^9\).

One of the main reasons behind such disparities is the use of different practices to store information at different organizations, which makes the process of normalizing concepts harder in a real setting. While there exist automated methods for concept normalization\(^9\), they are not tailored to the practices of a specific organization. Hence, it is important to learn these conventions at the organizational level where the QA system will be deployed.

In this paper, we propose a novel approach to construct a sizeable corpus of question-logical form-answer triplets using a FHIR server in a relatively short amount of time. Precisely, the list of available FHIR resources for a patient is shown to the annotators who, then, create a question, select the correct answer, and construct the corresponding logical form. We make use of the FHIR resource answers to automatically annotate concept normalizations for highlighted question phrases, which reduces the overall annotation time. Further, we train a semantic parser over the constructed dataset to learn the underlying logical forms. We also implement a concept normalizer tailored to the annotated concepts present in our corpus. Because of the shorter time and lesser prerequisite knowledge requirements for such corpus construction, the approach can be scaled across the organizations.

**Background**

We divide the related work into the following two sections based on the type of data used by medical QA systems.

1. **Unstructured Data**

Numerous studies in medical QA focused on the unstructured data sources such as biomedical literature, health-related social media data, and free text EHR data\(^{1,12}\). Several studies aimed at extracting relevant documents from the biomedical literature\(^{13–16}\). The BioASQ challenge\(^{17}\) introduced a decent sized dataset for machine comprehension (MC), i.e., answering a question on the basis of a given free text, from biomedical scientific articles. Similarly, a small MC dataset was released as part of the QA4MRE task\(^{18}\). Further, a recent study created large scale MC dataset using PubMed\(^{19}\). Another work constructed a small dataset using the resolved question-answer pairs from community-based health forums\(^{20}\). The MedQA task\(^{21}\) involved a large scale reading comprehension dataset which was built using data from certification exam for medical practitioners. Using the same certification exam dataset, a study proposed a framework for automatically generating question-answer pairs\(^{22}\). Further, with the MedicalQA task\(^{23}\), a dataset was developed utilizing various components of EHRs such as history of present illness. Raghavan et al.\(^{24}\) defined a process of annotating question-answer pairs using the EHR clinical notes.

Moreover, several efforts aimed at structuring the data present in unstructured form. Goodwin and Harabagiu\(^{25}\) proposed an approach for converting MIMIC-III medical records to knowledge graph for QA. Another study by Ayalew et al.\(^{26}\) created an ontology for the dataset of online frequently asked questions to assist in QA.

The majority of the datasets proposed for medical QA from unstructured data are based on biomedical literature whereas, only recently, the unstructured EHR data is gaining attention. Nevertheless, many studies are directed toward information extraction from free text present in EHRs\(^5\). Our aim, however, is to construct a corpus using the structured EHR data.

2. **Structured Data**

Very few works concentrated on QA from the structured biomedical data. Asiaee et al.\(^{27}\) and Amith\(^{28}\) worked on QA over a medical ontology. Pampari et al.\(^{29}\) constructed question-logical form and question-answer pairs using a template-based approach. QA dataset generation using templates limits the variety of questions to a certain extent and are not representative of the real world queries. Our previous work included annotating a set of EHR questions with their corresponding logical forms\(^7\). As stated earlier, logical form annotations are time-consuming to annotate, especially because of difficulties involved in annotating the concept normalizations. In this paper, we aim to quicken the process of concept annotations utilizing FHIR. To our knowledge, this is the first work to construct a dataset for EHR QA using FHIR resources.

**Materials and Methods**

The following sections describe the methods used for constructing and evaluating the dataset. A graphical representation of our methods is shown in Figure 1.

1. **Dataset Construction**

We set up a local FHIR server which serves as an underlying data source for constructing the dataset. An annotation tool is implemented to present the information contained in the FHIR server to the annotator. The annotators reviewed
the available patient resources and constructed questions along with their corresponding simple logical forms. An institution-specific concept normalizer is trained based on these annotations. We further processed the constructed questions to be used in training a semantic parsing system. Each of these tasks is explained further in the following sub-sections:

1.1. FHIR Server

We deployed a FHIR server locally using an existing open source implementation by the MITRE Corporation for DSTU2 version (v1.0.2)\(^*\). To generate the data for this local server, we used Synthea, a tool for producing realistic health care records\(^3\). The FHIR resources generated by Synthea are added to the local FHIR server using the REST APIs provided by the server. We chose to use the local FHIR server instead of any online available sandbox servers to maintain stability and consistency.

1.2. Annotation Tool

We implemented a web application to facilitate the browsing of FHIR resources present in the local server for an efficient annotation process. The tool displays all the available patients along with their resources from the server. The three main components of the tool interface allow, for a selected patient, viewing all the resources, viewing all the resources of a selected resource type, and entering the constructed question with its corresponding logical form. The user interface for the annotation tool is shown in Figure 2. The main components of the tool are explained below. Indices in the parentheses, (#), point to the corresponding elements in Figure 2.

I. Patient Details

This view gives an overview of all the FHIR resources for a selected patient. A list of available patients along with a count of questions constructed for them can be seen using the dropdown (1). The patient can be changed using this dropdown or by refreshing the browser. The gender and date of birth information are shown below the dropdown at (2) for a selected patient.

The table in this component shows the information common to all the FHIR resources, namely, resource type, name, ID, and time. All the entries in this table can be capped, filtered, and/or sorted using the corresponding functionalities at (3), (4), and (5). Such flexibility in viewing the resources facilitates the overview of patient history.

II. Selected FHIR Resource

This part enables the annotator to view more granular details for the resources of a selected type. All the available resource types for the selected patient can be seen in the dropdown (6).

\(^*\) https://github.com/mitre/fhir-server
The table under this section has similar functionalities in terms of filtering and viewing the results. In addition to these, the table allows selecting one or more resources from the list using checkboxes (7). This selection serves as the answer to a constructed question.

III. Annotations

Above this section at (8) is an ongoing count of the total number of questions the annotator has constructed so far. This count takes into account the questions constructed for all the patients to show the overall annotation progress. The question text box in this component allows the annotator to input their constructed question. The concept boundaries can be highlighted using a set of opening and closed square brackets. The marked text is automatically normalized to the medical concept present in the selected answer. The text box for simple logical form is used for entering the logical form for the constructed question. There is another text box for entering the comments in regard to the annotation, if there are any. The submit button is used to save the annotation to the corpus.

The tool is equipped with certain validation checks which ensure that a correct annotation is saved. Specifically, the tool checks for the following:

- a. At least one FHIR resource is selected as an answer
- b. The question contains a highlighted concept
- c. The simple logical form is valid (check for balanced parentheses and valid logical predicates)

1.3. Annotation Process

The description of the annotation tool provides some intuition to the annotation process. In this section, we explain the overall annotation process in detail.
The annotator starts with a selected patient and views all the FHIR resources for them in the Patient Details component. The annotator decides to ask questions based on the available resources of a patient. After getting a quick overview of the patient, the annotator moves to the Selected FHIR Resource component and selects a resource type to construct some question. The annotator enters a question in the Question input and selects the corresponding FHIR resource(s) containing the answer. Finally, the user enters a corresponding simple logical form and hits submit. We follow the logical form structure as described in our previous work on annotating the EHR questions2. After the submission of an annotation, the highlighted concept in the question text is automatically normalized to the medical concept of the selected FHIR resource(s). The annotation is saved to the corpus with this normalized concept. For instance:

**Answer Resource:** Condition resource Rupture of appendix with concept code C0267628

**Question:** When was the [appendix ruptured]?

**Normalized Question:** When was the nn:concept(C0267628)?

**Simple Logical Form:** time(latest(lambda(concept)))

**Logical Form:** time(latest(λx.has_concept(x, C0267628)))

Again, only the Question and Simple Logical Form are typed by the annotator. The Answer Resource comes from the checkbox (7) and the Normalized Question is computed automatically.

### 1.4. Post Processing

After the annotation process is completed, the constructed corpus is further processed to add more annotations. Particularly, we employ rule-based approaches to identify the person references, temporal references, and measurements. These additional annotations are important to separate the task of semantic parsing from concept normalization4. The following question exemplifies such normalization categories:

**Question:** Did her hemoglobin A1c exceed 6% in the past 3 years?

**Normalized:** Did pos:person nn:concept exceed measurement(‘6%’) in the temporal_ref(‘past 3 years’)?

These additional references are easier to annotate automatically because a small number of patterns can cover the majority of cases. For instance, the person references can be found in the question text using a set of patterns such as the patient, she, he, her, and him. The temporal references are identified using the regular expression patterns, e.g. yesterday, past n years, and last n days. Similarly, the measurements are extracted by employing patterns like n units where units can be C, F, lb and so on. These rules for identifying the additional concepts are motivated by our previous work.

### 2. Evaluation

For assessing the quality of annotations using our tool, we employ a concept normalization and a semantic parsing model. Each of these models is separately explained in this section.

#### 2.1. Concept Normalization

For assessing the effectiveness of learning an institution-specific concept normalizer, we use simple deep learning models based on convolutional neural network (CNN) and recurrent neural network (RNN) architectures. Specifically, we follow the technique inspired by LimSPatham and Collier51, which make use of the publicly available pre-trained embeddings to normalize medical concepts from health-related social media messages. We randomly initialized the embeddings for the words present in questions and concepts.

To train these models, we input the highlighted concept phrase in the question along with the automatically annotated concept term from FHIR. Using the above example of Rupture of Appendix,

**Highlighted phrase in question:** appendix ruptured

**Annotated concept:** Rupture of Appendix (C0267628)

The concept normalizer learns these mappings from the dataset and aims to translate the medical terms present in natural language text to the standard medical concepts. Note that we do not train a concept boundary classifier, as this is an extremely common clinical natural language processing (NLP) task32–36.
2.2. Semantic Parsing

We train a semantic parser over the question and logical form annotations following a hybrid approach using both rule-based and machine learning-based techniques. Full details of the employed method can be found in our previous work on semantic parsing\(^6\). We update the lexicon, which maps lexical phrases present in questions to the corresponding logical operations, to extend its coverage. Moreover, we use similar rules for candidate generation and same features for the machine learning model as used in our previous approach.

Results

Two annotators (a physician and a biomedical informatics doctoral student) were involved in constructing the corpus of 1000 questions. Each annotator independently created 500 questions following the annotation guidelines presented in the methods section. The individually constructed annotations were cross reviewed by both the annotators after the completion of the first 50 and all 500 annotations to ensure the completeness. We stored the timestamps for each annotation which gave us the ability to analyze our annotation times in detail. We kept track of the review times manually. The first checkpoint of 50 annotations was completed in 2.5 hours by each annotator and was reviewed by both the annotators together in 1 hour. Each annotator took about 24 hours to complete the remaining 450 annotations, which were then separately reviewed by both the annotators in 8 hours. The whole annotation process was completed in less than one calendar week. By contrast, Roberts and Demner-Fushman\(^7\) required multiple weeks to annotate less than half as much data, while their concept normalization choices were likely incompatible with many hospitals as it was not built from a reference FHIR instance.

We observed a total of 10 unique FHIR resource types which were used as answers in our corpus. The distribution of these resource types is presented in Figure 3. We note that the most number of constructed questions were about Observation resource followed by Condition and Procedure resources.

Based on the annotated logical forms, we enumerated 11 answer types. Figure 4 shows the distribution of these answer type frequencies in our annotated corpus. Each type can be perceived as a logical predicate applied to the FHIR resource(s). For e.g., Time answer type is assigned to questions which return the time of a specific resource. Similarly, Is state type aims to determine the state of some specific resource(s). It should be noted that these answer types are based upon the outermost logical predicates in logical forms.

We analyzed the combinations of FHIR resource and answer types in our dataset to get the impression of most frequent question varieties. We present the top 5 of these combinations with example question and logical forms in Table 1. The most frequent number of questions, specifically 92, were about querying the value of Observation resource, which succeeded by querying the Max/Min and Is state.

The results of training semantic parser and concept normalizer are shown in Table 2. Using rules and features of the best performing model from our previous approach9, we achieved an accuracy of 94.2% with leave-one-out validation. We trained the concept normalizer models based on RNN and CNN for 50 epochs each, as per the evaluation results presented in the original paper91, and achieved an accuracy of 76.0% and 70% respectively.

Discussion

Annotating concept normalizations during the logical form annotation is a challenging and time-consuming task. We aimed at automating this step using the highlighted concept text in question. This intervention reduced a significant amount of time for annotating the logical forms in comparison to our previous approach7. Another advantage of this approach is that the annotated concepts in our corpus are well-aligned with concepts used in the referenced FHIR server. This enabled us to train a concept normalizer tailored to the FHIR server used for annotations.

The result of the semantic parsing evaluation highlights the quality of generated corpus. The accuracy of the semantic parser on our corpus is slightly less than that on the dataset it was originally built on. This difference might have resulted from increased vocabulary and variety of questions in our corpus.

The decent performance of the concept normalizer shows the potential of this annotation approach for concept normalization. In comparison to other methods32-36, we trained on less data. Also, our corpus contains a wider variety of concepts than just disorders or diseases. Other concept normalizers such as DNORM37 could be trained but that was not the focus of this work.
Using the proposed annotation approach, a large annotated dataset of questions can be created comparatively faster. This dataset can then be used for building a semantic parser to support natural language queries.

We used a rule-based approach to identify the temporal expression spans, as this approach was able to capture the variety of expressions in our corpus. More sophisticated temporal information extraction systems can be incorporated in the future.38,39

One of the limitations of our study is that we limit the answer resources selection to a single concept type. In other words, the constructed questions could be about a single type of concept. In the future, we aim to include multiple concept types during answer selection which can result in the creation of more complex questions.

Conclusion

We have described a novel approach for constructing an annotated corpus of EHR questions using FHIR. The process of annotating concept normalizations is automated which significantly reduced the overall annotation time. Using the proposed approach, two annotators created a corpus of 1000 questions in less than one week. We evaluated our constructed dataset by training a semantic parser and a concept normalizer, both of which showed promising results with accuracies of 94.2% and 76% respectively.

Learning Inter-Sentence, Disorder-Centric, Biomedical Relationships from Medical Literature.

Anton H. van der Vegt, BE, BSc 1Guido Zuccon, PhD 2Bevan Koopman, PhD
1The University of Queensland, St Lucia, Qld, Australia; 2CSIRO, Brisbane, QLD, Australia

Abstract

Relationships between disorders and their associated tests, treatments and symptoms underpin essential information needs of clinicians and can support biomedical knowledge bases, information retrieval and ultimately clinical decision support. These relationships exist in the biomedical literature, however they are not directly available and have to be extracted from the text. Existing, automated biomedical relationship extraction methods tend to be narrow in scope, e.g., protein-protein interactions, and pertain to intra-sentence relationships. The proposed approach targets intra and inter-sentence, disorder-centric relationship extraction. It employs an LSTM deep learning model that utilises a novel, sequential feature set, including medical concept embeddings. The LSTM model outperforms rule based and co-occurrence models by at least +78% in F1 score, suggesting that inter-sentence relationships are an important subset of all disorder-centric relations and that our approach shows promise for inter-sentence relationship extraction in this and possibly other domains.

Introduction

Deriving the relationships between a disorder and its related symptoms, tests and treatments is a critical part of medicine. Consider the relationships that exist between symptoms and their associated disorders in Figure 1. Such disorder-centric relationships are necessary for a myriad of medical tasks and research including automated problem lists1, clinical decision support, medical information retrieval, data mining and knowledge base construction. However, in medical thesauri such as the UMLS and SNOMED CT, such relationships either do not exist, or at least are sporadic. While hand-coding such relationships is prohibitively laborious, it is possible to automatically derive these from free-text using biomedical relationship extraction (BRE) systems. Most systems, however, consider one specific, highly focused relationship set; for example, locations of bacteria2 or protein-protein interactions3. Those that are broader in coverage, and can be used for disorder-centric relationship extraction, exhibit poor performance (in terms of precision and recall).

Figure 1: The title (in bold) and first 2 sentences of Medline article PMID=19707415. Medical concepts have been extracted with MetaMap4 and disorders have been underlined, symptoms have been italicised. Medical terms mapped as both disorders and symptoms are both italicised and underlined.

The old and new therapeutic approaches to the treatment of giardiasis: where are we?

Giardia lamblia is the causative agent of giardiasis, one of the most common parasitic infections of the human intestinal tract. This disease most frequently affects children causing abdominal pain, nausea, vomiting, acute or chronic diarrhea, and malabsorption syndrome.

Figure 1 also highlights another important issue: relationships span across multiple sentences. Without the capability to detect inter-sentence relationships, all of the symptoms (nausea, vomiting, etc.) in the second sentence would not be related to the disorder giardiasis in the title and first sentence. Current state-of-the-art relationship extraction systems such as SemRep5 and PASMED6 only extract intra-sentence relationships. New methods for inter-sentence relationship extraction are needed.

Extracting inter-sentence, disorder-centric relationships involves a number of challenges7. Grammar rules reset between sentences so features, such as shortest dependency path (SDP) analysis, cannot be relied upon. Patterns are harder to identify for inter-sentence, rule-based approaches and the number of possible patterns and/or relationships expands dramatically. To overcome these issues, we recast the inter-sentence relationship extraction task as a sequential labelling problem; a Long Short-Term Memory (LSTM) model is proposed to process a multi-sentence input for a given relationship label occurring across sentence borders. The main contributions of this research are:
1. A deep learning model to perform inter-sentence, disorder-centric biomedical relationship extraction.
2. An empirical evaluation of existing relationship extraction techniques when applied to inter-sentence relationship extraction. In addition, we make available an inter-sentence, disorder-centric, human labelled dataset for training and evaluation purposes, as well as UMLS concept embeddings based on 23 million MEDLINE citations.

**Background and Related Work**

Extracting medical concepts (or entities) from biomedical free-text has had considerable attention. There are well established tools for mapping free-text to UMLS concepts such as MetaMap and QuickUMLS. While these tools identify concepts (including disorders), they do not identify the important relationships that exist between them.

Clinicians tend to ask a common set of medical questions, with the following 4 accounting for 40% of all questions:

1. How should I treat condition $x$?
2. What is the drug of choice to treat condition $x$?
3. What is the cause of condition $x$?
4. What test is indicated in situation $x$?

Based on these findings we focus on extracting relationships between: Disorder and treatments (DT); Disorders and symptoms (DS); Disorders and medical tests (DE); and Disorders and other disorders (DD), as these are often viewed as symptoms for disorders, e.g., hypertension.

We now review previous relationship extraction approaches; these fall into four categories: co-occurrence based, rule based, machine learning based, and more specialised deep learning based.

**Co-occurrence based**: A common approach is to simply infer a relationship between two concepts if they *co-occur* within some window of text (e.g., a sentence). Ding et al. used a variety of window sizes — phrase, sentence, sentence pair and entire abstract — to assess the impact on precision and recall. A window size set at the sentence or abstract level provided the best combination of recall and precision; adjacent sentences produced the worst results. However, interestingly, adjacent sentences nearly doubled the number of distinct relationships found and generated high recall, but also a considerable drop in precision. These insights suggested to us that if the target relationships were much broader than biochemical-noun interactions (relationships) and the selection model more discriminating than the simple co-occur model, then inter-sentence BRE could dramatically improve the recall of biomedical relationships, without a corresponding drop in precision.

**Rule based methods**: incorporate NLP to parse biomedical text and identify specific relationships with either hand-crafted, or automated rules. Rules are created on the basis of syntactic or semantic patterns which describe specific relationship cases; for example, using POS tagging, noun-phrase chunking and dependency parsing to define the rule set. Dependency parse trees enable relationships to be identified where the medical concepts do not appear close together. Other approaches use verbs in the sentence by analysing the phrase-level conjunction to extract relationships.

The main disadvantage of rule-based approaches is that they are usually applied to a narrow set of relationships.

Machine learning methods are commonly employed to perform relationship extraction with supervised classification solutions, such as support vector machines (SVM) and conditional random fields (CRF). Most machine learning methods require careful feature engineering, with a mix of both domain knowledge and NLP experience. Rink et al. trained an SVM on eight relationship types between concepts within a sentence. While 21 features were used, context features proved to be very important and in particular the concept and concept types. In contrast, Uzuner et al. found that lexical features, in particular the tokens occurring between candidate concepts, were most informative in their SVM approach. Quirk et al. employed a distant supervision ML model to extract relationships across sentence...

boundaries, and this model was used with success for extracting drug-gene interactions from biomedical literature. However, this model did not incorporate UMLS concept-to-concept relationships and the relationships detected were very niche. Like most machine learning approaches, these methods suffer from complex feature engineering.

Deep learning methods have proven effective across a range of biomedical tasks, including relationship extraction\textsuperscript{18}. Deep learning approaches can avoid the laborious feature engineering of the aforementioned machine learning methods. For relationship extraction, a deep autoencoder was used to produce word embeddings of the medical concept word features\textsuperscript{18}. These were then fed into a CRF classifier to identify relationships. Results showed only subtle improvements over the standard feature input set. However, we posit that perhaps using a much broader medical concept vector, across the whole of Medline, could provide greater benefit. Outside the medical domain, long short term memory (LSTM) recurrent neural network (RNN) models have proved highly effective on other tasks\textsuperscript{19}. This approach incorporated shortest dependency paths (SDP) and linguistic information into a multi-channel RNN. Each SDP for each sentence is sequenced from either direction of the SDP using LSTM units and this is done for 4 different channels of information (word representation, POS tag, grammatical relationship and WordNet hypernyms). It was insightful to note that the word embedding had by far and away the greatest impact on performance, and each other channel added at most 1% to the score or combined, only 1.6%. Li et al.\textsuperscript{20} used a similar, bi-directional LSTM model, in the biomedical domain, for the extraction of adverse drug events and bacteria biotopes. Their model also employed SDP information as well as word, POS and character embeddings of the words in the sentence. Gupta et al.\textsuperscript{21} also made use of SDPs, however within a deep learning model incorporating bidirectional RNNs to identify relationships across sentences in biomedical text. This model evaluated with the Bacteria Biotope relationship extraction task, showed very promising performance, however the task incorporated very specific relationships (habitats of bacteria), and unlike our proposed approach, medical text rather than medical concepts were the source of relationships. This is an important distinction because concept space disrupts the natural grammar and syntax of sentences, needed for SDP analysis. The use of SDP within LSTM deep learning models is popular, however for inter-sentence relationship extraction, it is not really possible\textsuperscript{22}. Kim et al.\textsuperscript{7} raised this as a general challenge for participants in the BioNLP shared task in 2009. For this reason, we investigate alternative designs for using the LSTM RNNs to employ for inter-sentence, UMLS concept relationship extraction.

Proposed Disorder-Centric Relation Extraction Model

Typically, deep learning relationship extraction models operate on an intra-sentence basis and therefore the input sequence is limited to, at-most, a sentence of words and often much less if the two entities are closer together. The objective of our approach is to extract relationships within 1 to N sentences, resulting in a significantly larger potential sequence of words between the related entities. To reduce the complexity of this problem, we decided to divide the relationship extraction task into two components: relationship detection and relationship classification. In this way, the deep learning model is employed to detect the presence of a relationship between a disorder and one of treatment, test or symptom concepts, i.e., a binary classification task.

Relationships classification is then done on the basis of the concept types involved in the relationship; for example, if a relationship exists between a symptom and a disorder concept, it is assumed to be a DS relationship. The concept types are based on the UMLS semantic types (semType). SemTypes provide a broad, yet consistent, classification of every UMLS concept. Table 1 defines the semType sets used for classification of concepts into the four types.

Disorders are derived directly from the Disorders semGroup excluding symptoms and findings, which are used in the Symptoms concept category. Tests and treatments semTypes are selected using the semMed DB\textsuperscript{14} predication table. For test semTypes, we counted the predications found for each semTypes involved in a diagnoses relationship and
selected the top 2. For treatments we counted the predictions for semTypes involved in a TREATS relationship and selected the top 3 excluding the Amino Acid, Peptide or Protein semType.

Figure 2 describes the information flow and network architecture of the proposed disorder-centric, relationship detection model. Unlike Xu et al. and Mehryary et al., the sequence components in our model are not divided into feature channels, such as POS, words or grammatical relations. Instead, we use UMLS concepts as the basis of each sequence line and can therefore capitalize on UMLS concept embeddings that span the Medline data set. Concepts have a number of advantages over words for use in embeddings. First, the same medical entity expressed in different ways is aggregated into a single concept making for a denser set of relationships between entities. Second, n-grams are also encapsulated within a single concept — especially important in biomedicine where multi-term entities are common and used as a means of distinguishing them; e.g., over 100 are disorders entitled “[something] hypertrophy” (e.g., pseudo hypertrophy). We posit that embeddings of real biomedical entities (rather than the words ‘pseudo’ and ‘hypertrophy’) are more discriminative. The individual elements of Figure 2 are detailed next.

Input Sentences consist of zero or more title sentences, a target sentence and the sentence before the target (if it exists), called the pre-sentence. The target sentence must contain at least the related concept. The disorder concept may exist in any of the sentences.

CUI-Word Mapping. The input sentences are converted to UMLS concepts using MetaMap (with word sense disambiguation) to extract the best match candidates from each sentence, as well as the POS of each word, and punctuation. Sentences are then converted into a CUI-Word Mapping format, which expresses each word or punctuation mark in the sentence as either part of a CUI, together with its semType, or a word, together with its POS.

CUI Line Sequence Vectors (CLSV) are then generated. The lines are constructed starting from the beginning of the title sentence and moving through to the pre-sentence, finishing at the end of the target sentence. Each CUI that is found along the way, forms a CLSV. A CLSV consists of the words leading up to a single CUI and the CUI itself. Therefore, the sequence will consist of \( n \) lines where there are \( n \) CUIs found across the input sentences. Each CLSV is a concatenation of feature vectors which include:
1. **CUI2VEC embedding for the CUI in the CLSV:** Two CUI embeddings are tested. The first is the 500 dimensional CUI embedding recently generated by Beam et al.\textsuperscript{23} containing 108,477 CUIs, based on 20M clinical notes and 1.7M full text biomedical journal articles. We developed the second using the DL4J word2vec model, which uses Skipgram, CBOW or DBOW feature extraction. The best mapping CUI candidates were extracted from over 23M Medline citations by parsing the 2015 MetaMapped Medline collection. These CUIs were then input to the word2vec model and by applying a window size of 10 and a minimum word frequency of 1 a set of 440-dimensional embeddings were generated for 558,764 CUIs. (500 or 440 dimensions)

2. **Location:** A one-hot vector representation of the location of the CUI in this CLSV. The locations are within either the title, pre-sentence or target sentence. (3 dimensions.)

3. **COSine similarity:** Calculated using the CUI embedding vectors above, the cosine similarities between the CUI in the CLSV and the assessed (i) diagnosis CUI and; (ii) related CUI. Note, the CUIs assessed for relationship presence will appear in at least one CLSV each across the sequence of CLSVs. (2 dimensions.)

4. **SemType:** A one-hot vector representation of the semType of the CUI in this CLSV. (135 dimensions.)

5. **POS tag of up to N words preceding the CUI:** A one-hot representation of the 11 POS tags plus a separate tag for each of full stops, commas, other punctuation and invalid words. In addition a present/not present flag dimension was used to identify all zero POS embeddings for no-word situations. This occurs frequently where less than N words or punctuation marks appear before the CUI. (N x 16 dimensions)

**RNN LSTM model:** An LSTM unit was applied to each sequence line; i.e., each CLSV. For the LSTM, the ‘no peep-hole’ variant\textsuperscript{24} was instanced through DL4J. Standard settings include weight initialization, \textit{tanh} activation function for the LSTM layer and a cross-entropy loss function combined with SoftMax activation for the RNN output layer\textsuperscript{25}.

**Deep Learning Model Tuning & Testing:** During this testing phase a number of model and feature set changes were trialled in order to develop the most effective overall disorder-centric relationship detection system. Important model/feature combinations are reported later in the results section (Table 4). The layer size was set to 300 throughout; batch size to 32 and learning rate to 0.005. From Table 4, the extra LSTM layer (Id=S2) was added in series immediately after the first layer. The dense layer (Id=S3) is a fully connected feed forward layer, connected to the output of the second LSTM layer and feeds into the final RNN output layer.

**Training and Evaluation Methodology**

A **label data set** for training the deep learning model and evaluating the BRE systems was developed. Existing label collections were too specific to utilise; for example, labels derived for protein-protein interactions\textsuperscript{3} or adverse drug events\textsuperscript{26}. The closest suitable label data set, the i2b2 challenge\textsuperscript{4}, was developed for clinical text, not biomedical literature, which is very different, rendering it unsuitable. The high cost of constructing a \textit{gold} label collection — one constructed from expert annotations, of sufficient size — made the gold option not possible. However, based on the reduced requirement for relationship identification, rather than classification, non-expert labellers (via crowdsourcing, with appropriate quality controls) were employed to detect pre-identified concepts within 754 Medline citations. The final label values were assigned through a voting system across multiple labellers (n=5) and multiple tests of the same relationship, found in different parts of the text, with a positive label awarded when the proportion of actual to possible votes for the relationship exceeded a threshold of 0.4. Details of this \textit{silver}, disorder-centric relationship, label set are provided in Table 2. Note the collection is heavily weighted towards negative labels, which is as expected, because across one or more sentence boundaries, the majority of concepts are not directly related.

**Table 2:** Final label counts for the disorder-centric silver label set. Numbers summed by relationship type. DS=Disorder-Symptom DE=Disorder-Test, DT=Disorder-Treatment, DD=Disorder-Disorder.

*QuickUMLS* version 1.2 built on UMLS dataset 2018AA; **SemMed v3.1** using SemRep v1.7. Predication table containing the relationships processed Medline articles up to December 31, 2017; ***MetaMap** v2016v2 with UMLS dataset 2018AA.

For the LSTM model comparison with the existing models, five fold cross validation was employed where 80% of the label data was used for training and 20% was set aside for testing. The best average F1 score across the five folds for a single epoch was then used for comparison. Cross-fold validation was not employed for trialling and comparing the LSTM models and features, however training and test data was divided using the same 80/20 split.

**Instantiation of Existing Models For Detecting Disorder-Centric Biomedical Relationships**

The proposed LSTM model is compared with a number of existing models; these baselines were selected according to the following criteria: (a) Relationships are extracted from the Medline corpus and/or the TREC 2014 document collection, consisting of the Open Access Subset of Pubmed Central, taken on January 21, 2014, herein called OA-Subset2014. This subset of Medline was selected because it is well defined, commonly used and easily accessible to researchers; (b) The extracted relationship types must include at least the four disorder-centric relationships targeted in this study; (c) The extracted biomedical relationships must be expressed as a relationship between two UMLS concepts so that evaluation between extraction methods can take place in the UMLS concept space. Table 3 defines each baseline model, the settings employed for each and the statistics of the resulting test collection. Figure 3 defines the generic pipeline employed for preparing each model to generate the test collections.

**Figure 3:** Pipeline Diagram with the text along the top describing the steps used to extract relationships and the text along the bottom providing examples of each step

For all models, a semType filter was applied, matching the disorder-centric concept classifications specified in Table 1. In addition, because SemRep also included a fixed set of predicates, we limited the predicates to those appropriate for each relation (e.g., disorder-treatment (DT) relationships were limited to treats, neg_treats predicates). (For the sake of brevity, these are not listed here, however are available upon request.) Generic, high-use concepts, such as treatment, patient, disease were removed prior to labelling, and therefore not tested in our evaluations.
In addition to the settings identified in Table 3, the following pre-processing steps relate to specific models. For the co-occurrence models, a text window size of 5, within sentence was used to capture two concepts within a relationship. The BestMatch setting relates to the CUI(s) selected within the co-occur window. When bestMatch=false, all possible concepts extracted from the window of text are included within the window, i.e. often more than one concept for the same text and concept borders can overlap, whereas when BestMatch=true, concept borders can not overlap and only the best concepts are selected. PASMED relationships were extracted by firstly filtering for the correct semType combinations, then MetaMapping both of the medical terms in each relationship to identify the CUIs and filtering across only those CUIs within the label data set. Because an actual relationship type was not provided, but rather the verb relating the two CUIS, all relationships were considered valid if the CUIs formed a valid disorder-centric semType pair, irrespective of the order of the CUIs. This provided PASMED results with optimistic recall.

Results and Discussion

LSTM Model Selection Results

Table 4 lists the model and feature definition changes and their impact on the extraction system performance. The changes made at each step are cumulative, such that each model builds upon the model and feature set of the previous model. The cumulative impact on F1-score is graphed in Figure 4.

The baseline model consists of a single LSTM layer and output RNN with input features including the location, cosine similarities, POS of a single pre-word to the CUI and CUI embeddings\(^\text{23}\) (500 dimensions). Improving the input features had a smaller overall impact (16.1%) on F1-scores, when compared with improving the model (38.6%). Incorporating a dense layer, i.e., a fully connected feed forward layer, at the output of the second LSTM, was the most important model improvement, adding 21.6% to F1 with all of the benefit arising from a 58.5% improvement in recall. The intuition behind the addition of the dense layer was to introduce a learning layer at a higher level of abstraction that might identify patterns across the output of the LSTM units. In particular the authors speculate that because of the wide variation in input sequences, the dense layer can take this variability into account to identify enable the identification of more positive relationships. The most important feature addition was the CUI semType embedding, improving recall, over the previous model, by almost 15%, resulting in the best overall, recall model (R=70.3%). No available learned semType embeddings from Medline were available, and so one-hot vectors were employed. A learned embedding of semTypes is likely to result in further gains, which was left for future work.

Introducing positive semMed\(^\text{14}\) training data had the second highest impact (9.4%) on model performance and the greatest positive impact on precision across all changes. It is widely recognised that training deep learning models on imbalanced label sets can adversely impact model performance. The silver label data set contains 2.4 times more negative than positive labels (Table 2). To balance the training data set, disorder-centric semMed relationships were selected from source documents outside of the silver label set but within the OA-Subset2014 collection, until the positive/negative label ratio was equal. The balanced and larger training set improved precision by 28.9%, however it is unclear what proportion of this change is due to the larger training set or better label balance. Training the model with a balanced silver data set would reduce its size by 41%, thereby rendering the results equally unclear and semMed only provides positive labels, so balance cannot be achieved by adding equal positive/negative labels. Better understanding the causal elements for this improvement has been left for further investigation.
Although the input features had a lesser impact on performance, each feature added at least 3.7% to the F1 score. The most important feature, CUI embeddings, were incorporated into the baseline model. Switching to our custom embedding, improved the F1 score by 3.7%, however this may have been a result of the expanded training base. The custom embedding supported more than 5 times the number of CUIs enabling a 39% increase in the training set size. 

Like the addition of semMed training data, the performance increase was the net result of improved precision and decreased recall (+7.5% vs -1.8%). It is unknown whether the improvement was due to the increased training set or the change in CUI embedding used. Understanding the relative benefit would be helpful and was left for future work. Also left for future work was replacing the CUI embedding with a deep, pre-trained model, such as those used in language model or text classification (E.g., ELMo, ULMFiT) which incorporate contextual information beyond that of the semantic embeddings used in this work.

**Comparative Results**

Table 5 lists the results by test system evaluated on the silver label data set. The label collection was derived from 754 documents within the OA-Subset2014 citation collection so that all systems tested on this corpus have equal access to the source documents.

The LSTM, inter-sentence relationship detection model achieved the best performance, compared with all systems, whether they utilised the whole of Medline or the OA-Subset2014 collection to derive their relationship sets. It achieved improvements of +82% in precision, of +57% in recall and of +78% in F1-score, when compared with the best corresponding result for any other system. Three limitations to the evaluation warrant mention here. First, the label collection quality is classed as ‘silver’: the detection of relationships is done by non-experts assessing each sentence from an English grammar standpoint, rather than a medical one. The use of multiple labelers and multiple validation paths for each label is designed to minimise poor labels, however until the data set is validated by a domain expert, errors may exist. Explication and validation of this silver dataset is the subject of future work. Second, at this point it is not possible to confirm that the superior performance of the LSTM model is due to the ability to detect more relationships, via inter-sentence relationship capture, or other factors. Analysis of the label collection reveals that 58% of the labels are inter-sentence, which might favour this hypothesis, however confirming this is left to future research. Third, the LSTM model was trained via 5-fold cross validation on the label collection. While over-fitting may occur for such a method on a smaller dataset, the standard deviation of F1 scores across five folds was 0.0307, which was 5.0% of the F1 average, suggesting minimal over-fitting.

**Table 5:** Performance results for each system based on the data collection.

Between the test systems that were constructed with the OA-Subset2014 citation collection, the co-occurrence model with bestMatch=false produced the best F1 score (0.3458) with the highest recall (0.4146). It was hypothesised that this model would generate higher recall than the alternative bestMatch=true model because of the increased number
of CUIs and therefore relationships that are identified. However, it was not expected to produce similar, or even higher precision. This result is possibly explained by the quality of CUI mapping, which despite the setting name, bestMatch, struggles to select the correct CUI for a set of medical text. By using the BestMatch=false, more CUI options are created within the selection window, generating more correct relationships and because of the disorder-centric filter, less of the invalid relationships are kept. Although semRep generated particularly low recall results (0.1037), the relationships that were identified were more likely to be correct than in the co-occurrence models, reflected by a +14.6% improvement in precision over the best co-occurrence model precision.

Expanding the source of relationships from the OA-Subset2014 citation collection to the whole of Medline improved the SemRep system F1 performance by +86%, solely through a +164% increase in recall. PASMED, which demonstrated a +71% increase in recall over SemMed in Nguyen et al.’s work, showed a +45.5% increase in this comparison. The lower increase could be a result of the specific disorder-centric nature of the relationships extracted in this work. Overall, the PASMED system produced the best F1 score of all the existing baselines.

All of the existing baselines utilise within-sentence relationship extraction methods and the maximum recall achieved by any system was 0.4146, which would indicate that many of the labelled relationships were indeed inter-sentence. This helps to explain why the LSTM model could achieve a step-wise improvement in relationship-detection, over these existing baselines. This hypothesis could be tested in future work by extending the co-occurrence window to citation level co-occurrence, which should capture all relationships. If many relationships are cross-sentence, as indicated, then the disorder-centric LSTM model may have broader application in other BRE domains where relationships also occur between sentences.

Conclusion

In this paper we introduce a deep learning model to detect disorder-centric relationships between medical concepts across sentence boundaries. Relationships between disorders and their associated tests, treatments and symptoms underpin essential information needs of clinicians and can support biomedical knowledge bases, information retrieval and ultimately clinical decision support. The task was re-cast as a sequential labelling problem that could be tackled by a deep learning LSTM model approach. An inter-sentence, disorder-centric silver quality label collection was created by non-expert humans for training and evaluation purposes.

The cumulative contributions of word POS, punctuation and semType embeddings are compared together with important model changes. The resulting solution is then tested against other existing broad, biomedical relationship extraction methods, including co-occurrence, semRep and PASMED. The LSTM model outperforms these other models by at least +78% in F1 score suggesting that (a) inter-sentence relationships form an important component of disorder-centric relationships in biomedical literature and (b) the proposed LSTM deep-learning model and input sequence definition is a suitable approach for extracting these relationships. Although the LSTM model tested here was a suitable initial investigation, the next step is to consider other more recent deep learning models, for example transformer and end-to-end learning models, to compare the impact on BRE.

We also explore the impact of concept extraction methods (bestMatch = true/false) and collection size (Medline versus a 700K subset of Medline) on relationship extraction performance. Corpus size improves recall with a reduction in precision and using a broad concept selection policy (bestMatch=false) improves recall without deteriorating precision.

In conclusion, we provide a promising, new approach to inter-sentence, disorder-centric biomedical concept relationship extraction with noted limitations and numerous avenues to expand the technique to other biomedical domains.

Implementing the VMC Specification to Reduce Ambiguity in Genomic Variant Representation

Michael Watkins, Shawn Rynearson, Alex Henrie, and Karen Eilbeck
Biomedical Informatics, 421 Wakara Way, University of Utah, Salt Lake City, Utah 84108

Abstract
Current methods used for representing biological sequence variants allow flexibility, which has created redundancy within variant archives and discordance among variant representation tools. While research methodologies have been able to adapt to this ambiguity, strict clinical standards make it difficult to use this data in what would otherwise be useful clinical interventions. We implemented a specification developed by the GA4GH Variant Modeling Collaboration (VMC), which details a new approach to unambiguous representation of variants at the allelic level, as a haplotype, or as a genotype. Our implementation, called the VMC Test Suite (http://vcfclin.org), offers web tools to generate and insert VMC identifiers into a VCF file and to generate a VMC bundle JSON representation of a VCF file or HGVS expression. A command line tool with similar functionality is also introduced. These tools facilitate use of this standard—an important step toward reliable querying of variants and their associated annotations.

Introduction
As we near twenty years since the completion of the human genome and ten years since the breaking of the sequencing cost barrier, the amount of genomic variant data which has been generated and made available for research and clinical use is staggering. These variants are represented using nomenclatures and file types which are designed with enough extensibility to account for the growing complexity of variant data.

The most common variant file type is the Variant Call Format (VCF), which stores all variants from a single reference sequence in a tab-delimited format based on genomic coordinates. The most common variant representation nomenclature is called HGVS after the Human Genome Variation Society that develops it. This nomenclature specifies how to represent individual instances of genomic variation in a way that is human-readable.

Although typical analyses using variant data utilize both HGVS and VCF, there are a few fundamental differences between the two methodologies. For example, each methodology uses different variant normalization methods. Normalization refers to the position of a variant in the context of a nucleotide repeat—they can be left or right shifted. HGVS requires variants to be right-justified while VCF requires left-justification. This is further complicated as both HGVS and VCF continue to evolve to accommodate the growing complexity of variants. Versioning differences between tools implementing HGVS or VCF cause ambiguity in how these variants are represented, leading to complicated querying and annotation in later use.

Research institutions have been able to adapt their individual methods in response to this ambiguity. However, this has not been the case for clinical institutions that rely on strict informatics standards. Reproducible variant research and full clinical utilization of variant data all require a fundamental change in variant representation methods to address ambiguity. Individuals and institutions must be able to exchange variants and communicate about them with a surety that they are referring to the same genomic change on the same genomic reference sequence.

Ambiguity in Variant Representation
Ambiguous variant representation, caused by inconsistency in syntax structure, results in two or more representations of a single variant. Even the change of one letter in the syntax used to represent a variant can cause inconsistency and result in ambiguous representations. This causes downstream complications in associating annotations with that variant. Here we outline some causes of ambiguity in two popular variant representation methods.
VCF
The VCF standard has de facto become the principal variant file format in clinical practice, surpassing others such as genomeVCF and the genome variation format (GVF)\(^3\). This is more likely due to its long history and vast set of supporting software tools than to its ability to avoid ambiguity. In fact, the VCF specification is extremely flexible with many optional parameters (local phasing information, reference calls, no-calls, quality, likelihood, etc.) and many recommended, but not required, parameters (accession version, VCF version and HGNC gene identification)\(^3,\)\(^13\).
While this flexibility allows VCF to be used for a wide variety of applications, it creates two problems when translating to clinical space. The first is that clinical decision support applications require reliable data fields in the source data which they compute over and the variable nature of most of the fields in a typical VCF file leaves it unsuitable\(^12\). The second is ambiguity in the representation of the individual variants themselves. A simple example is acknowledged in the latest VCF specification\(^3\) and is shown in Figure 1.

Figure 1. Different representations of a two base genomic deletion.

Though difficult to detect at first, this entry shows an allelic variant which could occur at two different locations on the reference sequence. While this example is a simple two base pair difference in location, it would result in redundant entries to a variant archive and would complicate future extraction and annotation of the variant.

There are many more instances of ambiguity in the representation of variants which are possible because of the flexibility of the VCF standard. Most arise unexpectedly and, as mentioned previously, are accounted for in the research space by adjusting methods and processes in a way which is not feasible in clinical application.

HGVS
The HGVS nomenclature has been designed to describe the wide array of sequence variation including not only sequence changes, but biological mechanism, predicted events, and complex states\(^14\). There is an important distinction to be made between variant representation and variant annotation. A variant representation captures information related to the position of the variant with regards to a particular reference, where as an annotation refers to additional information such as interpretations made about the variant. Annotating a particular variant depends very much on the unambiguous representation of that variant. One study demonstrates the difficulty for several institutions to fully implement the HGVS nomenclature correctly in representing variants\(^15\), with many other studies showing downstream complications in annotating variants represented by ambiguous HGVS representations in variant archives\(^16\)-\(^22\).

A study by Yen et al. (2017) identified ambiguous HGVS representations both generated by certain tools and found in different variant archives. The study compared them to the preferred HGVS representation which was compiled using the most recent HGVS specification version. These examples are included in Figure 2 and show the ambiguity and discord which results from tools and archives not being able to keep up with a constantly evolving nomenclature. Interestingly, the study also identified ambiguous representations which each comply with the most recent HGVS specification version. These are shown in the last two rows of Figure 2 and demonstrate that ambiguity is an issue in the nomenclature itself and not just a result of differing versions being used by tools and archives. This issue must be addressed before reliable and standardized computational approaches to using variant data can be implemented.

**General sources of ambiguity**
While fundamental aspects of VCF and HGVS make them particularly prone to ambiguous variant representation, there are additional more generalized sources of ambiguity that vary between tools and archives. These include whether coordinates are 0-based (as they are in the UCSC genome browser\textsuperscript{23}) or 1-based (as they are in the Ensembl genome browsers\textsuperscript{24}), which reference sequence is used, and whether or not the coordinates used are inclusive or interbase.

**Clinical effects of ambiguous variant representation**
Two independent studies have produced technical desideratas for the integration of genomic data into a clinical setting\textsuperscript{8, 10}. These describe a future of clinical systems which leverage information from many different genomic and non-genomic data sources in order to increase the ability of clinicians to use genomic data to make relevant treatment changes or recommendations. However, the studies conclude that this ideal is only possible through certain technical changes in how genomic data is represented and stored. For example, the actual variant data should be separated from clinical observations and should support lossless data compression\textsuperscript{8}. Variants should also be able to be classified into groups of common clinical impact while still supporting the ability to reference at the individual variant level when necessary\textsuperscript{10}. One desiderata also calls for a common knowledge base which is deployed at and developed by multiple independent organizations. This would allow affordable access to comprehensive genomic data\textsuperscript{10}. However, such a federated approach would likely have a high tolerance for redundant submissions and ambiguous entries unless a more reliable representation standard is adopted.

Although the opportunity for clinical genomic innovations and tools to provide recommendations and decision support to clinicians is constantly growing\textsuperscript{9, 25-27}, their implementation is stymied by the issue of ambiguity in variant representation\textsuperscript{8, 29}. Mismatched variant annotations and subsequent false treatment changes could be disastrous\textsuperscript{10}. These issues have begun to be addressed by a GA4GH task force, which assigned a sub-group, the VMC, to develop a variant model and a defined specification to facilitate variant representation and reliable exchange.

**Variant Modelling Collaboration**
The purpose of the Variant Modelling Collaboration (VMC) is to address the issue of unreliable genomic data exchange by developing a fundamentally different approach to representation. The workgroup developed new data models to represent not only allelic variations, but variation at the genotype and haplotype level. These models are straightforward and well-adapted to future modifications\textsuperscript{14}. The data models themselves are computationally digested
to generate unique identifiers to serve as a machine-readable representation of the variant. Thus, the VMC data model unambiguously names variation, with respect to reference sequence, and is well-equipped to foster reliable exchange between institutions or queries from external variant knowledge bases.

The VMC specification breaks variant data into fundamental components. These components are represented in specific data models and then run through the VMC digest algorithm (a combination of hash and encoding algorithms) to create unique identifiers which represent those specific components\textsuperscript{14}. The following is an example, shown visually in Figure 3, of creating a VMC identifier for an allelic variant:

1) Take the raw sequence data for the reference sequence and run it through the digest algorithm. This returns a VMC sequence identifier.
2) Take the start and end coordinates for the allelic variant and use them, according to the VMC interval model, to create a VMC interval object.
3) Run both the VMC sequence identifier and VMC interval object through the digest as a VMC location object, according to the model, to generate a VMC location identifier.
4) Use the VMC location identifier and the alternate base(s) found in the previously specified interval (referred to as state in the VMC specification) to create a VMC allele object according to the model. Then digest that object to generate the ultimate goal of a unique VMC allele identifier.

The current VMC specification also has data models to represent and digest identifiers for haplotypes and genotypes. A VMC haplotype is used to designate multiple VMC alleles as being in phase or “cis”. A VMC genotype is used to designate a group of VMC haplotypes. Both models are included in Figure 3.

**Figure 3.** Identifier generation for data types needed for variant representation.
standardized VMC data model digested into a unique identifier removes variant representation ambiguity and fosters reliable variant matching.

**Implementation**
We have developed a VMC Test Suite as an implementation of the schemas and digest algorithm explained in this first version of the specification. The Test Suite has four tools which have been made available as publicly accessible web tools hosted at http://vcfclin.org. The code can be found at https://github.com/eilbecklab/VMC-Software-Suite.

1) The first tool, shown in Figure 4, accepts a user-uploaded VCF file. It then goes through each variant of the file and pulls location intervals and alternate bases in order to generate a VMC allele identifier for each entry. It stores that identifier, along with the VMC sequence identifier and VMC location identifier used in the process, in the info field of that variant entry. It also adds requisite header lines which explain the additions. The modified file can then be downloaded back by the user.

2) The second tool also takes a user-uploaded VCF file as input. However, rather than give back a modified VCF file for download with VMC identifiers added in, the user is given a VMC bundle object, represented in the JSON format, which contains each of the VMC objects and identifiers generated from the file. The VMC bundle is envisaged as a mechanism to integrate complex variant data such as haplotypes into a workflow.

3) The third tool implements existing code found in the VMC GitHub repository which converts an HGVS string into a VMC bundle. This VMC bundle is a JSON object which holds each of the VMC identifiers generated for the variant encoded by the HGVS string.

4) A command line tool has also been developed with very similar functionality to each of the three tools. It is a lightweight implementation of the core data models and digest algorithm included in the VMC specification. It is publicly available through a GitHub repository.

---

**Figure 4.** One of the VMC Test Suite tools which adds VMC identifiers to a VCF file.
Evaluation

In order to confirm correct implementation of the VMC data models, digest algorithm, and output format, three validation tests were performed on the VMC Test Suite. These tests focused on the three main processes which enable the functionality of the tools in the suite.

1) The first test was to validate our process of generating sequence identifiers. SeqRepo is a large collection of biological sequences which is made available by Biocommons. The VMC developers were granted access to SeqRepo and generated a sequence identifier for each entry. We used SeqRepo as the gold standard for this test.

2) The second test was to validate our process of generating allele identifiers. Since allele identifiers require a location identifier (as shown in Figure 3), this would also test our process of generating location identifiers. The VMC developers created Python code which generates VMC identifiers for HGVS expressions. We used outputs of that code as the gold standard for this test.

3) The third test was to validate our implementation of the VMC bundle JSON schema. This schema is available on the VMC GitHub repository and was used as the gold standard for this test.

Test 1: Sequence identifiers

The tools in the suite each draw from a custom database of pre-digested sequence identifiers which grows as new variants are encountered. This cuts down on future processing time. The suite must use information from the VCF entry to download the appropriate reference FASTA file for that entry from NCBI. This FASTA file is then run through the VMC digest algorithm in order to generate the sequence identifier. Since a difference of even one base in the FASTA file used would result in non-identical sequence identifiers, our process of locating and digesting the appropriate FASTA file had to be validated. To do this, we simply compared the sequence identifiers in our database to those found in a gold standard database. Both associated an accession number with the sequence identifier, making the look-up process simple.

We found that, of the 1720 accession numbers which were shared between the databases, each one had identical sequence identifiers. There were 204,819 accession numbers in our database which weren't found in SeqRepo but since the process used to generate their corresponding sequence identifiers was the same as the 1720 matches, these can be assumed to be accurate sequence identifiers as well.

Test 2: Allele identifiers

As explained previously, VMC allele identifiers are each generated by digesting a data model which includes a VMC sequence identifier, a VMC location identifier, and an allelic change. After getting the right sequence identifier for a given VCF entry, the suite extracts all the information needed to fill the location and allele data models. It digests the location data model and uses it to complete the allele data model. This model is then digested into an allele identifier.

To test these processes, we needed a VCF file which had HGVS expressions for each entry. This would provide an HGVS expression to use as input for the HGVS conversion code written by the VMC developers. Allele identifiers generated with this code would serve as a gold standard. We would then be able to compare that identifier to the one generated by the suite (generated from the other fields of that VCF entry). Identical allele identifiers would show that the suite is generating allele identifiers (and, by extension, location identifiers) properly.

ClinVar provides a weekly release VCF file of their variants which have HGVS expressions included in the INFO field for each entry. An example entry from the file, with portions of the INFO field omitted to highlight the included HGVS expression and rsID, is shown in Figure 5. The included rsID was also important because it allowed the suite to select the appropriate sequence identifier.
### Figure 5. Entry from the ClinVar weekly release VCF file.

Of the 393403 variants in the file, the suite generated allele identifiers for 381257 of them (96.91%) which were identical to the gold standard allele identifiers. Of the non-identical allele identifiers, 11450 of them (2.91% of total) came from deletions, 682 of them (0.17% of total) came from insertions, and 14 of them (0.0036% of total) came from indels. On closer inspection, these non-identical allele identifiers represent an assortment of edge cases where the coordinates of the VCF entry doesn’t match the location in the corresponding HGVS expression.

The identical allele identifiers include a high percentage of all forms of variation accepted by the gold standard HGVS conversion code (substitutions, insertions, deletions, and indels). We believe this test validates our approach for generating correct VMC identifiers and points to rare situations where VCF and HGVS are not aligned.

**Test 3: VMC bundle JSON**

To ascertain the JSON representation of the results of the tools was true to the VMC bundle JSON schema included in the VMC specification, we used the jsonschema Python tool to check each field. This tool confirmed that the output of our second VCF tool (creates a VMC bundle in JSON from a VCF file) matches the schema.

**Discussion**

The VMC specification provides an important building block in the effort to overcome ambiguity in variant representation and resulting discordance in variant archives. It also provides a backbone for naming complex variants such as haplotypes, a feature necessary for communication of pharmacogenomic and immunologic variants. It takes a fundamentally different approach to the process of representing variants and provides unique identifiers to enable reliable querying and annotation of those variants. However, the next important problem which must be considered is that of equivalence.

General sources of ambiguity such as different reference sequences, different coordinate systems, alternate transcripts, etc., do not go away with the VMC data models. However, VMC does provide more stringent representation standards and as a result, the concept of equivalence definitions is now a possibility. Four specific types of equivalence are discussed here with the acknowledgement that additional considerations will continue to become more apparent as the VMC standard is adopted.

**Normalization**

Different normalization strategies and tools can result in slightly different location intervals. These differing location intervals could lead to different VMC identifiers being generated which should be considered equivalent. Anticipating this, the VMC specification requires that the VT normalization algorithm be used to normalize variants prior to their inclusion in the data model and digestion into a VMC identifier. By requiring all variants to be normalized using the same algorithm, it will be possible to computationally determine normalization equivalence and account for it in future implementations of the VMC specification.

**Projection**

A variant may be represented on a genomic sequence, on a transcript, or on a protein sequence. With the volume of genomic data now available it is likely that any particular variant could be represented in all three ways. Location
coordinates and reference sequences will be different for each representation but, in the end, they are referring to the same variant and should be considered equivalent. This would allow the combination and utility of all three levels of annotation associated with those sequence types.

Alternate transcripts
A common source of ambiguity is different variant locations arising from alternate transcripts. Biologically, the different splice sites of a particular genomic region can result in a variant being found on two non-identical transcripts. While the transcripts themselves are non-identical, the variant is functionally the same. The different transcripts lead to different variant locations which ultimately would result in different VMC identifiers. However, these different identifiers should be considered equivalent because they refer to a functionally-equivalent variant. Establishing this equivalency would require computation over gene annotations and genomic-level interpretations. While the computation would be complex, VMC makes this equivalence possible to determine in future implementations.

Lift-over
The idea of lift-over is purely systematic and not biological. It refers to the ability to take a variant backward and forward between different genome builds and versions while maintaining equivalence. Each genome build and version will generate a different VMC identifiers which are functionally identical and should be considered equivalent. NCBI currently hosts a lift-over tool called Remap which projects annotation data between different coordinate systems\(^{35}\). Providing this functionality for variant representations on a larger scale will be a possibility as VMC implementation continues to grow and many more VMC identifiers are generated and associated.

**Conclusion**
We have presented an implementation of the GA4GH VMC specification, with the hope that these tools will facilitate the use of this variant representation standard. Using VMC identifiers to represent variant data will reduce redundancy within variant archives. The computationally stringent implementation requirements will also significantly reduce discord among tools used to generate VMC identifiers. This reduction in ambiguity in variant representation will allow more reliable and precise data queries, resulting in more reproducible research methods and many useful clinical applications which were not possible before.
Acknowledgments
GA4GH is increasingly involved in standards development for biological data. The VMC group provides an open environment for discussion and development of specifications and tools for variant representation. We are thankful for the productive weekly discussion and innovation. We want to highlight Reece Hart for initiating this group and for his leadership. This work was supported by the National Institute of Health: R01HG008628 to KE, and NLM T15-LM007124 training predoctoral slot to MW.

Relation Extraction from Clinical Narratives Using Pre-trained Language Models

Qiang Wei, M.S.¹, Zongcheng Ji, Ph.D.¹, Yuqi Si, M.S.¹, Jingcheng Du, B.S.¹, Jingqi Wang, M.S.¹, Firat Tiryaki, B.S.¹, Stephen Wu, Ph.D.¹, Cui Tao, Ph.D.¹, Kirk Roberts, Ph.D.¹, Hua Xu, Ph.D.¹
¹School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX, USA

Abstract
Natural language processing (NLP) is useful for extracting information from clinical narratives, and both traditional machine learning methods and more-recent deep learning methods have been successful in various clinical NLP tasks. These methods often depend on traditional word embeddings that are outputs of language models (LMs). Recently, methods that are directly based on pre-trained language models themselves, followed by fine-tuning on the LMs (e.g., the Bidirectional Encoder Representations from Transformers (BERT)), have achieved state-of-the-art performance on many NLP tasks. Despite their success in the open domain and biomedical literature, these pre-trained LMs have not yet been applied to the clinical relation extraction (RE) task. In this study, we developed two different implementations of the BERT model for clinical RE tasks. Our results show that our tuned LMs outperformed previous state-of-the-art RE systems in two shared tasks, which demonstrates the potential of LM-based methods on the RE task.

Introduction
Electronic Health Records (EHRs) contain massive free-text data documented by healthcare professionals during the course of patient care, such as clinical notes, discharge summaries, lab reports, and pathology reports¹. Compared to structured data, free-text data often records detailed information of clinical events and communications between teams in hospital settings. Much important patient information often exists in unstructured format only, and manual extraction of such information is expensive and time-consuming. Therefore, applying natural language processing (NLP) technologies to extract related patient information from clinical notes is highly recommended to support clinical research and applications².

Relation extraction (RE), one of the essential tasks of information extraction, aims to identify semantic connections between mentions of concepts in a document³,⁴. For example, in the sentence “an MRI revealed a C5-6 disc herniation with cord compression,” we attempt to identify that the test “MRI” reveals two medical problems “a C5-6 disc herniation” and “cord compression”. Previous studies have investigated diverse types of relations, such as disease-attribute pair extraction⁵,⁶, temporal relation identification⁷, adverse drug event detection⁸,⁹, etc. Recently, the clinical NLP community started a series of shared tasks on relation extraction from clinical notes, including the Informatics for Integrating Biology and the Bedside (i2b2) challenges⁷,¹⁰, the Semantic Evaluation (SemEval) challenges¹¹,¹², the BioCreative V task¹³, and the most recent 2018 National NLP Clinical Challenge (n2c2)¹⁴. These open challenges greatly facilitate the development resources (e.g., corpora) and methods for RE in the medical domain.

Early RE systems can be classified into two major categories: (1) rule-based methods; and (2) machine learning-based methods. Rule-based methods such as dependency trees¹⁵ and coreference chains¹⁶ are used to extract relations. Machine learning-based methods such as Support Vector Machine (SVM)¹⁷ and Conditional Random Field (CRF)⁴ are widely applied. However, current existing RE methods largely rely on heavy preprocessing steps that require extracting features from text, such as lexical, syntactic and semantics information¹⁸. Those extraction at early steps might introduce sources of errors that would accumulate to the following RE task¹⁹. These limitations severely restrict the portability and generalizability of RE to other novel resources.

In the past few years, deep learning methods have demonstrated their effectiveness and often achieved the state-of-the-art in diverse NLP tasks. Sequential-based deep learning methods including recurrent neural networks (RNN), convolutional neural networks (CNN) and their variants have been applied to clinical relation extraction²⁰,²¹. More recently, Bidirectional Encoder Representations from Transformers (BERT)²² introduced masked language models and reported superior performance on multiple benchmark datasets of diverse NLP tasks. BERT is pre-trained on a large corpus in an unsupervised manner and can then be fine-tuned on a downstream task with a simple layer on top of its architecture. By fine-tuning as a whole, the network adjusts the entire language model and thus encodes more contextualized information. BERT has shown its benefits in downstream NLP tasks such as concept extraction²³,²⁴, text classification²⁵, question answering²⁶, and text generation²⁷, especially pre-trained on a large clinical or
biomedical corpus. Due to their ability to capture contextualized information, deep language representation approaches achieve a task-specific architecture by simply appending the deep learning model for the downstream task.

Despite BERT’s success in the open domain and biomedical literature, it has not yet been applied to clinical RE tasks. In this study, we aim to investigate how to apply BERT to clinical RE tasks by (1) comparing two different implementations of the BERT model for clinical RE; (2) evaluating BERT models across different clinical RE tasks; and (3) assessing four BERT models trained from the open domain, biomedical literature, and clinical text on the clinical RE task. To the best of our knowledge, this is the first study to apply pre-trained language models of BERT to clinical RE tasks and our evaluation results show that it outperformed the previous state-of-the-art systems in clinical RE.

Material and Method

Tasks and Datasets

In this study, we used two datasets: the 2018 National NLP Clinical Challenges (n2c2) corpus and the 2010 Informatics for Integrating Biology & the Bedside (i2b2) challenge corpus. All named entities (clinical concepts) were given, and the task here was to identify relations between entities.

The n2c2 corpus included 505 discharge summaries, which came from the MIMIC-III (Medical Information Mart for Intensive Care III) clinical care database. The corpus contained nine types of clinical concepts including drug and eight attributes (reason, frequency, ADE, strength, duration, route, form and dosage). The relations between drug and the eight attributes were also provided (statistics of relations are in table 1). The task is to recognize all relations between drugs and attributes. The training set included 303 discharge summaries and the test set included 202 discharge summaries.

The other dataset used in this study came from the 2010 i2b2 challenge relation extraction task, including 426 discharge summaries collected from 2 hospitals. The dataset is a subset of the original dataset used in the challenge, since the University of Pittsburgh Medical Center’s data is not available to the public and was removed from the original dataset after the challenge. Only 170 of the original 394 training documents and 256 of 477 test documents were available for download, so we combined and re-split them in this study. The dataset includes 3 types of entities (medical problem, lab test and treatment) and 8 types of relations between them (Table 1).

BERT-based relation extraction

Given entities annotated in sentences, the relation extraction task can be transformed into a classification problem. A classifier can be built to determine categories of all possible candidate relation pairs $(e_1, e_2)$, where entities $e_1$ and $e_2$ are from the same sentence. For the n2c2 dataset, we generated candidate pairs by pairing each of the drugs with each of the attributes in a sentence. For example, given sentence “Furosemide 10 mg IV ONCE Duration : 1 Doses”, there were five entities “Furosemide”, “10 mg”, “IV”, “ONCE” and “1”. All possible candidate pairs were (10 mg, Furosemide), (IV, Furosemide), (ONCE, Furosemide) and (1, Furosemide). For the i2b2 dataset, we generated candidate pairs by pairing each of the problems with the other entities: including problems, treatments and tests. Before we build the classifiers for relation extraction, all documents went through a pre-processing procedure that includes basic steps such as sentence boundary detection and tokenization, which were done using the CLAMP (Clinical Language Annotation, Modeling, and Processing) Toolkit.

In this study, we developed two BERT-based methods: Fine-Tuned BERT and Feature Combined BERT to determine relation categories for these candidate pairs, described below.

**Fine-Tuned BERT (FT-BERT)**

*Input representation*

In order to represent a candidate relation pair in an input sentence, we used the semantic type of an entity to replace the entity itself. For example, as described above, there were four possible candidate pairs in the sentence “Furosemide 10 mg IV ONCE Duration: 1 Doses”, and it would be transformed into four samples (Figure 1). Each of them contained one candidate relation pair. In Sample 1, two entities “Furosemide” and “10 mg” were replaced by their semantic type
labels “@Drug$” and “@Strength$”. Note that even if an entity contains multiple words, it is still replaced by one label.

*ADE: adverse drug event.*

**Original sentence**  
[CLS] Furosemide 10 mg IV ONCE Duration : 1 Doses

**Transformed samples**

1. [CLS] @Drug$ @Strength$ IV ONCE Duration : 1 Doses
2. [CLS] @Drug$ 10 mg @Route$ ONCE Duration : 1Doses
3. [CLS] @Drug$ 10 mg IV @Frequency$ Duration : 1Doses
4. [CLS] @Drug$ 10 mg IV ONCE Duration : @Dosage$ Doses

**Figure 1.** An example of transformed samples from an original sentence used in FT-BERT.
**FT-BERT model**

Devlin et al.’s BERT model was used, and a linear classification layer was added on top to predict the label of a candidate pair in sentential context (Figure 2). In detail, a classification token [CLS] was added at the beginning of a sentence, whose output vector was used for classification. As typical with BERT, we used a [CLS] vector as input to a classification layer. Then a softmax layer was added to output labels for the sentence.

![Figure 2. The architecture of FT-BERT. CLS represents the [CLS] token; W_i represents words in sentence; E_1 and E_2 represent replaced semantic type labels of entities.](image)

**Feature Combined BERT (FC-BERT)**

**Input representation**

Instead of replacing entities with semantic type labels, we used additional BIO tags to represent entities in sentence, where “B” represents the beginning of an entity, “I” represents other words inside an entity, and “O” represents all other non-entity words. Compared with the input representation in FT-BERT, the BIO representation keeps entity word information so that the model has more information to classify. Figure 3 shows how to use BIO tags to represent sample (1) from Figure 1. Both sentence words and their tags are used together as input for FC-BERT.

![Figure 3. An example of the input representation in FC-BERT. The traditional BIO (Beginning, Inside, Outside) tags are augmented with the semantic types of the respective tokens.](image)

**FC-BERT Model**

We utilized the BERT model to generate vectors for all words in sequence; in parallel to the BERT model, the BIO tag sequence of the sentence was represented in an embedding layer. The vectors for words and the vectors for tags were concatenated (according to the original index position) and then sent to a classification layer, which was a BLSTM neural network with attention. Output labels per sentence were obtained via softmax.
Baseline methods

We also included a few baseline methods for comparison with the BERT models. For the n2c2 dataset, two strong baseline methods, the CNN-RNN method and the JOINT method were used, which were developed by our group and achieved the best performance on relation classification task in the n2c2 challenge\textsuperscript{32}. For the i2b2 dataset, the baseline methods used were the Seg-CNN method from Luo et al.,\textsuperscript{33} and the SDP method from Li et al.,\textsuperscript{34} which both outperformed the best systems that participated in the i2b2 challenge. We also compare with Li et al.’s recent Seg-GCRN method\textsuperscript{35}, which improves upon the Seg-CNN results incrementally. The Seg-CNN and Seg-GCRN evaluations used the original 2010 i2b2 dataset (including data from the University of Pittsburgh Medical Center) to develop and evaluate their methods, while the SDP method (and our experiments) excluded the Pittsburgh data. All results of baseline methods came from their original paper without re-running.

Experiments

For each BERT-based method, we evaluated four pre-trained language models, namely, (1) uncased BERT-large\textsuperscript{23}, (2) cased BERT-large\textsuperscript{23}, (3) the BioBERT model that was pre-trained using PubMed Central full text articles and PubMed abstracts\textsuperscript{24} and (4) the cased MIMIC BERT model that was pre-trained using the MIMIC III dataset\textsuperscript{25}. The difference between uncased BERT-large model and cased BERT-large model was that the former converted all words into lower case and the latter did not. For the n2c2 dataset, the original training set was randomly split into a new training set and a development set of 242 and 61 documents respectively (about 4:1), and the original test set (202 documents) was still used as test set for evaluation. For the i2b2 dataset, we mixed the original training set and test set together, then randomly split it into new training, development and test sets (with a ratio about 3:1:1). The development set was used for optimizing parameters, and the test set was used for evaluation. Note that this split of data implies that our i2b2 results are not directly comparable with the published literature using the original corpus. The evaluation metrics used in this study were as follows.

\[
\text{precision} = \frac{\text{true positive}}{\text{true positive} + \text{false positive}} \quad (1)
\]

\[
\text{recall} = \frac{\text{true positive}}{\text{true positive} + \text{false negative}} \quad (2)
\]

\[
F1 = \frac{2 \times \text{precision} \times \text{recall}}{\text{precision} + \text{recall}} \quad (3)
\]

Model parameters. The parameters of BERT were not frozen during training. The parameter maximum sequence length for both of methods were 128. The hidden layer size for Bi-LSTM in FC-BERT was 100 and embedding size of tag in FC-BERT was 100. For other parameters, we used the default parameters in the BERT.
Results

Table 2 shows results of the FT-BERT/FB-BERT models and baseline methods using four different pre-trained models on the n2c2 dataset. On the n2c2 data all four FT-BERT models that used different pre-trained BERT models outperformed the baseline method CNN-RNN. Three of them (except the FT-BERT that used cased BERT) outperformed the JOINT method on F1 score (up to 0.0023). All FC-BERT models performed worse than baseline method JOINT, but the uncased BERT model was better than the CNN-RNN method. Among FT-BERTs that used different pre-trained models, the FT-BERT that used the MIMIC BERT model was better than the one that used other pre-trained BERT models on F1 score and precision. The pre-trained BERT model using biomedical literature (BioBERT) showed no improvement on the clinical datasets compared with the models trained on data from the open domain. This may be because the BioBERT model trained based on the original BERT-base model includes fewer parameters than the original BERT-large models used in the study.

All FT-BERT models outperformed the baseline method SDP on the i2b2 dataset under all three metrics of precision, recall and F1 score (Table 3). Only the FT-BERT models that used uncased BERT and MIMIC BERT outperformed the other two baseline methods Seq-CNN and Seq-GCRN. All FC-BERT models were worse than baseline methods. Among the FT-BERT models, the one that used MIMIC BERT was still the best on the i2b2 dataset.

*These two methods were developed and evaluated on the original dataset of the 2010 i2b2 challenge.

Table 4 shows the F1 scores of our methods on each category of the n2c2 dataset. All four FT-BERT models performed better on all categories than CNN-RNN. The JOINT was slightly better than FT-BERT on four categories (Strength→Drug, Frequency→Drug, Form→Drug and Route→Drug). Compared with JOINT, three of four FT-BERT models improved the performance on the most difficult categories, reason and ADE; the FT-BERT models that used MIMIC BERT performed best (0.7674 vs. 0.7552, JOINT; 0.8124 vs. 0.7871, JOINT). The FC-BERT models performed better than the CNN-RNN but worse than the JOINT on these two categories.
In order to compare our methods with previous studies, we also merged all eight types of relations into three. Relations between tests and problems (TeCP and TeRP) were merged as Test-Problem, relations between treatments and problems (TrCP, TrAP, TrWP, TrNAP and TrIP) were merged as Treatment-Problem, and relations between problems and problems were kept unchanged. The performances of our methods were calculated on the merged categories. Table 6 shows the results. On overall performance, FT-BERT was 0.01 higher than the best baseline method Seg-
BERT method. First, the FC \( BERT \) made a substitution for all entities. In contrast, FT \( BERT \) made the patterns clear by replacing all entities with their semantic types. For example, in sentence “… given nebs, IV solumedrol and dose of levofloxacin IV and admitted for copd exacerbation.”, FT \( BERT \) recognizes all relations correctly and FC \( BERT \) fails to recognize all of them. The fact that FC \( BERT \) uses all information including words may also cause the failure of recognizing some parallel structure. For example, in sentence “… Vancomycin / Cefepime for Staph …”, FC \( BERT \) can only recognize relation between Cefepime and Steph, but fails to recognize relation between Vancomycin and Staph.”. Second, in the FC \( BERT \) method, a random initialized embedding layer was used to represent BIO tags, which may be too simple to capture the difference and connections between BIO tags. A pre-trained vector may improve the performance of FC\( BERT \).

The MIMIC FT \( BERT \) model performed the best on both of these two datasets, but on the i2b2 dataset it was only slightly better than the uncased \( BERT \) model. It may be because the n2c2 dataset was a subset of the MIMIC III corpus, so that MIMIC \( BERT \) was trained on in-domain data. Both cased \( BERT \) and uncased \( BERT \) were pre-trained on corpora from the open domain, but the performance of the latter was better. It may be because the word shape feature doesn’t help for RE. The \( BERT \) model that pre-trained on biomedical literature only slightly improved the overall performance on two datasets. One possible reason for this was that it is pre-trained on \( BERT \)-base instead of \( BERT \)-large, and the language used in biomedical literature is different from the language used in clinical narratives.

This is just the first attempt to apply \( BERT \) to clinical RE and there are different aspects that can be further improved. Our study followed the traditional framework of classifying candidate relation pairs, using the FT \( BERT \) and FC-
BERT models. Because the architecture of the JOINT method showed good performance on the n2c2 challenge, in the future, it’s possible to improve performance by combining BERT with JOINT. Moreover, we plan to further evaluate pre-trained language models from clinical corpora, e.g., supplement additional medical vocabulary and train uncased MIMIC III models.

**Conclusion**

In this study, we developed and evaluated BERT-based methods for clinical relation extraction. Our results show our RE methods based on pre-trained language models outperformed previous state-of-the-art RE systems in two shared tasks. In addition, our evaluation shows using clinical data to pre-train BERT models can benefit clinical RE.

Towards Interpretable Skin Lesion Classification with Deep Learning Models

Alec Xiang¹, Fei Wang, PhD²

¹Horace Greeley High School, Chappaqua, New York; ²Weill Cornell Medical College, New York City, New York

Abstract

Skin disease is a prevalent condition all over the world. Computer vision-based technology for automatic skin lesion classification holds great promise as an effective screening tool for early diagnosis. In this paper, we propose an accurate and interpretable deep learning pipeline to achieve such a goal. Comparing with existing research, we would like to highlight the following aspects of our model. 1) Rather than a single model, our approach ensembles a set of deep learning architectures to achieve better classification accuracy; 2) Generative adversarial network (GAN) is involved in the model training to promote data scale and diversity; 3) Local interpretable model-agnostic explanation (LIME) strategy is applied to extract evidence from the skin images to support the classification results. Our experimental results on real-world skin image corpus demonstrate the effectiveness and robustness of our method. The explainability of our model further enhances its applicability in real clinical practice.

Introduction

Skin disease is one of the leading causes for global disease burden. It is reported that about 85 million Americans (27% of population; more than 1 in 4 individuals) were seen by dermatologists in 2013 and more than 9,500 people in the U.S. are diagnosed with skin cancer every day¹,². The diagnostic criteria of the skin diseases usually involve visual inspection of the skin lesions from their dermoscopic images as the first step. One such example is melanoma, which is one of the deadliest cancers. The diagnosis of melanoma includes two steps: visual inspection and biopsy. Because of the invasiveness of biopsy to patients, the accuracy of visual inspection is crucial. ABCDE (Asymmetric Shape, Border, Color, Diameter and Evolution) has been a popular rule for visual screening of melanoma based on the geometric characterization of the skin lesions³. However, without the equipment of these clinical knowledge, melanoma patients may not be aware of the severity of the disease they have and thus miss the best timing for treating their conditions.

In recent years, because of the rapid development of both computer hardware and software technologies, a large volume of skin images has been collected and sophisticated deep-learning based models have been trained to perform automatic analysis of these skin images. These models hold great promise as screening tools for skin diseases because of their superior capabilities of image analysis. For example, Esteva et al. proposed to adapt the Google Inception v3 model for melanoma detection from skin images⁴,⁵. The model, with parameters fine-tuned on 130K skin images, achieved classification performance comparable to human dermatologists. Kawahara et al. proposed a Fully Convolutional Neural Network (FCNN) model to extract multi-scale features skin images and perform lesion classification and achieved an accuracy of 81.8% on a 10-class skin disease classification problem, while the best reported classification accuracy on the same dataset is 67%⁶. Bi et al. proposed to leverage the deep Residual Network (ResNet) to perform melanoma detection and achieved state-of-the-art performance⁷,⁸.

Despite the good quantitative performance of these existing models, there are still some challenges to be addressed.

1) Model robustness. Existing research usually adapted well-established deep learning models (e.g., Inception or ResNet) trained on general computer vision tasks. It is difficult to guarantee any single model can work consistently well on different skin lesion images.

2) Sample limitation. In most of the existing studies, the amount of available skin images for training the complicated deep learning model is not enough⁹,¹⁰. Thus, these models typically will need to be pre-trained on other large-scale image data sets and the limited skin images will be used for fine-tuning to facilitate convergence.

3) Decision interpretation. Only quantitative classification results would not be enough for decision support in real clinical practice. As we introduced above, the dermatologists have specific diagnostic criteria to follow when they make the diagnosis. Therefore, the model we developed should also be able to generate the necessary evidence to support the classification results.
With the above considerations, we propose a novel deep learning pipeline for skin lesion classification in this paper.

![Pipeline Diagram](image)

**Figure 1.** Deep learning pipeline for skin lesion classification

It is worthwhile to highlight the following aspects of our pipeline, as shown in Figure 1:

1) Rather than using a single model, we ensembled a set of deep learning models (including VGG16, DenseNet, Xception, and Inception-ResNet v2) that have demonstrated to be effective on different computer vision tasks. In this way, we can sufficiently leverage the strength of different individual models and enhance the overall model robustness. We have also investigated different ensemble methods such as simple majority voting and model stacking.

2) In order to augment the training image set, we adopted the condition-based generative adversarial networks (GANs) on top of the traditional image augmentation approaches such as rotation and resizing.

3) Local interpretable model-agnostic explanation (LIME) strategy is implemented to interpret final model predictions, so that image features that lead to the final classification are highlighted.

We evaluate the effectiveness of the proposed pipeline using the Human Against Machine with 10000 training images (HAM10000) data set, which consists of 10015 dermoscopic images collected from different populations.

**Preliminaries**

**Convolutional Neural Network (CNN)**. CNN is a popular deep neural network model whose architecture design is inspired by the biological fact that the neuron connectivity patterns resemble the anima visual cortex, and for specific stimuli only the cortical neurons in a small region (a.k.a. receptive field) will respond. CNN has been shown to be very effective on computer vision tasks such as image and video analysis. Two basic operations in CNN are convolution and pooling. Convolution convolves the whole image with a small filter mimicking the response of the receptive field (defined by the filter) centered around every pixel, and the resultant map after convolution will further go through a nonlinear activation function to obtain the final response. The pooling layer is for downsizing the image maps. A typical CNN architecture includes a series of convolution and pooling layers. The final resultant feature map will be stretched into a vector and fed to a fully connected layer for endpoint task (such as classification).

**Generative Adversarial Network (GAN)**. GAN is a class of machine learning models that generates by mimicking real data distribution. There are two networks in the GAN model: a generative network that generates the data and a discriminative network to evaluate the generated data. The goal of GAN is to generate data objects as real as possible through zero-sum gaming. Many variants of GAN have been proposed in recent years. Particularly, in our case, we want to leverage the GAN technique for generating more skin image samples, and those samples should be not only real, but also can help improve the lesion classification performance. Mirza and Osindero proposed conditional GAN which makes both the data generation and discrimination probability conditioned on the data classes. Odena et al. further proposed “Auxiliary Classifier GANs” (AC-GAN) by expanding the conditional GAN. In the AC-GAN framework, the generator accepts a class label or condition along with the noise, while the discriminator estimates the probability that the image is real or fake along with the class probability. The authors note that although this modification is not tremendously different from previous works, it provides stability to the GAN’s notoriously unstable training process, in avoidance of problems like mode collapse, where the model collapses to a single mode; and training collapse, where the model stops improving.

**Methods**

As illustrated in Figure 1, there are 4 modules in our pipeline, and we will introduce them in detail in this section.
Data Preprocessing. The HAM10000 skin lesion dataset used for this work contains about 10,000 RGB images of skin lesions at a resolution of 450x600 pixels. For the purposes of this work we used 3 of the 7 skin lesion classes represented in the dataset that provided adequate samples for our GAN to learn conditional distributions, leaving a relatively small dataset of around 8900 images belonging to the disease classes of melanoma, nevus, and benign keratosis (the excluded images belonged to the 4 other classes).

Of the selected 8900 samples, 80% were used for purposes of training the models and 20% were set aside as for a final, testing set (Table 1), with both sets stratified. While training the CNNs we set aside 20% of the training dataset for internal validation.

The training set was preprocessed by application of the Gray World color constancy algorithm followed by a random 90% square crop (for more focus on the regions of interest), while for the testing dataset we took a 90% square center crop of the images. For training the CNNs, all images were then resized to 224x224 pixels, while for training the GAN, all images were resized to 64x64 pixels (later upsampled to match the CNN input size).

</tbody>
</table>

Data Augmentation. We first augment the data with traditional methods, which have been shown to reduce overfitting when the number of samples is lacking. For each training sample we applied random distortions in contrast and brightness, clipped zoom, rotations, and flips, generating 4 samples per training sample. The validation and test sets were not augmented.

In addition, we also implemented the AC-GAN model for generating additional images. We followed the framework of a two-network minimax game. The generator accepted the product of random normal noise and a class embedding, outputting an image of dimensions 64x64x3, with a tanh function bringing the pixel values into the range [-1, 1]. The discriminator accepted both real and fake images and output both the probabilities of the images being real, with a sigmoid function; and the probability of the image belonging to a specific class, with a softmax function.

In our implementation, we used convolutional transpose layers in the generator network and convolutional layers in the discriminator network. For both of them we used Leaky Rectified Linear Units (Leaky ReLU) activation functions and batch normalization layers, both of which have been found to be able to help improve the training stability in GANs. The generator and discriminator models are displayed in Figure 2.

In order to address the problem of mode collapse, where the generator only learns one or a few modes of the training data’s distribution, we implemented mini-batch discrimination layers in the discriminator network. During the training process, when the discriminator is fed both real and generated mini-batches, the mini-batch discrimination layers compute the entropy of the mini-batch. Since mini-batches with much lower entropy than real mini-batches are more likely to be generated, the discriminator can provide feedback to the generator in order to increase sample diversity.
Classification Model. In order to promote the robustness of the classification model, we adopted a model ensemble scheme, instead of just using a single model. Popular image classification architectures, including VGG-16, DenseNet, Xception, and Inception ResNet v2, are adopted as base classification models\cite{VGG16, DenseNet, Xception, InceptionResNet}. As VGG simply stacks convolutional and pooling layers it is greatly inefficient, having an unfavorable proportion of parameters to accuracy. More recent architectures employ microarchitectures to improve performance such as the Inception module, residual connections, and dense connections between layers, aiming to allow networks to be deeper and more accurate. Xception modifies the Inception v3 architecture by stacking depthwise convolutions with residual connections and demonstrated a more efficient use of model parameters. Inception ResNet v2 adds residual connections to Inception v3, aiming to accelerate the training process and perhaps improve accuracy. DenseNet, by using dense connections between layers, encourages parameter sharing and feature reuse, thus achieving higher performance with fewer parameters. The different approaches taken by the different architectures allow them to have variance in their test-time errors, allowing an ensemble to of architectures to reduce variance and improve accuracy.

Because we are handling a multi-class classification problem, the categorical cross entropy (CCE) is adopted as the loss function for training the individual deep learning classifiers. Moreover, to further consider the size of different classes, we weight the cross entropy of different classes by their empirical prior probabilities calculated by Eq.\>(2). The final objective loss is shown in Eq.\>(1), where $\hat{y}_j$ and $y_j$ are vectors representing the predicted softmax labels and true one-hot labels, respectively, with $j$ as the index of the classes and $J$ as the number of classes. $\hat{y}_j$ is computed from softmax as shown in Eq.\>(3), where $s_j$ is the input to the softmax layer for class $j$.

\[
CCE = - \sum_{j=0}^{J-1} w_j y_j \log (\hat{y}_j) \tag{1}
\]

\[
w_j = \frac{\text{total} \# \text{of samples}}{\# \text{of samples of class } i} \tag{2}
\]

\[
\hat{y}_j = \frac{e^{s_j}}{\sum_{l=0}^{J-1} e^{s_l}} \tag{3}
\]

In order to evaluate the performance of the models, we adopted balanced multiclass accuracy (BACC), defined in Eq.(4). The true positive predictions of each class are denoted by $TP$, the false positive predictions of each class are denoted by $FP$, $c$ denotes a class, and $N$ denotes the number of classes.

\[
BACC = \frac{1}{N} \sum_{c=0}^{N-1} \frac{TP_c}{TP_c + FP_c} \tag{4}
\]

For the ensemble strategy, we implemented mean ensemble, where the softmax layers of the CNNs are averaged to get the image’s predicted class labels; and an RBF-kernel support vector machine (SVM)\cite{SVM}. With the SVM ensemble method, we trained the ensemble on concatenations of softmax layers from the validation data, evaluating on the hold-out test set.

For a baseline, we compared our model to scale-invariant feature transform (SIFT) with an SVM\cite{SIFT}. In this process, the RGB images are converted to grayscale. The images are then clustered with the k-means algorithm by their SIFT keypoints (128-length vectors), in order to perform vector quantization. An RBF-kernel SVM is then fit and evaluated with the dictionary of keypoints.
**Model Interpretation.** LIME is a package built to provide model-agnostic interpretations for classifiers. Being model-agnostic means that LIME acts without knowledge of the internal workings of a classifier, treating it as a black box and locally learning a mapping of input to output.

For interpretation of our models’ decisions, LIME also treats the CNNs as black boxes, perturbing an image it feeds to a given CNN and estimating the CNN’s decision function. The CNN’s decision function is estimated through a sparse linear model around a single image. By learning this decision function, LIME is able to highlight superpixels of images that lead to certain diagnoses by CNNs based on the importance of these superpixels.

**Experiments**

For all models we started their training with the ImageNet weights (available from Keras Applications). We used the Adam optimizer with a mini-batch size of 32 and learning rate of 0.0001, training for 20 epochs with early stopping. As the models displayed a tendency to overfit the training data, training was stopped when the validation accuracy and loss no longer improved. Moreover, DenseNet-169 was trained with GAN-generated samples (upscaled to model input size with Lanczos resampling) and traditional data augmentation.

Table 2 displays the balanced accuracies for each model and ensembles of models. In the ensembles we excluded SIFT with SVM, VGG-16, Xception, and DenseNet-121 as including these models decreased the ensemble accuracy.

Our results show that, with 20% of the image set aside as independent validation, our pipeline can achieve a classification accuracy of 0.8569 over three skin lesion classes, while the traditional image classification method with Support Vector Machine (SVM) trained on Scale-Invariant Feature Transformation (SIFT) features can only get a classification accuracy of 0.5326.

Figure 3 displays the normalized confusion matrices for various models on the testing set. The confusion matrices show the accuracy in predicting each disease across each row, e.g. in the first matrix, DenseNet-169 had 82% accuracy in predicting melanoma, 81% accuracy in predicting nevus, and 72% accuracy in predicting benign keratosis. Since the different CNNs learn different mappings of input to output, they have demonstrated different strengths in predicting the three diagnoses. While the final ensemble in the third confusion matrix is composed of more models than just DenseNet-169 and DenseNet-201 (50% GAN Augmentation Level), these confusion matrices demonstrate how an ensemble can balance out individual model predictions to improve classification accuracy. For instance, DenseNet-201’s poor melanoma classification accuracy being balanced out by DenseNet-169’s melanoma classification accuracy, and likewise, DenseNet-169’s poor benign keratosis classification accuracy is balanced out by DenseNet-201’s benign keratosis classification accuracy.

During the training of the CNNs, we evaluated different levels of augmentation with generated images over DenseNet-169 and DenseNet-201. The results are shown in Figure 4. Each level indicates the proportion of images that were generated and added to the training set, i.e. a level of 50% indicates the number of images equivalent to 50% of the original dataset (before traditional augmentation) were generated by the AC-GAN and added to the training set. For both DenseNet-169 and DenseNet-201, we employed augmentation levels of 0% (no additional augmentation), 20%, 40%, 50%, 60%, 80%, and 100%. DenseNet-169 achieved the highest balanced accuracy of 0.8009 at a level of 40%, and DenseNet-201 achieved the highest balanced accuracy of 0.8156 at a level of 50%. This indicates that a deeper model such as DenseNet-201 has more capacity for additional features provided by generated images compared to DenseNet-169. The trend for both models indicates an optimal level of augmentation at a moderate level with a performance drop with more generated data. As the level of augmentation increases, the classification accuracies of the models return to baseline levels, which may be attributed to the imprecision in generated data causing the models to lose generalizability to the testing set.
During training of AC-GAN, we did not use an imbalanced training procedure (e.g., training the discriminator on 10 batches for every time the generator is trained). Instead, we used a balanced training procedure, training the discriminator and generator equally, with a batch size of 64, with the AC-GAN converging in about 20,000 updates.

Figure 5 displays generated images side by side with their nearest neighbors (measured by Euclidean distance) in the training dataset. While we can see that skin lesions generated by the AC-GAN are similar in size, shape, and color to skin lesions from the actual training set, the AC-GAN seems to have produced original skin lesions rather than memorizing and reproducing skin lesions from the training set. Additionally, although some samples within classes are highly similar, there is still some diversity in the generated skin lesions both within each class and between the three classes, indicating the capability of AC-GAN for capturing of multiple modes of the data distribution and the absence of mode collapse.

In order to validate the acquired representation of the AC-GAN, we used latent space interpolation, which performs linear interpolation between two noise vectors (with the same class label). The results are shown in Figure 6. As the generated samples displayed smooth transitions with an absence of “holes” in the latent space of the AC-GAN, we can conclude the AC-GAN has learned meaningful features of the training distribution, rather than overfitting and producing discrete transitions.
Figure 5. Images Generated by AC-GAN*

*Leftmost column of each class of images holds the generated images, while the 3 columns to the right of it hold the 3 nearest neighbors for each generated image.

Figure 6. Latent Space Interpolation. The leftmost and rightmost images were generated from vectors sampled from a normal distribution, and the other images were generated from interpolations between the two original vectors.

For diagnosis algorithms such as a CNN to be used in real clinical decision support, we cannot just provide the classification score, but also demonstrate the evidence on how the classification decision is made. We use a model-agnostic method, named LIME, to “open a black-box” of CNN and achieve such a goal.
Figure 7 displays a few examples of positive diagnoses by Inception ResNet-v2 explained by LIME. The region bounded by a yellow line or highlighted for each lesion contain the top groups of pixels for each prediction. While LIME appears to highlight meaningful regions of the skin lesions, it may be lacking in specificity due to the difficulty of the classification task for both machines and humans. However, LIME does show that regions of the skin lesions are considered foremost before the backgrounds of the images, validating that the CNN is using relevant information for its diagnoses. There are also inherent limitations of the LIME’s model agnostic approach that come with its wide applicability, including its inability to use information from the weight activations of the CNN.

**Figure 7.** True positive diagnoses for melanoma (0), nevus (1), and benign keratosis (2) from the test set with Inception ResNet-v2.

All CNNs and the AC-GAN were trained on an Amazon Web Service p3.2xlarge EC2 cloud instance, which has an NVIDIA Tesla V100 GPU, using the Keras deep learning framework with a TensorFlow backend. We release our source code and a demo web interface at [https://github.com/alxiang/lesion-GAN](https://github.com/alxiang/lesion-GAN).

**Conclusions and Discussions**

From Table 2, the results of the classification task, the top individual model was DenseNet-201 with GAN augmentation, with a test-time accuracy of .8156, while the less complex SIFT with SVM and VGG-16 models were unable to compete. For model ensemble strategies, averaging and SVM led to better classification accuracies, and we can also observe the expected decrease in variance obtained from combining multiple predictions.

We also found models tended to overfit without the regularization effect of data augmentation and converged faster by starting with the pre-trained ImageNet weights. We still observed overfitting with data augmentation and early stopping, which suggests that our exploitation of the data is still suboptimal, and more extensive data augmentation (e.g., with GAN-based methodologies) may improve results.

The results of the AC-GAN, displayed in Figures 5 and 6, showed that it can capture meaningful representations of the data, which correspond to the multiple modes of the data distribution in different classes. Moreover, the latent space interpolation experiments with the AC-GAN provide additional validation for the generator’s learned distribution. While generating 64x64 images with the AC-GAN was stabilized by inclusion of the class condition and batch diversity during training, we were unable to scale up the GAN to 256x256, closer to the desired input size of the model.

For the classification task, there is possible room for improvement through modifications to the CNN models including test-time augmentation, more advanced ensemble strategies, and more extensive data augmentation. Even deeper models are also promising, as they may have the useful capacity for deeper features in the training dataset.

Additionally, scaling up the resolution of images generated by the AC-GAN while preserving meaningful features of the training data could improve training of the CNNs, though in our experience, higher-resolution GANs were highly unstable to train. In future attempts of high-resolution image generation, generation prowess of different GANs can be evaluated through their aid in improving the accuracy on the classification task.

Analysis of Spatial Trends in Smoking Status Among Patients with Obstructive Airway Diseases Highlight Potential for Targeted Smoking Cessation Interventions

Sherrie Xie, BS, Rebecca A. Hubbard, PhD, and Blanca E. Himes, PhD
Department of Biostatistics, Epidemiology and Informatics, University of Pennsylvania, Philadelphia, PA, USA

Abstract

Because chronic obstructive airway diseases like asthma, chronic obstructive pulmonary disease (COPD) and asthma-COPD overlap (ACO) increase individual susceptibility to the harmful effects of cigarettes, smoking cessation programs could strengthen their public health impact by targeting smokers with these conditions. We performed spatial analyses on data derived from the Electronic Health Records (EHRs) of 25,119 asthma, 3,323 COPD, and 3,620 ACO patients and a community-based health survey of 18,740 residents to identify regions in the Greater Philadelphia Area with a high density of current smokers among patients with obstructive airway diseases and the general population. We identified areas in North and West Philadelphia with high prevalence of current smokers across all patient groups and community members that should be prioritized in smoking cessation initiatives. Neighborhood deprivation, which was linked to patient data using residential geocodes, was associated with greater smoking prevalence in these regions.

Introduction

Cigarette smoking is a leading cause of morbidity and premature death in the U.S. and has been a target of many federal and local policy initiatives.\textsuperscript{1-4} Asthma and chronic obstructive pulmonary disease (COPD) are common obstructive airway diseases that increase individual susceptibility to the harmful effects of cigarettes. Among individuals with asthma, smoking increases symptom severity, accelerates lung function deterioration, and decreases therapeutic response to corticosteroids.\textsuperscript{5-8} Most COPD-related deaths are caused by smoking, and the mortality risk for smokers with COPD is twice that of smokers with other conditions.\textsuperscript{1, 9} People who have both asthma and COPD, referred to as asthma-COPD overlap (ACO), have more comorbidities and exacerbations than those with asthma or COPD alone.\textsuperscript{10-12} While ACO had been under-studied partly because asthma and COPD trials commonly excluded patients with both conditions, the recognition that people with ACO have worse outcomes has resulted in it being a topic of recent interest.\textsuperscript{13, 14}

While no study has explicitly considered the effects of smoking cessation on people with ACO, the beneficial effects of smoking cessation on those with asthma or COPD are well documented. Smokers with asthma who quit smoking experience decreased symptoms and improved lung function,\textsuperscript{7, 15} while smokers with COPD who quit smoking experience slower lung function decline and improved survival\textsuperscript{16, 17} and smoking cessation is considered the most effective treatment for COPD.\textsuperscript{17} Given the high prevalence of obstructive airway diseases in the U.S.\textsuperscript{18, 19} and the substantial benefits that smokers with these conditions stand to gain by quitting, smoking cessation initiatives can increase their public impact by reaching these vulnerable individuals.

Here, we leveraged data derived from Electronic Health Records (EHRs) and a community-based health survey to understand how smoking cessation could geographically target patients with asthma, COPD, and ACO. Our study aimed to (1) determine how smoking cessation among patients with asthma, COPD, or ACO compares to that of a representative community sample, (2) identify factors associated with smoking status among patients vs. community members, and (3) identify geographical areas with high densities of current smokers that should be prioritized for smoking cessation interventions.

Methods

Study population. Our study population consisted of (1) adults with asthma, COPD, or ACO encountered at the University of Pennsylvania Health System (UPHS) in 2012-2016, and (2) residents of Southeastern Pennsylvania who were part of the Southeastern Pennsylvania Household Health Survey (SEPA-HHS, henceforth referred to as HHHS). UPHS operates several large hospitals, specialty medical centers, and satellite clinics in the Greater Philadelphia Area, including five counties in Southeastern Pennsylvania (Philadelphia, Bucks, Chester, Delaware, and Montgomery counties, henceforth referred to as SEPA). We obtained de-identified, patient-level data from Penn Data Store, the
Variables extracted included geocoded patient residential addresses, codified demographic information (i.e., gender, birth year, race/ethnicity, height and weight measures), as well as codified smoking history (i.e., whether a patient is a current smoker, has quit smoking, or never smoked). Medications prescribed during encounters were obtained from codified entries as well as NLP-extracted values from clinical notes. Patient insurance class was obtained from an encounter-level codified billing field that was re-categorized into four groups: Private Insurance, Medicare, Medicaid, and Other/no insurance. Patients were assigned the most frequently occurring insurance class among all encounters. Patient age was defined as age at first encounter.

For the current study, patients were included if they had: (1) at least one ICD-9 or ICD-10 code for asthma (i.e. ICD-9 493* or ICD-10 J45*) or COPD (i.e. ICD-9 491*, 492*, or 496*; ICD-10 J41*, J43*, or J44*), (2) non-missing smoking history, (3) non-missing residential geocode and (4) residence within SEPA. Patients were classified as having asthma if they had at least one ICD code for asthma, prescription for a short-acting β2-agonist, and did not meet the criteria for COPD. Patients were classified as having COPD if they had at least one ICD code for COPD, prescription for a short-acting β2-agonist or short- or long-acting muscarinic antagonist, and did not meet the criteria for asthma. Patients were classified as having ACO if they met the diagnosis and medication criteria for both asthma and COPD.

The HHS, a community-based survey of SEPA residents conducted by the Public Health Management Corporation (PHMC) in 2012 and 2015, was a random-digit-dialing mobile and home telephone survey that aimed to capture the health status and behaviors of the local population and included survey items on individual-level demographics (e.g., age, gender, race, BMI, health insurance status) and smoking history. PHMC recorded residential street addresses or nearby cross-streets of survey respondents, which were used to match respondents to residential census tracts.

Neighborhood disadvantage metrics. While little information on socioeconomic status (SES) is collected in EHRs, residential geocodes can be used to link patient data to high-resolution information on neighborhood environments. We sourced data on neighborhood SES from the Neighborhood Atlas, an online tool that provides a standardized score for neighborhood disadvantage, termed the area deprivation index (ADI), for all block groups in the U.S. ADI is a factor-based score that captures multiple dimensions of SES (poverty, education, employment, housing quality) by combining several measures from the 2013 American Community Survey Five Year Estimates. It has been validated for detecting socioeconomic gradients in a number of health outcomes, including cancer mortality and hospital readmission risk. Block group ADI is reported as a national percentile ranking (taking integer values 1-100) indicating each block group’s economic deprivation relative to all others in the U.S., with higher values representing greater disadvantage. The geographic distribution of ADI in the SEPA region is shown in Figure 1. We determined neighborhood disadvantage for each patient by using residential geocodes to link their EHR-derived data to their block group ADI, which was then transformed to an ordinal variable with four levels (1-15, 16-50, 51-84, and 85-100).

Statistical analysis. Three smoking-related rates were computed for each patient group (asthma, COPD, ACO) and HHS: current smoker prevalence, ever smoker prevalence, and smoking cessation rate. Current smoker prevalence was defined as the proportion of subjects who currently smoke, and ever smoker prevalence was defined as the proportion of subjects with a positive smoking history. Smoking cessation rate was defined as the proportion of subjects who quit smoking among those with a positive smoking history. Note that while the total population served as the denominator...
for current and ever smoker prevalence, only those with a positive smoking history formed the denominator for smoking cessation rate.

Rates for community members were calculated using survey weights provided by HHS to correct for nonresponse bias, allowing estimates to more accurately reflect the SEPA population. Patient rates were standardized by gender, race, sex, and county residence using weighted HHS as the standard population via the direct method. Briefly, patients within each disease group were cross-tabulated by gender, race/ethnicity (“Non-Hispanic black,” “Non-Hispanic white,” “other”), age (18-34, 35-54, 56-74, >75), and county residence, for a maximum of 120 cells, and cells were collapsed in some patient groups to avoid cells with count 0. Subsequently, standardized rates for each patient group were calculated as the weighted average of cell-specific rates, where weights represented the relative frequency of each demographic combination in the weighted HHS sample.

We produced choropleth maps for rates aggregated at the census tract level to visualize the geographic distribution of smoking behaviors across the three patient groups and HHS. To correct for instability of rates estimated from small samples (median census tract n = 7, IQR = 3-15), we applied an empirical Bayes estimation method for small area prevalence of non-rare conditions, where crude rates were corrected towards local, county-wide means to a degree inversely proportional to the sample size. Regional differences in patient smoking behavior compared to that of local community members were visualized by subtracting HHS rates from those of each patient group for all census tracts.

We performed two-tailed Wald tests to test the null hypothesis that the difference between each smoking-related rate for each patient group vs. HHS equaled 0. To determine whether demographic factors (i.e., gender, race, age, BMI category, insurance billing class, county residence, and neighborhood disadvantage) were associated with smoking cessation for each group, we used multivariable logistic regression analyses. A separate model was constructed for each group (asthma, COPD, ACO, and HHS). Statistical analyses were conducted with a type I error rate of 0.05 and performed in R version 3.5.1.

**Geospatial analysis.** We identified significant smoking cessation cold spots (i.e., regions where the relative density of current smokers was high) for each patient group and HHS using methods described previously. Briefly, we used generalized additive models (GAM) to estimate the log odds of smoking cessation among subjects with a lifetime smoking history as a function of their location of residence before and after adjustment for individual-level covariates. Because residential geocodes were not provided by HHS, the residential location of each HHS respondent was approximated with the mean center of population for their census tracts of residence. The GAM included a bivariate smooth term S(x,y) smoothed using a loess function, a locally-weighted regression smoother which adapts to local variation in patient/respondent density. The amount of neighboring points utilized by the loess was determined by a span size optimized by minimizing the Akaike Information Criterion.

We used GAM to determine the log odds of smoking cessation on a grid of 10,000 points arranged across SEPA, which was converted to an odds ratio by using the global odds of smoking cessation within each patient group as reference. Two GAM models were fit for each patient group and for HHS respondents: one with and one without individual-level covariate adjustment, for a total of eight models. Variables selected for adjustment were the significant independent predictors of smoking cessation as determined by multivariable logistic regression: gender, race, age at first encounter, BMI category, insurance billing class and neighborhood disadvantage. County residence was not included in adjusted models to prevent over-fitting. Global tests were performed to test the null hypothesis that smoking cessation rates did not vary by geographic location by running 999
permutations of the assignment of cases (those who quit smoking) and controls (those who did not) over all residential locations. Given a significant global test, a local test was performed to identify areas of increased or decreased odds of smoking cessation. The model fit to the permutations was used to produce a distribution of log odds at each point on the grid, and points that ranked in the upper and lower 0.5% of the permutation distributions were defined as “hot spots” and “cold spots”, respectively. GAM analyses were performed in R using the MapGAM package.

Results

Characteristics of patient groups and community members. A total of 71,029 patients encountered by UPHS between 2012 and 2016 met the criteria for asthma and/or COPD. Of these, 16,530 (23%) were excluded for missing residential geocodes, 12,655 (18%) were excluded for residence outside SEPA, and 4,782 (7%) were excluded for missing smoking history, leaving 37,062 patients for geospatial analysis and the calculation of smoking-related rates. A total 20,066 HHS respondents were surveyed in 2012 and 2015. Of these, 102 (0.5%) were excluded for missing smoking history, 555 (3%) were excluded for missing residential census tract information, and 669 (3%) were excluded for missing demographic information (age or race/ethnicity), leaving 18,740 respondents for estimation of local population rates.

Demographic characteristics of UPHS patients and HHS respondents are provided in Table 1. The distribution of characteristics vary considerably between patients and HHS respondents, accentuating the importance of adjusting group-specific rates by demographic factors so that they can be compared appropriately. The median

Figure 3. Standardized current smoker prevalence, ever smoker prevalence, and smoking cessation rate colored by patient group or HHS. Error bars represent 95% confidence intervals.
ages of COPD and ACO patients were older than that of HHS respondents, while the median age of asthma patients was younger. Asthma and ACO patients were disproportionately female (asthma 71.8%, ACO 65.7% versus COPD 50.2%) and Non-Hispanic black (asthma 40.5%, ACO 53.1% versus COPD 31.8%), consistent with findings from previous studies of asthma and COPD in UPHS and other patient populations. All groups were enriched for subjects that lived in Philadelphia relative to other counties, though this enrichment was more pronounced in patient groups than HHS.

**Differences in smoker characteristics between patient groups and community members.** Smoking history varies markedly by age among asthma, COPD and ACO patients, and HHS respondents (Figure 2). Although COPD and ACO patients have higher proportions of current and ever smokers for all age groups, the distributions of ever smokers show a roughly unimodal distribution across all groups, with highest rates in middle to older age (45-74). The distribution of current smokers is also roughly unimodal across all groups, with peaks that occur at relatively younger ages (25-54) compared to ever smoker distributions.

Standardized rates of smoking and smoking cessation vary by patient group (Figure 3). Current smoker prevalence was higher among COPD (35.5%) and ACO patients (31.5%) compared to HHS respondents (17.9%), (p < 0.001 for both comparisons). However, current smoker prevalence was lower among asthma patients (10.3%, p < 0.001). Similarly, ever smoker prevalence was higher in COPD and ACO patients compared to HHS respondents (COPD = 77.7% and ACO = 71.9% vs. HHS = 43.4%, p < 0.001 for both comparisons), while ever smoker prevalence was

![Choropleth maps of SEPA census tracts shaded according to subject counts (top row) or smoking-related rates (bottom three rows). Tracts with no data to calculate rates are colored white, and county boundaries are represented by black lines.](image)

**Figure 4.** Choropleth maps of SEPA census tracts shaded according to subject counts (top row) or smoking-related rates (bottom three rows). Rates were corrected for small sample variability via an empirical Bayes method in which crude estimates were corrected toward county means to a degree inversely proportional to tract-level sample size. Tracts with no data to calculate rates are colored white, and county boundaries are represented by black lines.  

1260
lower among asthma patients (38.1%, p < 0.001). Rates of smoking cessation were similar between ACO patients and HHS respondents (57.8% vs. 58.7%, p = 0.47). Smoking cessation rates were also similar between COPD patients and HHS respondents, though the difference reached marginal significance (55.4% vs. 58.7%, p = 0.03). In contrast, smoking cessation rates among asthma patients were significantly higher than that of HHS respondents (74.0% vs. 58.7%, p < 0.001).

**Geographic distribution of chronic airway disease patients by smoking status.** Current and ever smoker prevalence estimates for Philadelphia census tracts were generally higher than those of the surrounding counties, and this trend held across patient groups and HHS (Figure 4). In addition, smoking cessation rates were generally lower in Philadelphia census tracts than those of the surrounding counties across all groups. Among the suburban counties, smoking rates appeared to be higher in Chester and Delaware compared to Bucks and Montgomery, especially among COPD patients, though this trend was less striking among HHS respondents. As a result, positive rate differences were evident in Chester and Delaware counties, where smoking rates tended to be higher in patient groups compared to HHS (Figure 5), though we did not test for statistical significance. The higher smoking rates among COPD and ACO groups compared to HHS extended across all SEPA census tracts, and this difference in rates does not exhibit a discernible spatial trend (Figure 5).

**Neighborhood disadvantage measures.** Block group-level neighborhood disadvantage measures are shown in Figure 1 for the five SEPA counties studied. Philadelphia county encompasses many highly disadvantaged neighborhoods, with over one-fifth of its block groups ranking among the nation’s most disadvantaged (91-100th percentile). The surrounding suburbs (Bucks, Chester, Montgomery, Delaware counties) are markedly more affluent, with large regions that rank among the nation’s bottom 10th percentile in neighborhood disadvantage.

**Factors associated with smoking cessation.** Multivariable analyses found that older age and overweight/obese BMI were consistent independent predictors of smoking cessation across patient groups and HHS (Table 2). On the other hand, Medicaid insurance (a crude indicator of low individual-level SES) and neighborhood disadvantage (an indicator of low neighborhood-level SES) were consistent independent predictors of subjects not quitting smoking.

**Spatial trends in smoking cessation rates.** Smoking cessation rates were heterogeneous in SEPA across all groups (Figure 6). The global test statistic for spatial heterogeneity was significant for all 8 GAMs (p<0.01), indicating there was significant spatial heterogeneity in smoking cessation rates, and these trends were not fully explained by the covariates considered. The cold spots identified by the crude models (top row of Figure 6) showed considerable overlap, particularly in North and West Philadelphia, suggesting that smoking cessation rates were low (i.e., relative proportion of current smokers was high) for all patient groups and community members in these regions. While spatial trends were still present in the adjusted models (bottom row of Figure 6), the cold spots in North and West Philadelphia were absent, suggesting that the decreased smoking cessation rates in these regions were explained by spatial variation of the covariates considered.

**Discussion**

A strong evidence base supports the effectiveness of community-based interventions for smoking cessation. Policy makers interested in maximizing the impact of smoking cessation programs determine how to target groups that are most susceptible to the harmful effects of cigarettes and identify regions with the greatest number of current smokers.
We leveraged data derived from EHRs and a community-based survey to understand the smoking characteristics of patients with asthma, COPD and ACO relative to those of local populations, and we determined where smokers in these groups live. We found smoking rates among ACO and COPD patients to be nearly twice as high as those estimated from community members, and smoking rates among asthma patients to be somewhat lower than local community estimates. In addition, while smoking cessation rates were not substantially different between COPD and ACO patients vs. community members, cessation rates were significantly higher among patients with asthma. The high prevalence of smoking among patients with COPD and ACO highlights the need for smoking cessation programs that target these patients. Although smoking rates were lower among patients with asthma, the number of smokers with asthma were substantial, accounting for over 90% of smokers in our patient population. Because asthma is highly prevalent in Philadelphia,35 smokers with asthma should not escape the notice of local policy makers.

Table 2. Factors associated with smoking cessation among UPHS patients with a positive smoking history, stratified by patient group and HHS. Adjusted odds ratios (ORs) were derived from multivariable logistic regression models with smoking cessation as the outcome. Shown are ORs and 95% confidence intervals, with significant results in bold.
Factors associated with smoking cessation were similar across patient groups and HHS. Consistent with reports from the U.S. and other developed nations that the most deprived groups have the highest smoking rates and the lowest rates of quitting,36-38 those with a positive smoking history across all groups were less likely to quit if they had low individual-level SES (coarsely identified by Medicaid insurance status) or lived in disadvantaged neighborhoods. These results reaffirm the need to target smoking cessation interventions toward disadvantaged communities. Obesity also had a robust association with subjects quitting smoking, though this was likely an instance of reverse causation, as smoking suppresses appetite and individuals who quit smoking tend to gain weight.39, 40

Our unadjusted geospatial models identified consistent cold spots for smoking cessation in North and West Philadelphia (Figure 6 top row), regions with high neighborhood disadvantaged relative to SEPA and nationally (Figure 1). The loss of these cold spots in adjusted models confirmed the association of smokers’ neighborhood socioeconomic environment with quitting smoking status. Additionally, our results are promising from a policy perspective because the consistency of these cold spots indicates that initiatives that target areas with low smoking cessation rates in the general population may also target similar high-needs areas for populations with specific diseases. However, overlapping hotspots in Bucks and Montgomery county remained in the adjusted models for asthma and COPD patients, and a partially overlapping hotspot remained in the adjusted model for HHS. These hotspots suggest that the higher rates of smoking cessation in these regions cannot be fully explained by their relative affluence or the spatial distribution of the other covariates considered. Investigating the smoking-related policies in these communities could uncover the drivers of high smoking cessation rates in these regions and provide insights on effective steps that can be pursued in regions with low cessation rates.

Our findings are subject to limitations, including those inherent to analyses of EHR-derived data. Phenotyping errors can result from the use of ICD codes for the classification of disease status, though the combination of diagnosis codes with additional EHR components, such as medication information (e.g. prescriptions of short-acting ß2-agonist or short- or long-acting muscarinic antagonist used in the present analysis), can improve phenotyping performance.41

Future analyses will incorporate other EHR data, such as information from clinical notes, to further improve phenotyping accuracy. Another limitation common to EHR-derived data is data missingness. The variable with the highest degree of missingness in our EHR-derived data was patient residential geocodes, which were missing for 23% of patients. While the distributions of basic demographic characteristics (age, race, gender) were similar between patients with and without residential geocode information (data not shown), the lack of geocode information for patients in the latter group prevented us from ascertaining information about their neighborhood SES. Thus, we could not determine whether neighborhood socioeconomic environments differed between patients with missing and available geocode information. Given the strong associations between neighborhood disadvantage and smoking

![Figure 6](image-url). The spatial odds ratio for smoking cessation calculated for asthma, COPD, and ACO patients and HHS respondents who had a positive smoking history. The top row represents odds ratio surfaces estimated from unadjusted models, while plots in the bottom row include adjustment for individual-level covariates (i.e., gender, race/ethnicity, age, BMI, insurance billing class, and neighborhood disadvantage). Regions shaded blue represent areas where the odds of quitting smoking are below the global mean and areas shaded red represent areas where the odds of quitting smoking are greater than the global mean. County boundaries are represented by grey lines. Significant cold spots (with decreased rates of smoking cessation, p < 0.005) are indicated by blue contour lines, and significant hot spots (with increased rates of smoking cessation, p < 0.005) are indicated by red contour lines.
behaviors noted in the present analysis, it is unclear how the exclusion of patients without geocodes may have biased our results. A smaller, though not insignificant, proportion of patients (~7%) were excluded for missing smoking history. A disproportionate percentage of patients who were excluded for missing smoking history were Non-Hispanic black (41.3% vs. 30.1%) and lived in more disadvantaged neighborhoods (median ADI = 69 vs. 36), indicating a systematic bias in the ascertainment of smoking history among UPHS providers. Though the relatively small number of patients excluded for missing smoking history is unlikely to change our primary results, this bias in the ascertainment of smoking history warrants further investigation. The GAM models used in our analyses mapped the spatial distribution of smoking cessation rates without explicitly modeling spatial autocorrelation, and future analyses can incorporate geographically weighted regression or spatial autoregressive models to account for spatial dependence directly. In addition, future analyses can incorporate patients with non-respiratory health conditions, such as coronary heart disease and hypertension, to understand smoking characteristics across other susceptible patient populations.

A commonly cited limitation of EHR-derived data is a lack of variables, such as socioeconomic factors, that are relevant to the study of many health outcomes. We leveraged residential geocodes available in EHR-derived data to link patient data to high-resolution data on neighborhood disadvantage. The robust associations that we found between patients’ neighborhood disadvantage and their smoking status mirrored similar trends found using data from a population-based survey, thus demonstrating the utility of augmenting EHR-derived data with external geospatial variables through the use of residential geocodes. Factors that would be of interest to studies of other health-related behaviors that can be linked to EHR-derived data via similar methods include data on green spaces, walkability, crime, and locations of tobacco or alcohol outlets.

Conclusion

The efficacy of smoking cessation programs can be greatly enhanced by targeting regions with high prevalence of current smokers, particularly among those with obstructive airway diseases, which increase individual susceptibility to the harmful effects of cigarettes. We leveraged EHR-derived data on asthma, COPD, and ACO patients and data from a community-based health survey to identify several coinciding regions in North and West Philadelphia that had high densities of current smokers across patient groups and community members. These areas should be prioritized in smoking cessation initiatives.

Abstract

Blockchain and smart contracts (i.e., computer code that can be run on blockchain) are increasingly popular for healthcare applications. However, only very few implementations exist because of the complexity of the technologies. Although there are tutorials and reviews to introduce blockchain and smart contracts, a pragmatic comparison of such platforms is needed. In this study, we addressed practical considerations while building a healthcare blockchain and smart contract system, by (1) comparing technical features of platforms, (2) selecting three platforms, (3) constructing blockchain networks, (4) testing the blockchains, and (5) summarizing the experience and time used for implementation by students. We evaluated Ethereum, Hyperledger Fabric, and MultiChain, and confirmed that the selection of a proper platform depends on the requirements of the application. The findings of our study can accelerate the process and reduce the risk of adopting blockchain technology in biomedical and healthcare domain.

Keywords: Data Sharing, Interoperability and Health Information Exchange, Privacy and Security

Learning Objective: Understand smart contract blockchain platforms and their comparison for healthcare.

Introduction

Since Bitcoin,¹,² blockchain technology has evolved and is now considered as a new form of a distributed ledger, since arbitrary data can be stored in the metadata of the transactions.³ With this capability, many blockchain-based healthcare applications are emerging rapidly. Example applications include unalterable patient records,⁴ improved care data sharing/analysis without ceding control,⁵⁻⁷ and enhanced robustness for counterfeit drug prevention/detection systems in pharmaceutical supply chains.⁸

Figure 1. Example of smart contract for data queries such as “how many patients have hemoglobin test results for postmenopausal females”. (a) Traditional process of a researcher requesting a data query within a clinical data research network (i.e., from University A to University B), including the use of an electronic form as well as the need for a data concierge person to manage and respond to the queries. (b) Blockchain-based smart contract approach to manage/record the data queries automatically without human. Note that the choice of the query depends on the Institutional Review Board (IRB) approval as well as the Data Usage Agreement (DUA) signed between universities.
Among the new developments of the blockchain technology, smart contract is one of the most important advancements.9-19 Smart contracts refer to computer programs/code devised to manage smart properties, which are the digital properties recorded by blockchain.11 That is, a smart contract is a piece of computer code that can be run within a blockchain transaction. For example, a smart contract has been proposed to automate the workflow of medical licensure across multiple states.20,21 It removes the requirement for human confirmation of precursors and results, and instead relies on machines to automatically execute the logic stated in the program to accept or reject a request. Smart contracts are also transparent and immutable. An example is shown in Figure 1, demonstrating the potential to manage the data queries requested by an institution to another within a clinical data research network. Therefore, we consider smart contract as a very useful and desired feature for healthcare applications.

Many researchers have proposed to adopt blockchain and smart contracts in healthcare, genomic, or biomedical applications.4-6, 8, 22-35 but only very few have actually implemented these technologies due to their complexity.3 Therefore, understanding practical considerations while exploring smart contract technology is imperative, and can facilitate the adoption of the new technology for a wild spectrum of healthcare applications. Although there are broad tutorials and reviews about blockchain and smart contracts,36-39 a pragmatic comparison and evaluation of the smart contract platforms is needed.

Methods

In this study, we addressed the practical considerations while building a healthcare blockchain and smart contract system. Specifically, we compared the technical features of the smart contract blockchain platforms, selected platforms for our study, constructed a blockchain network for each of the platform, tested the blockchains, and summarized our experience and time used for the implementation by students. First, we selected technical features of the smart contract blockchain platforms based on our recent review/report.3, 38 as shown in Table 1. Based on the technical features described in Table 1, we identified three platforms to be compared in this study, out of ten popular platforms:3, 38

- **Ethereum**11, 43 is one of the most well-known decentralized smart contract blockchain platforms.11, 17, 43, 46 Ethereum is also a cryptocurrency itself, and has a large market cap.47 Microsoft adopted Ethereum as the core of its Blockchain-as-a-Service (BaaS) on the Azure cloud computing environment,48 however Ethereum can be run in any cloud computing environment. Ethereum has been used in healthcare applications and, most importantly, supports second-generation smart contracts.3 Ethereum can work with both external owned accounts and internal contract accounts.49 It also uses the concept of ‘gas’ to regulate computationally intensive smart contract code.46 Ethereum has a build-in currency (Ether), and Wei is the smallest fraction of Ether.50 The main reasons to select Ethereum were the capability to be configured as both a permission-less and a permissioned blockchain network, as well as the community-based development of the platform.
Hyperledger Fabric\textsuperscript{51-53} is an enterprise-grade cross-industry platform supported by IBM.\textsuperscript{53, 54} Hyperledger, a project under the Linux Foundation,\textsuperscript{51, 52} is a platform with various “dialects”, and we selected Hyperledger Fabric because it is one of the popular smart contract platform that requires no specific hardware to be executed.\textsuperscript{3, 38} Hyperledger also has a Composer component that supports a purpose-built modeling language for defining a business network, multiple ways of integrating blockchains with other services, and a platform for developing, testing and deploying custom business logic.\textsuperscript{25} The Hyperledger Composer, along with its Playground feature, enables developers to use pre-existing sample network frameworks to plan their network construction through a user-friendly, easily accessible web interface. There are also Software Development Kits (SDKs) available on Hyperledger Fabric ‘s website for potential C and Java developers. The main considerations to choose Hyperledger Fabric were the capability to be configured as a permissioned blockchain network and the access control feature with high granularity.

MultiChain\textsuperscript{56, 57} is a platform that currently only supports first-generation smart contracts as well as limited programs, or “smart filters”\textsuperscript{,58} It also does not yet support complex syntaxes based on Turing-complete programming languages that can execute any algorithm. Currently, a MultiChain smart filter is restricted to programming instructions that do not allow for operations such as loops and recursion. However, MultiChain provides many built-in functions to support basic building blocks for applications,\textsuperscript{58} and can be used directly for operations like sending or receiving transactions. MultiChain also supports data streams (i.e., key-value pairs) based on transaction metadata.\textsuperscript{59} Many MultiChain APIs have been developed for mainstream programming languages such as Java and JavaScript, enabling developers to run complex programs on MultiChain. The main reasons to include MultiChain were the simple setup process and the features inherited from Bitcoin Blockchain.\textsuperscript{1, 2}

Our comparative analysis was conducted by three undergraduate/graduate students with no prior experience in blockchain technologies to construct, test, and summarize the experiences related to the three selected platforms in parallel. While only one student developed code for each one of the platforms, they compared notes and discussed solutions as a group, with facilitation from a faculty member (T-TK). First, we constructed three selected smart contract blockchain networks. We used six virtual machines (VMs), each has 2-Core CPU, 8GB RAMs and 100GB storage, with 64-bit Ubuntu 14.04 operating system, on the Google Cloud Platform.\textsuperscript{60} We then tested the blockchain platforms by submitting transactions or deploying/executing smart contracts on them. Finally, we summarized our implementation experiences for these blockchain platforms, with an estimation of the required time for setup and learning time for an undergraduate or a graduate student.

**Results**

We compared the platforms by extracting the technical features,\textsuperscript{3, 38} and the results are shown in Table 2. Our experience and setup/learning time of constructing three blockchain platforms are summarized below.

- **Ethereum.** We constructed a blockchain network using Go-Ethereum.\textsuperscript{61} Then, we sent transactions with specified data and checked the transaction input for both servers were the same. Finally, we wrote, compiled, deployed and executed smart contracts using Solidity\textsuperscript{60, 41} on our blockchain network. An example smart contract pseudo code written in Solidity and executed on Ethereum\textsuperscript{11, 43} is shown in Figure 2, which corresponds to the use case described in Figure 1. The whole process to build the blockchain network took about 30 minutes, while the learning time for an undergraduate student (DW) was about 7 days.

- **Hyperledger Fabric.** We built a blockchain network using the Hyperledger Fabric images on Docker.\textsuperscript{62} Then, we send transactions to verify the connectivity of the network, and implemented/executed smart contracts using Chaincode in the Go language. An example pseudo code, corresponding to Figure 1 (b), is shown in Figure 3. The whole process to build the blockchain network took about 45 minutes, and the overall learning period for an undergraduate student (HY) was about 14 days.
**MultiChain.** We setup a blockchain network using MultiChain.\(^{57}\) Then, we sent transactions between nodes to ensure the validity of the network. We also tried to create data streams to disseminate key-value paired data. Finally, we investigated smart filters, and an example pseudo code is illustrated in Figure 4. The whole process to build the blockchain network took about 30 minutes, while the overall learning period for a graduate student (HS) was about 2 days.

> s.getQuery()
> ["0xd5a6c396a3e66b7e76949895f86dc878477f44b", "", "", ""]

> s.getQuery()
> ["0xd5a6c396a3e66b7e76949895f86dc878477f44b", "hemoglobin", "postmenopausal", "female"]

**Figure 2.** Example Ethereum Solidity pseudo code involved in a simple contract between two institutions (as described in Figure 1 (b)). University B deployed this `QuerySmartContract`, with two functions: `sendQuery` and `getQuery`, to the blockchain network. University A executed this smart contract and queried the data for “how many patients have hemoglobin test results for postmenopausal females” (the upper-right box). Then, University A retrieved the query from the blockchain, and can see the query criteria as well as the address of the contract owner (which is University B). Note that it takes some time for the smart contract to be enclosed in a verified transaction of a block, therefore the first query only returns empty values for the query. Also, this smart contract, as well as any function calls that change the state of the variables in the smart contract, will be logged in the immutable blockchain, which enables future attribution, auditing, dispute and resolution for both (and even a third-party) institutions.
Figure 3. Example Hyperledger Fabric pseudo code for the example shown in Figure 1 (b), and the execution results are shown in the upper-right box. Similar to the code shown in Figure 2, University B deployed this contract, and University A send the query (by calling sendQuery and getQuery functions).

```go
func (t *SimpleChaincode) sendQuery(stub shim.ChaincodeStubInterface) pb.Response { 
    fmt.Println("sendQuery")
    _, args := stub.GetFunctionAndParameters()
    var O, A, S string
    var patientOutcome, patientAge, patientSex string
    O = args[0]
    patientOutcome = args[1]
    A = args[2]
    patientAge = args[3]
    S = args[4]
    patientSex = args[5]
    fmt.Printf("%s, %s, %s/n", patientOutcome, patientAge, patientSex)
    stub.PutState(O, []byte(patientOutcome))
    stub.PutState(A, []byte(patientAge))
    stub.PutState(S, []byte(patientSex))
    return shim.Success(nil)
}

func (t *SimpleChaincode) getQuery() pb.Response { 
    var O, A, S string
    var err error
    O = "patientOutcome"
    A = "patientAge"
    S = "patientSex"
    outcome, err := stub.GetState(O)
    age, err := stub.GetState(A)
    sex, err := stub.GetState(S)
    if err != nil { 
        fmt.Println(err)
        return shim.Error(err)
    }
    fmt.Printf("%s, %s, %s/n", outcome, age, sex)
    return shim.Success(outcome)
}
```

University A:

```
$ multi-chain-cli query-chain
Interactive mode

> sendQuery (“patientOutcome”, “hemoglobin”, “patientAge”, “postmenopausal”, “patientSex”, “female”) > getQuery()
```

University B:

```
$ multi-chain-cli query-chain
Interactive mode

> subscribe query

> liststreamkeyitems query patientOutcome
```

Figure 4. Example MultiChain code between two universities. University A creates a stream query in the blockchain, and publishes a key (patientOutcome only, for simplicity purpose) with a value (hemoglobin, which is represented in hexadecimal number “68656d6f76c6f62696e”) in the stream. Then, University B subscribes the stream to inspect the value of the patientOutcome.
Comparison and Discussion
Based on our implementations, MultiChain is the easiest blockchain platform in terms of setup. The setup of Ethereum as a permissioned network took longer than MultiChain. Hyperledger Fabric contains more layers in its network to increase manageability and security, which can result in long setup time compared to other platforms. The installation of the software prerequisites for MultiChain and Ethereum are also easier compared to Hyperledger Fabric. On the other hand, Ethereum and Hyperledger provide the full-functional smart contract capability, while the support of smart contract for MultiChain is limited. The smart contracts are highly readable and easily programmable.

Considering the biomedical/healthcare applications, the salient characteristic of the three platforms are as follows. Ethereum is supported and maintained by a large community of developers around the world. This open property makes it a good choice while considering the long-term sustainability of the platform that the applications rely on. Hyperledger Fabric’s well-designed, multi-layered access control framework along with Hyperledger Fabric’s own certificates lead to high versatility, security, and manageability of the blockchain platform. MultiChain is designed to be a permissioned blockchain that is very simple yet powerful to use and inherits proven features of the famous Bitcoin Blockchain by forking from it.

Conclusion
To support the development of healthcare applications based on blockchain and smart contracts, we conducted a pragmatic comparison and evaluation of smart contract blockchain platforms. The main limitation of this study is that we only compared three platforms, so the scope may be restricted. Based on our results, an informatics researcher, IT expert, or technical leader in healthcare or other institution can assess the various practical aspects, such as setup/learning time and unique technical features, of the platforms. The selection of a proper platform depends on requirements of the application (e.g., maintenance for Ethereum, fine-grained access control for Hyperledger Fabric, and rapid-development for MultiChain). Such an assessment can accelerate the process and reduce the risks in adopting blockchain, an immutable, distributed, and automated technology, for biomedical and healthcare applications. We plan to identify more blockchain requirements for healthcare applications, conduct more structured and large-scale comparisons to include additional blockchain platforms (such as Corda) that may fulfill the requirements, and analyze the operation/performance aspects of the platforms in our future work.

Applying Blockchain Technology to Enhance Clinical Trial Recruitment

Yan Zhuang, BS¹, Lincoln R. Sheets, MD, PhD², Zonyin Shae, PhD³,⁴, Yin-Wu Chen, PhD³, Jeffrey J. P. Tsai, PhD³, Chi-Ren Shyu, PhD¹,²,³

Abstract

Patient recruitment for clinical trials is known to be a challenging aspect of clinical research. There are multiple competing concerns from the sponsor, patient and principal investigator’s perspectives resulting in most clinical trials not meeting recruitment requirements on time. Conducting under-enrolled clinical trials affects the power of conclusive results or causes premature trial termination. The Blockchain is a distributed ledger technology originally applied in the financial sector. Its features as a peer-to-peer system with publicly audited transactions, data security, and patient privacy are a good fit for the needs of clinical trials recruitment. The “Smart Contract” is a programmable self-executing protocol that regulates the blockchain transactions. Given current recruitment challenges, we have proposed a blockchain model containing multiple trial-based contracts for trial management and patient engagement and a master smart contract for automated subject matching, patient recruitment, and trial-based contracts management.

Introduction

Patient recruitment is essential to the success of clinical trials. Failure to meet recruitment goals in time results in a waste of funds and time, incomprehensible statistical results, and delay of the study timeline that could double the planned recruitment period¹⁻². 86% of clinical trials don’t achieve their recruitment goals on time³ and 19% of registered clinical trials were either closed or terminated due to failure to reach expected enrollment⁴. Barriers persist although there have been many research papers addressing the challenges of identifying and recruiting subjects to clinical trials over the past decades⁵⁻⁹.

Barriers to recruiting patients into clinical trials can be classified into three different categories (Table 1) based on (1) sponsor perspectives, (2) principal investigator perspectives, and (3) subject perspectives⁵⁻⁸. Sponsors initially need adequate participants for the potential trial to file an application with the Food and Drug Administration (FDA) for approval⁴. Inefficient advertising models such as radio, newspaper, physician referrals, flyers, cold calls, etc. make it difficult to meet the expectations of initial recruitment on time¹⁰. Sponsors need to design clinical trial protocols such as inclusion/exclusion criteria which can be used to check the eligibility of potential subjects. Detailed protocols can drastically narrow the subject population, which increases the difficulty of recruitment⁸,¹¹. Sponsors need to settle on trial sites without knowing the geographical distribution of future subjects⁷, but distant trial sites will deter many potential subjects⁸. For principal investigators, barriers include lack of awareness of available, appropriate clinical trials, excessive time spent to get the informed consent of participants, and insufficient trial protocols⁴,⁷,¹¹. Subject-related barriers are related to participation, such as patients’ lack of awareness of the available clinical trials; difficulty understanding complex protocols; high expenses if the trial has no clinical sites nearby; and distrust in the clinical trials⁸,¹¹,¹². With these persistent challenges, an efficient model is needed to enhance the recruitment process.

Blockchain is a distributed ledger technology first applied in the financial sector¹³. The success of the Bitcoin cryptocurrency, which is one of the blockchain’s most popular applications, shows the robustness, security and consensus mechanism of the blockchain system¹⁴. Blockchain also has other features such as decentralization,
immutability, ensuring data provenance, and public auditability\textsuperscript{14}. All the transactions that have occurred in the blockchain are distributively stored into each node which can be any active electronic device without hardware requirements inside the blockchain system. Any transaction needs to be validated by the users in the blockchain before it is written into the system\textsuperscript{15}. Since the system is fully decentralized, all the transactions can be audited publicly by all the users. The public auditability feature can solve the issue of lack of awareness.

The Smart Contract is a self-executing, coded protocol agreed between senders and receivers initially proposed by Nick Szabo in 1996 to regulate all transactions on the distributed ledger system\textsuperscript{16}. Most blockchain systems have added a smart contract function to their protocols such as Ethereum and Hyperledger\textsuperscript{17}. Since the Ethereum blockchain comes with a built-in Turing complete programming language used for the smart contract, any computational problem such as patient matching for recruitment, or checking the validity of a clinical trial can be coded as a smart contract\textsuperscript{18}. Once a smart contract is deployed into the system, the system will generate an application binary interface (ABI) of the smart contract and smart contract address for users to call the smart contract functions\textsuperscript{14}. All the users need to follow the smart contract’s regulation to make a transaction. The ABI and address are viewable to all the users rather than the source code or the data stored inside the smart contract, but the functions may not be executable to any user. This depends on the user’s privilege. For example, in the clinical trial recruitment setting, the inclusion/exclusion protocol can only be input into a smart contract by the authority who is in charge of all clinical trials. This ideally would be the FDA. Only the sponsors can send a matching request to the smart contract, then the blockchain system can automatically match the potential subjects. This matching of sponsors and subjects can help the sponsor to target eligible patients, save time for principal investigators and patients to understand the protocols, and ensure the completeness of the protocol. Once the eligible subjects are identified, the sponsor can select the trial sites based on the subjects’ geographical distribution which could solve the issue of inaccessible clinical sites for subjects. The smart contract can also ensure the validity of a clinical trial by checking the sponsor’s identity and whether the trial has a National Clinical Trial (NCT) identifier number which means the study has been approved by the authority\textsuperscript{19}. Patients can rest assured that the trial is legal, and that the sponsors are reliable. Original blockchain features and smart contract functionality can solve most of the barriers for clinical trial recruitment.

Despite the features of blockchain fitting most healthcare applications, there are several common challenges of the most current blockchain models for healthcare applications: (1) inadequate public/private key management systems\textsuperscript{20}; inability to retrieve any information once a user has lost the private key, (2) loss of privacy caused by transparency of the distributed system\textsuperscript{21, 22}; ability of all the users in the blockchain to view all the data stored in the blockchain, and (3) scalability constraints\textsuperscript{22, 23} considering Ethereum can handle roughly 15 transactions per second. Most blockchain applications in the healthcare area are still in the design stage and have not yet been implemented\textsuperscript{24, 25}. The abovementioned challenges are mainly caused by blockchain’s features instead of actual operation. We have implemented a blockchain system using Ethereum blockchain which is an open source platform with a built-in smart contract function to tackle the issues for clinical trial recruitment. We have tested our system by simulating clinical trial recruitment using a real dataset to test the feasibility and provide potential solutions to current common blockchain challenges. We have made the following assumptions to perform the simulation of the recruitment process using our system: (1) the authority, each clinical site and each sponsor needs to provide at least one node in the system; (2) patients have to opt-in to our system, they authorized the system to access their health records; (3) clinical sites agreed to connect the secured Electronic Health Records (EHR) database through blockchain node; (4) all the EHR are recorded in the same standard; (5) there is a universal patient ID to map the same patient across different clinical sites; (6) the authority, each clinical site and each sponsor needs an administrator to operate the system, patients need to operate the system as well.

**Blockchain**

Blockchain is a fully distributed peer-to-peer network\textsuperscript{14}. The blockchain system runs based on users’ consent rather than being managed by a third party. To protect the users’ privacy, every user in the blockchain will have a unique key pair which contains a public key and a private key to represent their identities\textsuperscript{26}. The public key is similar to a user’s bank account. The private key is similar to a user’s signature. Every transaction needs to be digitally signed by the sender’s private key\textsuperscript{26}. Once a user makes a transaction, all the users in the blockchain can see the sender’s public key instead of their real identity. The blockchain has a built-in mechanism to check whether the sender’s public key and the signed private key match, but keeps the private key hidden from other users\textsuperscript{13}. The stability of the blockchain relies on all nodes to provide computing power to validate the transactions. Once a transaction which is one-time exchange of data is made, the transaction will be sent to each user in the blockchain for validation. If a hacker wants to hack others’ accounts to made transactions using a fake private key, the transaction will be voted down by other users and discarded. Where blockchain was originally used in the finical sector, the transaction referred to an exchange
of cryptocurrency like bitcoin. The validation process validates whether the sender has sufficient balance to make the transaction. In our system, a transaction refers to the execution of smart contract function such as authority input inclusion/exclusion criteria of a certain trial into a smart contract. All the users will validate whether the sender’s public key is the authority, the data which is criteria will be encrypted and can only be decrypted by specific users instead of all users. Blockchain is a chain of blocks. Each block contains a unique block number, last block number and all of the transactions that occurred after the last block was generated. The block numbers chain the blocks together that can be used for tracing the source of the data. For instance, the sponsors need to check the patients’ records to check the eligibility for the trial, they can check whether the records were input by the hospitals by tracing the sender of the initial transaction. Once a transaction is verified and written into the block, the record and data cannot be altered anymore.

Blockchain can be built as a “public chain” or a “private chain” meaning all the users can join the public chain without additional setups and permission. “Bitcoin” and “Ether” are applications on the public blockchain and public Ethereum blockchain, respectively. The private chain is called the “permission chain”. The creator of the private chain has control over who can join the chain. In order to join the private chain, all the nodes need to deploy the same “genesis block” which is the starting block of the private chain provided by the creator and add at least one peer node which already in the chain. The “genesis block” of a private chain determines the private chain’s characteristics such as the ability to estimate block generation rate. The genesis blocks are different from different blockchains so that they can only be acquired from the creators. In our scenario, the authorities will be the creator of the system. All the nodes provided by the clinical sites and sponsors need to get the “genesis block” file from the authority. The “genesis block” file is a JSON file that can be embedded into a program used for blockchain system installation. All the nodes also need to add the authority’s node as a peer using its IP address and node identifier which is automatically generated by the blockchain. This procedure can also be embedded into the install program provided by the authority. Since the blockchain is a fully distributed system, the creator can decide who has permission to join the chain. Other nodes have the same privileges to operate the system such as sending transactions, using smart contracts, auditing transactions, etc.

Since blockchain is not allowed to communicate with servers outside of the chain, we need to rely on a blockchain adapter to check the patient’s EHR data and push the result back to the blockchain in order to precisely match the subject with complex inclusion and exclusion criteria. For example, the sponsors from different IPs send requests to a clinical site’s adapter to identify potential trial candidates from EHR systems. Each node provided by the clinical site needs to be built as a “blockchain adapter” to join our system. Blockchain adapter is a Remote Procedure Call (RPC) server which can connect the clinical site’s own secured EHR database protected by the hospital’s firewall. RPC server executes functions after clients from different IPs send requests to the server. When a patient opts-in to the blockchain system from a clinical site, this site’s administrator needs to create a blockchain account for the patient through their node. The blockchain account will then be associated with the patient’s universal patient ID in the EHR database. The administrator needs to create accounts for clinical research coordinators (CRC) as well. The authority also needs to build its node into a blockchain adapter to communicate with the NCT database in order to check whether the NCT number and the sponsor’s information has been matched.

**Implementation**

To utilize the unique technological capability of blockchain for clinical trial recruitment, we implemented a private Ethereum blockchain system to simulate the recruitment process. The authority’s node as the creator node needs to start the blockchain system using a unique “genesis block” file, and other nodes and adapters then join the system using the blockchain identifier and IP address of the authority’s node. The whole system architecture (Figure 1) contains two modules: (1) A master smart contract is used for auto-matching of potential subjects for all trials using inclusion and exclusion criteria as shown on the left of the figure; (2) Multiple trial-based smart contracts are used for patients’ enrollments, trial management and future persistent monitoring for different clinical trials as shown on the right of the figure. In this setting, all the users can access the master smart contract so that it can reach any user in the system to perform the matching process. The trial-based contract is only available to the users to participate in that trial so that the trial-based contract cannot notice the users outside that trial. A use case is that the CRC can monitor the subject’s condition during the clinical trial through the trial-based contract, but they can’t access subjects’ records for other clinical trials in order to know who has participated in other clinical trials.
Only the selected group of users can execute specific functions in smart contracts. Users without privileges cannot see the data stored inside the smart contract (Table 2). To ensure the accuracy of input data, inclusion/exclusion criteria need to be input by the sponsors and executed by the authority, and the patients’ primary records which include demographic information, previous primary diagnosis and treatment from each visit that used for trial matching can only be input by the clinical sites. The authority has an oversight role in the system. All the clinical sites and sponsors need to get approval from the authority to provide a node to join the system. The authority will intervene in any inconsistent data such as differing patient records in the master smart contract and trial-based contract. The authority can trace the inputter of the records and investigate the reason. This setting can ensure the trial is conducted precisely under the authority’s real-time surveillance.

Module 1 requires all clinical sites to input the opted-in patient list and their primary records. Each sponsor needs to send a transaction to the authority containing the NCT identifier number and its own information for validation. After the authority validates the sponsor’s identity and the authenticity of the requested trial, the authority will input the inclusion/exclusion criteria to the master smart contract. In the meantime, a trial-based contract for this clinical trial will be generated and the contract address will be stored into the master smart contract. The sponsor can request the auto-matching process after sending the transaction to the authority. Part of the auto-matching smart contract code and the returned ABI after compiling this function is shown in Figure 2.

**Figure 1.** System architecture master smart contract and different clinical trial smart contracts
The patient matching is a two-step process. The first step is using the auto-matching function which can only narrow down the patient selection but cannot perform precise matching due to the complexity of the inclusion/exclusion criteria. The master smart contract will automatically match the criteria with the patients’ records stored in the smart contract to select potential subjects. Referring to the example shown in Figure 3, the master smart contract filtered out patient B due to the exclusion criteria of history of renal disease. The second step is performed by the clinical sites to precisely match the potential subjects’ health records in the hospital’s secured database with the patient’s information from the consents. The matching process is then followed by sending the result back to the blockchain through its own blockchain adapter. The exclusion criteria in the example in Figure 3 also has current tobacco use which is not recorded in patient A’s information. The master smart contract will notify patient A that there is a potential clinical trial that he/she might be eligible to participate in and need his/her authentication for the sponsor to access his/her EHR to double check with the details. The sponsor can communicate with the clinical sites which patient A visited before to check whether he/she uses tobacco currently with patient A’s consent by E-signature using the private key. The clinical site will perform precise checking for the sponsor.

Figure 2. Sample matching function and ABI ((a) The sample code of the matching function. The real function is calling several matching functions based on the criteria. (b) The ABI of the sample function which is viewable to every user.)

The patient matching is a two-step process. The first step is using the auto-matching function which can only narrow down the patient selection but cannot perform precise matching due to the complexity of the inclusion/exclusion criteria. The master smart contract will automatically match the criteria with the patients’ records stored in the smart contract to select potential subjects. Referring to the example shown in Figure 3, the master smart contract filtered out patient B due to the exclusion criteria of history of renal disease. The second step is performed by the clinical sites to precisely match the potential subjects’ health records in the hospital’s secured database with the patient’s information from the consents. The matching process is then followed by sending the result back to the blockchain through its own blockchain adapter. The exclusion criteria in the example in Figure 3 also has current tobacco use which is not recorded in patient A’s information. The master smart contract will notify patient A that there is a potential clinical trial that he/she might be eligible to participate in and need his/her authentication for the sponsor to access his/her EHR to double check with the details. The sponsor can communicate with the clinical sites which patient A visited before to check whether he/she uses tobacco currently with patient A’s consent by E-signature using the private key. The clinical site will perform precise checking for the sponsor.

Figure 3. An example of matching process using smart contract and ask consent to join the clinical trial
Module 2 is about how subjects send consent to join the trial chain. If patient A has fully matched the criteria, sponsor A will send a transaction to patient A to ask for enrollment, patient A can agree to join the trial using an E-signature. Then all of patient A’s primary records will be stored into the trial-based contract. Sponsor A can select the trial sites based on the density distribution after collecting all the enrolled subjects’ geographical information. The patients still need to go to the clinical sites to sign all paperwork and proceed with the trial. The sponsor can use the trial-based contract which can only be accessed by the participants of this trial publishing the trial detail and announcement.

We have also built a web-based Graphical User Interface (GUI) on the RPC servers for users to better interact with the system instead of using plain command codes in the blockchain console. To log in to the GUI, all users need to set up a username and a password. The username and password will be stored in the local RPC and mapped to the public key and private key. This could potentially be implemented using personal biometric information to log in to the system. All the functions showed in the GUIs are sending or receiving data from the blockchain rather than a cloud database. Different roles of users will have different GUIs to operate the system. The clinical site’s GUI will have the functions as input the patient’s primary visit records to the smart contract; check ongoing clinical trial as a trial site; check requests from sponsor to check on specific patient’s eligibility and send the result back to the blockchain (Figure 4(a)). The potential matched clinical trials requesting authentication will be displayed in the patient’s GUI. After the patient clicks “approve”, a transaction signed by the patient’s private key will be sent to empower the sponsor to request precise matching from the clinical sites. Patients can also check their basic information and the visiting records but cannot be changed. Patients can also check enrolled clinical trial information the same as the trial sites (Figure 4(b)). The sponsor’s GUI will have a list of ongoing, recruiting and completed clinical trials. For the recruiting clinical trials, they will show the list of matched subjects. Once the request is sent, it will deliver a transaction to the patient through the sponsor’s account requesting authentication (Figure 4(c)). The authority will have all the clinical trial lists and the trial details (Figure 4(d)).

Figure 4. GUIs for (a) clinical sites to input primary records and receive requests from sponsors, (b) patients to receive notifications and authenticate sponsors, (c) sponsors to request a precise match for potential subjects, (d) authority to monitor all the trials

Simulation

To test the feasibility and efficiency of the system, we simulated the recruitment process which started from the moment that the authority registered the trial criteria to the master smart contract, and continuing to the end of the
process when recruited subjects were added to the trial-based contract. We have randomly picked 10 currently recruiting clinical trials (NCT03778931, NCT03252431, NCT03367572, NCT02068092, NCT03152929, NCT03354611, NCT01185132, NCT03523585, NCT03529110, NCT03200704). Criteria such as specific medication use vary from different clinical trials. It is doable to code all the criteria into the master smart contract. To demonstrate the feasibility of using the system for recruitment, we only select the frequent criteria among those 10 trials for the simulation as listed in Table 3. All the selected frequent criteria can be matched from the auto-matching function directly. Five blockchain adapters are set up using the Intel NUC machines: (1) Authority (simulated authority) node as the starting node, (2) sponsor node, and (3) three different clinical sites. We have set up 2,000 synthesized patient accounts on each clinical site’s node. We use the data from Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute for the simulated cases. The SEER database contains cancer incidence and survival data covering 34.6% of the U.S. population. For our simulation, we randomly picked 6,000 patients with breast cancer from the SEER database and evenly distributed them into three clinical sites.

Table 3. Frequent criteria for breast cancer clinical trials among ten selected recruiting trials with frequency

</table>

We have created one database on each clinical site’s adapter. Before the simulation process, we have written scripts to populate all the patients’ previous primary diagnoses and treatments into the master smart contract through each clinical site’s administrator’s account. We have manually input the inclusion/exclusion criteria to the master smart contract sending the consensus transaction from their patient account. We created a control script in each adapter to only send five transactions from different patient IDs to the blockchain every second. All the patients have been successfully registered in the trial-based contract without breaking the chain. Figure 5 shows the results of calling the master smart contract and trial-based contract’s functions through the trial sponsor’s account as: (1) checking the total matched patients for the trial NCT103200704; (2) getting the trial-based contract address (the ABIs of trial-based contracts are the same and pre-stored in the adapters for deployment); (3) checking whether the address of the trial-based contract is matched with the address stored in the master contract; (4) receiving the amount of enrollment for this trial; (5) obtaining the geographical information of all enrolled subjects (only showing part of the 100 enrolled subject’s zip codes) for the trial NCT103200704. The results are from the blockchain console that shows the response of calling smart contracts functions from plain codes. Users

Results

Due to the limited information of the SEER database, we cannot check the pregnancy in the exclusion criteria or whether the breast cancer is persistent malignant. After executing the auto-matching function in the master smart contract, 1,145 patients out of 6,000 patients are matched in 2.13 seconds. We have used SQL to query the databases on the same criteria and got the same results. We have randomly selected 100 matched patients to join the trial smart contract using the trial address stored in the master smart contract by sending the consensus transaction from their patient account. We created a control script in each adapter to only send five transactions from different patient IDs to the blockchain every second. All the patients have been successfully registered in the trial-based contract without breaking the chain. Figure 5 shows the results of calling the master smart contract and trial-based contract’s functions through the trial sponsor’s account as: (1) checking the total matched patients for the trial NCT103200704; (2) getting the trial-based contract address (the ABIs of trial-based contracts are the same and pre-stored in the adapters for deployment); (3) checking whether the address of the trial-based contract is matched with the address stored in the master contract; (4) receiving the amount of enrollment for this trial; (5) obtaining the geographical information of all enrolled subjects (only showing part of the 100 enrolled subject’s zip codes) for the trial NCT103200704. The results are from the blockchain console that shows the response of calling smart contracts functions from plain codes. Users
will use the GUIs (Figure 4(b)) rather than the blockchain console to send requests and receive results in practical use. The NCT103200704_contract which is a trial-based contract shown in Figure 5 is automatically generated by the master smart contract.

Discussion

The blockchain features are a good fit for the clinical trial recruitment process. From the simulation we have done, all the users can see all the recruiting trials’ information. Sponsors and clinical sites need to get the authority’s approval to join the blockchain system and all the patients’ identities are verified by the clinical sites. The transactions are public auditable and also under the surveillance of the authority. The data component in the transactions is encrypted and can only be decrypted by a certain group of users. These features ensure the authenticity of the clinical trial, data security of the transactions and the accuracy of data exchange that has occurred during the clinical trial. After integrating with the smart contract functions, the blockchain system becomes more feasible for recruitment. The auto-matching function is expected to provide the patients an efficient tool to search potential clinical trials. Only auto-matched patients will get notifications from the sponsors. The patients can comprehend the details of the clinical trial after receiving the notification. The auto-matching process also saves time for the patients to understand the complex recruitment protocol. This process shows how blockchain solves the issue of lack of awareness of the eligible clinical trials. Since the criteria is inputted by the authority and all the clinical sites share the same version of the protocol, there won’t be an insufficient trial protocol. Using the blockchain system, the patients only need to opt-in and wait for notifications of the matched potential eligible clinical trials.

The trial-based contract mechanism optimizes clinical trial management. Only the trial participants can access the data in the trial-based contracts. Each trial-based contract is isolated from each other. From the simulation results, we have narrowed down the patients’ selection pool. Selected patients have been successfully added to the trial-based contract after sending their consent using a private key. The transaction processing time depends on the block generating rate which is defined in the genesis block file. In our system, a new block will be generated at around every 30 seconds. The time consumption is acceptable for the subject matching process, solving the issue for clinical sites matching with potential subjects.

The sponsor has received the subjects’ list after all the subjects have been registered to the trial-based contract. Then the sponsor can get the subjects’ geographical distribution by simply calling the smart contract function. Then the sponsor can select trial sites after considering the subjects’ geographical distribution. This approach could potentially reduce some opportunities for clinical sites to join the clinical trials but provides benefits for patients to access the clinical trial easier and sponsors to set efficient sites for the recruitment.

Our design also provides potential solutions to the current challenges for healthcare applications involving the blockchain. The username and password setting is a potential solution to the key management vulnerability. The user can also contact the authority user to rebuild a new account and remove the original one. To empirically prove that only legitimate trials can be accessed and matched with qualified patients, we have intentionally tested malicious behaviors, such as manually changing patient’s record to meet a trial criterion, registering a fake clinical trial that does not exist in the authority’s database through a sponsor’s account, and executing auto-matching process through a clinical site’s node, we found that all of these transactions were rejected by the smart contract as expected. These experiments ensure that only transactions follow the rules listed in smart contracts will be executed.

The user can audit all the transactions theoretically through the blockchain console. However, there are three reasons that there will not be any loss of privacy: (1) the data contained in the transactions sent to the smart contract cannot be decrypted by users; (2) users can only see that all the transactions are sent to different blockchain addresses but cannot know the receivers’ identities or decrypt the data contained in the transactions; and (3) users can only call the smart function to retrieve their own data stored in the smart contract; other actions will be discarded automatically.

To demonstrate the scalability of our implementation, we have simulated a clinical trial recruitment process which contains one request from a sponsor with a 2.13 second transaction time and 100 consensus transactions, as discussed previously in the Results section, from 100 patient accounts with a 24.69 second total transaction time. Using the latest report of global participation in clinical trials by the FDA, there were 131,749 total participants during 2015-2016. Our simulation result with a controlled input transaction frequency for five transactions per second through the RPC node leads us to project that it would take several hours for both matching requests and sending the consensus for the entire year. It is noteworthy to mention that our system setting could avoid Ethereum’s scalability limitation by spacing the transactions, but it is not to solve the known scalability issue of Ethereum.
Conclusion and Future work

Through our simulation process, our blockchain model shows features that can tackle the clinical trial recruitment issues. Using the master smart contract to match patients and trial-based contracts to manage the clinical trials can optimize the recruitment process as timesaving, identifying all potential subjects, patient empowerment, and the authority’s surveillance. Trial-based contracts can be used for EHR collection for subjects during the clinical trial. Blockchain features can ensure the data provenance is clinical sites, data consistency over time, data security that can only be decrypted by certain users and patient privacy. Our future work is to further evaluate Ethereum’s validating mechanism which could fundamentally solve the scalability issue. Our extended study will be to add an artificial intelligence component to our system for the real-time detection of significant adverse events of the collected EHR during a clinical trial.

28. Institute NC. Overview of the SEER Program.
Introduction—The use of clinical grouping software provides substantial value to end users by providing the capacity to facilitate dimensional reduction by transforming voluminous sets of granular International Classification of Disease (ICD) codes and grouping them into clinical groups at higher levels of representation. Many of the clinical data grouping software tools are commercially produced with substantial costs associated with licensing and use, however, several tools have available academic or non-profit organizational discounts. One non-commercial alternative for clinical data grouping is the Clinical Classifications Software (CCS) which is freely available and supported by the Healthcare Cost and Utilization Project (HCUP) which is a Federal-State-Industry partnership sponsored by the Agency for Healthcare Research and Quality (AHRQ).

Prior published work on the CCS has included use in a number of studies which use the software to deal with the highly granular data in clinical encounter data including over 14,000 codes in ICD-9-CM with 3900 procedure codes. In ICD-10-CM/PCS terminology there are over 69,800 diagnosis codes and 71,900 procedural codes(1). Such large and granular datasets provide a great deal of information with high levels of detail, but their breadth makes their use in modeling difficult due to their high dimensionality. The CCS provides mappings of the ICD codes to a set of 285 mutually exclusive categories using the single level coding for diagnoses and 231 mutually exclusive categories for procedures. The single level coding are of primary interest since they can facilitate risk adjustment and diagnostic ranking work for research or software applications(1). The HCUP website for the beta version of the CCS tool used for ICD10 indicates there are no publications on the CCS beta version making this an important area of research work.

Methods – The CCS was analyzed using 2 years of National Inpatient Sample data using the first three quarters of 2015 and the first 3 quarters of 2016 to provide seasonally matching data sets that included ICD9-CM clinical data for the 2015 data set and ICD10-CM/PCS for the 2016 data set. Three quarters were used since the conversion to ICD10 occurred for the last quarter of 2015 (starting October 1, 2015). The 2015 data provided the baseline incidence rates for each of the CCS categories and a cutoff of 20% change from 2015 to 2016 was considered significant in the evaluation.

Results: There were a total of 54.7 million CCS events in the 2015 ICD9 data. There were a total of 55.9 million CCS events in the 2016 ICD10 data representing a 2.2% increase in the number of events. The total counts for each CCS category were also totaled and the significant results are noted in table 1. A total of 62 CCS categories had change from baseline of 20% or greater in the number of events among the 285 different diagnostic categories. A total of 15 categories had a change of greater than 50% from baseline with 9 of the 15 with larger numbers of CCS events after ICD10 implementation.

Discussion – The change in clinical coding from ICD9 to ICD10 has created a number of issues with previously established clinical software and research methods which has been in use in the United States. Conversion involves identifying clinically equivalent codes which exist in both terminology systems, however, the larger number of codes with greater granularity provide greater capacity with ICD10. This increased knowledge representation may not provide equivalent representation before and after the implementation occurred. Additional work may be needed to adjust the coding groups in the beta version of CCS to insure correct knowledge representation is the CCS software with a particular focus on those categories with the greatest changes in events before and after ICD10 implementation.

The Impact of Transitioning from Availability of Outside Records within EHR to Integration of Local and Outside Records within EHR

Julia Adler-Milstein, PhD¹ and Michael Wang, MD¹
¹University of California San Francisco, San Francisco, CA.

Introduction
Substantial effort over the past decade has resulted in greater electronic availability of outside records for frontline clinicians. However, most approaches to enabling such availability require clinicians to go outside of their local EHR (e.g., by logging in to a community longitudinal record) or to go to a separate tab in their local EHR that houses outside records. Under either approach, clinician workflow is interrupted and cognitive effort is required to marry local EHR data with data available in outside records. Newer approaches seek to comingle local EHR data with data from outside records, such that clinicians stay within their workflow and are presented with an integrated list of encounters, lab results, problems, medications, etc. Given the substantial work required to achieve this “last mile” step of integrating data from local and outside records, it is critical to assess the impact of such integration. We therefore undertook the first-ever study to specifically investigate whether the frequency of outside record viewing increases after such integration as well as characterize for which types of encounters, viewers, and patients any increases accrued.

Methods
On July 11, 2018 UCSF Health, a large academic medical center, turned on a new feature that created a single, integrated list of local (from UCSF Health) and external (from any other Epic-based health system) encounters presented in the Chart Review (CR) tab. Prior to this switch, outside records were only available through the CareEverywhere (CE) tab, a section of the EHR exclusive to outside records. The new feature was supplementary, such that there was no change to user ability to view outside records via the CareEverywhere tab.

To study the impact of this change on patterns of frontline clinician viewing of outside records, we studied the 12-month period (calendar year 2018) centered on the new feature go-live date (July 11, 2018). We first conducted an interrupted time series analysis (ITSA) to assess overall changes in level and/or trend of volume of outside record views as captured in the Clarity User Event Log table. We repeated this analysis using the granular nature of the Event Log tables to measure how often an outside records view was preceded by opening Chart Review (CR) or CareEverywhere since we hypothesized that most/all of any increases would come from the new CR pathway. Next, we performed stratified analyses by user type (Residents, Attendings, Nurses, Others) and by encounter type (Emergency, Inpatient, Encounter, Other). Finally, we compared user and patient demographics for encounters with outside record viewing in the three month pre (March-May) versus post periods (August-October) to capture any differences in who/for whom outside records were viewed (e.g., younger patients).

Results

Changes in Volume of Outside Record Viewing

Figure 1. Number of Outside Record Views Before and After Switch to Integrated Local/Outside Records

Figure 1 displays the total weekly number of outside record viewing events, with a visible increase in week 28 when the new feature was switched on. In our interrupted time series analysis, there was a statistically significant increase in level of 22,646 views (p<0.001). There was also an increasing pre-period slope (244 views per week; p<0.01) and a decreasing post-period slope (-569 views per week; p<0.05). When we performed the ITSA for views preceded by opening Chart Review (CR) or CareEverywhere since we hypothesized that most/all of any increases would come from the new CR pathway. Next, we performed stratified analyses by user type (Residents, Attendings, Nurses, Others) and by encounter type (Emergency, Inpatient, Encounter, Other). Finally, we compared user and patient demographics for encounters with outside record viewing in the three month pre (March-May) versus post periods (August-October) to capture any differences in who/for whom outside records were viewed (e.g., younger patients).
in viewing level, revealing that increases were not concentrated among specific user or encounter types. All pre-period slopes were positive and significant, but many post-period slopes were no longer significant, indicating that specific subgroups (attendings, emergency and outpatient encounters) did not have an effect decay post-intervention.

**Changes in Characteristics of Users and Patients with Outside Record Viewing**

Table 1 presents the characteristics associated with encounters with outside records views in the pre-versus-post periods. Across encounter types, there were consistent increases in the number of outside records viewed per encounter as well as the number of unique viewers. We also observed some differences in viewer type (with a trend towards greater viewing among nurses) and some general trends (though many were not statistically significant) towards lower imaging utilization that could result from greater viewing of outside records as has been found in previous studies.

**Discussion**

While limited by a single-site, single EHR-vendor setting as well as the potential for simultaneous event confounding, we conducted a novel study that found that a user interface change that presented integrated local and outside records in the Chart Review tab resulted in a large increase in the level of outside record viewing. Increases were spread across user and encounter types, indicating the widespread impact of this change on ensuring that frontline clinicians have ready access to outside records. However, we did observe some reduction in post-period trend, suggesting a slow effect decay over time. Given the substantial federal investment in interoperability, our results indicate that the benefits will not be maximized unless we specifically focus attention on last mile issues of integrating external data, rather than simply ensuring it is electronically available. This is a blindspot in current interoperability policies, including Promoting Interoperability Program criteria and 21st Century Cures. It is therefore incumbent upon health systems and EHR vendors to push for integration of outside data into clinician workflows in order to mobilize data to improve patient care. Future work tying integration and resulting increased viewing to outcomes will help bolster such efforts.

An Evaluation of an Artificial Intelligence Clinical Trial Matching System in Australian Lung Cancer Patients

Marliese Alexander, B.Pharm, PhD\(^1\), Benjamin Solomon, MBBS, PhD\(^1\), David L Ball, MBBS, MD\(^1\), Mimi Sheerin,\(^2\) Irene Dankwa-Mullan MD MPH,\(^2\) Gretchen Purcell Jackson, MD PhD,\(^2\) Dishan M Herath, MBBS\(^3\),
\(^1\)Peter MacCallum Cancer Centre, Melbourne, Victoria, Australia; \(^2\)IBM Watson Health, Cambridge MA, USA

**Introduction:** Prospective clinical trials are the gold standard for assessing the potential harms and benefits of new cancer treatments. However, clinical trial recruitment is challenging and time-consuming.\(^1\) As of 2015, only about 6% of patients with a cancer diagnosis in the state of Victoria in Australia were recruited to clinical trials, with rates unchanged over more than a decade. A key deterrent is the tedious manual process of matching patients to clinical trials. IBM\(^\circledR\) Watson for Clinical Trial Matching (CTM) is a software platform developed to identify potential trials for an individual patient or potential trial candidates for an individual trial. CTM uses natural language processing (NLP) to intake trial and patient information from unstructured sources and match patients to trials for which they are eligible. The objective of this retrospective study was to evaluate the performance of CTM for lung cancer patients in an Australian cancer hospital.

**Methods:** Information about 10 phase I–III cancer clinical trials registered on clinicaltrials.gov and open to lung cancer patients at Peter MacCallum Cancer Centre, a specialist cancer hospital in Melbourne, Australia, was processed by CTM. Lung cancer patients were selected in reverse chronological order from an IRB approved research database, with data current for all patients as of August 2018. CTM-processed eligibility criteria were checked and refined by two clinicians (medical oncologist and pharmacist) who entered de-identified patient attributes such as histological diagnosis, stage and prior therapies into CTM. A timed query was executed for each patient to assess eligibility for potential trials, with trials classified as “Exclude” (patient not eligible) or “Consider” (patient potentially eligible). A gold standard for trial eligibility was determined for each patient and the 10 cancer trials by independent review of patient attributes entered into CTM (not the full medical record) by two clinicians with discrepancies discussed to achieve consensus. Accuracy, recall and precision of CTM trial classification was measured.

**Results:** A total of 102 lung cancer patients were included in the study. CTM evaluated a total of 7,252 patient attributes (per patient median 74, range 53-100) against 11,467 individual trial eligibility criteria (per trial median 597, range 243-4132). The median time taken for CTM to run a query and return trial results was 15.5 seconds (range 7.2-37.8 seconds). In establishing the gold standard comparator, clinician interrater agreement was high (Kappa=0.70–1.00), with disagreement due to selection error or overlooked features/criteria rather than material disagreement.

On a per-patient basis, the accuracy of CTM for eligibility classification across trials was 91.6%, recall (sensitivity) 83.3%, precision (positive predictive value) 76.9%, negative predictive value 95.7% and specificity 93.8%. When considering only trials classified as “Exclude” by CTM, accuracy was 95.7% with only 34 of 799 trials incorrectly excluded. Conversely, for trials classified as “Consider” by CTM, accuracy was 76.6%, with 52 of 221 labelled “Consider” that should have been excluded. CTM accuracy for individual trials ranged from 77%-100%, Table 1.

</tr>
</tbody>
</table>
Among all trials, 1490 trial eligibility criteria (inclusion/exclusion) were listed as ‘not met’ by CTM (90% agreement with gold standard), 1231 were ‘met’ (96% agreement), 8088 were identified as requiring further action to make a decision and listed as ‘action needed’ (89% agreement), 136 were identified as ‘unmet modifiable’ (90% agreement), and 522 consent criteria were reviewed (81% agreement). The number of data elements and criteria varied by trial, with trial 6 representing an umbrella multi-cohort design with notably higher number of criteria, Table 1.

Discussion

Previous studies have shown that an automated clinical trials eligibility tool and CTM can reduce the time taken to screen patients for clinical trials and increase trial enrolment. At Mayo Clinic, accuracy was reported as 87.6% for 4 breast and 74.9% for 3 lung cancer protocols. Other tools show similar results but accuracy data of this type is limited. This study expands the knowledge about CTM performance to a larger number of patients and trials, and to a setting outside of the United States. In our unselected patient cohort, CTM software was able to reliably exclude ineligible patients from trial consideration (>95% accuracy) but was less accurate for determining who was truly eligible (77%). One contributing factor was that for the 102-patient cohort, 8088 data items were identified as requiring further action (data input or clinician interpretation). This study has several limitations. First, although CTM is capable of processing structured and unstructured information from an electronic health record (EHR), only the matching components of the CTM system were evaluated because the EHR was not integrated with CTM for this study. Second, the study included a relatively small number of patients at a single center. Strengths of the study are a rigorous gold standard for eligibility with consensus agreement of two clinicians who had a high interrater reliability.

Conclusion

This study demonstrated that CTM allows efficient and reliable screening of Australian lung cancer patients for clinical trials, with excellent accuracy in exclusion and good performance in assessing potential eligibility. However, clinician input and oversight are still required for assessing nuances of patient characteristics against individual criteria. CTM demonstrates promise as a tool to pre-screen a large patient cohort to identify subjects suitable for further assessment.

Learning to Estimate Nutrition Facts from Food Descriptions

Hadi Amiri, PhD; Andrew L. Beam, PhD; Isaac S. Kohane, MD, PhD
Department of Biomedical Informatics
Harvard Medical School, Boston, MA 02115

Introduction.

Risk factors such as body weight, blood pressure, and blood cholesterol can help people make informed decisions about their health promotion efforts. Food choices are among the most effective of these efforts which can help preventing chronic diseases, such as heart disease, diabetes, stroke, and certain cancers[6]. Since different foods provide different energy and nutrients, healthy eating requires monitoring the nutrients that we consume. In addition, food offers new perspectives on topical challenges in Natural Language Processing and Computer Vision centering around computational models to extract nutrition facts from food-relevant textual content[1] or find representations that are robust to occlusion and deformation in processing of food images[2]. In fact, there is an emerging literature investigating Food Computing which aims to acquire and analyze food data from disparate sources for recommending and monitoring food consumption as well as addressing food-related issues in medicine, biology, gastronomy, and agronomy[7]. The availability of large-scale food datasets and the above recent advances in Food Computing can transform the way that individuals consume food. Established in the literature is the ability to match foods with databases that contain nutrition facts[1]. These approaches are effective for foods that exists in databases, but lack the ability to deal with large amount of new foods that don’t exist in such databases; as reported in[5], the average number of new foods per year is slightly less than 20K. In addition, there is a dearth of evidence as to whether learning food ingredients can help more accurate estimation of nutrition facts. Therefore, the aim of our study is two fold: (1) to develop effective computational models that accurately estimate nutrition facts of any given food, and (2) to investigate if computational modeling of food ingredients can help better estimation of nutrition facts.

Data Description. The USDA branded food products database[4] contains food description, nutrition facts, and ingredients for a large number of foods which are voluntarily supplied by food industry organizations to USDA. USDA standardizes the reported nutrition facts by calculating nutrient values per 100 grams from those values provided per serving. The dataset contains about 237K food items, 40 nutrition fact types, and 100K ingredient types respectively. It exhibits a power law distribution, $c \times \exp(-0.14x)$, as some nutrition facts match with only a small number of foods. Although the majority of foods in USDA dataset contain important nutrition facts, some food organizations provide no or partial information about their products. In addition, the dataset is updated on a yearly basis[4] and therefore many new foods do not exist in the dataset. These challenges inspires our work to develop computational models to automatically estimate nutrition facts from food descriptions.

Method. We developed multiple regression approaches including least squares Linear Regression (Linear) with L2 regularization (Ridge). In addition, the state-of-the-art approach for learning nutrition facts of foods given their descriptions was reported in[1]–a Convolutional Neural Network (CNN) which used word n-grams to match food items with USDA dataset to derive nutrition facts. We extended this approach through joint learning of nutrition facts and ingredients of given foods. In particular, as Figure 1 depicts, we developed a multi-task learning framework to enable joint learning of ingredients and nutrition facts given food descriptions. Note that nutrition facts were normalized scalars and learned separately (see Discussion), and ingredients of each food were represented by a vector of 0/1s with 1 indicating existence of a specific ingredient in the food. The shared layers were used to exploit commonalities.
and differences across tasks for more accurate learning. The network was trained by minimizing the following Mean Squared Error loss functions:

\[ L(I) = L_{\text{nutrition}}(I) + \alpha \times \beta \times L_{\text{ingredient}}(I) \]

where \( \alpha \in [0, 1] \) controlled the extent to which ingredients contributed in overall learning of the task; \( \alpha = 0 \) indicates no contribution and was considered as a baseline here (basic CNN), and the parameter \( \beta \) was used to establish a common scale for loss magnitudes across tasks\(^3\). Although, \( \beta \) could be tuned through grid search, we set \( \beta = L_{\text{nutrition}}^{0}/L_{\text{ingredient}}^{0} \) where \( L_{\text{ingredient}}^{0} \) indicates loss at first iteration. Both loss functions optimized minimum squared error (MSE). Our framework enables learning semantic relations between food items and ingredients, e.g. learning that “roasted” foods should have “oil” as their ingredients, as well as semantic relations between foods and nutrition facts, e.g. learning that “rice” generally has high calories. Such relations are important indicators for accurate prediction of nutrition facts as they capture aspects of nutrients which may not be effectively represented in food descriptions.

**Results.** Our multi-task learning framework was trained and tested on each nutrition fact separately. For each nutrition fact, we partitioned food items into training data (80%), development data (10%) for parameter tuning, and test data (10%) for evaluation. We used grid search to optimize \( \alpha \) for each nutrition fact using development data, then the resulting best model for each \( \alpha \) was applied to the test data. Models were compared based on Coefficient of Determination \( (R^2 \text{ score} \in (-\infty, 1], \text{where } R^2 = 1 \text{ indicates perfect regression}) \). Our multi-task learning framework outperformed Linear, Ridge, and basic CNN regressors on 70%, 55%, and 35% of nutrition fact categories respectively. In addition, Figure 2 shows the average \( R^2 \) performance over all nutrition fact categories for the top two best performing models, basic CNN and multi-task CNN respectively, across \( \alpha \) values. As the results show, \( \alpha = 0 \) led to \( R^2 \) of 22.40, while there existed other \( \alpha \) values, i.e. \( \alpha \in \{.1, .4, .8, .9, 1.0\} \), that further improved the performance. We attribute this improvement to our model’s ability in utilizing semantic relations between food items, and their ingredients and nutrition facts.

**Discussion.** In this work, we developed an effective regressor to accurately estimate nutrition facts of foods. Our work highlighted the importance of learning ingredients for accurate estimation of nutrition facts. Our research has high value for developing diet monitoring applications, which may generate results with significant public health impact. Future investigations might explore associations among food quantity and type with ingredients and nutrition facts. In addition, ingredients often have a hierarchical form, e.g. iodized salt, himalayan salt, and crystal salt can all be mapped to the ingredient salt, which could be utilized to create a better semantic space for ingredients. In addition, our learning framework is trained on each nutrition fact separately; joint learning of these facts might create stronger regressors.

Introduction: Since the 21st Century Cures Act was signed into law in 2016, there has been a growing interest in the use of Real World Data (RWD) and Real World Evidence (RWE) in healthcare. RWE has multiple uses – it can inform clinical practice guidelines and coverage decisions, provide information on drug safety for regulators and serve as endpoints in pragmatic clinical trials. One source of RWE, patient-reported outcomes, appears particularly well-suited to supplement adverse event reporting in the clinical trial environment, as they provide a patient-centric view of severity and impact of treatment side effects on quality of life (QOL). Internet and smart phone technologies now provide the opportunity to collect patient-reported outcomes in a more timely and efficient manner.

Here we describe the development and deployment of systems and related workflows for monitoring of patient reported adverse events (AEs) and QOL within an ongoing phase II breast cancer clinical trial using electronic patient-reported outcomes (ePROs) instruments. The instruments are administered within the Investigation of Serial studies to Predict Your Therapeutic Response with Imaging And mOLecular analysis (I-SPY 2 TRIAL), a phase 2, standing, randomized controlled, multicenter trial aimed to rapidly screen and identify promising neoadjuvant chemotherapy +/- new investigational treatments in specific subgroups of women with newly-diagnosed, high-risk for recurrence, locally-advanced breast cancer (stage II/III) that has been accruing since 2010. We will provide preliminary assessments of the feasibility and impact on the patient perceived quality of care and satisfaction.

Methods: The I-SPY 2 TRIAL currently has patients enrolled and randomized across 16 clinical sites in the United States. Paper-based QOL surveys include the EORTC QLQ-C30, EORTC QLQ-BR23, and PROMIS® measures and have been distributed by paper to patients starting January 2012. In previous work within the I-SPY 2 TRIAL, PROMIS® questions included in the paper-based I-SPY 2 QOL assessment were found to be the most appropriate and most sensitive for the early breast cancer setting. A decision was made to move from paper to ePRO in 2019. In the ePRO release, PROMIS measures selected address the following areas: Anxiety, Depression, Fatigue, Physical function, Sexual Function, and Sleep. For adverse events, the National Cancer Institute (NCI) had developed a patient-reported outcomes version of the Common Terminology Criteria for Adverse Events (CTCAE™), termed PRO-CTCAE™, which consists of a series of questions that characterize the frequency, severity and/or interference of 78 symptomatic treatment toxicities across 14 different domains. The PRO-CTCAE are focused on physical functions. These include symptomatic toxicities such as pain, fatigue, nausea, and cutaneous side effects such as rash and hand-foot syndrome. To reduce the survey burden on patients, I-SPY investigators, leadership and patient advocates identified a set of PRO-CTCAE domains/items relevant to the population to include in the ePRO survey.

Beginning in July 2019, we deployed the revised ePRO surveys to the OpenClinica (OC) Participate™ test environment and leveraged OpenClinica Insight™ for alerts and periodic reports of ePRO results. The reports will be sent to clinicians and site coordinators.

At the initial visit after the patient has consented, the site coordinator will link the patient’s email and subject ID in the OC Participate™ system. This information is encrypted in the study database. Three days prior to a specified visit requiring a survey, the patient is sent an email and/or short message service (SMS) notification requesting that they complete the assigned ePRO survey. Site coordinator will monitor data completeness. Patients who have not completed the survey prior to their visit are provided with a tablet computer with internet connectivity to complete the survey in the clinic waiting room and are supported by the site’s front desk personnel. The site coordinator will
confirm patient identification and have pre-loaded the web link to the survey to minimize patient burden. The site coordinator will pre-load the providers email information to ensure visibility in the clinic. Once the responses are captured and saved, the data results are normalized and available to investigators/providers. Thresholds will be established to send alerts/triggers to providers.

At the University of California, San Francisco (UCSF) Breast Cancer Clinic study site, we are piloting an integration with the UCSF Epic Electronic Health Record (EHR) system to receive the I-SPY 2 TRIAL individual patient ePRO results over time (Fig 1) into Epic for clinician review at the point of care. Patients at the UCSF site will be re-consented/consented to allow their PRO data to enter the UCSF EHR. An HL7 interface will be implemented to exchange data between UCSF’s Admission, Discharge, Transfer/scheduling systems and the I-SPY 2 Electronic Data Capture (EDC) system to establish the patient’s identity and match the summary ePRO report with the corresponding patient record in Epic.

Figure 1: Example plot available to providers within the UCSF Breast Cancer Clinic setting showing an I-SPY 2 patient PRO baseline result in relation to other I-SPY 2 patients in the study longitudinally through the course of the study.

Results: We will present results describing the feasibility of ePRO integration into I-SPY 2 by comparing historical paper-based survey completion rates to the ePRO completion rates over a three-month period. Patient summary ePRO reports and longitudinal plot summaries as shown in Fig 1 will be written back to the UCSF Epic system. We will compare historical paper-based QOL data to QOL collected with ePRO in the control arm to assess changes in the quality and accuracy of calculating QOL measures following ePRO use.

Discussion: Collecting patient-reported clinical trial data electronically provides the opportunity to extend the use of the data beyond the clinical trial research to: (1) provide clinicians with valuable summary information about that patient’s symptoms and quality of life at the point of care; and (2) provide real-time monitoring and alerts to clinicians for patients experiencing select adverse events or declining quality of life.

At the core of this project, transitioning from paper-based surveys to electronic surveys will improve the efficiency and accuracy of collecting patient-reported data for clinical trials. More importantly, however, will be the opportunities created by integrating this data with the EHR, transforming the uses of patient-reported clinical trial data beyond just efficiency to improve quality of care, patient safety, and health outcomes.
Characterizing the Urban Opioid Epidemic Using EHR Data

Amelia J Averitt, MPH MA MPhil; Benjamin H Slovis, MD MA; Abdul Tariq, PhD; David Vawdrey, PhD; Adler J Perotte, MD MA

ABSTRACT The opioid epidemic is a public health emergency. Unlike typical characterizations of individuals with opioid use disorder, this research leverages electronic health records (EHR) of a large, urban, academic medical center. We confirm the increase in opioid-related overdoses through the EHR data, present demographics, and analyze the data to highlight changes in medical encounters that surround the first overdose. These insights may inform abatement of the urban opioid epidemic in a targeted way.

INTRODUCTION Characterizing the opioid epidemic (OE) from a rich and inclusive data source is a keystone for its abatement. Many strategies towards abatement of the OE include prescription drug monitoring programs (PDMPs) or prescribing limitations. These methods aim to limit over-prescription of opioids, predominately at the state-level. However, important variations exist in lower-level geographic areas and at the individual level. A more informed approach to combating the OE would address opioid cases at the individual-level with consideration of geographic context. A thorough, longitudinal characterization of this cohort may support an individual-level intervention. Characterization of the OE is often done through the analysis of claims data or a manual review of clinical documentation. However, administrative claims data may be subject to coding biases and only captures billable encounters for the insured, and manual reviews of medical records is time-consuming. The electronic health record (EHR) is a rich, longitudinal data source that captures a variety of patients with greater detail. Unlike claims data, EHR data provides not only a means to uncover overall trends in overdoses (OD), but it also supports the identification of healthcare utilization trends that are common in OD patients. We present data on all non-heroin opioid ODs in the NewYork-Presbyterian Hospital (NYPH) EHR. We examine the OE in an urban environment, as recent estimates show that urban epidemic is worsening. In addition to tracking the frequency of ODs over time, we also contrast the healthcare utilization in the period just prior to and just after first OD. By characterizing patients according to patterns in their EHR, we provide another avenue that may support our understanding of the current OE in urban areas.

METHODS The NYPH EHR contains observational clinical data for 5.37 million individual subjects from 1986-2017. Patients encounters are documented in the EHR at each outpatient, inpatient (IP), and emergency room (ER) visit. Data modalities include, but are not limited to, diagnoses, clinical measurements, medications, and procedures. Case Identification. To investigate opioid OD in the NYPH EHR, we identified all non-heroin opioid OD patients between 1/1/2006 and 12/31/2015. We mapped validated codes for non-heroin ODs from ICD-9-CM to Observational Health Data Sciences and Informatics’ common data model concept IDs. Opioid OD patients (cases) who qualified for this review must have had at least one of these diagnosis codes in a hospital visit with the ER or as an IP. Trend Analysis. To confirm an increase in the number of opioid ODs at our institution, we fit a single effect Poisson regression to model the relationship between year (2006-2015) and the rate of admissions with opioid ODs out of all ER and IP admissions, regardless of diagnosis. Demographics Analysis. We present demographic data, such as age group, and sex, along with healthcare utilization, prescriptions, medical history, and death, for the subset of opioid cases. We present the same metrics over three periods of interest, (i) The Vanilla Period, which typifies the steady-state healthcare use of patients (12 to 6 months before OD); (ii) The Pre-OD Period that just precedes the first OD (6 to 0 months before OD); and (iii) The Post-OD Period that directly follows the patient’s first OD (0 to 6 months after OD). To better contextualize the opioid case cohort, we additionally present data on controls with no history of substance abuse. Controls were randomly selected to match the distribution of age and sex of the case cohort. Self-Controlled Disproportionality Analysis. To better understand patterns leading up to and directly after the first OD, we completed two experiments; (1) Pre-OD Analysis (Pre-OD Period vs Vanilla Period) to understand changes in exposures immediately before first OD; and (2) Post-OD Analysis (Post-OD Period vs Vanilla Period) to understand changes in exposures immediately after first OD. For the two experiments, we undertook disproportionality analyses (DPAs) to look at exposure signals in (i) conditions, (ii) procedures, and (iii) medications at the ingredient
hospitals, as the rate of opioid OD for IP and ERs at NYPH coincides well with the rates reported for New York City as a whole. The results of our demographics analysis (Table 1) demonstrate that a larger proportion of OD had prescriptions for analgesic drugs in all study periods compared to controls. When examining Opioid Analgesic, 8% of the control cohort held prescriptions for this medication class, while OD cases had notably increased opioid prescriptions in all study periods (16-30%). This implies that those with opioid prescriptions are at increased risk for OD.

Results of the self-controlled DPAs highlight trends that characterize the progression of our opioid case population. The DPA of procedures may indicate that a traumatic injury, intensive care treatment, or a scheduled surgical procedure took place just prior to the first OD. Similar high-odds procedures are seen just after OD, which may indicate that further traumatic injuries occur. No medications at the ingredient level were found to be significant. The DPA of conditions highlights the close relationship between drug abuse and mental health (Figure 2). The Vanilla+Pre-OD Period is marked by high pain conditions, which may suggest that ODs stem from legitimate prescriptions. The Post-OD Period is distinguished by complications of prolonged opioid use. However, in both periods, mental health appears to be strongly associated with opioid OD.

CONCLUSION The results of this analysis indicate that the continuum of the urban OE may begin with conditions associated with pain and that OD may be tied to legitimate prescriptions. Clinicians should consider that opioid dependence may develop in medically-necessary scenarios, and lead to an OD in the short-run. Informatics-based methodologies may play a role in better understanding those individuals who suffer from opioid dependency and OD, and may lead to future research and interventions that could successfully prevent morbidity and mortality associated with the OE.

Introduction

Pulmonary embolism (PE) is a life-threatening clinical problem and CT imaging is the current gold standard for diagnosis. In the past years, a substantial rise in the number of CT examinations for PE evaluation has been observed with a concomitant decrease in imaging yield (as low as 2 – 3% yield). Unnecessary use of CT not only carries risks due to radiation and intravenous contrast, but also the discovery of low impact incidental imaging findings which further expose patients to unneeded procedures, tests, and risks. Clinical decision support rules based on PE risk scoring models to inform CT imaging decisions have been developed but are underutilized, in part due to evolving risk factors for PE that are not included in static scoring systems (Wells, PERC, rGeneve). The purpose of this study is to design and evaluate a machine learning modeling approach for predicting PE imaging outcomes based on patient EMR data captured before the CT exam which includes demographics, vital signs (change from baseline), diagnoses, medications, lab tests, etc. In contrast with the current clinical scoring systems that rely on a very limited set of pre-selected EMR variables, our objective is to build a machine learning solution that can compute a patient-specific risk score for PE by utilizing complex correlation between hundreds of EMR variables without relying on hand crafted feature selection; we evaluate this model on intra- and extra-institutional patient data and compare to existing PE risk scoring systems.

Methods

Data

Internal dataset (SHC) – Using the STAnford medicine Research data Repository (STARR), we randomly retrieved 4512 contrast-enhanced CT chest examinations of adult patients performed between January 1, 1998 and January 1, 2016 at Stanford hospital and clinics (SHC). Each study was manually annotated by three experienced radiologists and assigned two binary class labels (PE present/absent and PE acute/chronic). Inter-rater reliability among the three raters were highly consistent for two categories, “PE presence” and “PE Acute”, with kappa scores of 0.959 and 0.969 respectively. Because we engineered the model to identify acute PE, we dropped chronic cases to generate the final annotated internal cohorts (SHC) of 3,397 annotated PE-CT exams from 3,214 unique patients (1704 women, mean (SD) age, 60.53 (+/- 19.43)). From the EMRs, we also extracted the following phenomic data and time stamps for these patients: (1) all diagnosis codes; (2) all inpatient and outpatient medications (normalized to RxNorm); (3) all laboratory data raw values; (4) all collected vital sign data (i.e. height, weight, BMI, pulse, respiration rate, systolic blood pressure, temperature, etc); (5) all demographics (i.e. age, race, gender).

External dataset (Duke) - As external dataset, we collected contrast-enhanced CT examinations of chest from Duke University Medical Center performed between January 1, 2013 and August 31, 2017. We retrieved similar set of phenomic data of these patients with encounter time-stamp details. The data were normalized according to the standards - RxNorm, IC9 code. In order to create an external annotated dataset for validation, we randomly selected 300 CT exams from Duke and performed manual annotation with the same group of radiologists. After dropping chronic case, the models were validated on 240 unique patients seen at Duke (132 women, mean (SD) age, 70.2 (+/- 14.2)).

Outpatient samples (SHC and Duke) - In addition, we also created separate outpatient dataset for SHC - 100 consecutive patients (67 women, mean (SD) age, 57.74(+/- 19.87)) and Duke - 101 consecutive patients (59 women, mean (SD) age, 73.06(+/- 15.3)), and these cases are independent from the internal SHC and Duke hold-out dataset.

Proposed System:

The PE prediction approach is outlined by the following problem statement: “Given a new patient encounter and access to prior structured EMR data (vitals, demographics, labs, inpatient and outpatient medication, diagnoses) predict the risk of pulmonary embolism (PE)”. This framing lends itself to be treated as a probabilistic classification
problem. The proposed workflow parses raw EMR data arranged as a timeline to transform into feature vectors of use in training a machine learning model based on PE imaging outcomes. For each patient, we defined their observation window as the 12 months leading up to a given prediction date (24 window of CT exam). Within the observation window, we created a feature engineering pipeline that computes a vector representation of the EMR snapshot of each patient by considering the temporal sequence within the records. The designed pipeline parse five core components of EMR - (1) all diagnosis codes (except current encounter); (2) all inpatient and outpatient medications; (3) all laboratory data raw values; (4) all collected vital sign data; (5) all demographics. Given the complexity of the EMR data and the requirement of temporality preservation, we carefully designed a EMR feature engineering pipeline able to parse varying types of EMR simultaneously while also tolerant of sparse records (a common limitation).

As machine learner algorithm, we used the same input features and compared between a regularized regression methodology, ElasticNet, and a novel deep learning model (PE Neural model) – an Encoder network with ReLU activation and sigmoid outcome. To optimize the hyperparameters of ElasticNet (regularization rate) and the PE Neural network architecture (number of hidden layers, learning rate, activation function, optimizer, number of epochs, dropout rate), we used Grid search on 10% training SHC training data to reduce overfitting. Trained models are then tested on hold-out intra- and new extra- institutional patient data as test sets as well as tested on separate intra- and extra- institutional outpatient population. We also compared the performance of trained machine learning models against three popular clinical scoring systems for PE- Wells, PERC, and revised Geneva.

**Results**

The performance of the machine learning models are summarized as AUC-ROC in Table 1. The models are only trained on a sub-sample of the SHC data in order to test the generalizability of the model on a same training population as well as on a different population from another institution. Both machine learning models scored high accuracy on the internal testset of 340 CT exams (PE neural 0.85 and ElasticNet 0.93) while ElasticNet model outperformed the PE Neural model (p = 0.013). Both machine learning models’ performance dropped on the external duke dataset compared to the internal hold-out SHC testset (PE neural 0.72 and ElasticNet 0.7). However, the AUC-ROC score stayed > 0.7 and both models performed equally well on the external data (p = 0.165) which shows the fact that even when trained on the SHC patients the models are generalizable to the Duke patients (Inpatient and Outpatient) population.

Given the criteria for usability of the clinical scoring systems for computing pretest probability, we randomly selected 100 outpatient samples from SHC and 100 from Duke, and created another hold-out cohort. We used the models that were trained using SHC patients and tested it on ED patients separately to judge the model performance of the ED cases in parallel with three popular clinical scorings (Table 1). The PE Neural model performed significantly better than the all other models/criteria on the Stanford and Duke hold-out ED patients including the ElasticNet model on the Duke data (p = 0.01).

**Conclusion**

In conclusion, we found that achieving prediction models based on available retrospective structured EMR data can consider multitudes of patient-specific risk factors and dependencies in order to arrive at a PE likelihood recommendation model is possible and these models may be more accurately generalized to new population distributions. Future work is needed in investigating the ideal application of these prediction models for clinical imaging decision support systems in suspected PE and ultimate effect on imaging utilization.
Implementing Predictive Analytic Models in Diverse Healthcare Systems: A Qualitative Study with Operational, Informatics, and Front-line Personnel

Natalie C. Benda, PhD¹, Erika Abramson, MD, MS¹, Lala Tanmoy Das, MS¹, Katherine Blackburn, MSPH², Amy Thoman, BS¹, Rainu Kaushal, MD, MPH¹, Jessica S. Ancker, PhD, MPH¹

¹Weill Cornell Medicine, New York, NY; ²University of Florida, Gainesville, FL

Introduction

Predictive analytics has the potential to identify vulnerable patients in time to prevent poor outcomes or allocate valuable resources, but in practice, the expectations have not been realized to the extent anticipated. Those attempting to implement predictive algorithms in medicine have encountered challenges related to: making the algorithms transparent to end users, ensuring algorithms are clinically meaningful, and establishing generalizability and interoperability between sites.¹,² Due to these issues, many models validated in research contexts are not meaningfully utilized in a clinical environment.³

The present study utilizes data analytic techniques and key informant interviews to develop a predictive algorithm to proactively identify patients who have high utilization of the healthcare system, so that preventative care interventions may be implemented earlier. Interviewees include operational, informatics, and front-line personnel to gain feedback from key informants with various scopes of practice. The combination of methods addresses gaps in current research that there is insufficient stakeholder engagement early on in algorithm development and the discrepancies between algorithms that are statistically predictive but not clinically meaningful or actionable.

We will focus on the results of the key informant interviews which aim to determine which stakeholders would find the predictive algorithm most useful, under what contexts, and how the algorithm may be operationalized across three diverse healthcare organizations. The results will be discussed in the broader context of important considerations in gaining early feedback from stakeholders for the development of clinically meaningful, actionable predictive algorithms.

Methods

We utilized semi-structured interviews to elicit feedback from key stakeholders including: operational leadership (e.g. chief medical officers, chief strategy officers), informatics personnel, and potential end users (e.g. care managers and primary care providers). Interviewees were recruited from healthcare institutions affiliated with the Clinical Data Research Network (CDRN) in New York City (INSIGHT) and the CDRN in Florida (OneFlorida). CDRNs are partnerships organized through the National Patient-Centered Clinical Research Network (PCORnet) to enable clinical research that is faster, easier, less costly and more relevant to patients’ needs.

Interview questions were developed based on Sittig and Singh’s sociotechnical model for studying health information technology in complex adaptive healthcare systems.⁴ Interviews covered broad themes, including: the utility of predictive modeling for the given context as well as barriers and facilitators to implementing and using predictive models in an applied environment. All interviews were conducted by the same moderator (NCB) accompanied by at least one additional member of the analysis team (EA, JSA, KB, TD). Interviews were audio recorded and transcribed. At least two members of the analysis team inductively coded each interview using group consensus coding.⁵ The institutional review board at Weill Cornell Medicine determined that this study was not human subjects research.

Results

Forty-eight total participants were interviewed to thematic saturation. Table 1 describes emerging themes with supporting quotations from interviewees.

Table 1. Key themes and higher level categories identified to date. Following each quote, the role of the person who conveyed this information (i.e. operational, informatics, or end user personnel) is listed in parentheses.

Discussion
Predictive analytics has the potential to aggregate complex information and inform key decisions in a healthcare setting. While creation of these models is data-driven, it is the humans in the system who must take action on the information to implement steps to facilitate patient care. Therefore, it is critical to understand practitioner needs, so that the models delivered may be meaningfully implemented and utilized. The results of this work demonstrate that successful integration of predictive models depend on a diverse set of factors related to institutional infrastructure, hardware/software constraints, the model itself, and the needs of front-line personnel. The results of this study will be discussed in terms of an implementation science framework to provide considerations for implementing predictive analytic models into applied healthcare settings.

Detecting Seasonal, Holiday, and Rare Events from Trauma Data in the Electronic Health Record

Timothy Bergquist, BS¹, Vikas Pejaver, PhD¹, Noah Hammarlund, PhD¹, Sean D. Mooney, PhD¹, Stephen Mooney, PhD¹
¹University of Washington, Seattle, WA

Introduction

Adoption of Electronic Health Records (EHR) has increased dramatically over the past two decades, creating opportunities to ask interesting population health data science questions. Most studies have focused on more traditional population health questions such as tracking chronic and infectious diseases and the geospatial mapping of those diseases.¹ The variety of patients that come to hospitals gives researchers opportunities to explore non-traditional population health questions. Recently, Melamed et al. linked diagnosis codes to seasonal trends and discovered a novel seasonal disease while also confirming previous literature on seasonally linked diseases.²

We explore the ability of EHRs to be used in detecting expected and unexpected trends as well as single-day injury or poison events at the university’s emergency departments. Our analysis finds codes that are statistically “enriched” (overrepresented) seasonally and daily. For instance, we confirm that injuries from snow sports like skiing, snowboarding, and snowmobiling are enriched in the winter months. Our work thus showcases the novel opportunities that EHR data can bring to population health.

Methods

We gathered ICD-9-CM diagnosis codes from all visits to the University of Washington Medicine system where at least one code fell in the category of Injury and Poisoning (E000-E999 and 800-999). The visits numbered over 3,000,000 and spanned from 1993 to 2017 across three main hospitals. We looked for enriched diagnosis codes for each of the four seasons and for each of the 365 days of the year. Each code count was propagated to its parent node in the ICD-9-CM hierarchy to enable detection of high-level diagnosis codes that are not used for billing purposes. To test for enrichment, we established a baseline frequency for each diagnosis code by counting the number of times the diagnosis code appears versus the total number of codes in the timespan of interest.

To test for seasonal enrichment, we grouped the code counts into each of the four seasons and used a binomial test to compare each of the code counts in the seasons to the expected rate of appearance calculated from the other three seasons. To test for each of the 365 days of the year, we established a baseline frequency for each code using all the data across the 24 years and performed a binomial test for each code in each day, where the total number of codes in the day were trials and number of appearances for the code of interest where success. In this manner, we generated a p-value for each code and could calculate a score by taking the negative log of the p-value.

Results

Seasonal Enrichment

We found that winter and summer had the most interesting profiles of seasonal enrichments. Winter was enriched for codes relating to winter sports, cold weather-related injuries, and slips and falls. Interestingly, toxic effect of alcohol as well as complications from surgical procedures were enriched. The summer months were enriched for injuries from animal and insects, burns and firework accidents (4th of July), boating accidents, and motorcycle accidents.
Figure 1. Visualization of the ICD-9-CM enriched codes for the summer season (June, July, August). The size of each node is proportional to the significance of the association between that code and summer. The lowest level nodes are the leaf or billable codes in the ICD-9-CM hierarchy, while the parent nodes are the increasingly broader categories of diagnosis. The most enriched codes are injuries related to fair weather activities such as boating accidents, fireworks from 4th of July, bug bites, and motorcycle accidents.

Day Enrichment

We identified 100 days on which at least one code was still enriched after a Bonferroni correction. Looking at the top scoring days with the highest scoring codes, we find that holidays and identifiable environmental events are disproportionately represented.

Days like July 4th and 5th have the expected enrichment of firework related accidents. January 1st has an enrichment of brawls, poisoning due to alcohol, and injury from fireworks. December 24th has an enrichment of alcohol poisoning and injuries undetermined whether purposeful or accidental.

We also detected one-time events, where a single day in a single year had an unusually high number of codes. We detected the Nisqually earthquake on February 28, 2001, where a high number of people came into the clinic for earthquake related injuries (E909.0). We also saw an increase in the number of carbon monoxide poisonings (E868.3) on December 15, 2006, which was the Hanukkah Eve windstorm where people were barbequing in their homes.

Discussion

While the events detected in this study may be obvious (July 4th and fireworks), future use of this method could expand to non-trauma diagnosis codes and incorporate other, EHR specific, data such as notes or lab results to bring more context to the diagnosis code enrichments and better inform the appropriate public health response.

Conclusion

We show that we can detect seasonal, holiday, and rare events in the EHR. These results showcase the potential utility of EHRs for public health, given the scope and depth of EHR data. Additionally, public health officials may discover novel events to help prioritize public health policy if a similar analysis is applied to non-traumatic diagnosis codes.

Continuum of Interoperability in Oncology EHR Implementations

Introduction

Interoperability is the “degree to which two or more systems, products or components can exchange information and use the information that has been exchanged.”1 With the widespread implementation of electronic health records (EHRs), there has been a great deal of attention focused on the ability to share structured (clinical) data between institutions; or, to be more precise, between EHR implementations2,3. However, interoperability has often been discussed as a binary property without consideration of the purpose. Clearly, it is possible for two systems to be able to share some data (e.g., demographics), but not others (e.g., laboratory results). In addition, the sharing of a particular data type may be suitable for one purpose but not another. Thus, interoperability is a continuum, rather than an absolute. To quantitate EHR interoperability, we determined the standards in use at oncology practices.

The American Society of Clinical Oncology (ASCO) launched the CancerLinQ platform that collects, aggregates, and transforms EHR data from oncology practices, for quality improvement and discovery.4 This presents the opportunity to evaluate the standards in use for structured data across a sample of oncology practices as well as the degree to which the EHRs implemented at these practices are interoperable with respect to structured data.

Methods

CancerLinQ data from 47 practices were analyzed with respect to the standards and variability of structured data including race, diagnoses, encounters, cancer staging, selected cancer-relevant medications, lab values and biomarkers. De-identified and aggregated data are presented. EHRs represented included ARIA, MOSAIQ, Allscripts, Centricity, Epic Clarity, Intellidose, NextGen, and OncoEMR. Although CancerLinQ collects individual patient data, this analysis was performed on aggregated data by vendor system. Our analysis focused on the data representation, rather than the content (e.g., the standard for representing laboratory results, rather than the laboratory results themselves); thus, no patient data were shared and/or analyzed.

We also analyzed a separate de-identified, aggregated data set from 48 installations of one of five EHR vendor products (Allscripts, ARIA, Epic Clarity, MOSAIQ, and OncoEMR) grouped by de-identified vendor. The specific data types analyzed are listed in Table 1 (results). For each data type, we divided the number of distinct inbound versions of a value mapped to a single codified value (e.g., the ways in which a particular laboratory test result was represented), divided by the number of implementations of that EHR. In addition, we calculated the total number of representations across all 5 of the EHRs and divided by the total number of installations of all five EHRs to assess the mean number of variants across all EHRs.

Results

Only 6 practices (13%) used non-standard race representation. All practices used ICD-9/10 for diagnoses. There was variability in coding of encounters. Sixteen practices always used Current Procedural Terminology (CPT), 5 practices always used Systematized Nomenclature of Medicine, Clinical Terms (SNOMED CT) and 26 practices used multiple standards. Multiple cancer staging systems were used. An average of 48% (range 11%-105%; including patients staged more than once) of patient records included coded staging information. Only one practice used a standard (Logical Observation Identifiers Names and Codes; LOINC) for laboratory data. No standards were used for medications or biomarkers. Table 1 shows the number of distinct inbound names for selected lab tests, medications, and biomarkers across implementations for the five EHRs with sufficient numbers of installations to make assessments. Each cell

1304
the table represents the number of distinct ways that the data item was represented in our sample, divided by the number of implementations. The row “All” represents the total number of distinct ways that the data was represented across all 5 system types. The row “Mean” represents the total number of inbound values for that data element (i.e. ‘All’) divided by the total number of installations of all EHRs.

### Table 1: Number of distinct names for selected data types

### Discussion

In this de-identified sample of 47 oncology practices, standards were used consistently for administrative data (diagnoses and encounters), often for race, and rarely for clinical data including medications, laboratory tests, and biomarkers. For data types where no standard was used, there was heterogeneity among vendor implementations in the consistency of representation. For example, vendor A typically has a mean number of inbound values less than 1.0 (reflecting homogeneity of values across implementations) but has a large mean (5.4) for inbound values of dexamethasone. The high mean number of inbound values seen for medications, particularly for specific vendors (e.g., vendors B and C), raises the question of whether standardization of EHR implementations might reduce confusion arising from medication spelling or trade names and have the potential to reduce medication errors.

We reviewed a relatively large number of practices with respect to common general and oncology-specific data types, including biomarkers. Other specialties may have different patterns of EHR implementation. Further, practices who choose not to participate in the CancerLinQ program may differ from the practices in our sample. Finally, our analysis does not address unstructured (text) data that pose different interoperability challenges compared to structured data.

Our results suggest that interoperability with respect to structured data is largely limited to billing data; probably due to payer mandates. Multiple projects, including CancerLinQ, have been able to map structured data across EHR implementations, involving significant manual effort. Large national and international efforts have been able to use observational data to reach novel and interesting conclusions. However, our results suggest that for the foreseeable future, interoperability will continue to require significant manual effort.

Institutions make EHR purchasing decisions in part on the basis of perceived interoperability. For example, an outpatient practice may choose the same vendor as a hospital with which they are affiliated. Our next steps will include analyses to determine whether it is the vendor or the implementation that has the most influence on interoperability. In other words, if two institutions share the same vendor, are their implementations more likely to be interoperable?

### Conclusion

With the exception of administrative data, few oncology practices used standards for structured data through their EHR. There were differences by vendor with respect to the likelihood of being able to share data of a specific type with other implementations of that vendor’s product.

Introduction

As the population ages, a key public health priority is identifying older individuals at higher risk of suffering an adverse health event. Identifying risk among the older adult population is a challenging task because chronological age is not a generalizable predictor of health status. Despite the utility of frailty to identify older adults at risk, outcome measures for frailty are not routinely used to predict risk in clinical settings, specifically on a population level.

The advent of electronic health records (EHRs) has facilitated the aggregation of many disparate pieces of clinical information collected about a given patient. In contrast to surveys, EHR data can be queried on a population level and integrated within a clinical setting making it well suited for automatic calculation of risk scores, including frailty. Indeed, EHRs represent a valuable source of data for frailty scoring, and ongoing development of frailty measures should consider what data is available in EHR to best use this growing data source.

In this study, we surveyed the literature to identify the most commonly-used variables by new and established measures of frailty. To characterize how well these variables are covered in EHR, we performed an overlap analysis between the variables uncovered in our literature review and the variables most commonly available in EHR systems (most commonly-available based on expert feedback and meaningful use criteria established by the Centers for Medicare & Medicaid Services).

Methods

We conducted a systematic review of literature to identify frailty instruments published between 1998 and March 2018. Frailty variables used in each of the frailty instruments were extracted, grouped, and categorized by type (e.g., clinical, social, behavioral, health services-related). The availability of the extracted frailty variables was evaluated by experts across various data sources (e.g., EHRs, administrative claims, and surveys).

Results

We identified 138 studies representing the same number of unique frailty instruments. We extracted 539 unique variables from the frailty instruments. Clinical variables were the most commonly-used variables across the frailty instruments (n=516; 87%), while social and health services factors included considerably fewer variables (n=33; ~5% and n=32; ~5%). Most frailty instruments require at least one variable that is not routinely available in EHRs or claims (n=115; ~83%). Only 23 frailty instruments have the potential to completely rely on EHR and/or claims data, and therefore possibly be operationalized on a population-level dataset (Table 1). We also analyzed the distribution of data types (e.g., EHRs vs. surveys) among variables extracted from the reviewed frailty instruments (Figure 1).

Figure 2: Distribution of potential data sources for 593 variables used in 138 frailty instruments

EHR-ST: EHR-Structured; and, EHR-FT: EHR-Free Text; Sorted based on the ratio of survey-only variables within each frailty instrument
Frailty instruments on the left predominantly include variables that are collected by surveys, while instruments on the right mostly include EHR-based variables. Frailty instruments in the middle can use a mix of data sources.

Discussion & Conclusion

Given the widespread adoption of EHRs and the push for value-based outcomes in the U.S., EHR-based frailty instruments can be a useful tool to stratify risk and better allocate resources among the older adult population. Unfortunately, many existing frailty measures are predominantly survey-based, are time-consuming to administer and fail to leverage the wealth of possible information in EHRs. More work is needed to develop and assess standardized, pragmatic, and generalizable EHR-based frailty instruments for clinical or population health management purposes.

Protecting Patient Privacy in Survival Analyses

Luca Bonomi, PhD1, Xiaojian Jiang PhD2, Lucila Ohno-Machado, PhD MD1
1UCSD Health Department of Biomedical Informatics, La Jolla, CA
2UT-Health School of Biomedical Informatics, Houston, TX

Introduction. In healthcare applications, survival analysis can provide useful insights on effectiveness of treatments, hypotheses testing, and outcome prediction through the analyses of temporal events.1,2 A variety of models have been proposed to conduct survival analyses, namely: parametric, semi-parametric, and non-parametric, which differ on the assumptions of the underlying distribution of time-to-events (e.g., recurrence, re-hospitalization, death). On one hand, parametric methods assume that the underlying data distribution is known a priori, and use statistical models (e.g., deep learning models) to learn the relationship between covariates and the outcome. On the other hand, non-parametric/semi-parametric methods require fewer assumptions and estimate the survival distribution directly from the data. While these methods can benefit clinical and epidemiologic research, sharing survival results may pose privacy concerns. Several previous privacy studies have shown that sharing aggregated results may lead to privacy disclosures.3,4 As survival analyses rely on statistical primitives (e.g., counts of time-to-events), they pose similar privacy risks. For example, an adversary who: (1) has knowledge of the time-to-events of individuals in the case and control group at a certain time (e.g., previously released survival curves), and (2) knows that a person of interest recently joined the study, may infer the presence of such an individual in the specific subgroup (e.g., in the “case” group of a case-control study), as the released curves are updated. Consider for example, the situation represented in Figure 1, where s2 is a previously released survival curve and s1 is a new updated version of the curve. Then, the difference between these curves reveals that a new patient with an event at time 42 recently joined the group, thus potentially revealing sensitive phenotypes (i.e., the individual is a “case”). Current privacy solutions for survival analysis provide limited privacy protection against such an attack. Several security solutions rely on cryptographic methods to encrypt data statistics to protect data access.5 However, those methods are vulnerable to privacy attacks in the presence of a malicious user who has access to the statistics. Other approaches use data perturbation to provide privacy protection.6 However, those solutions are unable to provide provable guarantees, as those methods may be vulnerable in the presence of an adversary with auxiliary information (e.g., previously released curve). In this paper, we outline our on-going study on privacy methods for survival analyses, which aims at assessing the privacy risks in survival analyses and developing privacy-protecting solutions based on the formal privacy model of differential privacy.7

Method. In this work, we focus on the study of the Kaplan-Meier non-parametric model, which is one of the most widely used methods in survival analyses.

**Privacy Solution.** In our work, we use the notion of \( \varepsilon \)-differential privacy,7 which provides provable privacy protection to the individuals contributing the data by introducing carefully calibrated noise. Intuitively, differential privacy ensures that the probability distribution on the released statistics should be “roughly the same” regardless the presence/absence of any individual, thus providing plausible deniability. Traditional differential privacy solutions introduce a perturbation noise on the output results. Because survival studies may span over a large period of time, traditional output perturbation methods may produce

![Figure 1 An adversary who compares the two curves s1 (updated curve) and s2 (past curve known to the adversary) can learn that their difference is due to an event at time unit 42. Thus, learning that an individual patient with an event at time 42 contributed to the updated curve.](image)

**Table 1** Mean absolute inference error (MAIE) in time units and mean absolute error (MAE) in probability for the original survival curve (KM) and our differentially private solution (DP-KM) with different privacy parameter (\( \varepsilon \)) and data size (N).

survival curves with limited usability. To overcome this challenge, we propose a solution that reduces the number of data releases by compacting the stream of events into partitions, in which the survival probability can be accurately computed over time using an input perturbation mechanism. Overall, our framework comprises of three main steps: (1) data partitioning, (2) survival curve computation via input perturbation, and (3) post-processing to enforce consistency in the released curve (e.g., monotonicity).

Privacy Risk Measures. In the $\varepsilon$-differential privacy model, the adversary’s probability of inferring the contribution of an individual in the survival curve is only a factor $(1+\varepsilon)$ larger than the probability without the inclusion of such an individual in the study. Thus, the privacy parameter $\varepsilon$ bounds the privacy risk of disclosing the participation of each individual in the study. In addition, we consider an empirical inference risk related to the disclosure of exact time-to-events. In this case, the adversary has prior knowledge about the time-to-events of other individuals and, by observing the released curve, the adversary aims at learning the exact time-to-event of an unknown individual in the study. We evaluate this empirical privacy risk by measuring the mean absolute inference error (MAIE) in reconstructing the time-to-event. Intuitively, the inference error measures how accurately the adversary can infer the time-of-event of the target in the data. Higher values of inference error indicate lower privacy risk for the patients participating in the study.

Results. We conducted our preliminary evaluations using the Surveillance Epidemiology and End Results (SEER)$^8$ dataset from which we sampled $N \in \{1000, 10000\}$ patients from 707,157 breast cancer patients with first diagnosis from 1973 to 2015. We evaluated the privacy in terms of mean absolute inference error (MAIE), while the utility of the released curve by our differentially private Kaplan-Meier method (DP-KM) was measured in terms of mean absolute error (MAE) with respect to the original non-private Kaplan-Meier survival curve (KM). From Table 1, we observe that the MAE for the non-private curve is as low as 1.75, which indicates that a knowledgeable adversary can re-construct the time-to-event with high accuracy (i.e., within 2 time units). With our DP-KM method we can significantly lower such a privacy risk, in fact the inference error of the adversary is now around 200 time units. We also notice that the released curve by our method closely resembles the original survival curve, as we can see from the small MAE values in Table 1 and from the visual comparison in Figure 2.

Conclusion. Our preliminary results quantified the privacy risk in sharing exact survival results, in particular when the number of patients in the study is small. Furthermore, we demonstrated that our differentially private method can significantly reduce the privacy risk while retaining the utility of the survival curve. As a future research direction, we plan to extend our privacy analysis to other survival models.

Introduction

Deploying accurate computable phenotypes in pragmatic trials requires a trade-off between precise and clinically sensible variable selection. For individuals with Opioid Use Disorder (OUD) who would benefit from medication-assisted treatment (MAT) in the clinical setting of the emergency department this study developed a phenotype using clinically available variables, and validated it in two health systems. OUD is a “problematic pattern of opioid use leading to clinically significant impairment or distress”2. The study was to support a pragmatic trial of a clinical decision support system to aid emergency physicians evaluating patients with OUD by initiating MAT and referring them for follow-up care. In addition to validating the phenotype’s accuracy, the team performed an evaluation of the gold standard diagnostic criteria. For OUD, the gold standard is meeting 2 of the 11 criteria and further qualifications listed in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5). These criteria generally describe “A problematic pattern of opioid use leading to clinically significant impairment or distress”2.

Methods

125 random patient charts were retrieved from Health System A, and 106 from Health System B. Both health systems consist of academic medical centers with extensions into urban and rural hospitals providing the majority of regional care. Not all charts met the computable phenotype. These charts represented a sample of the OUD patient-population, rather than the true prevalence of disease. Charts from Health System A were assessed using the algorithms in Figure 1, with two emergency medicine-trained physicians as reviewers and a third as adjudicator. In Health System B, the same validation process was performed; however, due to a small sample meeting algorithm 2, the algorithms were combined into a single phenotype. Given that population invariance conditions were not met, both in terms of the denominator problem3 and site comparison, a population sensitivity and specificity was calculated rather than a true prevalence-based sensitivity and specificity.4 Reviewers were asked to identify the DSM criteria associated with each case as a reference standard.

Results

In Health System A, inter-rater reliability was high, with a $\kappa$ of 0.9. Algorithm 1 had a positive predictive value of 0.96 (95% CI 0.863-0.995) and a negative predictive value of 0.98 (95% CI 0.893-0.999). Algorithm 2 had a positive predictive value of 0.8 (95% CI 0.593-0.932) and negative predictive value of 1.0 (one-sided 97.5% CI 0.863-1). In Health System B, inter-rater reliability was high, with a $\kappa$ of 0.85. The combined phenotype had a positive predictive value of 0.95 (95% CI 0.851-0.989) and negative predictive value of 0.92 (95% CI 0.807-0.978).

The most common DSM-5 criterion selected by the reviewers at both Health System A and Health System B was “opioids are often taken in larger amounts or over a longer period than was intended”. In Health System A, the least common criteria were those which express social dysfunction related to the use of opioids (including “recurrent opioid
Figure 1: Flow diagram for inclusion in the phenotype algorithms from left to right (Algorithm 1 and Algorithm 2). MOUD: Medication treating Opioid Use Disorder.

use resulting in a failure to fulfill major role obligations at work, school, or home” or “important social, occupational, or recreational activities are given up or reduced because of opioid use”). In Health System B, the least common criterion was “important social, occupational, or recreational activities are given up or reduced because of opioid use”.

Discussion

The phenotype performed well, with excellent positive and negative predictive values. For medical decision making, this provides a highly sensitive and specific means to classify patients such that they can be evaluated for the initiation of MAT. The reviewers’ evaluation of DSM-5 criteria suggest that diagnostic decision-making is being primarily made on the use of opioids over a threshold of temporality or magnitude of prescription. Furthermore, the patients’ social history in the context of OUD\(^5\)\(^6\) was not found to be present as a diagnostic criterion within the charts. While the DSM-5 diagnostic criteria are specific in identifying and defining OUD, they were noted upon debrief as having generally been inferred by reviewers from the patient’s history and limited documentation. It is suspected that this inference is due to the limitations of social history and emergency department documentation derived from the documentation focus of the Centers for Medicare and Medicaid Services guidelines. As such, in the pragmatic context, patients classified as having OUD will require a complete social history and psychiatric evaluation during the MAT referral process with results to be used both in terms of clinical operation and improving diagnostic precision.

The Process of Developing, Validating and Operationalizing a Personalized Machine Learning Algorithm for Clinical Decision Support: A Case Study

Sara K. Chokshi, DrPH, 1 Ji Chen, MS, Roshini Hegde, MA, Javier Gonzalez,1 Eduardo Iturrate,2 MD, Yindalon Aphiryanaphongs, MD, PhD,1 Devin M. Mann, MD, MS1,2

Introduction: Clinical decision support (CDS) alerts are designed to promote appropriate vaccinations and other evidence-based practices. Effectiveness of CDS alerts is blunted by the expansion of alerts in the EHR in recent years, leading to a growing epidemic of “alert fatigue” (a term describing a clinician’s desensitization to an overwhelming number and quality of safety alerts),1,2 and causing clinicians to ignore or respond inappropriately to alerts. Optimization of CDS tools has historically focused on manual approaches that are time consuming, difficult to maintain, and static, limiting their scalability. In their application of Signal Detection Theory to the study of CDS effectiveness, Ong and Coiera found both clinician performance and user experience are compromised as a result of a large quantity of alerts and poor alert reliability.3 These system-level factors created a high degree of system “noise,” detracting from the perceptibility of appropriate alert fires. Individual-level factors, including clinicians’ bias toward ignoring alerts and poor signal detection, combine with system-level factors to degrade CDS effectiveness and user experience.4 Machine learning (ML) is a powerful tool for identifying patterns in complex data by using past data to predict future performance. ML applied to EHR data, specifically, shows signs of promise as a tool for improving safety and quality of care. An EHR- integrated ML algorithm may be a powerful tool to increase the signal to noise ratio of CDS alerts and positively impact clinician interaction with alerts.

Objective: The objective of this paper is to describe the process of the development, validation, and implementation of a novel, ML-based CDS model (SmartCDS ML) that suppresses low value vaccination alerts.

Methods: We employ a case study approach to describe the process by which we developed, validated and operationalized a ML model to suppress shingles vaccinations alerts that have a high likelihood of being ignored. Using the shingles vaccination alert as our initial use case, we leveraged historical EHR interaction data (clicks) and patient/provider sociodemographic data to build and train a ML model that could predict the likelihood of provider interaction with the shingles vaccination alert [in submission].

Results: Model development (SmartCDS ML). The initial component of the process relates to the building of the alert suppression ML model. The initial building of the model involved historical data query to extract data related to the shingles vaccine alert, for which key data elements to be extracted from EHR databases were determined using a combination of descriptive analysis and clinical experience. After data cleaning, analysis was conducted, including examination of the historical changes in alert to determine the optimal time period from which to extract data for model training. Initial analysis examined average response rates for the alert as well as provider interaction with the alert for the purposes of determining an appropriate protocol for assigning one unique provider to each alert encounter. Large variation between clinicians in terms of frequency of interaction with the alert (0-92%), prompted our team to construct a variable for individual clinician activity history which was expanded to a short and a long term activity history variable; additionally, we included demographic variables for both clinician and patient in the model. Once the predictive variables were constructed, we then built and trained the whole model (SmartCDS ML), further refined the predictive variables and optimized model parameters over the following month.

Building operational capacity for SmartCDS ML implementation. To implement the SmartCDS ML model we built a new data architecture (Figure 1). The overall Smart CDS system is broken into three components: (1) The data extraction module which identifies (a) outpatient visits (or inpatients) for the next day with the intent to identify upcoming vaccine alerts to suppress, and (b) queries the EHR and extracts the variables required to run the ML module; (2) SmartCDS ML itself: the machine learning module built as described above; and (3) The suppression module, which leverages a series of application programming interface calls to the EHR to communicate which alerts to suppress. The data extraction module queries the EHR and extracts features then passed to the ML module. We worked with our enterprise IT team to determine the appropriate web service to “call,” created the rules necessary to appropriately respond to the data sent to that endpoint and, if appropriate, suppress the target alert (the shingles vaccination alert in this case).
Once built, we validated the SmartCDS system with the shingles CDS alert. Using data from the prior month, we suppressed shingles vaccination alerts if the likelihood of the provider interacting with the alert in that visit fell below a predefined threshold, using a conservative threshold of 50% suppression. Applying the model to live data extracted from our predefined views, we optimized the ML script, allowing for further feature engineering. From this process we generated model predictions (to suppress alert or not) which were saved the local database. The model is re-trained daily incorporating latest data changes to update the score threshold used to make decisions on upcoming hospital visits the next day. The SmartCDS system was designed to be modular and orthogonal with regard to call frequency, instrumentation, and configuration, allowing for easy adaptation to new environments. To ensure that the system is running properly from a safety and operational perspective, and to monitor process outcomes of interest, we developed a reporting dashboard.

**Discussion:** This paper describes the steps and considerations involved in the development and implementation of a ML model for suppressing low value alerts in the EHR and its application to the shingles vaccination. As predicted in our simulation, validation of the SmartCDS system demonstrated substantial reduction in shingles vaccine alerts at a limited vaccine ordering expense. The development of a robust reporting structure allows for the logging and monitoring of the system and its impact on clinical outcomes, which are necessary to ensure the stability and safety of the system. Future work, in line with the goals of our learning healthcare system, will involve adapting and applying the SmartCDS system to other vaccine alerts, further development of a reporting dashboard with effective, user-centered data displays, and the inclusion of an implementation theory informed process for establishing institutionally-aligned thresholds for alert suppression.

**Conclusion:** A ML model can predict future alert interactions and safely suppress low yield alerts. These results support a full-scale implementation of the SmartCDS system to reduce alert fatigue and optimize vaccination ordering by reducing the amount of alerts required to facilitate clinicians’ vaccine ordering.

A bring-your-own-device (BYOD) model for contributing mobile health (mHealth) data enables real-world data collection as patients go about their daily activities. To date, most mHealth research studies provision a specific wearable device (i.e., Fitbit) and have a constrained study period during which data is collected. A BYOD mHealth model allows for capturing data from patients’ routine lives and has efficiencies at scale, allowing researchers to better understand patient trajectories in a real-world deployment of devices. There are growing examples of BYOD data contribution for the purposes of research including the PCORnet Inflammatory Bowel Diseases (IBD) Partners (formerly Crohn’s and Colitis Foundation of America) patient-powered research network and NIH’s All of Us Research Program, where participants can currently contribute their Fitbit data.

IBD Partners allows for a wide range of wearable devices and apps to be connected to our research platform. This facilitates mHealth data contribution for those who participate in our longitudinal Internet cohort study. These mHealth contributors can connect different devices over time and can view their data trends in the IBD Partners patient portal. Participants also contribute self-reported survey data on health outcomes, such as disease activity, as well as on patient-reported outcomes such as depression and anxiety.

While BYOD has many benefits, there are also challenges due to the diversity of both devices/apps and usage patterns that come with real-world data generation. As this BYOD data contribution model is still an emerging one, there is little known about how many patients will choose to contribute their mHealth data, and how those patients may differ from those who do not. We examine which brands are represented across mHealth contributors within the cohort, the patterns for device wear-time (usage) among these participants, and blocks of missingness where devices/apps were not used. In this oral abstract, we present an overview of the characteristics of a BYOD mHealth study, Precision VISSTA, which is an NIH-funded study that seeks to develop preprocessing, machine learning, and data visualization methods for mHealth data to generate precision health recommendations for patients with IBDs as the initial use case.

Methods

Descriptive statistics were used to summarize sample characteristics and to examine patterns across mHealth data for physical activity and sleep. Two-sample t-tests were used to evaluate differences between mHealth data contributors versus those who were not for disease activity (Simple Colitis Activity Index (SCAI) for ulcerative colitis; Simplified Crohn’s Diseases Activity Index (SCDAI) for Crohn’s diseases) and patient-reported outcomes for depression, anxiety, sleep disturbance, social relationships, and pain interference.

Results

Of the 10,090 patients enrolled thus far, 437 patients have contributed mHealth data. ~71% of patients who contributed mHealth data were female, 91% were White, the majority were between the ages of 18-60 years old (18.5% 18-25 years, 44.6% 26-40 years, 30.9% 40-60 years), and 78.3% had a college or graduate school education. Of those who connected device(s)/apps to contribute mHealth data, 62% had Crohn’s disease and 36% had ulcerative colitis. For distribution of device/app brands across the cohort, 67% were Fitbit, 10.3% Garmin, 5.6% Strava, 5.2% Under Armour, 4.1% Jawbone, 2.1% Moves App, 1.8% RunKeeper, 1.3% Withings, 0.8% Microsoft, 0.6% Map My Fitness, 0.6% Misfit, 0.4% Fatsecret, and 0.2% Nike+.

Figure 1a visualizes various patterns of step count data in two patients as an example; blocks of missing data are shown in white. Patterns differ across the day of the week for some participants, while others have more heterogeneity in their step count patterns. The majority of participants have contributed between 6 months to 3 years of mHealth data (Figure 1b) and the size of blocks of missing data ranged from one day to ≥4 weeks (Figure 1c).

On average, participants had 5,384 total steps per day and 6.8 hours of total sleep per night. Approximately 29% of who contributed mHealth data had at least 150 minutes of moderate-to-vigorous physical activity per week. We
observed differences in outcomes for mean IBD disease activity scores for those who contributed mHealth data versus those who did not (SCAI=2.9 vs. 3.1, p=0.003; SCDAI=124.7 vs. 140.7, p<0.0001). For mean patient-reported outcome scores in the domains of pain interference, depression, anxiety, fatigue, social relationships, those who contributed mHealth data had better scores than those who did not [49.75 vs. 51.40, p<0.0001 for pain interference; 49.48 vs. 50.23, p<0.0001 for depression; 51.12 vs. 51.99, p<0.0001 for anxiety; 53.84 vs. 54.30, p=0.01 for fatigue; 50.85 vs. 49.24, p<0.0001 for social relationships (higher score is better for social relationships; lower score is better for pain interference, depression, anxiety, and fatigue)].

Figure 1. Example of step patterns and distribution of data contributions and missing data block size.

When mHealth data is examined in aggregate for an individual and for the cohort, there are both common patterns (such as weekday vs. weekend patterns in sleep; see Figure 1a) and systematic differences between brands (Figure 2a and 2b). For some sleep variables, such as deep sleep, changes in the algorithms that process sleep data can also be seen (i.e., August 2017 in Figure 2b).

Figure 2. Patterns of sleep across brands.

Conclusions

Thus far, ~4% of the IBD Partners Internet cohort have contributed mHealth data using our BYOD model across various brands. Participants were mostly female, educated, and less than 60 years old. The majority have either Fitbit or Garmin devices. Those who track and contribute mHealth data have significantly better disease activity scores and patient-reported outcomes. However, the difference in scores may not all be clinically significant. When examined in aggregate across the population, there are systematic differences across brands of devices/apps for physical activity and sleep. Our analyses suggest that simple visualization techniques can expose important features of mHealth data, such as changes in software algorithms that process the data. Ongoing work seeks to address challenges in preprocessing to deal with missingness and sparsity and the batch effects seen across brands of devices/apps.

Precision VISSTA: Machine Learning Prediction and Inference for Bring-Your-Own-Device (BYOD) mHealth Data

Tim Coleman¹, Lucas Menth, PhD¹, Kimberly Glass, PhD²-³, David Gotz, PhD⁴, Nils Gehlenborg, PhD³, Arlene E. Chung, MD MHA MMCI⁴
¹University of Pittsburgh, Pittsburgh, PA, USA; ²Brigham & Women’s Hospital, Boston, MA, USA; ³Harvard Medical School, Boston, MA, USA; ⁴University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Introduction

Precision VISSTA is a bring-your-own-device (BYOD) mobile health (mHealth) patient-powered research study focused on Inflammatory Bowel Diseases (IBDs). Participants report longitudinal survey data on outcomes such as disease activity along with patient-reported outcomes like as sleep disturbance, while also contributing mHealth lifestyle data from various wearable devices and apps (24 types). IBD patients have extremely heterogeneous phenotypes with symptoms that fluctuate. Prior work has suggested an association between increased self-reported physical activity and decreased disease activity¹, while self-reported sleep disturbance has been associated with increased disease activity². However, the precise nature and quantity of activity and sleep associated with improved outcomes is not well established. Our mHealth dataset contains numerous features describing physical activity and a number of other lifestyle characteristics, allowing for large-scale analysis of the features most associated with IBD disease activity and symptoms. Because of the complex underlying relationships within the data, we considered a number of flexible machine learning (ML) approaches in order to avoid the rigid model structure imposed by most traditional statistical models. We leveraged recent theoretical results on inference for supervised learning ensembles to develop and implement permutation-style hypothesis tests for feature significance on these otherwise “black-box” models. The primary study objectives were: (1) to formally establish the predictive relevance of mHealth features in forming more accurate predictive models than could be obtained with survey data alone, and (2) to infer which specific mHealth lifestyle features are most predictive of outcomes for patients with IBDs.

Methods

To determine whether disease activity [Simplified Crohn’s Disease Activity Index or SCDAI for Crohn’s disease (CD); Simple Colitis Activity Index or SCAI for ulcerative colitis (UC)] and patient-reported outcomes (depression, anxiety, pain interference, sleep disturbance, social relationships) could be accurately predicted using mHealth lifestyle data, we constructed various machine learning models and conducted significance tests for features within this framework to account for potentially complex, nonlinear relationships. Our analysis takes data from three sources: (1) survey data on outcomes, (2) demographic information from surveys, and (3) mHealth data collected longitudinally as patients complete surveys, including device or app type. We aimed to determine whether mHealth data adds predictive power beyond what can be learned from survey data alone (data sources 1 and 2). For each outcome, we conducted a cross-validation (CV) analysis to select the optimal ML method for forecasting patient outcomes on their next survey. Models considered included best subset regression (Best Reg), elastic net, random forests (RF), conditional inference random forests (C-RF), gradient boosting (GrBoosting), partial least squares (PLS), and multivariate adaptive regression splines (MARS), with each model carefully tuned using the R package ‘caret.’ For each outcome, models were ranked according to their 5-fold cross-validated mean squared error (MSE) with better models attaining lower average rank in terms of generalization error. As a baseline, partial F-tests were conducted for each mHealth data type and outcome. We then conducted inference on those models identified as highly accurate in the CV analysis and tested whether a model trained on all features (i.e. demographic and prior survey data with mHealth data) attains equal generalization error to one trained using only prior survey outcomes and demographic information. Features with missing values were imputed using a RF model to iteratively predict missing values based on other complete feature information. The hypothesis tests for significance were carried out using a permutation-style procedure informed by recent work on inference with random forests.⁴⁻⁵

Results

The analytic sample had 539 inter-survey observations from 371 unique patients, of which 332 observations came from CD patients and 228 from UC patients. The cross-validation analysis consistently suggested that C-RF and elastic net models generated the most accurate predictions across outcomes. The overall tests for significance
indicate that, in aggregate, mHealth data was predictive of pain interference across all three tests with more modest evidence for an effect on SCDAI disease activity (CD), social relationship, and depression scores (Table 1). The more granular tests for predictive significance of individual mHealth features suggest that time spent in moderate-to-vigorous activity (active_duration) was predictive of pain interference and disease activity for patients with either CD (SCDAI) and UC (SCAI) in the elastic net models (Figure 1). The tests on the elastic net model also suggested that distance traveled throughout the day was predictive of disease activity for UC patients and also predictive of sleep disturbance, fatigue, and depression scores across patients. While total hours of sleep (total_sleep) was only predictive of disease activity for patients with UC (SCAI), it was also predictive for depression and pain. Total steps per day was only strongly predictive for disease activity in patients with CD. Tests conducted on the conditional inference random forest model detected fewer significant results, and water consumption was the only mHealth feature consistently shown to improve predictions across outcomes. We suspect, however, that this may be an artifact of its low correlation with other features rather than an indication of strong predictive power.

Table 1. P-values for overall effect of aggregate mHealth features by outcome and test procedure. *p=0.05, **p=0.01

Figure 1. Conditional inference random forest and bagged elastic net results by mHealth data type and outcome.

Conclusion

Elastic Net and C-RF were identified as the top performing ML models with improved predictive accuracy when prior outcomes were included as features. C-RF models are inherently more flexible, and thus, we found fewer marginally significant predictive features since the models can better account for lost signal by detecting more complex signals from other available features. Best subset regression models performed poorly, demonstrating that traditional linear models fail to capture substantial predictive information contained within the mHealth data. Significance tests suggested that mHealth data are predictive of pain interference, even when accounting for prior patient-reported outcomes data. Moderate to vigorous physical activity (active_duration) was also highly predictive of IBD disease activity in both UC and CD patients in the elastic net models, while steps were predictive only for those with CD.

Quality Analysis of the All of Us Research Program Health Surveys

Robert M. Cronin, MD,1 Sarah Feng, MS,1 Brandy Mapes, MLIS,1 Roxana Loperena-Cortes, PhD,1 Regina Andrade, MS,1 David Schlundt, PhD,1 Kenneth Wallston, PhD,1 Mick P. Couper, PhD,2 Scott Sutherland, BFA,3 Cindy Chen, PhD,1 Joshua C. Denny, MD, MS1

Introduction

The All of Us Research Program (All of Us) is recruiting a million participants reflecting the rich diversity of the U.S. population to advance the science of precision medicine[1 2]. A variety of data sources will contribute information about a participant including health surveys, electronic health records (EHRs), and biospecimens. Collecting these data into a central resource will enable deeper exploration of biological, clinical, social, environmental and behavioral determinants of health and disease. Health surveys have been an important part of observational research and will play an essential role in All of Us. Prior to public release, these materials were rigorously created, evaluated and approved[3]. Methods included creation of initial survey content, translation into Spanish, qualitative and quantitative assessment, and review by Program experts. There are three surveys made available to All of Us participants at baseline: Basics, Overall Health and Lifestyle. These surveys focus on demographic information, general health, alcohol consumption, substance use, and smoking.

All of Us began collecting health survey response data in May 2017. Participants answer health survey questions via an online participant portal application developed by the Participant Technology Systems Center (PTSC). The participant portal is available on both computers and mobile devices, and guides participants through surveys to be completed. The data are subsequently sent and stored in the Data and Research Center’s (DRC) Raw Data Repository (RDR). Standard integration processes are in place, including end-to-end testing, to ensure data is seamlessly sent from one system to the other. However, there is a need to ensure the utility and quality of the data is intact prior to its future release to researchers. The Quality Assurance assessment presented in this podium abstract will serve as the first instance of full health survey response data review since surveys were integrated into these complex systems and publicly released. The scope of this assessment was to extract, review, and analyze the All of Us survey responses to confirm data integrity, alignment with expected values from other studies (where appropriate), and data missingness.

Methods

We analyzed data from the first three surveys in All of Us received between May 2017 and December 2018. Survey questions are available at https://www.researchallofus.org/. All data were stored on a Federal Information Security Management Act (FISMA) approved virtual machine. Data was extracted and transformed from its structured organization within the RDR into a single file compatible with statistical software. A codebook, describing the survey hierarchy, served as a reference guide for this work. Identifiable string values such as name were excluded. Analyses of the data included frequency distributions, missingness, and flagging potentially problematic data elements.

Statistical analysis: Two major statistical software packages were used to conduct analyses for this project: SPSS and R. The majority of these analyses were conducted by a member of the DRC team with expertise in both quantitative analysis and psychosocial metrics. A second statistician on the DRC team provided additional review and replication of the analyses as a method for confirming the validity of the data and performance of the questions in instances when areas identified for more granular inspection were prioritized. For the majority of survey questions, a simple frequency distribution of selected responses was generated. To confirm the overall performance of the measures, we compared a selection of responses from the All of Us sample to those from other national cohort studies. In addition to frequency distributions of selected responses, frequency of missing data was also calculated for each of the survey questions based on the number of participants that should have seen the question as dictated by survey “skip” or “branching” logic, where some participants might have gotten certain survey questions and others would not.

Results

There are a total of 32 potential questions that a participant could answer in the Basics, 24 in Overall Health, and 31 in Lifestyle. 116,319 participants completed the Basics, 112,544 participants completed Overall Health, and 111,512 participants completed Lifestyle. Frequencies of the All of Us responses were similar to other national surveys, but there were a few differences (Table 1). While most questions had a less than 10% missing rate, some of the following questions had higher missing rates (Table 2).

While the survey measures generally performed as expected with no major causes for concern, we identified a few data quality concerns affecting small amounts of the data. These included unanticipated branching logic behavior; failed field validation; and duplicate data transmissions. Each issue identified was meticulously investigated, documented, and communicated to the appropriate data management teams for resolution. Resolutions ranged from introducing additional validation checks into the survey deployment process to addressing technical configuration errors and amending the affected data.

Conclusion

This project is the first look at health survey data from the All of Us Research Program. This analysis helped confirm the integrity of health survey data for the initial three surveys of the program. We learned that the surveys are collecting data largely in line with expectations and have been technically implemented in accordance with intended survey operations. We also detected a small number of issues that offer an opportunity for remediation and improvement in data quality, including missingness in questions that targeted temporality. Compared to previous studies from which questions were derived, the survey questions are being answered by participants largely in an expected manner and, at this point, there were minimal changes recommended to some of the measures with high missingness. These changes included adding the word “about” to the age questions and adding text prior to certain questions to explain the importance of answering these questions. We will continue to monitor the performance of All of Us surveys over time, with particular interest in examining the utility of newly release surveys and exploring changes in response frequencies as the cohort evolves. By analyzing existing data from health surveys, All of Us can refine and adapt questions to improve their completeness, clarity, and provide accurate, cleaner data that researchers can use.

There were some limitations while conducting analysis, revealing areas for improvement and future directions. First, the population was skewed towards individuals identifying as white, female and/or with higher education attainment. This skewed population may have led to the differences in frequencies shown in Table 1. Analysis of a larger, more diverse population will likely generate different response distributions. Second, free text field responses were not included in the analysis due to the risk of receiving personally identifiable information. In the next iteration of assessment, free text fields will be analyzed to determine if other options should be added to existing response choices. Third, these analyses did not explore relationships between different characteristics, such as smoking relative to age or gender. Future analyses could look more closely at potentially dependent characteristics.

Addressing Diagnostic Errors Proactively using Electronic Events to Mitigate Harm during Inpatient Episodes of Care

Anuj K Dalal, MD,1,2 Kumiko Schnock, RN PhD,1 Nick Piniella,1 Kerrin Bersani,1 Pamela Garabedian, MS,1 Kevin Carr, MS, Ronen Rozenblum, PhD, MPH,1,2 Stuart Lipsitz, PhD,1,2 Jacqueline A Griffin PhD,3 Jeffrey L Schnipper, MD, MPH,1,2 David W Bates, MD, MS1,2

1Brigham and Women’s Hospital, Boston, MA, 2Harvard Medical School, Boston, MA 3Northeastern University, Boston, MA

Introduction: Diagnostic error in acute care represents an unresolved safety issue: error rates range from 4.8 to 49.8%. If the diagnosis is delayed or incorrect, the patient may not get correct treatment in a timely manner. Underlying contributing factors include system flaws (e.g., communication barriers) and cognitive errors (e.g., anchoring), factors that are often overlooked by workflow and technological solutions. Recent work (1) describing events typically captured by the electronic health record (EHR) has yet to be operationalized as “e-triggers” to identify cases of actual diagnostic error, as well as predictors that proactively identify patients at risk for preventable harm due to diagnostic error. As part of our new AHRQ-funded Patient Safety Learning Laboratory, a collaboration between Brigham and Women’s Hospital and Northeastern University, we aim to address diagnostic error in hospitalized patients by using these electronic events.

Methods: The study is being conducted at a large academic medical center in Boston, MA. Our team, comprised of experts in systems engineering, human factors, patient safety, quality improvement, clinical informatics, hospital medicine, and advanced statistics, is employing a sociotechnical approach to guide each project phase: problem analysis, design and development, and implementation and evaluation. Specifically, we are using the Safer Dx framework (2) to identify pertinent research questions across sociotechnical work system and diagnostic process dimensions, and to identify key activities and workstreams during each project phase.

Results: During the problem analysis phase, we identified three core activities (Table 1) in which we utilized systems engineering and human factors methods to analyze cases, understand stakeholders’ perspectives of actual diagnostic error, and validate previously described electronic events. First, we conducted a representative case analysis in which we identified cases of actual diagnostic error for 14 conditions (e.g., pneumonia) and undifferentiated symptoms (e.g., abdominal pain) from our hospital’s quality assurance committee, morbidity and mortality case reviews, safety reporting system, and patient and family relations department. We used Ishikawa and fault-tree analyses to understand system and cognitive factors that led to harm in these cases, and then prioritize key diagnostic process failures. Second, we conducted a qualitative analysis in which we performed structured interviews with key stakeholders and patient advisors to understand their perceptions of diagnostic error. Third, we conducted a quantitative analysis in which we retrospectively identified cases of potential diagnostic error by applying various electronic screening criteria to previously hospitalized patients. Currently, we are determining the sensitivity, specificity, and positive predictive value of these screening criteria by confirming the presence or absence of diagnostic error via chart review and a clinician adjudication process.

Discussion: We are using the knowledge generated from these core analytic activities to design and develop a robust digital health intervention (Figure 1, left) that will serve to engage patients and clinicians to ensure that clinical trajectories match the anticipated course for working diagnoses or symptoms, and align with patient and clinician expectations. We are using a user-centered approach to identify requirements according to key diagnostic process dimensions (Figure 1, right) and to improve utilization of existing EHR functionality (e.g., problem lists). We are also determining how specific electronic events can be used to identify potential cases of diagnostic error which will enable our team to evaluate the impact of the intervention on an enriched cohort of patients with actual diagnostic error. Our experience to date underscores the complexity and interdisciplinary expertise required to design strategies that leverage patient-reported and EHR data in real-time to enable front-line clinicians to proactively identify patients at risk for diagnostic error. During implementation and evaluation phases, our goal is to demonstrate a reduction in the rate of diagnostic error for patients admitted to general medicine units.

Acknowledgements: The PSLL project is supported by funding from AHRQ (R18-HS026613).

Table 1. Core Activities, Goals, and Methods used to Analyze Diagnostic Error in Acute Care

<table>
<thead>
<tr>
<th>Core Activity</th>
<th>Goals &amp; Methods</th>
</tr>
</thead>
</table>
| **Representative Case Analysis** | • Using medical record review and critical incident interviewing to identify representative cases  
• Using Ishikawa diagrams to identify key system and cognitive factors that lead to potential harm for 14 representative symptoms, clinical states, and conditions: chest pain, abdominal pain, altered mental status, dyspnea, failure to thrive, cough, anticoagulation, venous thromboembolism, asthma and chronic obstructive pulmonary disease, pneumonia, protein-calorie malnutrition, sepsis, cellulitis, soft tissue infection  
• Using fault tree analysis to understand and prioritize key failures in the diagnostic process. |
| **Qualitative Analysis**   | • Conducting semi-structured interviews to understand clinicians’ perspectives of diagnostic error: 1) general perceptions of diagnostic error; 2) types of system and cognitive factors associated with diagnostic error; 3) clinician behaviors associated with diagnostic error: lack of attentiveness to patient symptoms, questions, and concerns; disrespecting patients; failing to communicate; manipulation or deception  
• Conducting task analysis and workflow observations to identify key activities related to each diagnostic process dimension: admission/initial encounter, diagnostic test performance/interpretation, follow-up and tracking of diagnostic information, subspecialty consultation, patient experience, care team communication/collaboration |
| **Quantitative Analysis**  | • Validating screening criteria to identify cases of diagnostic error: transfers to ICU; discrepancies in observed vs expected LOS; unexpected surgery or procedure; code or rapid response; change of code status or diagnosis code; multiple medication changes or consultations; abrupt stop in medication; cancelled procedure  
• Using statistical methods to calculate, sensitivity, specificity, and positive predictive value for each criterion  
• Using risk assessment and prioritization to determine criteria that have greatest impact once operationalized |

Figure 1. Intervention Design & Development: Potential Use of EHR-Integrated Digital Health Tools to Address Key Diagnostic Process Failures

We are using systems engineering and human factors approaches to design, develop, and implement a suite of EHR-integrated digital health tools (left) to address high frequency errors in the diagnostic process (right) identified during the problem analysis phase. **Patient-facing health IT tools** (A, B) empower patients (or care partners) to visualize, understand, and self-report concerns about their care. **Provider-facing health IT tools** (A, C, D) reliably warn clinicians of potential threats to safety in real-time from both the patient’s and clinician’s perspective. Potential solutions will leverage both patient-facing (web-based survey tools to empower real-time self-reporting) and clinician-facing (dashboards, patient-centered communication apps, smart notifications) to address the system and cognitive failures in the diagnostic process that may lead to error. For example, at admission, our quality and safety dashboard could use EHR data services to identify newly admitted patients in real-time who have potential risk factors for diagnostic error (e.g., an unplanned primary care or ED visit or multiple ED/urgent care visits within 2 weeks prior to hospitalization, etc.). To evaluate the impact of intervention on the rate of diagnostic error, we are also developing a recent retrospective review process to identify actual cases of diagnostic error (i.e., an unplanned primary care or ED visit or multiple ED/urgent care visits within 2 weeks prior to hospitalization, etc.). To evaluate the impact of intervention on the rate of diagnostic error, we are also developing a recent retrospective review process to identify actual cases of diagnostic error (i.e., an unplanned primary care or ED visit or multiple ED/urgent care visits within 2 weeks prior to hospitalization, etc.). To evaluate the impact of intervention on the rate of diagnostic error, we are also developing a recent retrospective review process to identify actual cases of diagnostic error (i.e., an unplanned primary care or ED visit or multiple ED/urgent care visits within 2 weeks prior to hospitalization, etc.). To evaluate the impact of intervention on the rate of diagnostic error, we are also developing a recent retrospective review process to identify actual cases of diagnostic error (i.e., an unplanned primary care or ED visit or multiple ED/urgent care visits within 2 weeks prior to hospitalization, etc.).
A frame semantic overview of NLP-based information extraction for cancer-related EHR notes: a scoping review

Surabhi Datta, MS¹, Elmer V. Bernstam, MD, MSE¹,², Kirk Roberts, PhD¹
¹School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX
²Department of Internal Medicine, McGovern Medical School, The University of Texas Health Science Center at Houston, TX

Introduction

Unstructured clinical data about cancer patients is increasingly available in clinical notes in Electronic Health Records (EHRs) and other systems. There is increasing interest in utilizing this data for biomedical research. Many publications argue for the need to capture important clinical information on cancer within the free text information in EHRs, ranging from information about tissue specimens¹ to disease-related and outcome information², thus facilitating translational research by associating molecular information with disease phenotype. Some works are more focused on extracting information to improve cancer screening efficiency³. All these works have focused on deriving cancer-related information automatically using various natural language processing (NLP) techniques. More recently, deep learning-based NLP systems are gaining prominence for cancer information extraction from EHRs⁴. However, many of these researchers put sizable effort into designing and implementing NLP systems that extract similar information types. In this scoping review, we investigate the cancer information types and organize the extracted information into frames, based on the linguistic theory of ‘frame semantics’⁵. We review existing literature for clinical NLP related to cancer, and demonstrate why a frame semantic perspective is important. Our aim is to provide a list of cancer-related frames in existing work that would be valuable to the scientific community.

Methods

We obtained a total of 899 articles using keywords such as ‘natural language processing’ or ‘NLP’ anywhere in the article, and one of the keywords from ‘cancer’, ‘tumor’, and ‘oncology’ in the title from PubMed, Google Scholar, ACL Anthology, and two existing reviews. Results were limited to papers published between January 1, 2000 and September 20, 2018. We included articles if the title or abstract contained the description of an NLP method to extract cancer-related information from EHR notes. This resulted in selecting 173 papers, after which two further exclusion criteria were applied to the full text. We excluded articles where the extraction techniques used were too broad to be represented as frames (e.g., document classification) and also where very low-level extraction methods were used (e.g. identifying all clinical concepts in a cancer note). Finally, 78 articles were included in the review. We organized this information according to frame semantic principles to help identify common areas of overlap and potential gaps.

Results

Frames were created from the reviewed articles pertaining to cancer information such as cancer diagnosis, tumor description, cancer procedure, breast cancer diagnosis, prostate cancer diagnosis, and pain in prostate cancer patients. These frames included both a definition as well as specific frame elements (i.e. extractable attributes). We also constructed relationships between frames (shown in Figure 1). The different colors in Figure 1 correspond to the various broader categories of information type. We defined three kinds of frame relations based on those found in Berkeley FrameNet⁶. We found that cancer diagnosis was the most common frame among the reviewed papers (36 out of 78), with recent work focusing on extracting information related to treatment and breast cancer diagnosis. We also noted the distribution of papers at the frame element level, which reflects the important clinical attributes related to cancer that interest NLP researchers. The five most extracted frame elements along with the number of referenced articles are presented in Table 1.

Discussion

Our scoping review provides a detailed overview of the current research in the cancer information extraction domain from unstructured EHR notes using NLP. We conducted the review from a frame semantic perspective, described various frames along with their elements as well as examined the relations between frames. Since many researchers are trying to extract similar frames or frame elements (though not always using the language of frame semantics), this review can help develop a general-purpose cancer frame resource and NLP system that would extract a broad range of important cancer information types.

Collecting Individual-Level Social Determinants of Health to Inform Patient-Centered Outcomes Research in Mental Health

Joseph J Deferio, MPH1; Annie C Myers, MA1; John M. Meddar1, Judith Cukor, PhD2, Jyotishman Pathak, PhD1

1Department of Healthcare Policy and Research, Weill Cornell Medicine, New York, NY; 2Department of Psychiatry, Weill Cornell Medicine, New York, NY

Introduction: According to a 2018 World Health Organization (WHO) report, depression is listed as the largest global contributor to disability and is also a known contributor to suicide deaths.1 Global efforts aimed at mitigating depression prevalence recognize the importance of a multimodal approach to combating poor mental health. Recent studies suggest that providing adequate access to mental healthcare alone will not attenuate depression prevalence rates, but rather through addressing social determinants of health (SDOH), more pronounced and sustainable changes can be attained.2 Despite increased interest from health systems, public health agencies, and community organizations in understanding and addressing people’s social, economic, and environmental circumstances, individual-level SDOH collection efforts are uncommon, typically ad-hoc and disjointed, and there remains no firm understanding about which SDOH elements patients are even willing to share with their healthcare provider, health system, or publicly. In response, a number of health systems have developed tools to facilitate individual-level SDOH data collection, but their implementation is not yet widespread and they do not collect increasingly relevant online socio-behavioral estimates. The purpose of the study is to elicit from patients, in a structured and easily-deployable manner, information about experiences with depression/mental illness and how one’s particular social (physical and digital) and environmental conditions may or may not influence their mental health. We aim to use these results to design future observational and prospective studies that link individual-level SDOH data to other data sources, such as electronic health records (EHRs).

Methods: We designed a brief, anonymous, online survey to understand patient attitudes about sharing mental healthcare utilization, behavior, treatment, online/social media use, and general social determinants (factors) of health (http://bit.ly/wcmc_sdh). Our survey was constructed using 9 questions from existing instruments, such as the Protocol for Responding to and Assessing Patients’ Assets, Risks, and Experiences (PRAPARE) tool, designed to measure SDOH as well as structural and attitudinal barriers to healthcare.3, 4 From the existing PRAPARE tool, we drew questions that focused on structural environment such as housing situation, number of people living in household, and whether they felt physically and emotionally safe in their neighborhood. In addition, we created 28 new questions to describe the patient’s perception of neighborhood characteristics such as, but not limited to, safety, green space, access to public transportation, and blight. The survey is targeted towards patients that are currently experiencing depression or have a history of major depressive disorder (MDD) (including bipolar disorder), as defined by diagnosis codes or a PHQ-9 score ≥ 10. The survey is comprised of a total of 45 questions (multiple choice and free text), and can be completed in-person on a tablet computer set up specifically for the study at the health system clinic during their appointment, or at the patient’s leisure via a shareable hyperlink. All responses are automatically uploaded to a secure, HIPAA compliant database. This study has been approved by the Weill Cornell Medicine Institutional Review Board (#171008654).

**Results:** As of July 2019, we have collected data from 47 adult patients out of an initial recruitment target of 200 (see Table 1 for study population characteristics). On average, it took 9 minutes for patients to complete the survey. The survey respondents thus far include 19 men and 27 women (1 participant declined to report gender). More than half of participants (58.7%) reported being between the ages of 18 and 34.

89.4% of participants reported that daily events at home or in their community have caused increased sadness in the past 12 months. Nearly all participants (87%) have felt emotionally isolated from friends, family, and their community at some point in the past 12 months, with 19.6% feeling emotionally isolated nearly every day. When asked to share specific social and environmental triggers, common themes included pressure from relationships, work, and finances.

Our preliminary findings show that when seeking mental healthcare, 36.2% of participants reported facing difficulty and barriers to access. The most prominent barriers to mental healthcare were structural and included the uncertainty of where to go or which healthcare provider to see, and the financial burden of treatment. 72.3% of participants reported that they looked online or at social media for guidance before seeking care, with one-third relying on non-academic online resources such as WebMD. 85.3% reported looking online for three months to more than one year before deciding to seek professional help.

Regarding neighborhood safety, 65.2% of participants reported that they feel comfortable walking alone in their neighborhood during the day and night, while 30.4% reported only feeling comfortable during the day time. More than half (67.4%) reported feeling physically and emotionally safe in their current living situation, although 8.7% participants reported they do not feel safe, and 21.7% reported feeling unsure about their safety in their neighborhood. The majority (80.4%) felt that having access to public transportation has made them feel more connected to their city and community, and enabled improved socialization.

**Discussion:** This study was initiated because there remains a gap in knowledge about individual-level social determinants of mental health. While results are still preliminary, we have shown that patients are willing to share intimate details about different aspects of their lives, such as how they have dealt with their mental illness, social difficulties, and perceived neighborhood safety. We have also seen that relevant SDOH information can be collected from patients in a short amount of time, and at the patient’s convenience, thus requiring less of the healthcare provider’s time. Although we are currently focusing on individuals with MDD, findings from this study can also provide insight into the social factors that may be affecting the mental health population as a whole. Future integration with EHRs and other external datasets is another goal of this work. Survey tools like PRAPARE provide EHR templates which facilitate integration into patient clinical records, therefore it is possible for other such tools to do the same. Our study, as of July 2019, is limited by the number of participants at a single institution. In addition, the study sample suffers from bias in the population makeup, including higher SES and education, commercially insured, and those who are already receiving mental health care. Lastly, the study does not address issues on whether or not patients would consent to the collection of this data if the survey also included protected health information (PHI), and their results were linked to the EHRs.

**Acknowledgments:** This research has been supported in part by funding from NIH R01 MH105384.

Comparison of Free-Text Synthetic Data Produced by Three Generative Adversarial Networks for Collaborative Health Data Analytics

Gregory P. Dexter¹, Shaun J. Grannis MD, MS²,³ Suranga N. Kasthuriratne, PhD²,³
¹Purdue University, West Lafayette, IN, USA; ²Regenstrief Institute, Indianapolis, IN, USA; ³Indiana University, Indianapolis, IN, USA

Introduction. Fragmentation of Health Information Systems (HIS) and legal restrictions on sharing Patient Health Identifiers (PHI) limits access to healthcare data for research purposes. This impedes (a) sharing and re-use of Machine Learning (ML) solutions across larger audiences, (b) inter-organizational collaboration to address various healthcare challenges, and (c) building of generalized ML solutions targeting large geographic areas or multiple health systems. The advent of Generative Adversarial Networks (GAN)¹ capable of mimicking real-valued data present considerable potential to democratize access to health data. These approaches have already been used to generate numerical clinical data that is comparable to real data². However, valuable healthcare information is also trapped within free-text datasets. We leverage enhanced GAN algorithms that support free-text to generate high-quality synthetic free-text healthcare datasets capable of being used to train decision models that perform similarly to models trained using real data, and present limited re-identification risk.

Materials and methods. We extracted 6,770 salmonella laboratory test reports (17.91% positive, 82.08% negative) from the Indiana Network for Patient Care (INPC), a large statewide Health Information Exchange (HIE). The reports were split into train (90%) and holdout (10%) report sets. We used the training report sets to train SeqGAN, MaliGAN and RankGAN adversarial models³ using hyperparameter tuning techniques. Next, we generated synthetic datasets from each optimally trained adversarial model. We evaluate the quality of synthetic datasets by comparing them to real data using Bilingual Evaluation Understudy (BLEU) 1-4 and Google-BLEU scores⁴ which measure n-gram overlap between datasets. To evaluate their ability to replicate ML efforts, we vectorized the three synthetic report sets and the real (training) report set using methods described in a previous study⁵. We extracted the top 5, 10, 15, and 20 features from each of the four vector sets using Gini impurity. For each data vector and feature subset size, we built Random Forest⁶ decision models predicting a positive or negative outcome for salmonella, and assessed its performance using the holdout data vector. Re-identification risk was evaluated using techniques described by Choi et. al.² to calculate presence disclosure, which evaluates an attacker’s ability to determine if any given report was used to train a GAN model. Figure 1 presents our research process.

Results. BLEU 1-4 and Google-BLEU scores comparing real and synthetic data across positive and negative report sets demonstrate that SeqGAN and MaliGAN models were superior to RankGAN generated synthetic data (table 1). Analysis of the top 5, 10, 15, and 20 features extracted from each of the three synthetic report sets and the real report set determined that correlation between RankGAN vs. real features (only 30%-60%) was inferior to SeqGAN and MaliGAN vs. real features (~60% correlation) (table 2). When tested using the holdout dataset, models trained using MaliGAN and RankGAN generated data underperformed in comparison to models trained using real data. However, models trained using 10 or more features derived from SeqGAN generated synthetic data achieved performance measures that were statistically similar to measures reported by models trained using real data (figure 2). Further, presence disclosure assessment of SeqGAN based synthetic data using various hamming score thresholds determined limited re-identification risk.

Discussion. Our results inform two challenges; use of GAN models to generate synthetic unstructured free-text healthcare data with limited re-identification risk, and use of this data to enable collaborative research and re-use of decision models and analytical solutions. We found that SeqGAN generated synthetic data was superior to those generated by other GAN models, and suitable for creating synthetic free-text data that can be used to replicate ML solutions. Thus, an organization that possesses rich free-text data sources, but lacks adequate ML expertise can leverage our approach to generate synthetic data with low re-identification risk. This data could be shared with external experts who would use it to train machine learning models. Once optimal models have been identified, they could be applied to the original dataset with compatible performance measures. However, our study did not include any analysis of the readability or syntactic/grammatical accuracy of the synthetic reports. As such, these synthetic datasets are only suitable for ML purposes, and not as teaching or learning resources. Next steps include (a) manual assessment of the readability and syntactic correctness of synthetic reports using human experts (Turing test), and (b) investigation of other word and grammar-based measures that inform assessment of synthetic data.

Local and State Public Health Informatics Workforce Skills and Needs: A Descriptive Analysis using the PH WINS

Brian E. Dixon1,2, Timothy D. McFarlane1, Shaun J. Grannis2,3 P. Joseph Gibson1,4
1Indiana University Fairbanks School of Public Health, Department of Epidemiology, Indianapolis, IN; 2Regenstrief Institute, Center for Biomedical Informatics, Indianapolis, IN; 3Indiana University School of Medicine, Indianapolis, IN; 4Marion County Public Health Department, Indianapolis, IN

Introduction

In 2014, the Association of State and Territorial Health Officials and the de Beaumont Foundation fielded the Public Health Workforce Interests and Needs Survey (PH WINS), the first nationally representative sample of state agency (SHA) public health workers in the United States. Using data from that survey, Dixon and colleagues (1) estimated that public health informatics (PHI) specialists constitute 1.3% of the SHA workforce.

While the proportion of public health workers identifying as PHI specialists is small, informatics needs agency-wide are large for health departments to become “informatics-savvy.” As a result, informatics skills have been added to essential competencies across public health disciplines (2), and the Council on Education for Public Health has included informatics as a cross-cutting competency for master of public health programs (3).

In 2017, the PH WINS was fielded a second time, and the survey included a representative set of local public health department (LHD) workers in addition to SHA workers. Using data from the newer survey, we sought to update our prior analysis of the PHI workforce as well as assess the informatics needs of the broader public health workforce.

Methods

We performed a cross-sectional study using the nationally representative 2017 PH WINS. Details on the PH WINS sampling and data set construction can be found in the article by Leider et al. (4). The complete analysis summarized in this abstract, approved by the Institutional Review Board at Indiana University, can be found in the article by McFarlane et al. published in the Journal of Public Health Practice & Management (5).

Respondents’ perceived skills and needs were captured using 21 questions across 8 “strategic skill” domains. We focused on questions addressing core public health competencies possessing the greatest overlap with existing PHI competencies (6), including: identifying appropriate sources of data and information to assess the health of a community; collecting valid data for use in decision making; participating in quality improvement processes for agency programs and services; and identifying evidence-based approaches to address public health issues.

Respondents were asked to rate selected public health competencies with respect to the importance to their day-to-day work (ie, not important, somewhat unimportant, somewhat important, and very important) and their current skill level (eg, not applicable, unable to perform, beginner, proficient, expert). To identify the highest priorities for future workforce training, we present skill gaps. A skill gap was defined as discordance between self-reported importance (ie, need) and skill level, for example, those reporting the competency as “somewhat important” or “very important” and “unable to perform” or “beginner.”

Results

Of all public health employees surveyed, informaticians accounted for 1.1% (0.9%-1.2%, 95% CI) of SHA respondents and 0.5% (0.2%-0.7%, 95% CI) of LHD respondents working in a Big City Health Coalition agency, those that serve the top 30 most populous urban areas in the United States.

Table 1 below details discordant skills gaps by role and setting for two key informatics competencies. Informaticians reported the lowest discordance in all categories (with one notable exception in LHD), and public health workers overall were more likely to report a high need, low skill discordance than the reverse. The high need, low skill discordance represents a shortage of key skills in the workforce.

SHA = State Health Agency; BCHC = Big City Health Coalition

Public Health Roles Based on Self-Report: PHI = Public Health Informatics; IT/IS = Information Technology Specialist or Information Systems Manager; PHS = Public Health Science; CL = Clinical and Laboratory.

Discussion

An informatics-savvy health department requires PHI competencies not just among specialists (e.g., informaticians) but also among front line workers, program area managers, and executive leadership. While encouraging that informaticians generally reported having the skills needed for their jobs, our findings suggest that additional informatics training is necessary for the broader public health workforce. Discordance suggests that health departments should examine ways to enhance training for PHI-related competencies. AMIA and its members could work collaboratively with public health associations and schools to create opportunities for informatics competency training for existing workers in the public health workforce.

Towards a Universal Document-Level Clinical Text Encoder: Methods for Neural Network Pre-training with Applications to Substance Misuse

Dmitriy Dligach, PhD\textsuperscript{1}, Majid Afshar\textsuperscript{1}, MD, MSCR, Timothy Miller, PhD\textsuperscript{2}
\textsuperscript{1}Loyola University Chicago, Chicago, IL; \textsuperscript{2}Boston Children's Hospital and Harvard Medical School, Boston, MA

Introduction

Recent neural network models have shown state-of-the-art results on a number of natural language processing (NLP) benchmarks and even human-level performance on several narrowly-defined tasks such as question answering and machine translation. Yet, this success required tens or hundreds of thousands of labeled examples. Procuring annotated datasets of this size is not feasible for most tasks in clinical NLP due to the high cost of manual labeling.

This problem of insufficient training data is addressed in computer vision by means of pre-training classifiers on massive datasets such as ImageNet and subsequently refining them on a more specialized classification task. Recent years have seen a number of new approaches in NLP for word- and sentence-level pre-training. In this work, we investigate a form of pre-training that utilizes billing code prediction objectives; because billing codes are available in abundance in health care institutions and are linked to document-level entities, such as clinical encounters, we are able to move beyond sentence-level encoding to document level by means of supervised pre-training.

We investigate a simple text encoder that takes UMLS concepts or raw text as input and is trained using a billing code prediction objective. The encoder is subsequently used to generate patient representations that succinctly capture patient information. We also introduce a novel phenotype-specific encoder that makes it possible to trade the generality of the resulting text representations for better performance on a specific phenotyping task.

We evaluate our encoder on several phenotyping tasks using labeled datasets. First, in the interests of reproducibility, we evaluate on the publicly available i2b2 comorbidity challenge data, establishing a new state-of-the-art. We also apply our encoder to two novel and high-impact substance misuse tasks, predicting opioid and alcohol misuse in trauma patients.

Materials and Methods

We explore several neural architectures that work directly with text and simple named entity features automatically extracted from text. The first encoder is a deep averaging network (DAN) that takes a set of Unified Medical Language System (UMLS) concept identifiers (CUIs), maps them to their 300-dimensional embeddings, averages them, and projects them to the penultimate fully-connected hidden layer, encoding the input as a fixed-sized dense vector. During pre-training, the final (output) network layer consists of $n$ sigmoid units, each representing a unique billing code. The second encoder is a convolutional neural network (CNN) that operates directly on the text of the notes. The embedding layer is followed by a convolutional layer, a max pooling layer, and a fully-connected layer. The output layer is identical to the DAN architecture above.

Both encoders are trained using binary cross-entropy loss function and RMSProp optimizer to jointly predict billing codes. To use the patient encoder as a feature extractor, we freeze the network weights, push the text of the notes through the network, and collect the computed values of the hidden layer nodes, thus obtaining a dense vector representing the input text, that can be used as input for any machine learning task, e.g. to train a supervised classifier.

While our ultimate goal is learning a universal clinical text encoder, we also observe that it is possible to train a phenotype-specific encoder by restricting the billing code prediction targets to a set that is relevant to a specific phenotype. While a universal encoder could be more practical, since it needs to be pre-trained only once, a phenotype-specific encoder could potentially perform better for a specific medical condition. We train two phenotype-specific text encoders for detecting substance misuse status, by modifying the encoder's training objective to predict only the codes associated with two substance misuse scenarios: alcohol and opioid misuse.

Experiments

We pre-train all text encoders using the MIMIC III \cite{6869554} corpus. MIMIC III contains notes and structured data for over 40,000 Beth Israel Deaconess Medical Center critical care patients. To evaluate the quality of an encoder, we deploy it as a feature extractor to generate text representations we can use as input to a linear SVM classifier. To obtain a vector representing a patient, we freeze the network weights and push the patient text through the encoder, harvesting...
the computed values of the units of one of the intermediate network layers. We compare all models to a baseline SVM classifier that we train for each phenotype with bag-of-cui features.

For evaluation, we use a publicly available dataset from the i2b2 Obesity challenge [2], which consists of 1237 discharge summaries from the Partners HealthCare annotated with respect to obesity and its fifteen most common comorbidities. In addition, we use two in-house substance (alcohol and opioid) misuse datasets developed at the Loyola University Medical Center. We emphasize that the patient data we use in our evaluation originates from healthcare institutions (Partners HealthCare and Loyola) that are different from the ones on which the encoders were trained (Beth Israel). This evaluation is challenging yet it presents a true test of robustness of the proposed methods.

Results

Evaluation results are shown in Table 1. Our CNN-based clinical text encoder outperformed the bag-of-cuis baseline by a wide margin. Our DAN-based encoder outperformed the bag-of-cuis baseline and our previous encoder by a wide margin.

Table 2. Comparison of different input representations on the performance of an SVM classifier on the opioid misuse data. Bag-of-cuis input (baseline) is compared to the performance of the input obtained from a deep averaging network encoder pre-trained on different billing code prediction tasks.

Our DAN-based encoder showed the best performance on the comorbidity data and we proceeded by evaluating it on the opioid misuse data, where it helped to improve the classifier performance by over five points. Finally, when the encoder was pre-trained on the opioid-specific billing codes only, we obtained further improvements, outperforming the bag-of-cuis baseline by over eleven points. Similarly to the opioid misuse task, we find that the use of our text encoder helps to improve the classifier performance on the alcohol misuse detection task, although the size of the improvements is more modest (results not shown due to space constraints).

Conclusion

In general, we find that pre-training using billing codes is a viable route for pre-training. The representations generated by jointly predicting the billing codes associated with a patient encounter have properties of universal patient representations as they were beneficial for all the phenotyping tasks reported here. While phenotype-specific pre-training is beneficial, it is less practical since it requires additional effort tuning the encoder to a specific set of billing codes. Nevertheless, we find that this is a viable route for trading the generality of the pre-trained encoder for better performance on a specific phenotyping task.

Development of an Automated Provider-Specific “Learning List” within a Commercial Electronic Health Record

Robert El-Kareh, MD MPH MS1, Aaron Kemp, MS2, Samantha Hurst, PhD3

1Department of Biomedical Informatics, UC San Diego Health, La Jolla, CA; 2Information Services, UC San Diego Health, La Jolla, CA; 3Department of Family Medicine and Public Health, UC San Diego, La Jolla, CA

Introduction

Accurate and timely diagnoses and appropriate management plans are keys to avoiding patient harms from delays in effective therapy, exposure to ineffective treatments and unnecessary tests. Clinicians establish their skills during training and then we assume that clinical experience will enable them to improve their clinical skills and reduce errors over time. However, for this calibration to occur, practicing clinicians must get ongoing feedback of the outcomes of their decisions. In many hospital settings, our increasingly fragmented care models lead to multiple handoffs of care and significantly hinder this feedback. We sought to develop a system integrated into our electronic health record (EHR) to provide consistent feedback of patient outcomes through an automated and individualized “Learning List.”

Methods

We are taking a multi-level approach to understand the various perspectives of stakeholders involved in the “Learning List” that highlights important information or events across transitions of care. We conducted interviews with frontline clinicians and with patient safety leaders within our organization. Our participants to date have included four internal medicine (IM) attendings, two IM residents, three emergency medicine (EM) attendings, two EM residents, and three of our organization’s patient safety leaders.

Our early interviews centered on current practices and challenges related to following up on prior patients. Building on what we learned, iterative changes were made to expand later interviews to include participant opinions regarding: (1) the data elements that would be most helpful to include to remind clinicians about the context of their care with each patient; (2) the post-handoff events which would be most important to highlight; and (3) how the information would best be presented.

We implemented our prototype Learning List system using Crystal Reports (SAP SE, Walldorf, Germany) connected to the relational database for our Epic EHR (Epic, Verona, WI). The system identifies transitions of care using the Treatment Team construct within the EHR. In addition, through Structured Query Language (SQL) queries, the system identifies a set of post-handoff events that were previously identified to be potentially indicative of a diagnostic delay or error. This set includes events such as death, code blue, escalation of care, re-presentation to the emergency department, early transfer between medical and surgical services and others. The system is available to all providers on eligible service teams upon electronic request and is generated daily. Each provider’s Learning List contains all patients handed off by that provider during a set look-back timeframe.

Results

During our early interviews with IM and EM physicians, we obtained results similar to a prior study that surveyed residents about their post-handoff follow-up practices at our institution. We found that physicians had substantially varied practices to keep track of patients they thought warranted follow-up. Many of these practices required manual addition of specific patients to a list and were felt by subjects to be variably effective.

In our later interviews with physicians, we identified the data elements of highest value to our subjects to remind them of the patient encounters. These elements included patient name, age, gender, chief complaint, and date/time that the physician was on the treatment team. The information that subjects felt was valuable to display about the post-handoff course included the current principal problem for the patient along with the set of triggered events. Subjects felt that a graphical display using icons was helpful to quickly identify which patients experienced important events post-handoff. Based on this input, we updated our system to its current form (Figure 1).

Our interviews with local patient safety leaders provided additional organization-wide perspectives on the use of the Learning List. These interviews have included considerations of sharing learning opportunities across providers and expanding the system to support a wider range of provider types, such as medical students. In addition, the patient
safety leaders discussed the relationship between this system and a broader effort to continue to advance a culture of safety across the organization.

Figure 1. Format of Automated Provider-Specific Learning List.

Discussion

The EHR serves several purposes and we strongly believe that one priority should be to facilitate ongoing provider education and calibration of decision-making. We describe the development of an automated and provider-specific “Learning List” system implemented at an academic medical center and integrated into a commercial EHR. Through thoughtful aggregation of information and highlighting of important post-handoff events, preliminary results indicate that the system effectively reduces the barriers for providers to “close the loop” on prior clinical decisions. Our initial qualitative results are positive from residents, attending physicians and patient safety leaders. Through ongoing interviews with stakeholders, we are continuing to refine and expand the system.

This project is currently limited to a single academic institution however, we believe that our institution’s model with frequent handoffs of care is not unusual. Our system also currently only identifies patient handoffs for services which designate individual names on the “treatment team” in the EHR.

Future directions include: (1) further integration of the system into our EHR to enable more interactivity with the Learning List (e.g., dynamic addition/removal of patients to list, etc.); (2) quantifying the impact of the system on follow-up of patient outcomes; (3) enabling functionality to allow providers to flag cases for further learning (e.g., cases appropriate for teaching or morbidity & mortality conferences, cases which warrant further patient safety review, etc.); and (4) expansion of the system to support medical students and additional services.

EHR Sequencing: A Novel Approach for Constructing Predictive and Interpretable Data Representations from EHR Data

Hossein Estiri, PhD\textsuperscript{1,2,3}, Thomas H. McCoy, MD\textsuperscript{1,2}, Shawn N. Murphy, MD, PhD\textsuperscript{1,2,3}  
\textsuperscript{1}Harvard Medical School; \textsuperscript{2}Mass. General Hospital; \textsuperscript{3}Partners Healthcare, Boston, MA

Introduction

Despite the natural excitement emerging from the large amount of information presented by electronic health records (EHRs), daunting methodological challenges remain for effective secondary use of EHR data. EHRs contain important temporal information about disease progression and patients that can be harnessed to discover important medical knowledge\textsuperscript{1,2}. However, the temporal nature of observational data stored in EHRs has not been fully exploited by current methods\textsuperscript{3}. The time-stamped EHR observations are often acquired asynchronously and exhibit issues of sparsity and heterogeneity, thus provide fundamental methodological challenges for applying common temporal analysis methods\textsuperscript{4,5}. Advanced learning algorithms such as Recurrent Neural Networks and its derivatives have been utilized to synthesize temporality of EHR data. These algorithms often result in highly predictive models, but they are hard to understand, limiting their application in healthcare settings. While interest in approaches to process temporal data in EHRs is growing, progress is inhibited by complexities of adequately representing time in EHR observations. Only recently have investigators begun developing and applying methods to extract temporal knowledge from EHR data. Clinical observations in EHRs are often stored at multiple temporal granularities, requiring transformation into a more uniform dimension for data mining. Properly incorporating temporality of EHR observations can present new signals and yield to interpretable findings from large scale clinical databases. Temporal abstraction methods use domain knowledge to transform multivariate temporal data into a set of symbolic interval-based presentation of the clinical observations captured in EHR data\textsuperscript{6}. Considering electronic health records as ‘indirect’ reflections of a patient’s true health state, we apply temporal abstraction by sequencing EHR observations to construct new EHR data representations that are both interpretable and highly predictive.

Methods

We propose a high-throughput procedure for constructing the new sequenced data representations and test their prediction and classification performance (Figure 1), using medications and diagnoses observations from 207 chart reviewed patients with gold standard labels for congestive heart failure (CHF). We first utilized the i2b2 hierarchical ontologies implemented in the Research Patient Data Registry (RPDR) from Partners HealthCare to construct a set of raw EHR features at different levels of the hierarchy. Second, we performed temporal abstraction by sequencing observations. We only utilized the first occurrence of an observation at a given time and constructed 2-deep sequences (time \(n\) and time \(n+1\)) for each patient. Third, we performed dimensionality reduction through correlation-based feature screening and embedded feature selection to identify a set of highly informative features. In the correlation-based analysis, we excluded sequences that did not have a statistically significant correlation with the CHF labels. The embedded feature selection involved using Random Forest classifiers to compute Mean Gini Decrease (MDG), as a metric for variable importance, and rank the top features based on their importance.

In the fourth phase, we fed the selected features to \(L_1\) logistic regression models in order to perform classification and prediction – for prediction, we removed observations from the date of the first record for CHF in the medical records. The experimental design involved 100 iterations of the classifiers. We compared the area under the receiver operating characteristic curve (AUC ROC) obtained from both raw and sequenced data representations at different ontological classes.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1.png}
\caption{The 4-step study design.}
\end{figure}
Results

Utilizing the full data for classification, we mined 1,013,052 unique 2-deep sequences (or sequenced data representations) from the 20,001 raw EHR observations, extracted from the 4D4M ontology class. The correlation-based screening reduced the dimensionality to 1,141 sequenced data representations (at $p<0.01$). Overall, we found that sequenced data representations significantly outperformed raw EHR features in classifying congestive heart failure, by more than 10 percent, depending on the ontology levels. Ranking the classifiers by ontology class, we found that using the sequenced data representations from the 4th level of ontology for both diagnoses and medications resulted in the best classifier performance (mean AUC ROC of 0.926). Moreover, we also found that the sequenced data representations presented novel insight that are difficult to discern from raw EHRs observations. Based on the classification results, we used the 4th level of ontology hierarchy for prediction, which revealed more information about the predictive power of the sequenced data representations. In comparing the AUC ROCs in predictive classifiers, we also examined different number of features (Figure 2).

![Figure 2. The sequenced data representations collectively outperform raw EHR data.](image)

Discussion

We proposed a new approach to constructing predictive and interpretable data representations from EHR data through temporal sequencing. The new sequenced data representations capture the temporality nature of EHR observations and is capable to encode multiple parameters into a unique data representation. For example, in the simplest form of 2-deep sequencing, parameters A and B (two unique observations), and the information that B happened after A (a temporal dimension) are encoded into a single data representation, $A \rightarrow B$. In addition to the dimensionality reduction this approach offers, our results have demonstrated that harnessing knowledge of disease progression through temporal sequencing improve computational disease classification (phenotyping) and prediction using EHR observations. We found that sequenced data representations carry more information about existence of the disease and are also useful for predicting the disease onset before an observation of the disease is recorded in the EHRs. The sequenced data representations present information beyond single clinical observations that can potentially shed light on some dimensions of the healthcare processes. Given the rapidly increasing prevalence of electronic health record systems in today’s practice, exploiting the temporal information in EHRs can advance medical knowledge discovery and meaningfully change clinical care by identifying and validating novel disease markers.

Growing Disparities in Use of Policy-Supported eHealth Tools

Jordan Everson, PhD, MPP\textsuperscript{1}, Evan Butler, BA\textsuperscript{1}, Nicole Senft, PhD\textsuperscript{1}

\textsuperscript{1}Vanderbilt University School of Medicine, Nashville, Tennessee

INTRODUCTION

Online access to health information and health services (eHealth) has increased along with internet use (1, 2). Public policies have sought to accelerate the spread of eHealth tools related to communication between patients and providers but have not targeted other eHealth tools, such as those facilitating access to online health information that is independent of healthcare providers. Since 2000, observers of the diffusion of eHealth tools across segments of the U.S. population have noted a “digital divide,” with members of traditionally underserved groups (lower SES, older, racial/ethnic minorities) being less likely to engage in many eHealth activities.(3-5) However, it is not clear whether the digital divide in the use of eHealth tools targeted by public policy has lessened or grown in the years since enactment of supportive policy compared to eHealth tools that have not been directly targeted by policymakers.

To address this gap, we describe use of one policy-supported technology (communicating with providers via messaging) and one technology outside the scope of public policy (looking for health information online) over time and across socioeconomic strata and racial groups.

METHODS

We used data from eight iterations of the National Cancer Institute’s Health Information National Trends Survey (HINTS). The full sample included 37,300 individual-year responses from 2003-2018. We measured use of provider messaging using an item asking participants whether, in the past 12 months, they had, “used e-mail or the Internet to communicate with a doctor or a doctor’s office.” Looking for health information online was assessed by an item asking whether, in the past 12 months, they had used the internet to “look for health or medical information for yourself.”

We defined socioeconomic strata by level of education, categorized as four levels in all years: less than high school, high school graduate or GED, some college or technical school, college graduate or greater. To measure race/ethnicity, we defined six different racial groups: Hispanic, White, Black, Asian, American Indian/Native Alaskan/Native Hawaiian/Pacific Islander, multiracial. We also defined several related demographic and health-related variables for inclusion in multivariate models.

We compared trends in looking for health information online and provider messaging by education and race/ethnicity. In multivariate analysis, we compared how education and race/ethnicity related to provider messaging and looking for health information online in three periods: before major public investment (2005-2007), the first years of public support (2011-2013) and recent years (2017-2018). Analyses adjusted for household income, sex, age, marital status, insurance coverage, and general health.

RESULTS

Overall Trends

Growth in provider messaging was relatively slow during the first years of the study period, increasing by 9.0 percentage points (from 4.4% to 13%) between 2003 and 2011 and was more rapid in later years, increasing by 22 percentage points between 2011 and 2018 (from 13% to 36%). In contrast to provider messaging, growth in looking for information online was rapid during the first years of the study period and slowed in later years: from 2003-2011 use grew by 31 percentage points (from 32% to 63%), then increased by only 7.2 percentage points between 2011 and 2018 (from 63% to 70%).

Trends in Disparities

Education

Among individuals who did not complete high school, reported rates of provider messaging increased by 13 percentage points between 2003 and 2018, the smallest increase of any education group. Meanwhile, among individuals who completed college, the rate of provider messaging increased by 46 percentage points over the same period, the largest increase of any education group. Compared to provider messaging, the rate of increase in looking for health information online was more similar across education levels: reported rates of looking for information increased by 36 percentage points for individuals without a high school degree and 33 percent among college graduates.
**Race/Ethnicity**

Among Hispanics, reported rates of provider messaging increased by 22 percentage points between 2003 and 2018, the lowest rate of any group. Meanwhile, among non-Hispanic Whites, the reported rates of provider messaging increased by 35 percentage points. In contrast to changes in provider messaging, reported rates of looking for health information online increased most quickly among traditionally underserved racial groups. Among Hispanics, reported rates of looking for health information online increased by 49 percentage points between 2003 and 2018, the highest rate of any group. Meanwhile among non-Hispanic Whites, the reported rates of looking for health information online increased by 38 percentage points.

**Adjusted Predictors of eHealth Use**

In multivariate models, the magnitude of the association between education and provider messaging increased over time but were smaller than unadjusted differences. In comparison, the adjusted association between education and looking for health information online grew less strong over time. As with education, we observed diverging trends between race/ethnicity and rates of provider messaging and looking for health information online. In adjusted models in 2003-2005, non-Hispanic Whites were only slightly more likely to use provider messaging than Hispanics, but this difference grew by 2017-2018. In contrast, the adjusted association between race/ethnicity and looking up health information online lessened over time.

**DISCUSSION**

In data from 2003 to 2018, the “digital divide” in use of public policy supported, provider-focused eHealth (provider messaging) has widened, while the divide in independent eHealth (looking up health information online) has stayed the same. While use of both these activities has increased markedly, rates of provider messaging grew more rapidly in the years following public policy intervention, while rates of looking up information online began to stagnate during the same period. These findings indicate that public policy may have impacted growth in the technologies it targeted, but may have disproportionately accelerated growth among White and well-educated individuals relative to socioeconomically disadvantaged groups. Future policy should seek to decrease this gap, perhaps by creating outreach efforts to encourage disadvantaged patients to use eHealth to communicate with providers.

Tuning and Evaluating a State-of-the-Art Machine Comprehension Model for Clinical Why-Question Answering

Jungwei Fan, PhD\textsuperscript{1,2}
\textsuperscript{1}Division of Digital Health Sciences, \textsuperscript{2}Kern Center for the Science of Health Care Delivery
Mayo Clinic, Rochester, Minnesota

Introduction

The reasoning and decision-making in clinical practice can be naturally framed into a series of questions and answers. Making computers perform question-answering (QA) is deemed an accomplishment in artificial intelligence (AI) and vitally researched in the medical domain. Among the diverse information needs, why-QA is a distinct category that deals with cause, motivation, circumstance, and justification. In terms of prevalence, 20\% of the top ten question types asked by family doctors\textsuperscript{1} can actually be paraphrased into a why-question. Clinical why-QA is of great significance because: 1) toward a deeper solution the task resembles expert-level explanatory synthesis of knowledge and evidence, 2) toward a shallower solution it would practically identify decision reasons documented in clinical narratives.

The current study focuses on the second type of solution above, a modest yet very useful task of reason identification. It represents a “patient-specific” QA scenario in which a system tries to identify answers documented in the clinical notes. For example, why was his dobutamine stress test rescheduled? This is different from the other more commonly researched scenario of consulting knowledge sources to answer a non-patient-specific question. In non-medical domains, such patient-specific QA has its counterpart known as reading comprehension QA, with competitive open challenges and richly-annotated corpora. SQuAD 2.0\textsuperscript{2} is an iconic corpus and challenge, which requires QA systems to refrain from answering when no suitable answer is present in the reference document. A modeling approach that caught wide attention recently was Google’s BERT,\textsuperscript{3} for it achieved impressive performance not only in SQuAD 2.0 but multiple AI challenges. BERT offers two pre-trained language models for task-specific fine-tuning: BERT\textsubscript{base} (12 layers 110M parameters) and BERT\textsubscript{large} (24 layers 340M parameters). Another notable resource is emrQA,\textsuperscript{4} a large clinical QA corpus generated from the i2b2 NLP challenge datasets and with about 7.5\% of why-QA annotations.

As an initial step toward developing a clinical reason identification system, this study aims to adapt the promising BERT models for why-QA based on the patient’s notes. The experiments use the why-subset of emrQA for training/testing and require the system to execute judicious refraining as in the SQuAD 2.0 challenge. Quantitative and qualitative evaluations are performed to assess model capability and inform future improvement.

Methods

A subset of 27,517 QA pairs were extracted from emrQA by requiring that the question starts with “why”. Also, to train a why-QA model that can refrain from giving an answer when none exists in the text, an additional 2,839 negative why-QA pairs were automatically generated where neither the question anchor nor the answer presented in the clinical note, i.e., an unanswerable instance. Together the positive and negative instances formed the core study set, emrQA\textsubscript{why}. The emrQA\textsubscript{why} was then split into train/dev/test subsets of 13,083/4,203/13,070 instances respectively. The dev subset mainly served to tune the optimal cutoff for making the do-not-answer decision. Four models were trained and evaluated for comparison: 1) BERT\textsubscript{base} fine-tuned by emrQA\textsubscript{why}, 2) BERT\textsubscript{large} fined-tuned by emrQA\textsubscript{why}, 3) BERT\textsubscript{base} fine-tuned first by 1,833 SQuAD 2.0 why-QAs and then by emrQA\textsubscript{why}, and 4) BERT\textsubscript{base} first pre-trained by 1,474 independent notes (106,952 sentences) from the i2b2 NLP corpora and then fine-tuned by emrQA\textsubscript{why}. The fine-tunings of BERT\textsubscript{base} used 4 epochs with –max_seq_length=128 and –batch_train_size=32, while in fine-tuning BERT\textsubscript{large} –batch_train_size=6 was used to avoid out-of-memory. The jobs were run on a Tesla K80 with compute capability 3.7 and 11GB of memory. The evaluation followed standard SQuAD metrics, comparing system answers to the gold by exact and partial match (average F1 between the predicted and gold bags of tokens).

Results and discussion

(please refer to Table 1, Table 2, and Figure 1)

The total time used in training the four models in sequential order as shown in the tables were: 1h 49m, 5h 43m, 1h 56m, and 48h 27m respectively. As recommended by the official manual, –batch_train_size=6 was used in fine-tuning BERT\textsubscript{large} to avoid memory issue. However, it resulted in suboptimal accuracy due to the inadequate batch size, as warned in the manual. The injection of SQuAD\textsubscript{why} (in the third model) was to assess the smoothing effect from non-medical training data. Interestingly, the out-of-domain why-instances caused worse accuracy on the dev set but better accuracy on the larger test set, suggesting mild supplemental benefit beyond merely BERT\textsubscript{base} + emrQA\textsubscript{why}. Extensive re-training of BERT\textsubscript{base} with additional i2b2 notes was time-consuming (almost 2 days) but most helpful (~3\% increase in accuracy on the larger test set).
of accuracy). This indicates the importance of domain-customizing the fundamental language model. Although the system errs toward the conservative side (heavy refraining and recall capped at ~0.6 as shown in Figure 1), the predicted answers above the cutoff tend to be precise around 0.8, which is desirable for the target application. Model inspection and error analysis are ongoing with consulting domain experts. The preliminary inspection suggests that some predicted answers may be semantically acceptable, even not literally matching the gold annotation.

Figure 1. Precision-recall curves of the BERT\textsubscript{base} + Pretraining\textsubscript{i2b2} + emrQA\textsubscript{why} model evaluated on the test set

Conclusion

The state-of-the-art BERT language model is tuned and evaluated for the task of clinical why-QA. The results show promising precision and indicate the importance of fundamental domain customization. The qualitative analysis should shed light on model behavior and areas to improve. The main deliverable will be a reason identification system. The study did not compare with other baseline models, which is a limitation to be addressed in future work.

Tracking AMIA Health Informatics Educational Domains:
Lessons Learned from a Pilot Test

Sue S. Feldman, RN, MEd, PhD1, Sue Boren, PhD2, David E. Moxley, MLS2
Courtney B. Garza, MS1, Eta S. Berner, EdD1
1University of Alabama at Birmingham, Birmingham, AL, USA,2University of Missouri, Columbia, MO, USA

Abstract

This presentation will discuss different approaches for using Canvas, a learning management system, to track competencies mapped to AMIA Health Informatics foundational domains. This presentation extends the work of one organization (UAB), presented at the AMIA Academic Forum, to include the University of Missouri. Each program will discuss how they went about setting up Canvas to be used in a novel way. The presentation will include a description of data captured, reports produced, and how the data and reports are used to inform course and program improvement and accreditation activities. Lessons learned from a pilot test will also be presented.

Introduction

AMIA has published foundational domains to support graduate Health Informatics education at the Masters level. These foundational domains provide a framework for understanding the degree to which individual Health Informatics programs are addressing each foundational domain and at what level of competence. Competencies, as defined in an earlier AMIA document, are the integration of knowledge, skills, and attitudes in F4-F10 in Error! Reference source not found.; F1-F3 are working knowledge only without skills or attitudes attached (1).

Health Informatics programs will use these foundational domains to support competencies such that they can be measured and assessed. In understanding the relationship between foundational domains and program specific competencies, it is important to understand that all 10 foundational domains must have a degree of integration dependent on the focus of the individual program.

Methods

Repurposing existing Canvas fields, we were able to collect data and produce reports to inform course and program
improvement, AMIA foundational domain areas, and competencies. We then conducted a pilot test with two courses. The process started with the program competencies. Next, each course objective within each course used in the pilot was assessed to ensure alignment of the program competency. In other words, understanding if the course objectives align to program competencies align to program competencies. Then each course objective was aligned with the assignments and assessments used to measure that objective. The assignments and assessments were also aligned to the AMIA foundational domains. For each objective, the collective of the assignment, the assessment, and the foundational domain were then aligned to the appropriate level on Miller’s Pyramid. Figure 3 illustrates this process.

After this process was completed, we utilized the Outcomes feature in Canvas. The “outcome” in Canvas indicates the domain, the competency, and the level of Miller’s pyramid for each aligned assessment. Each domain/competency has a rubric with the levels of Miller’s pyramid indicated. These rubrics were added to the aligned assignment/assessment so that faculty could indicate, under the appropriate pyramid level, whether the outcome (domain/competency) was achieved in that assignment. When the assessment was accomplished at 80% or better, the competency was said to be attained and faculty scored that outcome as a 1 under the appropriate Miller’s level. If a student achieved less than 80% they were given a 0 on the outcome score. From these data, individual student and aggregate reports are able to be produced and analyzed.

Results

The results across the two university Health Informatics programs were two fold: 1) at a system level, using an existing LMS in a novel manner and 2) at a functional level, data reporting. Most LMS’s were intended more as a vehicle to store and disseminate course information. At a system level, we found that the ability to use the LMS to track and assess the AMIA foundational domains and student competencies meant that we did not need to develop another tracking program. Secondly, the outcome results report, which includes data for both courses, displays which students achieved which competency and at which Miller’s Level at the individual course level and across the program. These data are then aggregated and used to inform course and program improvement as well as accreditation activities.

Discussion of Results

Most LMS’s contain analytics centered around usage and grading. By repurposing some of the back-end administrative fields in the LMS, we were able to pull data out of the LMS that is better targeted at tracking and assessing the AMIA foundational domains and student competencies. The process, at this point, is a step in the right direction; however some challenges remain. Rather than have Canvas automatically apply a “score” based on a grade of 80%, the instructor needs to use the competency rubric at the point of grading to indicate attainment.

Conclusion

Integrating curriculum maps into Canvas facilitates monitoring achievement and measuring outcomes relative to program competencies. Doing so allows for a continuous process of program self-assessment. From this small pilot study, we conclude that learning management systems can be used for program monitoring. However, this small pilot illuminates an opportunity to work with LMS developers so that they better understand program needs. Doing so could create a “competency module” for use across multiple programs and broaden the use of a LMS in actionable data collection. Absent such a module, programs should examine their learning management system’s capabilities as to its ability to facilitate data collection that can be used to document outcomes for accreditation purposes. More exploration of this process is needed and additional reporting of future attempts at this or a similar project would inform the use of an LMS for competency capture and reporting.

Towards machine-learning informed early detection of dementia in UK primary care

Elizabeth Ford, MA DPhil¹, Johannes Starlinger, MD PhD²
¹Brighton and Sussex Medical School, Brighton, UK; ²Charité – Universitätsmedizin Berlin, Berlin, Germany

Abstract
We used UK primary care EHR data to discover a minimum set of best features which could identify the onset of dementia. After specifying 88 possible predictive features, we used random forest classifiers to identify the top features in the 5 years prior to diagnosis, in a dataset of >90,000 dementia cases and matched controls. Classification performance improved significantly within the last year before diagnosis, when memory loss was evidently recognized by clinicians.

Introduction
Dementia is a global public health challenge and is one of the most common and serious disorders in the elderly population. Dementia is characterized by progressive decline in memory and cognition; symptoms can be caused by a number of illnesses which lead to structural and chemical changes in the brain, and death of brain tissue¹. Currently there are no treatments which are curative for dementia, however, a timely diagnosis of dementia can still be valuable for patients, as they can be offered a range of support interventions, inform themselves about the condition, and plan for the future, which may help them maximize their quality of life². Yet, at the current time, only two-thirds of patients with dementia receive a diagnosis for the condition in the United Kingdom National Health Service³.

Primary care physicians, known in the UK as general practitioners (GPs), record information about all interactions with their patients in comprehensive electronic health records (EHRs). These records provide a valuable resource for understanding the onset and early presentation of dementia as recorded in general practice, and may provide a rich data source for creating diagnostic support systems for GPs to recognize dementia in a more timely way.

Many previous studies have modelled risk for dementia at a future time, but no models exist to detect patients who are in the early stages of dementia but as yet undiagnosed, using only clinical primary care data. The objective of this study was to use machine-learning methods to inform a minimum set of best features for dementia detection within the primary care EHR, and to investigate how early the onset of dementia could be detected in this dataset.

Methods
This study used data from the UK Clinical Practice Research Datalink (CPRD), which curates anonymized EHRs from UK primary care, from 13 million patients⁴. Data are captured using a structured hierarchical vocabulary called Read Codes; each of the 200,000 7-byte alphanumeric codes maps onto a term or short phrase describing a clinical concept. For this project we extracted the entire EHR of all patients who received a diagnosis code for dementia between 2000 and 2012 (N=47,653) and the entire EHR for a similar number of controls, matched on age, sex and GP practice and with no dementia code anywhere in their record (N=47,127).

Our feature selection was informed by a meta-analysis⁵ and a survey of GPs. This generated 88 separate clinical concepts, including conditions, symptoms, medications and other factors, which were thought to precede dementia diagnosis in the EHR; these were operationalized into Read Code lists.

We partitioned the original CPRD dataset to represent the course of care over time: the first partition (-5 years) holds all data within the fifth year prior the date of a patient’s initial diagnosis of dementia; the second partition (-4 years) includes the fifth and fourth year prior to diagnosis; and so forth. The last partition (-1 years) contains all data within the whole 5-year window up to 1 day before the data of diagnosis (excluding the first appearance of an actual dementia code). Matched controls were analogously included in each partition. For these, the index date is determined by the matching process. Within each of these partitions, we vectorized patients and controls by mapping the Read Codes recorded in the data to the feature space of the 88 code lists of relevant clinical concepts. A binary feature representation was used to model a simple, checklist style symptom assessment in practice.

We trained Random Forest classifiers for each partition with holdout test sets of 33%. The random forest algorithm was chosen because it intrinsically includes feature weighting and selection, which we exploited to identify the most
important features indicative of an upcoming diagnosis.

Results

After data cleaning, 93120 patients were included in the final analysis, of whom 35% were men and 65% were women. The median age at diagnosis date (or matched index date) was 82.6 years (range 64.5-109.9 years). All patients had at least three years’ worth of data, 90,351 patients (97.0%) had ≥ four years and 87,876 patients (94.4%) ≥ five years.

Figure 1 shows the ROC curves of the resulting models for each partition. In investigating how early detection could be achieved, we noted that classification performance increased significantly within the last year before diagnosis, preceded by only slight but continuous increases from years -5 to -2. Inspecting the five most relevant features within each partition revealed that this increase in model performance correlates to a gradual shift in the types of codes recorded for patients over time (see Table 1): while 5 years prior to diagnosis long term risk factors are predominant, the importance of codes related to health events and to symptoms of memory loss continuously increases towards the point of diagnosis. In the last year preceding diagnosis, action towards diagnostic underpinning becomes apparent.

Discussion

The observed change of features which contribute most strongly to the predictive classifiers, together with the continuous increase in classification performance, indicates that identifying onset of the dementia using decision support, much before GPs pick up symptoms, may be problematic. Future research on early detection of dementia could focus on linking multiple data sources, such as patient wearables, in order to gain insights on disease status which clinicians do not have access to. However, our list of best features gives clear indications of patients most at risk, and includes dementia risk factors, such as smoking and diabetes which are well-established in the literature. It is notable that memory loss symptoms are recorded but action towards a formal dementia diagnosis may not be taken for a number of years, this may be due to stigma or patient unwillingness. Our results suggest that delay in diagnosis may be related to patient or system factors rather than symptoms going undetected by physicians. We plan to work towards a feature set which can be operationalized into a computerized risk communication and discussion tool for GPs to use with their high risk patients.

References

Introduction

Understanding how effectively healthcare providers use Electronic Health Records (EHRs) to find relevant patient information is an active area of clinical informatics research. In the primary care setting, prior work has used cognitive task analysis to understand challenges in the efficiency and comprehensiveness of chart review. However, it is unclear, whether specific categories of search patterns exist, and, if so, whether these patterns are typical to a provider’s use of the EHR or are related to a focus of disease management. In our work, we used grounded theory to identify distinct categories of search used by primary care physicians (PCPs) reviewing charts of patients with diabetes and/or hypertension. We present a cognitive workflow model that can visually illustrate PCP information seeking patterns. We discuss the implications of our study results on EHR interface design and future work.

Method

Eight PCPs recruited from Atrius Health (a medical practice group in Massachusetts) consented to participate in the IRB-approved study. Ten patients, who were not under the care of the PCPs, consented to have their EHR records used for this study. The patients were over 18, had been seen at the medical practice for over 10 years, and had at least one active condition of hypertension and/or diabetes. Each PCP reviewed two to four records in a quasi-random presentation order. For each record, the physician was asked to see the patient for the first time for a chronic disease management follow-up. The session was audio-recorded.

Twenty-seven audio-recordings were collected and manually transcribed. Themes were extracted and encoded by the authors MF, YP, JS and SM using grounded theory. To understand what information is required and why that information is needed, we devised a coding system consisting of Information Seeking Categories (ISCs) and Intents. During the coding process, discrete segments of each transcript were marked as a unit of meaning that included both an ISC and a corresponding intent. During the initial pass, two authors independently reviewed and coded each transcript. Any disagreements were reviewed by the larger group, so that full intercoder agreement was achieved.

We used a network representation (Figure 2) to visualize the PCP’s cognitive workflow between discrete ISC segments during the chart review. In the network model, the nodes (or vertices) represent the various ISCs and a directed link (or edge) between nodes shows how the physician moved from one ISC to another ISC (or the same ISC) in the following segments found in the transcript. The size of a node represents the number of times that a single ISC was coded in the record review, and the width of the link indicates the frequency of times the PCP’s review transitioned from one ISC node to another ISC node (or the same node).

Results

Our coding process discovered nine types of ISCs. The ISCs of “Problem List”, “Medications”, and “Labs and Vitals” relate to the central elements of an EHR record. “Person’s Story” involves looking for social determinants of health. The ISCs of “Tests and Imaging” and “Surgeries” correspond to search related to these procedures. “Health Maintenance” includes search for routine procedures and tests. “Specialist Notes” and “Care Team” capture searches for information about who else treated the patient.

The average number of ISCs generated per physician per chart review was 51.3 (standard deviation 39.6). Figure 1 shows the average frequency of ISCs across all chart reviews. The top four ISCs in chart review, “Lab and Vitals”, “Problem List”, “Person’s Story” and “Medications”, accounted for over 80% of the information search. We measured the Markov probability of transition from one ISC to another ISC across all chart reviews, which we present as a transition matrix (Table). As shown visually by the color intensity, search of most ISCs was followed by further search of the same ISC. Otherwise, many types of searches were frequently followed by searches of the four most common ISCs. In inspecting the network representations of the cognitive workflows in the 27 chart reviews, we found a wide variety of search patterns. Figure 2 shows the different types of search patterns in the cognitive workflow of two PCPs reviewing the same two patient charts and illustrates that the pattern is neither specific to the PCP nor to the patient.

Figure 2. Cognitive workflows used by two primary care physicians (PCP1, PCP2) reviewing two patients (PT1, PT2). Abbreviations used: HM (Health Maintenance), LV (Labs and Vitals), Meds (Medications) and PL (Problem List).

Discussion

Our macro-level analyses indicate that, as expected, PCPs search for common ISCs relevant to chronic disease management. However, we also found significant variation in PCP foraging patterns at the micro level for each patient, as illustrated in the cognitive workflow visualizations. These four examples, plus the other twenty-three workflow diagrams, do not reveal prototypical search patterns indicative of a particular PCP’s style of chart review or of a focused disease management activity (such as achieving a treatment goal). These results suggest that efforts to redesign EHR interfaces to support linear workflows may inhibit the exploratory nature of PCP chart review. To reduce information foraging, our results suggest that frequently searched ISCs should be kept close together whereas less frequently needed ISCs can be further apart. In future work, we plan to analyze categories of intents for ISCs and examine the hierarchical nature of search behaviors. We will also assess whether our network-based representation for modeling cognitive workflow is broadly informative for understanding mental models in team-based care.

Introduction. The German Medical Informatics Initiative (MII) is a large-scale, long-term strategic funding program by the German Federal Ministry of Education and Research to establish a nationwide infrastructure for the secondary use of routine clinical data at academic hospitals (1). While the initiative envisions a multi-year timeline for the four funded consortia to install interoperable data structures, terminologies and interfaces as well as to coordinate legal and ethical issues, it is imperative to continuously demonstrate and communicate successful collaboration throughout the project duration. Harvesting “low-hanging fruit” early on in a “demonstrator study” requires a fast-track approach that skirts longer-term efforts required to integrate the individual platform concepts pursued by the consortia but at the same time proves successful procurement of local data sets and the required legal and ethical permissions to analyze them.

Methods. A modular core dataset was designed in the cross-consortia Interoperability Working Group, which supports a stepwise implementation starting with a mandatory basic set of billing data modules (demographics, inpatient cases, diagnoses, procedures) supplemented by laboratory findings and medication modules as well as use-case specific extension modules (2). Inpatient billing data can be provided by all German hospitals in a standardized “§21” format mandated by the German Diagnosis-Related-Group-based billing regulations. An Extract/Transform/Load (ETL) process to import §21 conformant datasets into the i2b2 (Informatics for Integrating Biology and the Bedside) biomedical query platform (3) was implemented previously in the Integrated Data Repository Toolkit (IDRT) project and readily available for use (4). Two research topics were selected, which can be studied with §21 conformant data by combining locally aggregated analysis results at each participating site to guarantee patient data confidentiality: Comorbidity scores were calculated from ICD10 diagnosis data and analyzed in relation to age, duration of stay, type of hospital discharge and other variables. Additionally, rare diseases were analyzed based on ICD10 diagnosis data to generate geo visualizations and calculate distances from patient zip areas to treating centers. Based on the MIRACUM data protection concept (5), distributed analyses with suppression of local result sets with less than 5 patients were used to prevent re-identification of individual patients. Additionally, rare disease diagnosis codes were collated into larger disease groups. All analyses were centrally designed as SQL queries against the i2b2 PostgreSQL database, distributed to participating sites via a collaboration portal and executed locally. Aggregated anonymous result datasets were returned to the study coordinators for further analysis and visualization by means of the R statistics package. For the rare disease dataset, additional preprocessing was carried out locally at the sites using Python and R scripts. A study protocol was designed and provided to all participating sites to initiate approval through their respective ethics boards, data protection officers and use-and-access committees (UACs).

Results. 20 of 24 funded MII university hospitals chose to participate in the demonstrator study. The demonstrator platform was deployed to the sites as a pre-configured Linux virtual machine (VM) containing a dockerized i2b2 installation, PostgreSQL database and the IDRT ETL process for §21 conformant source datasets (Fig. 1). As of submission of this abstract, all 20 sites have internally procured datasets, deployed the demonstrator VM and received UAC approval, 19 sites have received ethics board and data protection approval, and 17 sites have provided aggregated result datasets. Based on these sites, a total of 1.7 million patients with 3.1 million inpatient cases (2015-
Discussion. The study successfully demonstrated active collaboration across MII consortia as well as the ability to procure datasets and gain permission to use them in the scope of a shared analysis. Preliminary results are consistent with expectations e.g. regarding the correlation between comorbidity scores and hospital discharge type. The use of standard datasets (§21 conformant) and established open source tools (i2b2, IDRT) was essential to facilitate the rapid implementation and deployment of the demonstrator platform in a timeframe of about 5 months.

Limitations: Even though meta-analyses of locally aggregated results were chosen to ensure patient privacy, the duration to acquire ethics board and data protection approval varied substantially between sites (also due to the different privacy regulations at the German state level). In this context, the demonstrator study may act as a first step towards streamlining the approval process for future similar projects. While the use of standardized billing data served to facilitate a quick entry into collaborative analyses, quality issues as well as the narrow scope of billing data need to be taken into account. Also, coverage of rare diseases in ICD10 is severely limited. Potential future iterations of the MII demonstrator study need to include additional core dataset modules (e.g. laboratory findings), systematically analyze data quality issues and, in the end, make use of the full arsenal of cross-consortia semantic harmonization, standardized data structures and legal coordination goals, as they are implemented throughout the MII funding period.

Conclusions. Standardized datasets and open source platforms were successfully leveraged to rapidly implement and deploy a demonstrator study for the investigation of the prevalence of comorbidities and rare diseases with clinical routine data within the German Medical Informatics Initiative. The approach is not limited to Germany, but could be leveraged for pilot projects in any environment that provides a shared dataset format (e.g. billing data).

An Effort to A.C.T. (Accuracy, Comprehensiveness, and Timeliness) on Opioid Prescription Data

Esteban Gershanik, MD, MPH, MMSc, Brigham and Women’s Hospital, Boston, MA 02115, USA

**Learning Objectives:**
1. Understand the current manner in which opioid prescription rates are reported by the CDC and potential limitations for your state
2. Learn the benefits of and how to use the Prescription Monitoring Program (PMP) for more accurate, comprehensive, and timely data for addressing the opioid epidemic in your state.

**Introduction**
The opioid epidemic is a public health emergency in the USA with opioid prescriptions a contributing factor.1,2 To combat it, better data is needed for targeted interventions.1,3,4 The objective of this study is to compare the traditional CDC reporting of opioid prescription rates to the newer Prescription Monitoring Program (PMP) in Louisiana (LA) in hopes of more accurate, comprehensive, and timely data for targeted solutions.

**Methods:**
This study compares the LA opioid prescription rate reporting from the CDC and the state’s PMP. CDC uses the Quintiles IMS Data Warehouse that captures 88-94% of retail prescriptions in the USA and does not account for all counties. The PMP captures all state parish opioid prescriptions. Population data was captured from the USA Census Bureau. Trends were evaluated between the CDC reported USA and LA opioid prescription rates to that of the PMP from 2013 to 2016. For 2016, opioid prescription data was also broken down by each of LA’s 64 parishes between the two databases and main outcome measurements evaluated the gross and percentage difference between the two data sources.

**Results**
This study compares the traditional CDC reporting of opioid prescription rates to the Prescription Monitoring Program in Louisiana. While CDC and PMP both show a downward trend in LA opioid prescription rates from 2013 to 2016, there is a difference of an average 15 prescriptions between the two databases during those years (Figure 1). In 2016, database comparison demonstrated a 16% difference in opioid prescription rates reporting for the entire state (Figure 1) and greater than 100% discrepancy in 11 of 64 (17%) of Louisiana’s counties (Table 1).

**Discussion**
National reports and agencies have preached that better data is necessary to combat the exponential growth of the opioid epidemic.1,3,4 PMPs have shown to provide more accurate, comprehensive, and timely data on opioid prescriptions compared to previously used datasets and need to be utilized and optimized to ensure appropriately data-driven, targeted interventions in curbing this epidemic.

The Role of Informatics in Social Needs Care Integration: Selected Results from a National Academies of Sciences, Engineering, and Medicine Committee Report

Rachel Gold, PhD, MPH1,2, Amber Haley, MPH3, Lisa A. Cooper, MD, MPH4, Laura Gottlieb, MD, MPH5

1OCHIN, Inc., Portland, OR; 2Kaiser Permanente NW Center for Health Research, Portland, OR; 3University of North Carolina, Chapel Hill, NC; 4Johns Hopkins University, Baltimore, MD; 5University of California, San Francisco, CA

Introduction: We present the final report of a National Academies of Sciences, Engineering, and Medicine (NASEM) ad hoc committee that was convened in July 2018, and charged with examining the potential for integrating 'social needs care' – e.g., services addressing social needs / social determinants – into the delivery of health care, to improve health outcomes. The committee’s report discusses current and emerging approaches to social needs care integration in diverse healthcare providers / systems; roles of different disciplines, care organizations, and types of providers; and efforts to inform the delivery of effective, efficient care that addresses social needs, improves health, and reduces health inequities. The report includes recommendations on how to: expand social needs care services; coordinate social needs care providers within interprofessional care teams; optimize the effectiveness of social services to improve health; integrate traditionally social and medical services; train and retain the workforce needed to support social needs integration; finance such integration; and address barriers to implementing this integration, including barriers related to technological and informatics. This presentation will touch on all aspects of the report, with primary emphasis on informatics-related barriers and facilitators to social needs integration into medical care. Committee members will be recognized in this presentation; they include experts in health services research, health equity, social work, etc.

Methods: A broad literature search was conducted. This was not a systematic review as the committee recognized that much relevant information would come from sources other than the peer-reviewed literature – e.g., the ‘grey’ literature such as reports and case studies. The search identified several thousand potentially relevant references, the titles and abstracts of which were reviewed. Of these, several hundred full-text articles were selected and reviewed, and a subset of them provided the evidence base used to support the report’s conclusions and recommendations. Three public sessions were held to obtain further information and perspectives, and the committee met five times in closed session to deliberate on the evidence and to develop conclusions and recommendations. The final report underwent exhaustive peer review.

Results: The committee report highlights the health information and technology needs of social and medical care integration, among other topics. It includes an extensive review and evaluation of informatics-related barriers associated with the implementation of electronic social risk documentation tools, and suggests potential facilitators to those barriers. The report addresses issues such as usability of the associated informatics tools, and associated staff training and resource needs, interoperability concerns, and data safety and patient privacy concerns. Details from the report will be given at this presentation, but cannot be listed here as the report is not yet public.

Discussion: The NASEM committee report could influence policies for health information technology innovations related to medical and social care integration; if feasible, the presentation will discuss how the report has been used since its release (September 2019). Committee recommendations about how to design and integrate technologies that better support social and medical care integration are likely to influence adoption in new settings.

Interventions to Increase Patient Portal Use in Vulnerable Populations: A Systematic Review

Lisa V. Grossman¹, Ruth M Masterson Creber², Natalie C Benda², Drew Wright³, David K Vawdrey¹, Jessica S Ancker²

¹ Department of Biomedical Informatics, College of Physicians and Surgeons, Columbia University, New York, NY, USA; ² Department of Healthcare Policy & Research, Weill Cornell Medicine, New York, NY, USA; ³ Samuel J Wood Library, Information Technologies and Services, Weill Cornell Medicine, New York, NY, USA

Introduction

Last year, millions of Americans accessed their own health records online, more than ever before.¹ Secure websites called patient portals offer convenient, 24-hour access to records, as well as other health management features. Portals provide patients with unprecedented transparency into health information, which evidence suggests may prevent medical errors, increase shared decision-making, and improve health outcomes.

Some researchers initially hoped that portals could reduce health inequities, defined as avoidable differences in health outcomes in vulnerable populations. Health inequities lead to poor health management and outcomes, which contributes to rising healthcare costs. Vulnerable populations often demonstrate lower health literacy and experience significant barriers to care, such as inflexible job hours, cost, and insurance status. Portal features might increase convenience, improve health literacy, and overcome at least some barriers to care, thereby reducing health inequities.

Unfortunately, more than 100 studies now show substantial health-equity-relevant disparities in portal use (citations available on request). Vulnerable populations use portals less often, including elderly persons, racial minorities, and persons with low socioeconomic status, low health literacy, chronic illness, or disabilities. Relatively low portal use in vulnerable populations may lead to intervention-generated inequity, a phenomena where well-intentioned solutions worsen existing health inequities rather than reduce them. Developing, implementing, and evaluating strategies to reduce disparities in portal use is critical to ensure portals benefit all populations as originally intended.

In this systematic review, we explore how researchers have confronted differential use of patient portals. Our review focuses on two critical questions: (1) what interventions impact portal use or predictors of portal use in vulnerable populations? (2) what interventions impact disparities in portal use?

Methods

We conducted this systematic review in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA). A librarian searched Ovid MEDLINE, EMBASE, CINAHL, and Cochrane Reviews for eligible English-language research articles published before September 1st, 2018. Additionally, we searched tables-of-contents of pertinent scientific journals before December 1st, 2018 to identify recently published citations. We used Covidence systematic review software for citation screening, as recommended by Cochrane. Two reviewers independently selected English-language research articles that evaluated any interventions designed to impact an eligible outcome. One reviewer extracted data from the included studies, and another assessed accuracy. To assess risk of bias, we used predefined criteria from the AHRQ² to rate studies as low, medium, high, or unclear risk of bias. Two reviewers independently assessed risk of bias.

We conducted descriptive analysis of study characteristics and assessed intensity of intervention as per the Cochrane Handbook for Systematic Reviews of Interventions.³ Additionally, we categorized interventions according to the components described in the System Engineering Initiative for Patient Safety (SEIPS) model.⁴ The SEIPS model segments work systems into 5 tightly coupled components. Per the model, a person (component 1) performs a range of tasks (component 2) using various tools and technologies (component 3). Performance of tasks occurs within a physical environment (component 4) under specific organization conditions (component 5). Interventions may target one or more of the 5 components. We categorized interventions based on which component(s) were addressed. One team member categorized the interventions, and a second team member with experience applying the SEIPS model (NCB) reviewed the categorizations. Using the SEIPS model allowed us to determine gaps in the targets of current interventions and shortcomings related to failing to consider the interaction among components of the work system.
Results

Literature searches identified 719 potentially relevant citations. Of those, 91 studies were deemed eligible for full text review, and 18 studies fulfilled the inclusion criteria for this systematic review. Studies employed a broad variety of outcome measures over varied time periods, limiting their comparability. For example, when reporting portal use, studies variably reported login-days, total logins, activation, or another measure. Four out of 18 studies (22%) did not report on participants’ race, and 8 (44%) did not report on ethnicity.

Intensity of intervention varied widely across studies. An example low-intensity intervention was one-time assistance with credentialing, whereas an example high-intensity intervention was training participants across 4 weekly 2-hour sessions. Four of 18 studies (22%) had low risk of bias, 9 studies (50%) had medium, 3 studies (17%) had high, and 2 studies (11%) were unclear.

Figure 1 presents the SEIPS system components intervened on in each study. 13 of 18 studies (72%) intervened on the individual (person) component, 5 (28%) on the tool component (i.e. patient portal), 1 (6%) on the task component (e.g. prescribing portal content), 2 (11%) on the environment component, and 4 (22%) on the organization component. Seven studies (39%) intervened on 2 components, but no study intervened on more than 2.

Out of 18 included studies, 15 (83%) assessed an intervention’s impact on portal use and 7 (39%) assessed impact on predictors of use. Only one study reported on how an intervention impacted health-equity-related disparities in portal use. Ten out of the 18 studies (56%) were reports on how technical training or assistance for patients impacted portal use. Eight of the 10 reported or permitted calculation of statistical significance, of which 6 demonstrated benefit (i.e. the intervention increased portal use), 1 demonstrated neutrality (i.e. the intervention did not impact portal use), and 1 demonstrated mixed results (i.e. the intervention both increased and decreased aspects of portal use).

Discussion

A growing body of literature suggests that patient portals can prevent medical errors, increase shared decision-making, and improve at least certain health outcomes. Unfortunately, every year, studies continue to be published adding to the evidence of disparities in portal use, and interventions will be critical to ensure portals do not disproportionately benefit more advantaged populations. Our results suggest that few studies have evaluated interventions to reduce disparities in portal use. Due to the strong evidence for disparities in use, the limited research on addressing them, and the need to ensure all populations benefit from portals, we recommend that researchers shift from identifying disparities in portal use, 1 demonstrated neutrality (i.e. the intervention did not impact portal use), and 1 demonstrated mixed results (i.e. the intervention both increased and decreased aspects of portal use).

Out of 18 included studies, 15 (83%) assessed an intervention’s impact on portal use and 7 (39%) assessed impact on predictors of use. Only one study reported on how an intervention impacted health-equity-related disparities in portal use. Ten out of the 18 studies (56%) were reports on how technical training or assistance for patients impacted portal use. Eight of the 10 reported or permitted calculation of statistical significance, of which 6 demonstrated benefit (i.e. the intervention increased portal use), 1 demonstrated neutrality (i.e. the intervention did not impact portal use), and 1 demonstrated mixed results (i.e. the intervention both increased and decreased aspects of portal use).

Discussion

A growing body of literature suggests that patient portals can prevent medical errors, increase shared decision-making, and improve at least certain health outcomes. Unfortunately, every year, studies continue to be published adding to the evidence of disparities in portal use, and interventions will be critical to ensure portals do not disproportionately benefit more advantaged populations. Our results suggest that few studies have evaluated interventions to reduce disparities in portal use. Due to the strong evidence for disparities in use, the limited research on addressing them, and the need to ensure all populations benefit from portals, we recommend that researchers shift from identifying disparities in portal use to systematically addressing them. Additionally, we recommend that future studies measure interventions’ impact on disparities in use directly, as most studies to-date have not. Finally, categorization using the SEIPS model demonstrated that most interventions to-date addressed primarily the individual (person) component, and lacked coverage of the other components as well as combinations of components. To enhance impact, we recommend that future interventions affect, or at least consider the repercussions on, multiple components.

Upcoming Publication

This work was accepted at the Journal of the American Medical Informatics Association in February 2019. It is scheduled to be published in the November 2019 journal issue.

What will the attendee be able to do after being in your session?
At the end of this presentation, attendees will be able to identify potential predictors of emergency room (ER) visits and hospitalizations in Veterans enrolled in a home telehealth program (HT) for heart failure.

Description of the Problem or Gap: Use of HT for chronic disease monitoring and exacerbation management in the Department of Veterans Affairs (VA) is increasing, but little is known about the relationship between adherence to the daily use of HT devices and health service use outcomes, such as ER visits and hospitalizations.

Methods: Adherence to the use of HT by Veterans with heart failure who were enrolled in the VA Home Telehealth Program from 1/1/14 to 6/30/14 was obtained from VA Telehealth Services. Demographic, health service use, and facility-level variables were obtained from the VA Corporate Data Warehouse. Average adherence after 1 year of first device use was calculated from weekly reports of adherence (number of daily responses / expected responses or 7 days). Zero-inflated negative binomial (ZINB) regression was used to determine which variables influence the probability of having an outcome (ER visit; hospital admission) after HT enrollment and the expected frequency of the outcome occurring.

Results: A total of 3,449 Veterans met the inclusion criteria for this study. The majority were white (75%) and male (98%). Twenty-nine percent had a diagnosis of depression, 31% had a cardiac implant, and the average ejection fraction was 42.7% (SD=15.8). The average age was 71 years (standard deviation [SD] of 10.4) and the average Charlson Comorbidity Index (CCI) was 6.5 (SD=3.2). Almost 60% had a Care Assessment Need (CAN) score of 95% (high probability of hospital admission or death within 90 days at the time of HT enrollment). HT program size was divided in thirds with the largest HT program having between 850 and 1,495 patients. Average adherence was 57.1 (SD=30.6). There were less ER visits after HT enrollment - mean (SD) of 1.85 (2.8) the year after compared to the year before with 2.2 (3.4); 42% of the patients had no ER visits compared to the year before (33%). In addition, there were fewer hospital admissions after HT enrollment – mean (SD) of 1 (1.5) the year after compared to the year before with 1.2 (1.6); 56% of the patients had no hospital admissions the year after compared to the year before (44%).

* Model also included (not significant): age, white versus other minority (non-black), gender, program size, rurality, average adherence after 1 year of enrollment; the hospital admission model also included reason for enrollment (e.g., non-institutional care).

Discussion: Patient adherence to the use of home telehealth devices is important to the success of any home telehealth programs to support chronic disease monitoring and management. In this study, average adherence after 1 year was not associated with ER visits or hospital admissions. Older age, being from a minority group (non-Black), and belonging to a large HT program were associated with not having an ER visit a year after HT enrollment. Being in poorer health (i.e., high CAN score, having depression, high CCI, having prior ER visit, etc.) was associated with higher expected count of going to the ER and having a hospital admission holding all other variables constant after HT enrollment. Limitations of this study include those inherent in the use of secondary data, use of VA data only, and inclusion of only those Veterans with heart failure enrolled in the first part of 2014.

Conclusion: Adherence to the use of HT devices was not found predictive of ER visits or hospital admissions in the year after HT enrollment. Other outcomes, such as quality of life, patient satisfaction, and off-load of work from the primary team, may be better outcomes to consider success of HT programs. Depression in patients with heart failure enrolled in HT programs should be addressed as this is associated with health service use. Further research is needed to identify factors related to race differences in health service use, as well as organizational factors that affect health service use in Veterans enrolled in HT programs.
Design and Use of an Inpatient Peer Support Technology Probe

Shefali Haldar¹, Yoojung Kim¹², Ari H Pollack¹³, Wanda Pratt¹
¹University of Washington, Seattle, WA; ²Seoul National University, Seoul, South Korea; ³Seattle Children’s Hospital, Seattle, WA

Introduction
When patients are admitted to the hospital, they have many needs—such as understanding their care, and communicating with their providers—that manifest over the course of their stay. Some technologies have helped to address these care-specific needs,¹ but inpatients have additional informational, emotional, and experiential needs that are not currently fulfilled. Patient-peers can serve as a critical resource to meet these additional needs.² Peer support—the exchange of advice among patients with common health experiences—is attributed to many positive outcomes, such as increased self-efficacy, knowledge, and empowerment.³ Prior work has demonstrated a strong desire to exchange peer support among inpatients.⁴⁻⁵ Yet, technologies that facilitate peer support (e.g., online health communities) are commonly studied in every-day life and outpatient settings, or with patients managing chronic conditions. Although peer support programs have been created for both pediatric and adult inpatients, most involve in-person or phone encounters, and the potential for a technology-driven approach has not yet been fully realized. Therefore, we sought to investigate how patients use a peer support tool to interact with each other in the real-world context of their hospitalization.

Methods
We used the technology probe method, a Human-Computer Interaction approach to deploy a technology (i.e., probe) in a real-world context, study how it is used, and examine its impact on end-users.⁶ We first designed and built a fully functional inpatient peer support technology probe, then deployed it at a pediatric and an adult hospital. Patients were eligible if they were at least 7 years old, well enough to provide informed consent, and could communicate in English. Parental consent was obtained for all pediatric patients. We enrolled 30 participants (15 at each site) who were evenly divided among gender identity (female and male) and hospital service (medical and surgical). At the pediatric site, the mean age was 13 years (SD 2.56) and mean length of stay was 5.13 days (SD 3.74). At the adult site, the mean age was 55.8 (SD 15.84) and mean length of stay was 14.4 days (SD 22.79). We collected data about participants’ usage period of the probe, lasting from the time of their enrollment in the study until their discharge from the hospital. All study procedures were approved by our IRB.

Inpatient Peer Support Technology Probe Design
By using a subset of design recommendations we previously identified on this topic,⁴⁻⁵ we created an inpatient peer support technology probe that allowed an asynchronous exchange of peer advice among inpatients. We designed a web-based probe resembling an online health community with functional similarities to Reddit, a web content repository and social media site. Key features included stories (original posts), comments, and votes (analogous to “likes” on other social media sites). Our probe was built using WordPress and hosted at two domain names, one designated for each study site. Links to the probe were only given to study participants. All participants were given access to the probe via a research team-owned iPad.

Analysis of Usage Period Data
Descriptive statistics were used to analyze data about participants’ usage events on the probe (i.e., the number of stories, comments, and votes they contributed to the system). Using our previously identified peer support needs of inpatients,⁴⁻⁵ we did a deductive qualitative analysis of the content they contributed to the probe (i.e., the type of information shared with peers through posting stories and comments). To measure the emotional tone of these stories and comments, we conducted a sentiment analysis using the IBM Watson Natural Language Understanding (NLU) tool. Finally, we did a Social Network Analysis (SNA) to analyze the interactions that participants had with each other (i.e., comments in response to stories; which participants voted on which stories).

Results
Throughout our study period, 76% (23/30 participants) contributed to the technology probe. Pediatric participants averaged a total of 2.7 usage events and posted 13 stories, 2 comments, and 12 votes. Their adult counterparts averaged
a total of 2.2 usage events and contributed 6 stories, 14 comments, and 13 votes. Across both study sites, a total of 6 participants exclusively posted stories, 1 participant exclusively commented on stories, 5 participants exclusively voted on stories, and 11 participants did some combination of those three types of activities. The remaining users (2 pediatric and 5 adult participants) had no recorded usage events on the probe due to illness or disinterest in the content. Participants shared a variety of information and support for their peers, including how to adjust to the unfamiliar hospital environment (“if you are staying the night in the hospital, pack your own comfy blanket”) and encouragement to speak up to providers about a problem (“if you don’t think you’re getting the care you need, ask for the charge nurse as recourse”). Stories and comments of 81.8% of pediatric participants and 57.1% of adult participants received positive mean sentiment scores. Our SNA revealed pediatric participants’ interactions were relatively spread out and contained 80% (12/15) participants, while adult interactions contained 60% (9/15) participants, gravitating towards 2 primary interaction “hubs”.

Discussion and Conclusion

Our participants’ use of the probe suggest that technologies designed to enable inpatient peer support have great potential in this context. Our analysis revealed that pediatric and adult participants share advice that is largely encouraging to peers and positive in emotional tone. Moreover, each site had different usage patterns: pediatric patients shared individual stories and had distributed interactions, while adult patients had concentrated interactions with existing discussions. These distinct usage patterns might be due to generational differences regarding the perceived purpose and value of technologies resembling social media. Future inpatient-facing technologies must be designed to accommodate these differing usage patterns, as technologies must support broader patient populations. In addition, future work should explore strategies for long-term implementation of peer support technologies within hospitals.

Simulation Study of Just-in-Time Specimen Recruitment from University-Wide e-Phenotypes of Interest

Bashir Hamidi, MPH, Leslie A. Lenert, MD, FACMI, Alexander V. Alekseyenko, PhD
Biomedical Informatics Center, Medical University of South Carolina, Charleston, SC

Introduction
The ability to obtain for human specimens from precisely phenotyped cohorts is important for advancing translational research. A pool of suitable specimens, including blood and microbiology, are often available within medical centers incidental to delivery of routine care. After recording of the clinical test results, surplus aliquots of the biospecimens are usually available to be re-routed for research, albeit for a short window of time before they are discarded. Biobanking of such specimens could preserve them for future research use; however, the burden with setting up and maintaining blood or microbiology biobanks may be too large for many institutions. Therefore, systems and platforms for just-in-time re-use of surplus clinical specimens are necessary to minimize the regulatory burden for investigators and accelerate translational research. These systems and processes should allow investigators to perform population and cohort-based studies with de-identified specimens that qualify as non-human subjects research (exemption 4). Examples of existing platforms include: (i) Harvard’s Crimson system, which combines its i2b2 instances with a link to its laboratory specimen processing system; and (ii) the Vanderbilt BioVu system, which operates more like a traditional biobank with storage of specimens.

In conjunction with the MUSC Living BioBank (LµBB) system for surplus blood, we are developing the Living µBiome Bank (LµBB), a NIH/NCATS supported system for just-in-time capture of existing microbiology specimens for microbiome research. Both systems, LµBB, operate as a unit and rely on the state-of-the-art concepts in (i) e-phenotyping, to identify cohorts of patients for which specimens are necessary; (ii) research permissions capture, to ensure ethical and compliant specimen recruitment; and (iii) research data warehousing (RDW), to store de-identified microbiome measurements linkable to rich clinical data. The primary microbiology specimen source for the LµBB is the active infection surveillance culture program for methicillin-resistant Staphylococcus aureus and vancomycin-resistant Enterococcus. Annually, this program generates over 15,000 nasal swabs, which can serve as proxy for the oral and upper-respiratory microbiome, and 7,500 peri-anal swabs, which can serve as practical proxy for gastrointestinal microbiome. These swabs are collected incident to treatment and typically early in the treatment course. The surveillance testing typically results in 75% of the specimen volume remaining as surplus, which are suitable for marker gene sequencing-based microbiome assays.

Methods
The adoption of just-in-time biobanking concept relies on the ability of an investigator to specify electronic phenotypes (e-phenotypes) correctly and ensure that the resulting cohort captures the nuanced clinical characteristics of the desired study population. We have executed an expert-driven simulation study of the LµBB to understand the challenges involved in specification of e-phenotypes and to develop methods to estimate phenotype-specific accrual rates by simulating recruitment of specimens from retrospective RDW data. Many routinely collected specimens can be included in LµBB, but here we have focused on three specimen types: (i) blood; (ii) nasal swabs; and (iii) peri-anal swabs. MUSC IRB considered this a quality improvement project and therefore exempt from review.

Figure 1. Simulation study outline (left) and data obtained from RDW (right).
The outline of the simulation study design is shown in Figure 1A. We have identified 20 experts across MUSC, including College of Medicine, College of Dental Medicine, College of Nursing, and Cancer Center to serve as disease area experts to conduct the simulation study of 20 respective e-phenotypes and cohorts. The experts have completed an entry questionnaire to evaluate their degree of proficiency with i2b2 used for e-phenotyping. With assistance from study coordinator and honest broker each expert has specified their desired e-phenotype in i2b2 and transmitted it to Biomedical Informatics Center (BMIC), where the query has been translated into SQL query into RDW data. BMIC database team has simulated recruitment of 20 subjects matching the e-phenotype in historical de-identified RDW data. We have produced de-identified charts for these patients, along with accrual rates for the specimens and other relevant metrics (Figure 1B). Each chart has been reviewed by the expert to determine if it is a match or mismatch to the desired phenotype, or if it is hard to tell. An exit questionnaire has been offered to the expert to reflect on their experience using i2b2 system and their recommendations for the specimens obtained from L(µ)BB.

Results

The entry questionnaire included a single question aimed at gauging the experts' level of confidence in being able to specify an e-phenotype of interest using i2b2. Using a four-level Likert scale only 20% of experts were not at all confident, 15% were highly confident. Based on their feedback, most of the respondents conflated their own ability to use the i2b2 system, with expectations about the quality of the data, and their confidence in study coordinator and honest broker, which could have possibly confounded these results. The data simulated from RDW reproduced the total number of observed patients from i2b2 with correlation of close to 100%. The largest relative discrepancy in the numbers was observed in phenotypes with the least number cases.

For phenotypes where the experts have been able to review charts, the chart match rate to the desired phenotype varied dramatically (Fig. 2A). Interestingly, the mean match rate was inversely proportional to the expert confidence level (Fig. 2B). Most of the e-phenotypes yielded cohorts where blood and microbiome specimen accrual rates are reasonable for a pilot study with quick turnaround (Fig. 2C).

Discussion

This project revealed several issues with defining e-phenotypes for just-in-time biobanking: (i) e-phenotypes descriptions need to differentiate patient characteristics vs clinical events necessary for patient inclusion/exclusion; (ii) temporal constraints are hard to specify and are often not intuitive even for experienced i2b2 users; (iii) many data issues may affect the resulting phenotype and cause the expert to compromise their desired definition bases on the mapping status of diagnoses, problem lists, labs and heterogeneity of coding procedures by different clinical teams; (iv) medications are perhaps the most challenging single group of phenotype characteristic, especially because the route of administration often is not documented. In our talk, we will discuss these, and other issues identified in the project and present more details on the results. The details of IRB status of the L(µ)BB will likewise be discussed.

Effects of an Interactive Trust-enhanced Electronic Consent on Patient Experiences with Consenting to Share their Health Records for Research

Christopher A. Harle, PhD1,2, Elizabeth H. Golembiewski, MPH1, Kiarash P. Rahmanian MPH3, Babette Brumback, PhD4, Janice L. Krieger, PhD5, Kenneth W. Goodman, PhD6, Arch G. Mainous III, PhD3,7, Ray E. Moseley, PhD3

Introduction

Electronic health record (EHR) data has created many opportunities for research, including analysis of large-scale repositories, targeted research recruitment, and cross-institutional data sharing.1,2 However, ethical and legal standards suggest and sometimes mandate that patients consent to the use of their health information for secondary research purposes. For example, the U.S. Federal Policy for the Protection of Human Subjects (Common Rule) now permits health care institutions to seek broad consent from patients for future, to-be-specified, research uses of their EHR data.3 Broad consent has potential value for institutions, as it may facilitate the use of patient data to analyze treatment and outcomes over time, and it gives patients more control over their health records compared to waivers of informed consent. However, little guidance exists for best practices for obtaining broad consent in a way that is minimally invasive to provider workflows and easily scalable, while also ensuring that patients have the information needed to make an informed decision. In addition, little is known about how to present consent information electronically (i.e., as an e-consent) in order to maximize patients’ satisfaction with their consent decisions and their understanding of consent content. Therefore, in the context of broad consent for future research using identifiable EHR data, the objective of this study was to compare the effectiveness of an interactive trust-enhanced broad e-consent to an interactive only e-consent and a standard e-consent (no interactivity, no trust enhancement).

Methods

A randomized trial was conducted among adult, English-speaking participants making a regularly scheduled primary care visit. Each participant was given a tablet computer and block randomized to one of three e-consent application conditions, which were previously developed via a user-centered design process.4 Each condition asked patients for their consent to include their identifiable EHR data in a family medicine database for use in future, yet-to-be-specified research studies. The standard e-consent contained only the minimum federally-required elements of informed consent. The interactive-only e-consent included all information present in the standard e-consent, as well as clickable links to additional content. Finally, the interactive trust-enhanced e-consent included all elements of the standard and interactive only e-consents, as well as five short messages describing trust-relevant information on research regulations, researcher training, and data protections. Primary outcomes were patient-reported satisfaction (modified Satisfaction with Decision scale) with and subjective understanding of the e-consent (modified Quality of Informed Consent scale). Secondary outcomes were objective knowledge, perceived voluntariness, trust in medical researchers, and consent decision. All measures were based on existing scales found in peer-reviewed literature.5 Outcomes were assessed immediately after e-consent use, and at one-week and six-month follow-up. Mixed model regression analyses were used to estimate the relationship between consent condition and each outcome over time. Each model included a participant random effect and fixed effects for consent condition, time (immediate, one-week, or six-month follow-up), participant age, education level, gender, race, and ethnicity.

Results

At immediate follow-up, participants across all conditions (N = 734) reported moderate to high satisfaction with consent (mean 4.3 out of 5) and subjective understanding (79.1 out of 100; see Figure 1). In addition, over 94% of
participants consented to share their health record data. At immediate and one-week follow-up, no differences in primary or secondary outcomes were observed between conditions. However, at six-month follow-up, relative to participants who used the standard e-consent, participants who used the interactive, trust-enhanced e-consent reported higher satisfaction ($\beta = 0.86, p < 0.0001$) and subjective understanding ($\beta = 31.94, p < 0.0001$) as well as higher objective knowledge ($\beta = 2.11, p < 0.0001$), perceived voluntariness ($\beta = 3.87, p < 0.0001$), and trust in medical researchers ($\beta = 12.38, p < 0.0001$). Similarly, at six-month follow-up, participants who used the interactive only version reported higher satisfaction, subjective understanding, objective knowledge, and trust in medical researchers relative to participants who used the standard e-consent (all $p < 0.0001$). In sensitivity analyses to account for attrition, similar results were obtained when examining only the subset of participants (N = 472, 64%) who participated in all three follow-up surveys.

Figure 1. Satisfaction (1-5) and subjective understanding (0-100) at immediate, one-week, and six-month follow-up.

Discussion

In a randomized trial of three e-consent applications, a large majority of participants agreed to share their health information for future unspecified research. At six-month follow-up, patients who had used an e-consent with only standard information exhibited reductions in their initially high satisfaction with and understanding of the consent. Conversely, participants who had used an e-consent with interactive capabilities to obtain additional information and with messages designed to enhance trust in research institutions and processes tended to maintain high levels of satisfaction, understanding, knowledge, perceptions of voluntariness, and trust. These results suggest that systems designers, policymakers, and institutions that implement broad consent may achieve better patient consent experience outcomes by augmenting standard consent content with options to obtain more information and with factual messages designed to enhance trust by addressing patient concerns about how their data are used and safeguarded in research. As patient-facing informatics applications continue to integrate with healthcare delivery processes and information technology, e-consent tools are increasingly feasible. Still, the value of implementing and maintaining e-consent for research use of health records must be weighed against other, potentially conflicting operational objectives, such as patient throughput.

Is Online Portal Training Effective for Older Adults? An Experimental Study to Evaluate the Impact of Providing Patient Portal Multimedia Instructional Materials on Older Adults' Performance in Using Portals

Yuqi He, MLIS
University of Wisconsin - Madison, Madison, WI

Introduction

Patient portals (PPs) are recognized as one of the most important tools to solve the challenges of accessing and managing personal health information and support greater patient engagement. The growing aging population could greatly benefit from using PPs because of the prevalence of chronic conditions and high medication use, and therefore a more pressing need for ongoing health information management and self-management of conditions. However, when compared with other age groups, older adults are generally lagging behind others on portal enrollment and portal use. It is likely that older adults encounter more problems in using portals for a number of reasons, including age-related sensory and cognitive declines, increased risk of functional impairments, less experience with computers and internet, and higher prevalence of low health literacy and numeracy1.

One critical barrier to PP adoption is lack of sufficient training to instruct patients on use of a portal2. Research has shown that older adults with limited computer experience and limited health literacy3 require additional support to learn how to use the system. Studies also found that even older adults with adequate health literacy and internet experience desire instructions on specific tasks for using portals3. In spite of a strong need for portal training, this training is generally not given by health care providers due to lack of resources4.

In an effort to fill the gap on PP instructional support, we designed two forms of online PP multimedia instructional materials for new older portal users (see 5 for the design process). One was a PDF file using a combination of graphics (i.e., screenshots) and texts; another was a customized slide-show presentation (in HTML5 format) using graphics and narrations together. The aim of this study was to evaluate their outcomes to explore the value of training. In particular, we hypothesized that 1) participants who received training would demonstrate better outcomes than the control group in PP knowledge, PP self-efficacy, and usability metrics (task success, task time, task difficulty, and perceived usability), and 2) training would result in best performance on tasks identical to tasks learned in the instructional materials and worst performance on tasks different from tasks learned in the instructional materials.

Methods

Experimental Design: A randomized complete block design (RCB) was used to reduce variability within treatment conditions. Health literacy and computer experience were chosen to serve as blocking factor because these two factors have been identified as critical variables that affect portal use among older adults1,3. The experiment had three independent variables: block with four levels (inadequate health literacy (-HL) & inadequate computer experience (-CE), -HL & +CE, +HL & -CE, +HL & +CE), treatment/instruction with three levels (HTML5 instruction, PDF instruction, no instruction/control), and task type with three levels based on the closeness between the task problems and the tasks learned in the instructional materials (identical tasks, similar tasks, different tasks).

Eligibility: All participants were required to 1) be aged 65 years or older, 2) be native English speakers, 3) do not have a diagnosis of cognitive impairment, 4) be able to read a computer screen, 5) be able to hear sound from a computer, 6) be able to use a keyboard and a mouse, (7) and have not used a patient portal before (novice users).

Procedure: The researcher traveled to community places at participants’ choice for data collection. At the beginning of a session, participants were asked to complete a battery of questionnaires on demographics, computer and internet experience, health literacy6, and baseline PP knowledge. Next, the researcher provided basic computer training to the participants on the study laptop. Then, Participants were randomly assigned to one of the three treatment/instruction conditions. Upon the completion of instructions, participants were asked to complete 15 tasks (5 identical, 5 similar, and 5 different tasks) on a portal and the Single Ease Question (SEQ)10 appeared after each task for measuring perceived difficulty on a task level. Task time and participants’ on-screen activities were captured by a usability testing software (i.e., Morae) for later review. Last, participants completed questionnaires on System Usability Scale (SUS)11, PP knowledge, and PP self-efficacy (modified based on12). The whole research session lasted 90 minutes on average. The portal used for this study was a simulated patient portal based on Epic's MyChart, named "MyHealth Portal."
Results

Forty participants completed this study (the required sample size from power analysis was 36), including 14 men (35%) and 26 women (65%). The majority of them (80%) were White. Participants’ age ranged from 65 to 86 years ($M = 73.07, SD = 6.61$). The vast majority of them (95%) were retired and reported to be in good to excellent health. The sample was educationally diverse and had fairly low income.

Figure 1 below shows the percentage of participants (in trained and not trained group) who completed each task successfully. In both groups, the most successful task was Task 1 (identical task) and Task 5 (similar task). In contrast, the least successful task was Task 4 (different task) and Task 9 (different task). Analysis on task time and task difficulty revealed that Task 4 and Task 9 took the longest time and were rated as the most difficult tasks.

Figure 1. Success rates for 15 tasks

Statistical analysis showed that, when controlled for health literacy and computer experience, older participants who received portal training had significantly better outcomes in after-test PP knowledge scores ($p < .001$), PP self-efficacy ($p < .001$), total task success ($p < .001$), and SUS ratings ($p = .003$) than those who had no training, except for total task time ($p = .37$) and total SEQ scores ($p = .22$). The HTML5 instruction did not result in any significantly better outcomes than the PDF instruction ($p > .05$). These results indicate that the HTML5 instruction and the PDF instruction were equally effective in improving older adults’ performance in using patient portals.

Mixed ANOVAs were constructed to examine group (trained and not trained)-by-task type interaction for testing H2. The interaction term was significant on task success ($p = .03$) and SEQ scores ($p = .004$), but not task time ($p = .79$). These results suggest that, depending on the instructional content, training can result in best task performance (more tasks completed, lower task difficulty) on identical tasks; however, training has no notable effect on tasks that are different from the tasks learned in the instructional materials.

Conclusion

The findings of this study show that PP instructional materials are effective in improving older adults’ knowledge and confidence in using PP, and boosting task success rate and perceived usability of a PP website.

Redesigning PopMedNet™ for distributed regression analysis with vertically partitioned data

Qoua L. Her, PharmD, MSc¹, Yuji Samizo, MS², Thomas Kent, PhD², Aleksandra Slavkovic, PhD², Mia Gallagher, MPH¹, Sengwee Toh, ScD¹

¹Harvard Pilgrim Health Care Institute, Boston, MA; ²Department of Statistics, Penn State University, University Park, PA

Introduction

Generally, multiparty analyses involve two types of data partition environments, horizontal and vertical. Horizontally partitioned data refer to an environment where data-contributing sites hold distinct cohorts of patients with the same data attributes (Figure 1).¹ Vertically partitioned data refer to an environment where data-contributing sites hold distinct data attributes of a cohort of patients (Figure 2). Distributed regression analysis (DRA) is a privacy-protecting analytical method that allows investigators to perform multivariable regression analysis in both types of data environments, with only summary-level data.¹ DRA has been demonstrated to produce precise regression parameter and standard error estimates (<10⁻⁶) compared to the estimates obtained from regression analysis with the pooled patient-level data.¹,² However, DRA with some regression models requires an iterative process, where data-contributing sites compute and share summary-level data with a trusted-third party (often refer to as the analysis center) until the model converges.

This iterative process is laborious and susceptible to human error. We previously enhanced PopMedNet™, an open-source file-sharing software, to create an automatable and iterative file transfer process, to organize and facilitate DRA with horizontally partitioned data.³ We integrated the workflow with a SAS-based DRA application and perform DRA with horizontally partitioned data. Limited work has been done to facilitate DRA with vertically partitioned data. We explore the feasibility of using PopMedNet to organize and facilitate DRA with vertically partitioned data.

Methods

We gathered the statistical and informatic requirements of DRA with vertically partitioned data. We developed an R-based application to perform distributed linear, logistic, and Cox proportional hazards analysis with vertically partitioned data. We integrated the application with PopMedNet and identified and implemented additional PopMedNet enhancements needed to optimize the execution of the application.
**Results**

PopMedNet can be used to facilitate DRA with vertically partitioned data. Initially, we were able to compute precise regression results (< $10^{-7}$) with datasets of small sample sizes and few covariates (n < 5,000 and 10 covariates). DRA with larger datasets (more patients and covariates) would require significantly longer computational (> 24 hours) and file transfer times (> 24 hours), making PopMedNet inoperable with its existing configuration. To decrease the computational time of large datasets, we horizontally partitioned the two vertically partitioned datasets into blocks, performed the matrix computations within each block, and aggregated the computed summary statistics across the blocks. This approach greatly reduced the computational time, but at the tradeoff of increased overall file transfer time due to a greater number of files needed to be transfer, again making PopMedNet inoperable.

Thus, we implemented two new PopMedNet enhancements to optimize and facilitate the execution of the DRA application with vertical partitioned data. The first was concurrency of file upload and download. Prior to this enhancement, PopMedNet uploaded and downloaded only one file at a time. Concurrency increased the number of simultaneous file upload and download, which decreased overall file transfer times. The second was the option to transfer files directly between data-contributing sites. We previously designed PopMedNet to only transfers files between data-contributing sites and the analysis center. This enhancement allows PopMedNet to support DRA algorithms for vertical partitioned data that are computational more efficient. We were able to perform vertical DRA with datasets of 20,000 to 1,000,000 observations and five to 45 covariates, with precise regression results (< $10^{-7}$) compared to the pooled patient-level data analysis (Table 1). Full end-to-end execution times ranged from 6 to 92 minutes, depending on the regression model type, size of the dataset, and the number of covariates in the model.

**Discussion**

PopMedNet can be used to facilitate vertical DRA. To increase computational and operational performance, two new PopMedNet functionalities were developed and implemented.

Building Safer EHRs: Hospital Medication Order Safety Performance

A Jay Holmgren, MHI,1,2 Zoe Co, BS,2 Lisa P. Newmark, BA,3 Melissa Danforth, BA,4 David C. Classen, MD MSc,5 David W. Bates, MD MSc.2,3,6

1Harvard Business School, Boston, MA, 2Department of General Internal Medicine, Brigham and Women’s Hospital, Boston, MA, 3Clinical and Quality Analysis, Partners Healthcare, Somerville, MA, 4The Leapfrog Group, Washington D.C., 5University of Utah Health Science Center, Salt Lake City, UT, 6Harvard Medical School, Boston, MA

EHRs can improve safety via decision support-enabled CPOE, to catch adverse drug events (ADEs) before they reach the patient. A national sample of 1,527 hospitals from 2009-2016 took a safety performance assessment using simulated medication orders. The average EHR identified 54.0% of potential ADEs in 2009, rising to 61.6% in 2016. Hospitals which took the assessment multiple times performed better in subsequent years. The details of implementation and use of CPOE plays a key role in performance.

Introduction: Electronic health records (EHR) with decision support-enabled computerized physician order entry (CPOE) have become ubiquitous in US hospitals. CPOE allows decision support systems to intervene at the point of care, preventing potential adverse drug events (ADEs) before they reach the patient. However, evidence indicates that the effectiveness of these systems at improving quality is mixed.1 Hospitals have tremendous latitude with respect to what they actually implement with any vendor, especially around decision support. It is clear that EHR adoption does not necessarily lead to patient safety improvements – the structural quality improvement (EHR implementation) does not necessitate the process quality improvement (ensuring CPOE systems identify ADEs).2 We used a national hospital sample with data from a simulation designed to assess clinical decision support systems performance in identifying potential adverse drug events in hospital CPOE systems, to answer three research questions. First, how effective are hospital CPOE systems at identifying potential adverse drug events? Second, has hospital CPOE safety performance improved over time and as hospitals take the test repeatedly? Finally, what hospital characteristics are associated with better CPOE safety performance?

Methods: We used data from the Leapfrog Group’s CPOE assessment test from 1,527 hospitals in an unbalanced panel from 2009 to 2016 with 5,107 hospital-year observations. The Leapfrog CPOE assessment uses simulated patients and medication orders to evaluate what percentage of potential adverse drug events were correctly identified by an electronic health record.3 We linked these results with data from the American Hospital Association (AHA) Annual Survey from 2009 – 2016 to capture hospital demographic information. We first calculated mean CPOE assessment test scores over time, from 2009 through 2016. We then created a multivariate ordinary least squares regression model with hospital CPOE test scores as our dependent variable and our set of hospital demographics as independent variables, as well as number of years the hospital had participated in the CPOE simulation test. Our model also included hospital random effects and year fixed effects, as well as robust standard errors clustered at the hospital level.
Results: The mean CPOE performance test result increased over time, starting at 54.0% in 2009, and rising over time: 57.1% in 2010, 56.8% in 2011, 58.1% in 2012, 58.7% in 2013, 58.7% in 2014, 60.2% in 2015, and finally 61.6% in 2016. (Figure 1)

Figure 1. Mean Hospital CPOE Safety Performance Test Scores, 2009 – 2016

In the multivariate regression results, we found that each year of experience in taking the test was significantly associated with a 1.9% increase in CPOE safety performance scores ($p < 0.001$), even after controlling for other hospital demographics such as size, academic medical center status, location, and ownership.

Conclusion: While hospital performance on the Leapfrog CPOE assessment improved from 2009 to 2016, decision support systems still caught fewer than two-thirds of potential ADEs in simulated patient orders. Hospitals who took the assessment multiple times performed better in subsequent years than hospitals taking the test for the first time, suggesting that intentional quality improvement efforts as represented by participating in the voluntary CPOE assessment are an important enabler of higher safety performance.

Introduction

The era of precision health recognizes the increasing value of more diverse and granular data elements to inform our understanding of human health.1 In support of this approach, there is demand for new approaches for integrating clinical, social, genetic, environmental and other exposome data for individuals and populations. Regenstrief has partnered with several organizations addressing Indiana’s opioid epidemic, including the Indiana Management Performance Hub (MPH), to create both a technical infrastructure and a governance process to facilitate gathering, managing, sharing, and using population health data for both practice and research in Indiana. The technical infrastructure leverages a common data model that reconciles individual and population-level data. The governance model, which includes representation from stakeholders that both contribute and consume data, develops policies and processes for exchanging key data for priority use cases, including individual and population level data sets focused on opioid-related abuse and deaths.

The Regenstrief Institute curates many clinical data sources including electronic health information from over 100 institutions spanning Indiana.2 The Indiana MPH enables data sharing and transparency among myriad state organizations, maintaining data from the Department of Homeland Security, Indiana Commission for Higher Education, Department of Workforce Development, State Police and others, which can be leveraged in public-private collaborations to enable data-driven decision making. Regenstrief and MPH partnered to pilot a data integration project to enhance the usability of clinical and social determinants of health data to study the opioid epidemic in Indiana. This presentation describes the process for matching patient-level emergency department visits with Indiana Department of Homeland Security emergency medical service (EMS) run data.

Methods

EMS run data was made available for the years 2014 through 2017 by the Indiana Department of Homeland Security (DHS) and the Indiana MPH. From 2014 through 2017 a total of 2,228,796 EMS runs were reported through the Indiana DHS and attributed to 1,258,294 individuals. An emergency department utilization cohort was generated from the Indiana Network for Patient Care (INPC), one of the nation’s largest health information exchanges. Individuals with one or more emergency department (ED) encounters from 2014 through 2017 were included in the study cohort. From 2014 through 2017, a total of 18,204,788 ED encounters were reported through the INPC and attributed to 3,169,999 of individuals.

We used a privacy preserving record linkage (PPRL) process to protect unique patient identifiers within both cohorts.3 Both Regenstrief and MPH applied the hashing methodology to their respective cohorts. In addition to the hashed identifers, we created a unique pseudonymous identifier for each individual, which maps back to each source’s original data. Regenstrief securely transmitted hashed identifiers and pseudonymous ID’s for the INPC cohort to Indiana MPH. After identifying matching individuals with one or more EMS run, MPH then securely transmitted the EMS data payload to Regenstrief with the Regenstrief pseudonymous ID attached. (Figure 1)

![Figure 1: Data Matching Process. Regenstrief and MPH each created and exchanged local hashed identifiers, identified matching records, and created a composite payload dataset.](image)

Results

The matching process yielded a total of 244,421 unique individuals linked between the two data sets. Of these linked individuals, a total of 331,666 ED encounters could be linked to corresponding EMS runs. Table 1 highlights the yearly breakdown of the linked ED encounters and EMS runs, as well as those who received naloxone during an EMS run.

Discussion

We achieved two important aims in this pilot. First, we enabled a real-world reproducible process for securely hashing, matching, and transferring de-identified data among two or more distinct institutions. Second, we created a unique dataset linking ED encounters from an HIE to their corresponding EMS run from DHS. The benefit of linking the EMS and ED data allows for a more comprehensive understanding of the care continuum, beginning with EMS pickup and continuing through the ED encounter, and will enable future discovery and innovations. (Figure 2)

![EMS Care Continuum](image)

Information such as naloxone administration, which is often not captured in a systematic fashion in the ED, can be used to supplement clinical observations seen in the ED. Alternatively, organizations such as Indiana DHS can improve situational awareness with a better understanding the dispositions for EMS run patients receiving ED care. Enabling the linkage of these two data sources can support a host of research questions aimed at identifying the needs and characteristics of EMS/ED patients across the state of Indiana. Specific emphasis will be placed on examining the readmission rates and clinical outcomes of those individuals who received a naloxone administration during an EMS encounter. We will also refine this generalizable framework to link and share additional data as well as align the technical infrastructures supported by both MPH and the Regenstrief Institute. Our future work will support further integration and analysis of other clinical and non-clinical datasets to support research efforts including the opioid epidemic, precision health, and beyond.

Conclusion

It is feasible to develop collaborations and technical infrastructure to integrate clinical and nonclinical data using reproducible, deidentified, and scalable approaches.

Abstract

The Cox proportional hazards model is a popular semi-parametric model for survival analysis. In many situations, data of the same cohort of patients might reside at different institutions. We aim at developing a federated algorithm for the Cox proportional hazards model over vertically partitioned data. Our algorithm, namely VERTICOX, is to obtain the global model parameters in a distributed fashion without collecting individual patient-level data.

Introduction

Survival analysis is widely used for time-to-event healthcare data and can facilitate the comparative study of treatment effectiveness and outcomes of interest (i.e., mortality, disease, recurrence). There have been a lot of studies including individualized survival analysis to evaluate prognostic factors in oncology. Among survival analysis studies, Cox proportional hazards [1] is one of the most popular models. It utilizes the hazard function to assess the significance of covariates to the survival times of individuals or subjects. The model can exploit covariate information to determine the importance of predictors, establish flexible and robust regression models considering time-varying effects, and examine the variation of treatment effects across multiple institutions, among other applications. To make full use of Cox model, we would like to integrate all pieces of fragmented healthcare information associated with patients (i.e., different visits, different sources, different modality, etc.) However, inter-institutional exchange of patient-level data is often restricted due to institutional policies, legislation, or privacy concerns. For example, in the United States, patient data shall be hosted by covered entities in HIPAA-compliant environments [2] without disclosure to unauthorized third parties. The NIH Genomic Data Sharing (GDS) policy [3] requires participants’ consent to exchange genomic data. Effective May 2018, the General Data Protection Regulation (GDPR) [4] of the European Union (EU) requires institutions collecting or processing personal data of EU citizens to protect their privacy. Analysis and prediction methods that do not explicitly exchange patient-level data can enable distributed data analyses in many practical applications. Federated data analysis methods allow researchers to build global statistical models without sharing patient-level data with other parties.

There is a need to develop a survival analysis model using distributed data across multiple institutions. Prediction and analysis of diseases and effectiveness of treatments can be enhanced by making use of massive healthcare data collected by numerous organizations such as hospitals, research institutions and government agencies. For example, the patient-centered Scalable National Network for Effective Research (pSCANNER) [5] integrates data from over 31 million patients to facilitate comparative effectiveness researches and prospective analyses, without sending those data out of their institutions. In this work, we will introduce a recently proposed method, called VERTICOX, for distributed survival analysis over vertically partitioned data, which is based on the alternating direction method of multipliers (ADMM) framework [6]. Distributed optimization is made for the federated data analysis over covariates that are vertically distributed across multiple institutions. A client-server architecture is established for iterative optimization for model parameter estimation.

Method: In the proposed framework, each institution only transmits aggregated intermediary results to the server at each iteration while the individual patient data are kept private within their host institutions (see Figure 1). Distributed model parameter estimation for the Cox proportional hazards model is developed using the Breslow’s partial likelihood function [7] (see Figure 2) based on the aggregated intermediary results. Thus, model parameter estimation and subsequent survival estimation can be conducted in a privacy-protecting fashion. VERTICOX is demonstrated to
converge at a linear rate under the ADMM framework. The proposed method is evaluated on real-world applications over the Internet. Experimental results demonstrate that the proposed method can achieve equivalent accuracy in the estimation of model parameters and statistics when compared to its centralized counterpart.

![Diagram of Breslow's partial likelihood function](image)

**Figure 2**: Estimation of Breslow’s partial likelihood function can be decomposed into a set of linear problems by ADMM

**Results**: The SEER dataset ([https://seer.cancer.gov/data/](https://seer.cancer.gov/data/)) was sampled from 55,007 breast cancer patients with first diagnosis from 2001 to 2009. Twenty features were derived from 9 covariates including age at diagnosis (AAD), race, marital status, histology, grade, tumor size (TS), number of nodes examined (NNE), number of positive nodes (NPN) and estrogen receptor (ER) status using dummy coding. The training set for model parameter estimation involved 1,726 records for 97 distinct event times and the test set consists of 1699 records with 20 features randomly extracted for survival analysis. Table 1 shows the time cost and estimation error for the collaboration between 2 and 3 institutions with respect to its centralized counterpart.

**Discussion**: Our results show the proposed method can achieve equivalent accuracy in distributed computation to that of its centralized counterpart. However, the model still has some limitations, especially for very high dimensional data scenarios, in which numerical instability will become challenging and sometime the solver cannot determine unique solutions. Furthermore, as a future research direction we plan to develop a verification mechanism to assess the integrity and faithfulness of the model.

Design and Implementation of an Electronic Survey for Follow-Up of Acute Conditions in Primary Care

Vijan Joshi, MD, John Schrom, MPH, Kyle Munkittrick, MA, Carlo Stearns, MS, Svetlana Ivanova, MSIST, David Hoang, Lenard I Lesser, MD, MSHS, Tamer Fakhouri, MD, Andrew Diamond, MD, PhD
One Medical, San Francisco, CA

Introduction: Acute conditions make up a large portion of the reason for visits to primary care practices1. These acute conditions can sometimes progress to more serious illnesses. Resource limitations make scheduling follow-up visits, calls or messages to check for resolution of these conditions impractical. Awareness of patient outcomes helps prevent clinicians from making unintended diagnostic errors, and engaging patients to seek follow-up care if they are not improving creates a diagnostic safety net2,3. This study aimed to assess provider and patient engagement in an electronic follow up survey after a primary care encounter for an acute condition.

Methods: We identified seventy acute primary care conditions based on their frequency and expected clinical resolution time. When these problems were added to the electronic health record (EHR) of a national primary care system, an electronic survey order was automatically created and sent to the patient at a predetermined follow up interval unless the clinician opted out of the order. The survey (see inset) asked the patient if their condition was now resolved, improving, unchanged or worse. Patients whose conditions were unchanged or worse were prompted to send a message to their provider or schedule a follow-up visit.

We analyzed new, acute problems created during the four week period following the initial roll-out of the surveys. We explored provider opt-out of and patient responses to the surveys, along with attributes of the provider, patient, and condition. Using stepwise logistic regression, we examined the association of provider characteristics and condition type with the likelihood of provider and patient engagement with the feature. Analyses were performed in R v3.4.1 with MASS v7.3.

Results: The sample consisted of 20,402 acute problems created in the four weeks after January 25, 2019. Providers opted out for 43% of the problems, allowing 12,809 follow up surveys to be sent. Once sent, the patient response rate was 46%. Most often, patients indicated the problem was either resolved (28%) or improving (54%), while fewer patients responded saying it was unchanged (16%) or worse (2%). Select results from preliminary models are shown in the table. Provider characteristics seemed to play a substantial role in opt-out behavior, with providers who had been at the practice longer and those who had longer panel waitlists being less likely to opt-out of follow-up. Provider characteristics, including having a primary care relationship with the patient, did not seem to influence patient engagement. The specific condition seemed to impact both provider and patient behavior. Providers more consistently opted out of sending surveys for musculoskeletal-related pain, gastrointestinal issues and vaginal concerns, but were less likely to opt out of sending surveys for acute respiratory problems. Patients seemed to respond more consistently to requests for follow-up on their gastrointestinal issues and some respiratory complaints, but were less likely to respond to requests related to certain musculoskeletal pain.
**Discussion:** Electronic surveys appear to be a useful method for collecting information about patient progress and the natural course of acute conditions. Initial models begin to paint a picture of testable hypotheses and potential caveats that can be further investigated as use of this feature grows.

The provider engagement characteristics evaluated here suggest opportunities for improving change management and mentoring of newer providers in the use of this feature. It also suggests that the type of condition may influence engagement in the feature, as providers may not seek follow-up for certain conditions, and patients may similarly not respond. These biases may be concordant, as seen with musculoskeletal pain, or discordant, as with gastrointestinal complaints. There are multiple hypotheses for why this may be: differences in treatment plans based on the type of condition, provider or patient comfort regarding the topic, or incorrectly calibrated follow-up criteria or timeline. Further study is warranted to understand and mitigate these phenomena.

The utility of this new data source is exciting: having contemporaneous progress data about acute conditions opens doors for direct and timely follow-up, clinical phenotyping of acute conditions and smarter clinical decision support. These initial results find that patients and providers largely embrace this tool for many situations. Further study is underway to understand patterns of provider adoption and condition-based variations in provider and patient engagement.

Creating a Database for Health IT Event Reports by Using a Hybrid Deep Learning Model

Hong Kang, PhD, Yang Gong, MD, PhD
School of Biomedical Informatics, the University of Texas Health Science Center at Houston, Houston, Texas, USA

Introduction

Health information technology (Health IT, HIT) has been widely applied in the clinical settings in the forms of electronic health record (EHR) systems, administrative or practice management systems, automated dispensing systems, laboratory information systems, diagnostic imaging systems, etc. Safe use of HIT holds promise in helping healthcare system save costs, improve patient outcomes, decrease occurrence of medication errors, and refine healthcare process measures across diverse settings. However, unavailability, malfunction, and improper use of HIT have created new risks in practices which encourage workarounds and increase the likelihood of adverse events.

Listed in the top 10 technology-hazards for healthcare and comprised of one sixth all patient safety events, HIT events are a major concern for patient safety. Collecting reports of HIT events is essential for aiding the understanding, characterization, discovery, and reporting of HIT events toward improved patient safety. The Agency for Healthcare Research and Quality (AHRQ) has spearheaded this task by developing a set of standardized event reporting Common Formats (CF). In the latest CF Hospital Version 2.0, HIT is considered a set of contributing factors rather than as a specific event category. This modification highlighted the significance of HIT factors in patient safety events yet increased the difficulty of archiving HIT event reports in Patient Safety Organization (PSO) institutes. Usually, reporters prefer to leave HIT fields blank due to lack of knowledge in patient safety event reporting, which greatly hinders the accumulation of valuable reports and blocks the opportunity to learn from previous events. Therefore, a rich resource for HIT events is urgently needed for the patient safety community.

We previously proposed a review strategy to identify HIT events from the US Food and Drug Administration (FDA) database, Manufacturer and User Facility Device Experience (MAUDE), based on a keyword filter and sociotechnical model. The review identified 3,521 HIT event reports and revealed that MAUDE holds up to 50,000 HIT event reports, and is currently the most abundant resource of HIT events. To assist manual review, we further applied TF-IDF and topic modeling to develop a classifier, which exhibited a relatively low recall of the identified reports. Recently, the application of advanced artificial intelligence algorithms has shown promise in advancing biomedical research. In this study, we assessed 9 individual and 120 hybrid models that are commonly used in the deep learning community in the identification task of HIT events. By applying the optimal hybrid model on all MAUDE reports (1993-2018), 48,997 reports were identified for establishing the first database of HIT event reports.

Methods

Data source. 6,994 reviewed reports (narrative), including 3,521 HIT event reports and 3,473 non-HIT event reports were identified from MAUDE database from 2008-2016. The dataset was split into a training set (70%), development set (10%), and test set (20%). Individual models. Nine individual models were developed for the identification of HIT event reports, including four classic machine learning models (SVM, logistic regression (LR), naive Bayes (NB), and random forest (RF)), and five popular deep learning models for document classification (CNN, RNN with/without attention layer (RNN, RNN_att), and Hierarchical RNN with/without attention layer (HRNN, HRNN_att)). TF-IDFs were calculated and applied as the report features of SVM, LR, NB, and RF models, while word vectors derived from Global Vector for Word Representation (GloVe) were applied as the features of deep learning models. Hybrid models. The best seven individual models from the nine were selected for hybrid model construction. 120 hybrid models (all possible combinations of the seven, i.e., \( C_7^2 + C_7^3 + \cdots + C_7^7 \)) were constructed by concatenating the output layers and all models were evaluated to determine an optimal hybrid model. Second-round evaluation. The MAUDE 2017 database (935,715 raw reports), independent from the training, development, and test sets, was used for a second round evaluation. The raw data was pre-processed by a keyword filter before being fed to the optimal hybrid model. Six domain experts in two groups reviewed 850 (~10%) reports sampled from the 8,462 filtered reports to identify HIT events. Google universal-sentence-encoder was applied in the sampling task to ensure the semantic diversity of sample reports. Divergences among the reviewers were fixed through group discussion. The review results were used to further assess the optimal hybrid model. Database for HIT events. We applied the keyword filter and the optimal hybrid model on all MAUDE reports from 1993 to 2018 (7,903,397 reports) to establish a database for HIT events.
Results

We used accuracy and $F_1$ score on the test set to measure the model performance. NB and RF models were excluded from the construction of hybrid models due to their weak performance. Figure 1a indicates that 1) deep learning models generally outperform classic models, and CNN ($\text{Acc}=0.892, \text{F}_1=0.864$) has the best performance among individual models; 2) most hybrid models outperform individual models; 3) the hybrid model (the purple dot at top right corner) which consists of CNN, HRNN, and LR ($\text{Acc}=0.902, \text{F}_1=0.876$) is optimal. The second-round evaluation shows that the optimal model has a ~0.862 accuracy on MAUDE 2017, an independent dataset (Figure 1b). The accuracy stabilizes after evaluating 400 most diverse reports, so the sample size of 850 is sufficient for this evaluation. With the help of our model, we established the first HIT event database, containing 48,997 reports identified from the MAUDE database of all years, from 1993 to 2018 (Figure 1c).

![Figure 1.](image)

Discussion

Learning from HIT events is challenging due to the lack of specific databases. This study provides a solid strategy to identify HIT event reports from a public database, and has established the first database for HIT events. The strategy is intended to organize the events by connecting and synchronizing them with large databases, which would help reporters and reviewers describe, understand, and integrate the events connecting to a fuller spectrum of HIT events. The database will help researchers conduct root cause analysis and develop learning tools or systems to improve the safe use of HIT. Additionally, manufacturers can use the database to improve the surveillance of product quality. We performed a systematic comparison of classic machine learning models and popular deep learning models. All possible combinations of individual models were evaluated, and an optimal hybrid model consisting of three individual models (CNN, HRNN, and LR) was proposed. With the superiority of deep learning, the hybrid model has the potential to be applied on other datasets with narrative reports. An extended training set involving the resources from FDA, PSO, and AHRQ PSNet could improve the applicability of our model and facilitate the data interchange among healthcare institutes. The hybrid model also has the potential to identify reports of other event subtypes such as patient falls and medication errors.

Conclusion

We proposed a hybrid deep learning model to provide a standardized process for identifying HIT events from an FDA database. The hybrid model helped identify 48,997 HIT event reports, which verified our prior estimation in establishing the first database for HIT events.

Abstract

Physician burnout and distress is a growing problem due to complex combination of loss of autonomy, increased administrative tasks, and inefficient work environments. The EHR and information technology (IT) systems are often cited as major contributors. Decreasing cognitive load across multiple areas of the EHR can have a cumulative impact in improving provider efficiency and experience with the EHR.

Introduction

Attention and the realization of the importance of “physician burnout” has been growing the past several years. Studies are recognizing that physicians, and clinicians in general, are facing increasing pressures and stress, increasingly “ugly” stress, due to imbalance of resources, lack of control, and lack of meaning.[1-3] This is due in no small part to a “perfect storm” of increasing financial pressures, shorter patient visits, and compliance, regulatory, & payer documentation requirements, the EHR is the hammer often used to meet those burdens. The loss of autonomy and control and increased pressures for higher productivity, at least by patient volume, are significant contributors to feelings of burnout. While there are many different facets and components to physician burnout, and therefore requisite different strategies, we will focus on some of the key information technology approaches for mitigating burnout. Locally, we have dubbed this strategy, “Less time typing, more time caring.”

Methods

We implemented a toolkit of Information Technology interventions and evaluated the impact of each including:

1. Secure Messaging Application: Introducing a secure, HIPAA compliant messaging application that also serves as provider directory, makes it easier for users to communicate efficiently, in a secure manner, while decreasing the time previously spent in playing ‘phone tag’.

3. Speech Recognition: Physician satisfaction is very high for speech recognition. [5, 6]. A phased rollout of speech recognition software, integrated with the EHR allows providers to use a combination of voice-to-text, keyboard shortcuts, and EHR shortcuts to improve documentation time and quality.

4. EHR Integration with State prescription monitoring program (PMP): CT State mandates checking PMP information for every patient who is prescribed an Opioid. This required logging into a separate system, searching for patient and scrolling for information. Creating a single sign on integration with patient context, we improved access to this vital information, eliminating barriers and saving time.

5. Clinical Decision Support (CDS) Curation: By creating dashboards and tools to monitor utilization of CDS alerts, and establishing an oversight committee we were able to retire alerts, modify others, and change decision support to other non-interruptive modality in several areas.

6. Virtual Scribes: Juggling the keyboard, mouse, microphone, navigating EHR is a cognitive burden that hinders patient-physician interaction. Scribes can document in real-time, and navigate the chart via voice commands. Working with technology vendor, transcription experts, EHR vendor, and compliance, we created a program where a scribe is available to providers via secure phone connection, and can document in the EHR concurrently during the visit.
Results

To date, results show promising progress made by each IT strategy to save time or improve clinical workflow and decrease time spent at the computer.

Figure 1: Impact of targeted IT strategies on reducing physician burnout

Discussion

EHR and supporting systems are understandably often viewed as barriers to patient care due to design and implementation decisions made to support billing, compliance, and data security. Informatics plays an important role in mitigating these frustrations and contribution to physician burnout. Individually, each tool may not be as impactful, but as a collective strategy it has been noticed and appreciated. Highest satisfaction and perceived impact has been from speech recognition and virtual scribe program. Making it easier to do the right thing, there is decrease in unsafe workarounds like copy/pasting in notes, using phones to text colleagues about patient care inadvertently including PHI, canceling important alerts and warnings by habitual action. A common theme across all these applications is to decrease cognitive load, remove meaningless tasks to background, while allowing providers more time to focus on patient and patient care needs. Less time typing, more time caring.

Future Direction

We continue to evaluate Technology and Informatics methods to mitigate inefficient workflows, clicks, and time spent in the EHR including expansion of virtual scribe program, Piloting cloud speech recognition solution, Review & improve security log off timings, Continue CDS curation to decrease alert fatigue, and Advocate for billing reform.

Conclusion

While EHR and electronic systems are perceived as a major contributor to burnout, information technology solutions can also help mitigate or lessen the impact. Continued evolution and application of mitigating solutions is critical in supporting physicians facing more pressures than ever before.

Introduction

Machine learning algorithms are becoming a standard tool for retrospective analysis of clinical data. Such algorithms frequently expect input data in a sparse multidimensional array, aka a very wide table. The columns in the input dataset are called “features” and represent curated knowledge, such as “date of first diagnosis of diabetes mellitus”. We will call such sparse arrays “computable tables”.

A structural transform is needed, as most clinical data warehousing models use narrower tables with one row per record (e.g., one row per diagnosis, lab result, or observation). But, developing such a computable table is also predicated on a deep understanding of coding systems and value sets. Typical clinical data is made up of standard codes (e.g., ICD), proprietary codes (e.g., Epic procedure codes), and local codes (from customized local systems). Codes are retired and added on a regular basis. Additionally, some of the knowledge is local to an institution - both the local codes and the knowledge of what codes are used (e.g., RxNorm ingredient vs dose-forms). These challenges necessitate some type of knowledge-management system.

Moreover, it is frequently possible to describe these codes in terms of hierarchical groups, and efficient grouping at varying levels of granularity is essential for computable tables. For example, to develop predictive algorithms of disease using co-morbidities one might want a high-level feature like “cerebrovascular disease”, whereas when predicting outcomes after cerebral infarction, one might want much more granular diagnostic features, such as “cerebral infarction due to thrombosis of cerebellar artery.”

A variety of projects (such as UMLS, BioPortal, OHDSI, PhcKB, VSAC) handle the knowledge management and/or grouping of standardized code content, to varying degrees. However, the next step of generating feature-oriented computable tables is performed by hand, with manual per-project programming to combine curated code dictionaries with valuesets and analytic data models.

Here we propose two approaches to automate production of computable tables for machine learning algorithms by using curated hierarchical ontologies. We believe these are straightforward enough for use by researchers and data analysts. We discuss our preliminary results implementing and deploying these approaches at Partners Healthcare.

\textit{i2b2 Ontologies}

i2b2, now in its fifteenth year and in use at over 200 institutions worldwide, is the eldest tool for data exploration on large clinical data warehouses. \cite{1} It was designed with a robust ontology system as an organizing principle. Folders of codes are arranged hierarchically, and many standard hierarchies (via BioPortal, OHDSI, and UMLS for example) have been imported to i2b2 and can be augmented with local codes added into the hierarchies.

i2b2’s ontology is primarily seen in the web-based cohort-finding tool, but the robust API makes it programmatic access possible as well. Our approach leverages the i2b2 ontology system, which is implemented at Partners Healthcare to organize local and standard terminologies in a 3-million patient enterprise data warehouse.

\textbf{Method}

At times, researchers are studying problems that are sufficiently well-defined so that the desired computable table can be described at the time of the data request. At other times, researchers desire the flexibility of having all of the detailed data, but in this case, they need tools to arrange new computable tables as the problem becomes better understood. To support both cases, we have defined a pre-computed and just-in-time approach.

\textit{Pre-computed}

We developed an approach and user experience that allows users to interactively define a computable table by specifying groupings driven by ontology definition (e.g., as general as “Gastrointestinal disorders” or as specific as “Crohn’s Disease of the small intestine”). We identified the following groupings, based on our experience with data requests at Partners Healthcare: by date (date of first occurrence, or date of most recent occurrence), by existence (presence/absence, or count of occurrences), and by code (most frequent code, or list of all codes).

We implemented this approach as an i2b2 webclient plugin. It allows users to, starting from a previous cohort query, add ontology items, select the information groupings, and export the data in CSV format for use in analytical tools.

\textit{Just-in-time}
Inevitably, researchers ask for more detailed data than is available in the pre-computed table, because it is often preferable to slice-and-dice the data in different ways as the research methods mature. For this use-case, our approach is to provide users access to subsets of data in the source data warehousing format and augment this with tools for analysts to later perform the same type of ontological groupings described in the pre-computed approach. At Partners Healthcare, this source format is the raw i2b2 “fact” table. This is a long, narrow table in which each row represents a single, specific fact about the patient. Such an extract has limited utility on its own, but when combined with an ontology, hierarchical organization and grouping become possible.

We implemented this approach with an i2b2 bulk-export plugin and an additional plugin that provides ontology metadata and SQL code for generating code sets for groupings. For example, if a researcher drags ‘Diabetes Mellitus’ into this plugin, she will retrieve a SQL code snippet to build a value set of all codes (both standard and local) in the local database that represent that disease. (See Figure 1.)

In combination with the fact table export, a data analyst can use these code sets to create their own analytical views of these data that can be output to machine learning algorithms.

Results
Partners Healthcare plans to deploy these plugins on its enterprise data warehouse, a 3-million-patient dataset already organized around a customized i2b2 ontology. This “Partners Data Enclave” will be a sandboxed analytic environment for investigators.

An Enclave pilot was recently completed as part of a machine learning challenge. Teams created algorithms to solve problems using machine learning and statistical algorithms. Teams registered to access clinical data for the over 80,000 Partners Biobank patients. The teams were given access to the Biobank Portal, an enhanced i2b2 query tool for cohort design with genomic and clinical data. [2] Our plugins were debuted in this environment (see Figure 1).

At present, development of the Data Enclave environment for the full enterprise data warehouse is underway. The tools and dataset are being adapted for this significantly larger endeavor. A pilot test of the Enclave, studying inherited heart disease, is being conducted concurrently with development.

Discussion
Moving data into data warehouses has been the focus of much work (Extract, Transform, and Load tools), and cohort-finding analytic tools are becoming mature. However, a critical step in the analytic pipeline is to structure and organize the data for analysis by external tools. The optimal characteristics and methods to create computable features in these wide, sparse, curated tables are not well well-studied. For example, a feature must be specific enough to have some predictive power yet must be frequent enough to have statistical significance.

We propose approaches that leverage the mature, well-tested capabilities of hierarchical biomedical ontologies to enable researchers to easily build these tables. We demonstrate this in the mature i2b2 platform, where we provide two approaches to support researchers’ development of computable tables.

Conclusion
Data warehouses must be combined with hierarchical biomedical ontologies to develop the curated, complex computable tables needed by machine learning algorithms. Here we demonstrate tools that support researchers in this task using i2b2. We are pilot testing these tools in a machine learning challenge at Partners Healthcare.

Background
Cirrhosis, irreversible scaring of the liver, causes decreased mental, physical, and biochemical function. The prevalence is estimated between 400,000 and 3,000,000 persons in the United States, and the disease causes 44,000 deaths annually.1 Hepatic Encephalopathy (HE), a potentially reversible neuro-psychiatric complication of cirrhosis, causes significant morbidity and mortality. Symptoms range from inattentiveness and mild personality changes to coma. Hepatic Encephalopathy frequently leads to hospital admission if uncaught and left untreated, costing $1.6 billion to $2.0 billion annually.2

Symptoms may rapidly fluctuate with a time course of hours to days. HE is frequently divided into various stages depending on severity. HE is classified into two broad categories: “Covert” and “Overt” HE. Symptoms of covert HE include inattentiveness, sleep cycle disturbance, and anxiety. Overt HE, which can result in coma, occurs in 30 to 45 percent of patients with cirrhosis, and covert HE is estimated to affect up to 60 percent of patients.3 Patients frequently do not present to the healthcare setting until their disease progresses to overt HE. Though the symptoms of covert HE are protean, they have been associated with increased motor vehicular accidents and is a risk factor for progressing to overt HE.4 Early identification may motivate early treatment; however, diagnosis of covert HE requires complex and time-consuming neuropsychological testing, which is often infeasible in the clinical setting.

A possible solution is the use of passive sensors: activity and exercise monitors, location trackers, heart rate sensors, etc.. The use of passive sensor technology has been tested on detecting mood changes in psychiatric disorders.5–7 This interaction between health and technology has been termed the “digital phenotype.”8 We designed and conducted a feasibility study using mobile health technology and wearable sensors to monitor patient’s activity levels, vital signs, technology interaction, and sleep hygiene as a means of “phenotyping” hepatic encephalopathy.

Methods
We used a prospective cohort design with repeated measures to structure this feasibility study. We recruited adult patients with cirrhosis who were able to use a smartphone when cognitively intact. Exclusion criteria included severe disease with Model for End Stage Liver Disease (MELD) score > 30, uncontrolled neuropsychiatric diagnoses, psychoactive medications apart from stable antidepressants, red-green color blindness, and active drug or alcohol abuse.

The primary outcome measure was cognitive function as assessed by a battery of neuropsychological testing. Cognitive testing occurred monthly in a controlled environment by a trained professional and included three tests: the Psychometric HE Score,9 the Inhibitory Control Test (ICT),10 and the Encephalapp Stroop test.11 The Encephalapp test, a standard Stroop test, measures the time for a subject to complete an activity in the presence of a distractor. Normal ranges for subjects with intact cognition range from 120 seconds to 150 seconds depending on age, gender, and education. Additionally, we measured cognitive status in the home setting weekly by having subjects perform the Encephalapp Stroop test on their smartphone.

We combined multiple digital datastreams from patients with advanced liver disease collected from the patients’ smartphone utilizing the BiAffect app,7 which unobtrusively and continuously collects typing speed, typing accuracy, and accelerometer data. Additionally, we fitted subjects with a wearable activity monitor (FitBit Charge 2, FitBit, Inc.) for sleep, activity level, and heart rate measurement. We collected basic demographic data including age, biologic sex, and education level and clinical data relevant to patients with advanced liver disease.

Figure 1: Overall study design for digital phenotyping of hepatic encephalopathy.
As this was primarily a feasibility study, we did not attempt to power this study for hypothesis testing. Instead, we focused on identifying barriers to recruitment, subject acceptance, and technical integration. In this report we qualitatively report our results.

**Results**

We evaluated 24 subjects for participation, 15 were excluded based on chart review. Reasons for exclusion on chart-review included: high MELD score (4), active drug or alcohol abuse (9), and severe extra-hepatic disease (2). Nine subjects were approached and 4 were excluded because they did not own an iPhone and 3 declined to participate. Reasons to not participate included: insufficient compensation (1) and no information given (2).

Presently, two subjects are actively enrolled. Average age was 42 ± 4 years. Average MELD score was 19 +/- 3. Causes were viral hepatitis in one case and Budd-Chiari syndrome in the second. Eighteen total neuropsychological assessments were performed between the study clinic and the home setting. Thirteen of eighteen assessments indicated that the subject had covert hepatic encephalopathy. Of a total of 211 potential patient-days (patients x days) of data collection, subjects’ smartphones and FitBits submitted 114 patient-days of data. Subjects did not report any adverse events related to the study. The greatest amount of missingness occurred in collecting sleep data from the associated FitBit. Figure 2 depicts selected correlations of the Encephalapp Stroop score against several of the predictor variables.

**Discussion**

Improving care for hepatic encephalopathy will require novel care models including approaches that leverage technology. Early hepatic encephalopathy often remains undiagnosed partly due to underreporting as well as under-ascertainment. In this study we demonstrate the feasibility of a digital phenotyping platform that collects continuous data from multiple datastreams including keyboard kinematics from a smartphone and activity and sleep patterns from a wearable activity monitor. In this feasibility trial, barriers to enrollment included rigorous inclusion/exclusion criteria and lack of an iPhone (the BiAffect app currently only runs on the iOS platform). Technical challenges included data integration from datastreams with widely different scales and measurement frequencies as well as integrating disparate technological platforms. Though this study is not powered to formally test association, trends between the digital phenotype markers and measures of cognitive function exist (Figure 2). Future directions include expanding recruitment protocols and implementing robust methods of analyzing temporally varying data.

Expanding the Precision Medicine Landscape: How to Prepare Providers Who Serve Underserved Minority Patients

Rita Kukafka, DrPH, MA1, Margaret Sin, MA1 Thomas B. Silverman, MPH1, Katherine D. Crew, MD, MS2

1Department of Biomedical Informatics, Columbia University, New York, NY; 2Department of Medicine, Columbia University, New York, NY

Introduction

A goal of precision medicine (PM) is to replace the “one-size-fits-all” approach with customized preventive and therapeutic options that take individual genetic, environmental and lifestyle variability into account.1, 2 While the implementation of PM into clinical practice has been slow3, 4, the Cancer Moonshot Blue Ribbon Panel recommends a focus on what can be done now, even without new scientific breakthroughs.5 Embedded in this recommendation, is a call for increased testing for hereditary cancer syndromes in individuals with an increased likelihood of having a pathogenic variant. Such testing allows those identified as mutation carriers to begin early cancer prevention.

Hereditary Breast and Ovarian Cancer (HBOC) syndrome is among the most common of the inherited cancer syndromes. Women with HBOC have a substantially higher breast and ovarian cancer risk than those without susceptibility mutations, with a cumulative risk of developing breast and ovarian cancer of up to 80% and 40%, respectively. Identifying women with genetic risk provides an opportunity to offer personalized cancer risk management strategies. Currently available strategies can decrease breast and ovarian cancer incidence by up to 95% and 90%, respectively.6, 7 However, for such benefit to be realized, at-risk individuals need to be identified. Fewer than 15% of women at risk for HBOC are referred for genetic testing; less among women from racial/ethnic minorities. Most individuals who receive genetic testing for BRCA 1/2 mutations are white, well-educated, and have high incomes. Providers that serve minority patients are less likely to identify and refer patients for genetic testing.8

Major obstacles to increasing genetic testing for HBOC and downstream care in minority populations include patient lack of awareness, financial, and competing life concerns. Provider-level barriers include low levels of perceived clinical value of testing; gaps in genomic knowledge and skills; and other competing clinical and educational priorities.9

Our team developed the RealRisks Patient Decision Aid and the BNAV Provider Decision Support system to simultaneously address both patient and provider-level barriers to expanding genetic testing for HBOC. These tools are integrated into the clinical workflow of outpatient clinics of Columbia University/New York Presbyterian Hospital in New York, which serves a large population of low-income and minority patients. These tools are currently being evaluated in a cluster randomized trial.10 Eighty providers who have enrolled in the trial completed a baseline survey to assess preparedness for implementing genetic testing and managing high-risk breast cancer patients. While previous surveys have been conducted, little is known about providers that serve minority low-income patients.

Methods

Among primary care providers (N=80), including internists, family practitioners, and obstetrician-gynecologists (OB/GYN), we administered a survey which assessed demographics, confidence in managing patients with family history of breast or ovarian cancer, knowledge of predictive genetic testing for breast cancer, orientation towards shared decision making, attitudes towards making a referral for genetic testing (ATT), subjective norms (SN)—i.e., how providers feel that patients or other providers expect them to make decisions about genetic testing referral—perceived behavioral control (PBC) in making a referral to genetic testing, and lastly, behavioral intention (BI) of making a genetic testing referral. We measured ATT, SN, PBC, and BI variables using 7-point Likert scales. Confidence was measured using a scale of 0 to 4 where a higher score indicated higher confidence. The last four constructs (ATT, SN, PBC, and BI) are drawn from the Theory of Planned Behavior, which posits that ATT, SN, and PBC can be used to explain an individual’s BI, which in turn can predict an individual’s behavior. We examined whether there were any differences observed between obstetrician-gynecologists (OB/GYN) and non-OB/GYN providers. In order to detect possible differences between provider specialties, we ran two-sided Mann Whitney U tests comparing OB/GYNs and non-OB/GYNs. We also generated a descriptive analysis on participants’ baseline characteristics, and fitted the Theory of Planned Behavior constructs into a multiple linear regression model to assess whether ATT, SN, and/or PBC predicted providers’ BI of recommending genetic testing.11
Results

About half of the providers were OB/GYN’s (37; 46.25%) and the rest were from family practice (13; 16.25%) or internal medicine (30; 37.50%). The majority of respondents were female (71; 88.75%), and not Hispanic or Latino (67; 84.81%). Most of the providers had good knowledge of predictive genetic testing for breast cancer and favorable attitudes towards making a referral. Providers were only moderately confident in managing patients with a family history of breast/ovarian cancer (M=2; SD=1.4), and about one third (37%) reported having ever using a breast cancer risk assessment tool. Compared to non-OB/GYNs, the OB/GYNs were more likely to report that they have had patients who requested genetic testing in the past 2 years (p<.001). OB/GYN’s were also more likely to report that patients and other providers expect them to make a genetic testing referral after risk assessment (SN; p=0.035) and that it was easier for them to make a decision about a genetic testing referral (PBC; p=0.005). Among all respondents, we found that the TPB constructs of ATT (p=0.051), SN (p=0.003), and PBC (p=0.099) are significant, positive predictors of BI to make a genetic testing referral.

Discussion

The expansion of PM into primary care settings that serve minority populations will depend on the extent to which providers are prepared in incorporating advances in genomic medicine into practice. Our results demonstrate that while providers held positive attitudes and adequate knowledge about genetic testing, they were only moderately confident in managing patients with a family history of breast/ovarian cancer. The TPB provided useful insight into how providers’ intentions are shaped. Overall, our findings strongly suggest that perceived expectations of patients and peers (SN), together with perceived confidence (PBC), are strongly predictive of intention to make a genetic testing referral. Therefore, efforts to expand genetic testing should help providers become more comfortable in managing high-risk patients and referring them for genetic testing services. They should also support the incorporation of risk-stratified prevention into routine care. Education coupled with skill building resources that are designed to foster confidence in identifying and managing patients with a history of breast/ovarian cancer is needed. Confidence is one of the most important personal factors influencing clinical decision making, and it is also critical in patient-provider communication, which strongly influences utilization, access, and uptake of genetic testing.12 These findings confirm the need for decision support tools like those we are currently evaluating in a clinical trial.

Hidden Gaps in Using Common Data Models to Achieve Interoperability Between Electronic Phenotypes and Clinical Data

Fabrício S. P. Kury, MD¹, Li-heng Fu, MD¹, Chi Yuan, MS², Ida Sim, MD, PhD³, Simona Carini, MA³, Chunhua Weng, PhD¹

Abstract

Common Data Models (CDMs) help address the portability barrier of electronic phenotyping algorithms. In this presentation, we share empirical knowledge of how interoperability takes more than what is currently defined in current state-of-the-art data models and how they can be enhanced, leveraged by our experience with manually annotating the free text of the eligibility criteria of 1,000 clinical trials. We discuss how those criteria, as a depiction of clinical researchers’ “real-world” phenotyping needs, highlight three types of difficulties in specifying a phenotype: domain uncertainty, granularity uncertainty, data table uncertainty; and we postulate that these challenges might be addressable by implementing heuristic conventions as a component of the data model.

Introduction

Electronic phenotyping is one of the most pursued secondary uses of the electronic health records data. Prior work has studied phenotype development (how to specify or uncover its normalized codes and workings) and implementation (how to address limitations of observational data), while assuming that selecting what types of patients are worthy of phenotyping is not a concern. Our group has pursued the latter, that is: given a large dataset of types of patients of demonstrable scientific interest, how could they be phenotyped at scale? The referred dataset are the eligibility criteria of recent clinical trials in ClinicalTrials.gov, which we envision could be phenotyped at scale via machine learning capable of translating such free-text into executable database queries. We further assume those queries would be made against a database conformant to the OHDSI OMOP Common Data Model version 6 (hereafter called “the CDM”), as an example of a popular data model with an extensive set of tools. With these premises, our group has annotated the eligibility criteria from 1,000 trials. In this presentation we focus not on this dataset itself, but rather on our findings in performing such task, in order to demonstrate and discuss how clinical researchers’ “real-world” needs cast light onto open challenges yet to be addressed when using a common data model to specify a phenotype.

Methods

Dataset: We extracted from ClinicalTrials.gov the eligibility criteria of a random sample of 1,000 clinical trials of Phase 4 that were actively recruiting as of August 2018, which we then loaded into the brat annotation tool (http://brat.nlplab.org). Two annotators with medical background (FK and LHF) annotated the criteria over 8 months, producing 85 thousand individual annotations.

Annotation: The development of the annotation model followed an informal, interactive process between the two annotators (FK and LHF), both with medical training, and the machine learning developer (CY), upon the shared goal of producing the best possible training data for the machine to learn. It was evident that, whichever intermediate model we used to represent the free text, at some point it would be necessary to translate it into the tables, columns and values needed to compose the intended query. This led to the approach of directly reusing, as an annotation model, the precise definitions of the data model. For example, whatever element in a given eligibility criterion the CDM specifies as belonging to the Measurement Domain, the annotators should demarcate as a Measurement entity; and so forth for all Domains and Data Tables. Upon this basis, other annotation constructs were added to allow for specification of logical operations and relationships between the CDM-based entities.

The CDM: The OHDSI OMOP CDM is designed to hold all observational health data elements that are relevant for analysis use cases in a person-centric schema. At its core are the Standardized Clinical Data Tables, which obey a strict relationship to each of the CDM Domains. As per its documentation, “Domains are identified and separately defined (...) if they have an analysis use case and (...) specific attributes that are not otherwise applicable.” For example, and again paraphrasing the official documentation, “the ‘Condition’ Domain contains Concepts that
describe a condition of a patient, and these Concepts can only be stored in the condition_concept_id field of the CONDITION_OCCURRENCE and [its derivation, the] CONDITION_ENA tables.”

**Results and Discussion**

When attempting to define a phenotype’s database queries from its free text description, some barriers are caused by the nature of the free text, and some by particularities of the desired data model. The former have been explored in the field of Natural Language Interfaces to Databases⁵, could be mitigated by manually rewriting the text with less ambiguous statements, and are not discussed here. The latter are data model-specific, could hardly be addressed by rephrasing unless extensive rewording is accepted, and we discuss below. It is important to clarify that, even for a Phase 4 trial, the needed data might not be present in a “regular” EHR from routine care; however, we considered that what constitutes “routine care” is difficult to define and can vary, and chose to take the following perspective: assuming that the patient information was stored in the EHR in some form, what challenges would one face to query that data? This way, we used the real-world need as a guide for how to approach Medical Knowledge Representation.

**Domain uncertainty** designates when it is unclear what is/are the appropriate domain(s) to assign a given piece of free text, particularly amidst iterative micro-level semantic role labelling⁶. If a criterion reads *Known to be severely alpha-1-antitrypsin deficient*, does *alpha-1-antitrypsin deficient* belong to the Condition domain (SNOMED 30188007) and therefore to the CONDITION_OCCURRENCE CDM table, or is *alpha-1-antitrypsin a Measurement* (SNOMED 88884005) and *deficient* its result (SNOMED 260372006)? In other cases there are also valid codes within the Procedure domain, which adds further uncertainty, for example *HBsAg-positive* (SNOMED procedure code 314099008 *Hepatitis B antigen screening*).

**Granularity uncertainty** describes the unknown preferences between pre- and post-coordination, which is particularly prevalent in a pan-vocabulary data model such as the OHDSI OMOP CDM. For example, if a criterion mentions *moderate chronic obstructive pulmonary disease*, is *moderate* (SNOMED 371927002) a qualifier entity apart from *chronic obstructive pulmonary disease* (SNOMED 13645005)? Or are they together a single entity (*Moderate chronic obstructive pulmonary disease [SNOMED 313297008]*)? What about the case of *untreated intraductal carcinoma in situ of unspecified breast?*

**Data table uncertainty** is caused by the CDM’s design of storing medical history in a separate location from active problems. As per Convention no. 4 in the definition of the CONDITION_OCCURRENCE table, “past diagnoses (‘history of’) are not recorded in the CONDITION_OCCURRENCE table. Instead, they are listed in the OBSERVATION table.” However, today’s active problems are tomorrow’s medical history, and from the perspective of observational, retrospective analyses, all patient data is historical. Furthermore, unless the data holders continuously update and move records between tables as needed, at the time of the query (phenotyping) it is unknown whether, at the time the data was recorded, any given piece of information was deemed active or historical.

**Conclusion**

This presentation calls for attention to semantic interoperability gaps in defining electronic phenotypes using a standardized data model. From our experience with specifying phenotypes for the eligibility criteria of 1,000 recent Phase 4 clinical trials, we found that these “real world” clinical researchers’ needs illuminate aspects that can be further discussed to allow for more robust secondary use of patient-level medical records.

Piloting Telemedicine for Emergency Treatment of Opioid Use Disorder

James R. Langabeer II, PhD1; Kimberly Chambers, MD2; Andrea Yatsco, PhD1; Tiffany Champagne-Langabeer, PhD1

1The University of Texas Health Science Center, School of Biomedical Informatics, Houston ER Opioid System, Houston, Texas; 2 The University of Texas Health Science Center, McGovern Medical School, Department of Emergency Medicine, Houston, Texas

Abstract

Opioid mortality rates continue to rise annually, but treatment is often inaccessible. Availability of emergency treatment involving partial agonist medication can be beneficial for initiating recovery; but geographic, transportation, and other barriers limit access. Telemedicine is one tool with potential to transform emergent interventions for individuals with opioid use disorder (OUD). In this clinical research study, we developed and piloted a telemedicine solution to examine feasibility, and here, we describe our study framework and initial outcomes.

Introduction

Telemedicine technology has had significant diffusion in recent years for both inpatient and outpatient care, but in addiction medicine it has not been widely adopted. This is due in part to requirements that the Drug Enforcement Agency (DEA) has for use of telemedicine and prescribing controlled substances. However, as mortality rates involving opioids continue to rise, as well as addiction rates overall, it is essential to identify novel ways to initiate and maintain treatment. Technology solutions are being proposed, including both mobile health and telemedicine; however, there have been few published manuscripts demonstrating feasibility of the conceptual framework. For individuals with OUD and those who have experienced non-fatal overdoses, it is critical to initiate rapid treatment while individuals are still experiencing withdrawal symptoms and before they re-engage in prior behaviors. Barriers to entering recovery programs exist for patients, including lack of familiarity with where and how to enter treatment, a scarcity of addiction medicine providers particularly in some geographic areas, cost of care, and limited transportation. Published national research suggests there are significant regional gaps in current treatment availability.1 Telemedicine could offer one solution.2 In this study, we present the framework for a telemedicine solution developed in Houston, Texas.

Objective

The objective of this research was to demonstrate the feasibility of a pilot telemedicine program for initiating medical treatment of patients with OUD and to analyze initial outcomes for treatment retention after the telemedicine intervention.

Methods

This study was conducted between August 2018 and February 2019 in Houston Texas. We designed an interventional, single-arm study. The process involved three steps: needs analysis and process flow (first three months); testing (fourth month); and deployment (final 3 months). A commercial, HIPAA-compliant telemedicine solution was implemented using both stationary equipment (in three locations) as well as a mobile solution for phones and tablets. The needs analysis and protocol involved establishing the originating site (location of the patient accompanied by an advanced nurse practitioners and a licensed social worker) and a distant site (involving DEA specially registered physicians). Due to telemedicine policy restrictions, significant effort went into establishing the correct infrastructure to support telemedicine. All providers were officially employees of the same university. The protocol consisted of obtaining initial enrollment information, baseline history data, and informed consent at an enrollment site. Advanced nurse practitioners (ANP) provided the medical screening and clinical assessments (e.g., clinical opiates withdrawal scale, diagnosis of OUD, confirmation of opioid in urine drug screen). This information was provided electronically to affiliated physicians, board certified in emergency medicine at a large urban hospital. The physicians were specially trained to provide addiction treatment and received a Drug Addiction Treatment Act (DATA 2000) waiver from the DEA, which is required to prescribe opioid agonist medication for treatment of OUD. Patients were seen through synchronous video conferencing. Physicians assessed the patients for opioid dependence, completed a brief history and medical exam, and ensured patients were in at least moderate withdrawal. Patients were followed longitudinally, through daily and weekly telephonic follow-ups to measure retention in treatment 30-days post-telemedicine
Inclusion criteria consisted of adults presenting with OUD or recent non-fatal overdose.

**Figure 1: Telemedicine Process Flow for Opioid Treatment**

Results

There were 10 patients presenting with OUD treated by telemedicine in the pilot study. Baseline characteristics for this sample are shown in Table 1. After 30 days, nine patients (90%) treated through the telemedicine encounter were still actively involved in medication-assisted treatment.

Discussion

Feasibility of a model for utilizing telemedicine in the emergency initiation of opioid agonist treatment was demonstrated in this pilot project. Initial outcomes, 30 days after telemedicine encounter, are promising and suggest that immediate treatment of individuals remotely through telemedicine can positively initiate and retain individuals into treatment for the short-term, and help mitigate geographic, transportation, and cost barriers to care. There are policy implications for telemedicine opioid treatment which need to be explored, including federal policy restrictions for widespread use of telemedicine. We recommend that a larger randomized clinical trial be conducted over longer study periods further confirm the initial feasibility and efficacy from this pilot study.

Introduction

Many healthcare organizations integrate data analytics as part of their current efforts to improve patient access, satisfaction and quality of care. Effective data analytics requires a movement from data to information, to knowledge, to wisdom\textsuperscript{1} as proposed by the DIKW model. This progression towards a “data informed culture” requires introducing new systems, knowledge, and skills.

This study explores early frontline experiences in the Veterans Health Administration (VHA), under the Clinical Practice Management (CPM), an initiative driven by congressional mandate, which leverages data analytics to support overall monitoring and improving access to primary care across multiple levels and services. We use this context to study and model how healthcare organizations can cultivate a cultural transformation of “data to information to knowledge.” Such transformation efforts are critical for learning organizations to gain the insight needed to formulate intelligent responses to analytics, and the wisdom on how to leverage resources to actualize a response strategy.

Methods

This qualitative study used semi-structured interviews to collect data from 56 key informants associated with five VHA sites prototyping the CPM initiative to improve primary care access. Data was collected at multiple points in time over the first year of implementation. The interview protocols were guided by the Consolidated Framework for Implementation Research\textsuperscript{2} (CFIR) and included open-ended questions and structured prompts designed to elicit rich descriptions regarding: overall impressions, practice management strategies, goals, activities, relationship to clinic roles, data analytics usage, challenges, barriers, and facilitators. Key informants included national (central office) staff engaged with program implementation, Group Practice Managers (a new role created under the CPM), clinic leaders, and frontline staff. Inductive and deductive coding methods were used to identify key themes from interview transcripts. Data analysis was completed when the team reached consensus that all quotes were appropriately coded, and the resulting themes were stable.

Results

We distill our findings into a model for cultivating analytics based culture, as depicted in Figure 1.

Figure 1. Model for cultivating analytics based culture to support learning organizations.
Through analysis of empirical data, we identified five key action domains that align with the socio-technical nature of building a foundation of “data to information to knowledge”, as described in Table 1. Three domains relate to shoring up data analytics structures; and two domains are about mobilizing a CPM culture.

Table 1. Action domains

| Democratize the Data | • Enable access to data  
  • Release data from silos  
  • Move from data as a performance scorecard to objective gauge |
| Determine the Right Metrics | • Ensure covering all relevant outcomes (e.g., quality, access, patient satisfaction)  
  • Provide meaning to metrics through explicit definitions |
| Invest in the Right Tools | • Accommodate data summary & drill down (dashboards)  
  • Avoid Information and tool overload  
  • Organize and structure Information to help discern patterns  
  • Accommodate timely reporting |
| **MOBILIZE A CPM CULTURE** | |
| Invest in the Right People | • Formalize data analytical roles & leadership  
  • Cultivate a workforce willing to learn and adapt to analytic tools and processes  
  • Train people to identify actionable options in response to metrics (e.g. case based training) |
| Engage in analysis | • Promote metrics as core decision support tools  
  • Recognize counterbalancing metrics in decision making |

Discussion

This study demonstrates that a proactive, socio-technical approach that considers the path from data to wisdom is needed if we are to leverage increasingly massive sets of clinical and operational data collected in the modern healthcare space.

By developing a model that recognizes the importance of building analytics based decision making culture to support systems striving to be learning organizations, this study provides insights and approaches that can help inform the efforts of health care organization beginning to aggregate data and leverage analytics as part of their efforts to improve patient access, satisfaction, and quality of care.

Measuring the Quality of Demographic Data Captured in Maryland’s Hospital and Emergency Department Discharges

Ashley Li, BS1, Hadi Kharrazi, MD PhD2
1Johns Hopkins University, Biomedical Engineering, Baltimore, MD; 2Johns Hopkins School of Public Health, Baltimore, MD

Introduction

Data quality remains an important issue for many sources of healthcare data such as hospital discharges, EHRs, and HIEs. Past studies have addressed completeness and accuracy of various health data sources; however, those studies focused on measuring the quality of clinical data and few examined demographic variables like age and race. In this study, the Maryland Healthcare Cost and Utilization Project’s (HCUP) inpatient, ambulatory surgery and services, and emergency department databases for the years 2013 and 2014 were examined for data quality issues. The data fields examined were sex, age, race, marital status, and zip code.

Methods

Maryland HCUP’s demographic data (2013 and 2014) were assessed for completeness, fidelity, and plausibility. Completeness ensures the lack of missing values, while fidelity questions the data’s dependability, and plausibility determines whether data is believable. These rules were derived from prior work in establishing a common data quality terminology. To ascertain these data qualities, the “visitlink” data element was used as the unique patient identifier across all HCUP’s underlying data sources: state inpatient database, state ambulatory surgery and services database, and the state emergency department database.

Completeness was measured by the proportion of non-missing data; the null count for a data element was compared with the patient’s total number of visits. Fidelity was assessed for sex, age, race, and marital status. Sex was assumed to not change due to the rarity of sex reassignment procedures. Age could not be less than 0, greater than 120, a range greater or equal to 2 within a year, a range greater or equal to 3 within 2 years, or standard deviation greater than 0.5. Patients who died in 2013 were flagged if reported to visit in 2014. Race was assumed to not change. Patients were flagged if they reported two or more non-null race statuses. In Maryland, it is illegal for minors younger than 15 to get married thus patients younger than 15 were flagged for non-individual or null marital statuses. Plausibility was assessed for marital status and zip code. For marital status, patients were flagged for 3+ marital status changes in a 60-day period for switching between individual and married, divorced and widowed, married and legally separated, or married and divorced. Zip code violations of plausibility included 4+ distinct zip codes in a year or 3+ zip code changes in a 60-day period.

After flagging patients for sex, age, race, marital status, or zip code data quality issues, a population specification table was created for the starting population, removed population, and remaining population. To compare the populations, a t-test was used for age, a binomial test for sex, and chi-square goodness of fit for marital status and race. The completeness, fidelity, and plausibility analysis were performed using R version 3.4.3 and MySQL 6.3 CE.

Results

After performing a completeness analysis, the starting population of 3,263,864 dropped to 3,076,908. 5.73% of the starting population was flagged for completeness errors. No patients were flagged for completeness issues in sex, but 245 were flagged for age, 146,274 for race, 37,523 for marital status, and 2,941 for zip code. Then plausibility and fidelity analyses were performed on the remaining patients leading a final population of 2,956,513 a drop of 9.42% from the starting population. After aggregating issues across demographic variables, 790 were flagged for age, 257,026 for race, 61,817 for marital status, and 5,254 for zip code (Table 1). Since sex had no issue in any aspect, it was dropped from the analysis. 307,351 patients had at least one issue among age, race, marital status, or zip code. 32 patients had an issue with age, race, marital status, and zip code simultaneously (Figure 1). The ‘cleaned’ population resembled the starting population’s age (mean and SD), sex, race and marital status distribution; however, all variables showed a statistically significant difference from the original population (p-value < .001).

Discussion & Conclusion

Data quality can affect the analysis that informs decisions and policy. Literature did not address HCUP’s data quality specifically the temporality of demographic fields. We sought to show data quality issues in HCUP’s demographic data while addressing completeness, fidelity, and plausibility. Through this analysis, ~9.42% of the starting population was removed to form the final population. The removed population differed from the final population in race and marital status composition especially with the removal of null entries. Based on the rules, the removed population may encompass patients of multi-racial background because race comprises 83.62% of the removed population.

There are limitations on the study. Maryland’s HCUP database is highly curated. Several assumptions of temporal patterns and time limits were made but we tried to keep it logical and practical. Future research should examine the best data quality rules, temporal patterns, and time limits for hospital discharge data. Although atemporal issues remain the focus of data quality assessments, temporal patterns represent an area of further data quality research.

Detecting unanticipated actions downstream from clinical decision support: a data mining approach

Ron C. Li, MD, Imon Banerjee PhD, Daniel Rubin MD MS, Jonathan H. Chen MD PhD
Department of Biomedical Data Sciences, Stanford University, Stanford CA; Department of Medicine, Stanford University, Stanford CA; Department of Radiology, Stanford University;

Introduction
While there have been increasing efforts to develop more accurate algorithms for clinical decision support (CDS), less attention has been placed on understanding the downstream clinical decisions associated with CDS when deployed in the real world setting. Small scale ethnographic studies involving direct observations of clinicians using CDS are costly, yield limited insights, and are subject to the Hawthorne effect. Other studies evaluating CDS using electronic health record (EHR) data typically rely on measurements of a priori defined process or outcome metrics with limited insight into the unanticipated downstream actions taken by clinicians. For example, our institution, a quaternary care academic medical center, recently deployed a rules based early sepsis detection CDS that was initially evaluated with metrics such as frequency of appropriate antibiotics and diagnostic lab ordering after the CDS go live. These metrics, however, capture only a subset of possible downstream actions taken by clinicians after being exposed to the CDS in the real world setting, some of which are difficult to anticipate and may impact patient outcomes. Detection of unanticipated actions associated with CDS continue to rely on sporadic anecdotes and incident reports. This gap in our ability to systematically evaluate how CDS affects how clinicians think and behave hinders the design and implementation of safe and effective CDS for patient care. We demonstrate a data driven approach to detect downstream actions associated with a recently deployed severe sepsis CDS by mining ordering patterns in the EHR.

Methods
The severe sepsis CDS system is a rules-based alert that activates if a set of clinical criteria are met based on clinical data in the EHR. The alert is delivered via a text-page sent directly to the treating physician, and has been live on the inpatient medicine ward at our institution since 2014. To identify downstream clinician actions, we started by selecting all medication orders (mapped to RxNorm) entered for a given patient 24 hours after the firing of a sepsis alert. We combined sequential pattern mining and interactive graph representation to allow easy exploring of the CDS ordering space. First, we formulated the sequences (<A><B><C, D>) by maintaining temporal ordering pattern from the list of medication orders grouped by patient and alert where medication <A> was ordered before <B>, and <C> and <D> were ordered at the same time. Only one alert per 24 hour time period was considered for each patient and sequences were excluded if the first medication was ordered after one hour of alert firing. Afterwards, we applied a modified version of sequential pattern mining algorithm PrefixSpan (Prefix-projected Sequential pattern mining) which extracts the frequent sequential patterns through the use of “divide-conquer” method and also allows to compute the confidence of the sequential patterns. The method divides the raw sequence database into smaller projection databases, and then mine the sequential pattern in smaller databases given a predefined minimum support threshold. In this study, in order to capture both anticipated and unanticipated order pattern, we used a more flexible minimum support value which is above 5% of the total number of sequence.

To support interactive exploratory analysis of the discovered patterns, we computed a directed graph representation of the sequential pattern content where nodes are medication orders explored by modified PrefixSpan and directed connections represent ordering sequence. For example, {<A>+<B>} and {<A>+<C>} are two valid patterns, the graph (G) will have nodes <A>, <B>, <C> with a edges connecting the nodes <A,B> and <A,C>. The generated graph is interactive which allows the end-user to click on a
edge and visualize the support and confidence value for each transition of medications calculated by the sequence mining algorithm.

**Results**

A total of 6992 alerts fired for 4024 patients hospitalized on the inpatient medicine ward between 2014 and 2017. 5300 unique alerts from medicine were included in our analysis and 1425 sequences above the minimum support threshold were identified. Most sequences included items that are expected to be administered after the sepsis alert, such as an intravenous (IV) fluid bolus and vancomycin (Table 1). However, we also identified a frequent sequence containing furosemide, which was unanticipated, since administering a diuretic would be counter to the expected action taken for a patient with severe sepsis. Further, furosemide disconnected from other items in any other frequent sequences (Figure 1).

**Discussion**

We describe a novel approach to detect unanticipated actions downstream from a severe sepsis alert on an inpatient medicine ward. While expected actions such as administration of IV fluids and antibiotics were indeed identified as common sequences, we did discover an unanticipated frequent sequence consisting of furosemide administration. Furosemide is a diuretic, which is atypical and in fact often opposite of what is expected to be given for patients with severe sepsis. We also see from the graph that furosemide exists separately from the other more connected items in frequent sequences, which indicate that this may represent a distinct decision pathway. It is possible that the furosemide containing sequences represent patients who triggered false positive alerts, or patients with both volume overload and severe sepsis. Further exploration of these previously unidentified insights may be important for iteration of CDS design and deployment strategy.

Development and Evaluation of a Machine Learning-based Approach to Detect Errors in Pediatric Weight Data

Lei Liu, BS\textsuperscript{1,2}, P.J. Van Camp, MD\textsuperscript{1,2}, C. Monifa Mahdi\textsuperscript{1}, S. Andrew Spooner, MD\textsuperscript{1,2}, Danny T.Y. Wu, PhD, MSI\textsuperscript{1,2}, Yizhao Ni, PhD\textsuperscript{1,2}

\textsuperscript{1}Cincinnati Children’s Hospital Medical Center; \textsuperscript{2}University of Cincinnati, Cincinnati, OH, USA

Introduction

Inaccurate weight measures can cause critical safety events in pediatrics due to the frequent use of weight-based dosing. Previous efforts to mitigate weight errors, including interruptive alerts during data entry, rely heavily on manual vigilance and detect only a fraction of errors. Sustaining effective and accurate detection of weight errors remains a challenging issue among pediatric healthcare institutions. This study focused on developing a machine learning (ML)-based approach to analyze pediatric growth data and detect potential weight errors.

Methods

We collected de-identified patient weight data from Cincinnati Children’s Hospital Medical Center between 2010 and 2018. A total of 4.3 million weight points were collected from the institutional electronic health record system for 347,056 patients. Following our earlier study\textsuperscript{1}, weight points documented in the first 24 months were excluded because newborns can have more complex growth patterns. A subset of 4,000 patients with over 50,000 weight points were manually reviewed by three domain experts to create a reference standard set of weight errors (Cohen’s Kappa=0.628 and prevalence-adjusted and bias-adjusted Kappa=0.994)\textsuperscript{1}. For the full dataset, three established weight error detection methods, including a modified-z-score-based method developed by the Centers for Disease Control and Prevention (CDC)\textsuperscript{2}, a computerized approach for determining implausible weight values developed by Children’s Hospital of Philadelphia\textsuperscript{3}, and a linear regression method developed in our earlier study were applied to identify abnormal weight values. The majority vote of the three methods served as a pseudo reference set of weight errors\textsuperscript{4}.

The sub and full datasets were used to train and evaluate the predictive models. To assure that each chart had sufficient data to demonstrate its patterns and dynamics, patient charts with fewer than 4 weight points or with clear evidence of errors (e.g., weight z-score over 100) were excluded from the two datasets. For each data point we extracted seven variables to capture weight characteristics and growth dynamics: 1) subject weight in kilograms, 2) LMS z-score according to the subject’s sex and age\textsuperscript{2}, 3) the distance of the weight value from the reference median in units of one half of the distance between 0 and +2 z-scores\textsuperscript{2}, 4) percentage of the reference population that is below the weight\textsuperscript{2}, 5) absolute age difference from the previous weight point, 6) absolute weights difference from the previous weight point, and 7) absolute z-scores difference from the previous weight point. ML algorithms were developed to predict weight errors, including multivariate logistic regression with L2 normalization (LR), support vector machines with polynomial kernels (SVM-P), decision trees (DT), random forests (RF), and artificial neural networks (ANN).

We performed a stratified random sampling based on individual patients to split each dataset into two parts, 70\% for training and 30\% for evaluation. Ten-fold cross-validation was utilized in training the computerized algorithms, where model parameters were optimized with grid search parameterization. Stratified down-sampling was integrated into cross-validation to improve class imbalance. For model evaluation, we adopted the area under the receiver operating characteristic curve (AUC) as the primary measure and reported positive predictive value (PPV), sensitivity (SEN), negative predictive value (NPV), specificity (SPEC) when SEN reached 90\% (a level required for production). This study was supported by the Mary K Logan research award received by Dr. Wu in 2018.

Results

There were 3,692 patients with 45,892 weight points in the reference standard set and 222,508 patients with 3,009,762 in the full dataset. The error rates were 0.51\% (233 weight errors in 194 patients charts) and 0.14\% (4,278 weight errors in 3,360 patients charts) respectively. The model performances on the two datasets are presented in Table 1 and Table 2. The ML algorithms performed generally better on the full dataset with pseudo reference. RF achieved the best performance on both datasets (AUCs of 93.2%/99.8\% on the test data) although its improvements over LR and ANN were not significant at 0.05 level. Figure 1 visualizes four example charts representing true positive (TP), false positive (FP), all true negative (TN) and false negative (FN) predictions of the best performing RF on the reference standard test set. To understand rules determining a weight error, Figure 2 presents the best-performing decision tree (AUC of 87.2\%) developed on the reference standard set.

Discussion and Conclusion

The ML approach demonstrated good performance in detecting abnormal weights in pediatric weight data. The PPV and SEN achieved by the best-performing RF on the reference standard set suggested that with using the ML approach a clinician could capture 90\% of errors by reviewing approximately 20\% of weight points. The TP/TN examples...
suggested that RF was good at learning pediatric growth trends to capture sudden weight changes. However, it would fail when there was paucity of data (the FP/FN examples), revealing a major limitation of ML-based methods. The analysis of DT suggested that data points with higher z-score and weight changes within a short time period (as evidenced by age difference) have higher risk of being errors. Finally, all algorithms showed better performance on the full dataset because the pseudo reference was more determinate than human judgment. As such, our future work involves annotating the full dataset to further evaluate the algorithms in a more realistic setting.

By visualizing ML predictions on weight data, timely correction could be made to avoid weight errors and to mitigate its effects on patient safety. Consequently, we hypothesize that the ML-based approach, when rolled out for production, holds great potential to significantly reduce medication safety events among pediatric patients.

YouTube Video Analytics for Patient Self-Care of Chronic Diseases

Xiao Liu, PhD¹, Bin Zhang, PhD², Anjana Susarla, PhD³, Rema Padman, PhD⁴
¹University of Utah, Salt Lake City, UT, USA, ²University of Arizona, Tucson, AZ, USA, ³Michigan State University, Lansing, MI, USA, ⁴Carnegie Mellon University, Pittsburgh, PA, USA

Introduction

Chronic diseases, such as heart disease, cancer and diabetes, are among the most expensive and yet preventable health problems (WHO 2013). Effectively managing chronic conditions through patient self-care is a major focus of health policy. However, self-care is a complex set of activities and requires significant amount of medical knowledge. Only 12% of the US population are estimated to be proficient in health literacy (HHS 2008). Most people face difficulties in interpreting and using health information. Purely text-based medical instructions result in poor patient attention, comprehension, recall, and adherence, which translates to poorer health outcomes and higher healthcare costs in the overall economy, especially for patients with low literacy levels (Moorehead et al. 2013).

Visual social media sites such as YouTube host videos containing information on the pathogenesis, diagnosis, treatments, and prevention of various conditions. These health-related videos offer an effective way to understand medical knowledge and to bridge this health literacy gap (Madathil et al. 2014). Nevertheless, healthcare videos on YouTube range from homemade ones expressing personal opinions and experiences to videos made by reputable healthcare entities and expert clinicians for professional education (Pant et al. 2012). Due to the heterogeneity of content quality and content helpfulness (Pant et al. 2012) of visual social media sites, patients, healthcare providers and government agencies have expressed concerns about the quality and reliability of such information. In this study, we examine the impact of encoded medical information on user engagement by proposing an interdisciplinary lens that synthesizes deep learning methods to understand the level of medical information encoded in YouTube videos and its impact on the distinct types of user engagement.

Methods

We present our research approach in Figure 1. We collected YouTube videos related to diabetes care with the YouTube Data API and 200 diabetes related search keywords. We fetched the top 100 videos according to the YouTube’s search ranking for each search term and store the ranking of returned videos and their metadata in a database for further analysis. The information we collected includes channel ID (account name), publish time of the video, video title, video description, video tags, video duration, video definition, video caption availability, video rating, view count, like count, dislike count, and comment count. In total, we collect 19,873 unique videos.

We extracted medical terminology from the videos’ metadata using a deep learning method. We devised a BLSTM model to extract medical terms from the user-generated video descriptions at the sentence level. The video descriptions were first tokenized into individual sentences and words. The BLSTM model achieved 95% in precision, 91.8% in recall, and 92.9% in F1 for medical term extraction. A machine-learning model was devised to classify the encoded medical information in videos using the inputs from deep learning and video level features. These two research associates independently viewed these 600 videos and ultimately labeled the videos for high or low medical information. The high or low medical information categorization was based on the annotators’ experience as a consumer/viewer of the videos. A domain expert (a medical doctor) viewed all videos and consolidated the annotation results. The inter-rater reliability for classifying encoded medical information in videos is 0.92.

Figure 1. Proposed Research Approach

</tbody>
</table>

The performance of the classification is reported in Table 1. We deployed this classification model to classify the remaining videos in our collection. In total, we have 7,948 videos classified as high medical information and 11,325 videos classified as low medical information.

**Results and Discussions**

PCA reveals three broad categories of user engagement: non-engagement, sustained attention driven engagement, and selective attention driven engagement. Sustained attention driven engagement relates to measures of views, comments, likes, and dislikes. Selective attention driven engagement strongly relates to measures of relevance, which reveals the extent to which the content of a video matches the interests of users. Table 2 illustrates the estimated treatment effect on the three principal components of collective engagement.

Table 2. Estimated Treatment Effect

<table>
<thead>

<td>0.03</td>
<td>0.09</td>
</tr>
</tbody>
</table>

We find that medical information is significantly negatively linked to the measure of non-engagement. It implies that videos containing valuable medical information are more engaging to a user. Secondly, we find a positive and marginally significant relationship between medical information encoded in the video and selective attention driven engagement. This suggests that high medical information can increase the chance for the initiation of engagement. At the same time, we also find a negative relationship between medical information and sustained attention driven engagement. The higher density of medical information does not necessarily result in sustained attention driven engagement. Videos with a higher amount of encoded medical information may lead to disengaged users. The complexity of encoded medical information may discourage users from deeper interaction due to the high cognitive load to comprehend the information.

**Conclusion**

Our study underscores that it is crucial for clinicians and practitioners to understand how patients engage with medical information in social media settings. The Internet has reduced much of the information asymmetry between healthcare practitioners and consumers by providing multiple avenues whereby patients can educate themselves with user generated content. While healthcare organizations or consumers produce patient educational materials, not only should they think about what the medical information to deliver but also how to meet the interest and health literacy level of the consumers.

Introduction
Flowsheets provide a rich source of clinical data and represent a major source of documentation within the electronic health record (EHR); however, the content is not standardized within and across organizations. While the expansion of EHRs provides organizations the opportunity to evaluate, share and compare data for quality improvement and research strategies to improve the effectiveness, efficiency and care outcomes, this lack of standardization presents a significant barrier. “Information models” represent clinical concepts, definitions, and their relationships for consistent documentation and sharing across EHR platforms1. Information models (IMs) with associated data standards normalize differences in documentation to improve data sharing. Nursing data are underrepresented in much IM work. Westra et al.2 used flowsheet data from one health system with over 2.4 million patients to develop 10 reference IMs. The current work represents a nation-wide effort to bring leaders from large, integrated health systems to conduct a “bottoms up” approaches to validate similarities and identify differences, gain consensus, and inform future data standards and EHR design.

This study used a data-driven approach to validate and refine existing IMs with metadata extracted from the EHRs of multiple large integrated health systems to refine and extend the models with value sets. Three IMs were validated: pain; genitourinary (GU) system including catheter associated urinary tract infections (CAUTI); and falls. Pain represents a commonly occurring problem assessed and managed by all nurses, and CAUTI and falls are nurse-sensitive measures3. Flowsheet metadata were analyzed to standardize concepts, definitions, and associated values sets for assessments, goals, interventions and outcomes, recognizing that some content is not captured in flowsheets. The goal was to provide direction for improving the ability to share and compare nursing data and improve patient outcomes in the future.

Methods
A retrospective observational study was conducted using an iterative consensus-based approach to map, analyze, and evaluate data contributed by nursing informatics researchers from 10 health care organizations. A convenience sample of participants active in the Nursing Knowledge Big Data Science Initiative represented their organizations as participants in the study4. Organizations that provided flowsheet data included Allina Health, Aurora Health Care, Cedars Sinai, Duke University Health System, Fairview Health Services, Kaiser Permanente, North Memorial Medical Center and UCLA Health. Organizations that provided information about their EHR content included Bumrungrad International Hospital and Partners Healthcare (for pain IM only). Each organization determined if IRB approval was required and if so obtained it to participate in the study.

De-identified metadata representing the actual flowsheets used in patient care were extracted from the clinical databases of participating organizations, securely transferred, and imported into a secure server at the University of Minnesota. Meta-data included a unique identifier for each flowsheet row, internal description and name for the flowsheet row (concept/question), name of the groups and templates from data entry screens, the pick list values (answers) associated with the flowsheet row, the number of observations, encounters and patients, and the data of first and last uses. FloMap data mapping software supported aggregation and comparison of data across organizations5. Each informatics specialist mapped their organizational metadata to the established concepts in the pain, GU and falls reference IMs using FloMap. The mappings aided in identifying similarities and differences

1397
within and across organizations to inform the pain, GU and falls IMs and terminology. Reports were generated for comparison across organizations to drive consensus during bi-weekly meetings. Consensus addressed which concepts to keep, combine, remove, or add. The group discussed use cases, evidence-based practice, regulatory and accreditation requirements to inform consensus, develop definitions and determine the associated value sets.

**Results**

The aggregated metadata from the EHRs of eight large health care organizations and the design content from two additional organizations represented flowsheet data from 6.6 million patients, 27 million encounters, and 683 million observations. A comparison of the reference and validated models for pain, GU and falls and their associated classes, concepts and value sets are represented below (Table 1). The validation examined the generalizability of the reference IM and used consensus to recommend the essential content with the removal or items that were redundant or rarely used.

**Table 1.** Classes and concepts for reference and validated information models.

</tbody>
</table>

In most cases, the validated IM reduced the number of classes and concepts, such as the pain IM that contains 30 concepts, 4 panels (classes), and 396 value set items with descriptions, definitions and value sets for the most important concepts currently captured in nursing-based flowsheet documentation for pain management. The final IMs were more robust with the inclusion of goals and age/condition specific pain scales with a considerable reduction in the number of classes and concepts going forward. Genitourinary included a key concept for a within defined limits assessment and then classes for voiding assessment, urinary incontinence assessment, urine assessment genitalia assessment, genitourinary (GU) device type, GU device assessment, and GU interventions. The validated fall prevention information model expanded to seven classes while reducing to 43 concepts with 179 value set items and increasing the fall risk screening tools from two to 10. Overall the final IMs were more comprehensive, inclusive of more tools and scales, and streamlined for efficiency as appropriate. Examples of the models will be shared.

**Discussion**

The consensus-based IMs for pain, GU and falls represent refinements proposed after in-depth analysis of the actual meta-data generated by nurses in EHR flowsheet documentation from participating systems. The findings provide direction for improving the ability to share and compare nursing data and support strategies that will lead to improved patient outcomes in the future. The concepts and value sets are in the process of encoding with LOINC and SNOMED-CT. The encoded standards then will be available to extend common data models used to support nursing data exchange and research nationally and internationally.

Comparing the Distribution and Predictive Power of Medication Adherence Indexes Derived from EHRs and Claims in Forecasting Healthcare Utilization

Xiaomeng Ma, MS\textsuperscript{1}, Changmi Jung PhD\textsuperscript{2}, Hadi Kharrazi, MD PhD\textsuperscript{1}

\textsuperscript{1}Center for Population Health IT, Johns Hopkins School of Public Health, Baltimore, MD; \textsuperscript{2} Carey School of Business, Johns Hopkins University, Baltimore MD

Introduction

Electronic health records (EHRs) and administrative claims data capture medication (Rx) orders and fills. Previous studies have focused on extracting Rx information from a single data source (e.g., measuring Rx possession ratio). No attempt has been made to probe the correlation of Rx adherence indexes in linked EHRs and claims. Rx complexity, as reflected in EHRs, can impair patient Rx filling adherence recorded in claims, and may associate with adverse outcomes such as hospitalization and increased cost\textsuperscript{1}. We sought to explore constructing patient-level Rx adherence measures - Medication Regimen Complexity Index (MRCI) \textsuperscript{1}, Medication Possession Ratio (MPR) \textsuperscript{1}, and Rx Fill-rates\textsuperscript{2} using administrative data. By quantifying their correlation in a population, we can understand to which level medication complexity affects patients adhering behaviors. Subsequent models were also developed to improve utilization prediction.

Methods

The study population comprised 65,653 patients with continuous enrolment in a single insurance plan from 2012 to 2013\textsuperscript{2}. Patients had at least one outpatient visit within two years and did not reach 65 by the time of inclusion. We developed and compared MRCI, MPR and Fill-rates based on linked patient records extracted from the integrated single-provider system. MRCI is an instrument to quantify medication complexity for outpatients, synthesizing the complexity caused by dosing frequency, dosing form and additional directions on EHR e-prescribing. MPR is another common index, measuring the ratio of medication supplied days and intervals between fills on claims. Fill rates is an Rx indicator we have proposed previously\textsuperscript{2}, to evaluate medication adherence by capturing the prescription filled at the pharmacy within a designated interval (7 and 30 days). All Rx adherence indexes were constructed based on National Drug Codes (NDCs) in EHRs and claims. To accommodate condition like Rx substitutions at pharmacy counters, we mapped Rx NDCs to 62 RxMG prescribed medication defined morbidity groups (derived from Johns Hopkins Adjusted Clinical Groups® (ACG®)\textsuperscript{3}) to construct Fill rates. Outpatient prescription count and Charlson Comorbidity Index were also calculated at the patient level. Patients were stratified by their demographics and utilization history, to demonstrate the distribution of Rx indicators in subpopulations. Statistical analysis was performed to evaluate the correlation of MRCI and MPR.

To evaluate the impact of MRCI, MPR and Fill rates on prospective utilization predictions, we split the dataset by year, predicting 2013 outcomes based on 2012 data. Three base models were tested. Binary hospitalization indicators and total medical cost (capped at top 1% total cost) were outcomes of interest, and were analyzed with logistic regression and linear regression, respectively. We added MRCI, MPR and Fill rates respectively to the base models. Changes of interpretable variation in enhanced models in contrast to base models were examined to show the added values to prediction of these three medication indices. For validation, we conducted bootstrapping (200), splitting the complete dataset into 1:1 training and validation sets for performance measures of adjusted $R^2$ and AUC. Improved Integrated Discrimination Improvement (IDI)\textsuperscript{4} and $R^2$ were adopted to account for the significance of variation change. R v3.5.1 was used for statistical analysis.

Results

The mean age of 65,653 patients was 38±18 years old. Among sampled population, 13,854 (21.1%) and 4,630 (7.1%) patients had visited emergency department or hospitalized during 2012–2013. The mean prescription count and mean MRCI were 5.7±6.8 and 16.5±21.2 after dropping the inpatient prescriptions. The average of MPR for both years was 0.56±0.51, and 20,794 (42.8%) patients showed a very low level of medication adherence (MPR<0.5) to their outpatient prescriptions. Statistical analysis indicates MRCI and MPR were negatively correlated in a given year (Pearson correlation = -0.17). In comparison to MPR, the 30-day Fill rates and 7-day Fill rates in this population were 0.77±0.24 and 0.67±0.29. The flagged patient who hospitalized in any of these two years had more complex medical regimens (MRCI: 30.2±38.1 vs. 11.4±11.8), but low adherence to outpatient prescriptions (MPR: 0.49±0.30 vs. 0.58±0.30; 30-day Fill rates: 0.76±0.20 vs. 0.79±0.30) compared to outpatients (Table 1). A cohort of 48,435 patients had complete MRCI, MPR and Fill rates scores for predictive modeling. MRCI added predictive value to demographic base-models for hospitalization and medical cost predictions (IDI: 234.4 [198.0 – 273.2%]; improved $R^2$: 4.8% [4.2 – 5.2%]). However, the added-value decreased
when adding Charlson Index to the base model (IDI: 49.9 [38.3 – 63.4%]; improved \( R^2 \): 2.3% [2.2 – 2.4]). A similar pattern was observed for MPR, but with minimal predictive effect than MRCI. The added-value for hospitalization and total medical cost predictions were significantly decreased after adding ACG risk scores to the base model (Table 2).

### Table 2. Performance of enhanced models added with Rx derived indicators in contrast to base models

### Conclusion

This study primarily investigated the quantitative measures to evaluate patient medication adherence. High medication regimen complexity is associated with the low Rx filled at pharmacy among outpatients. Although patients tend to fill the their very first prescriptions on schedule, the overall adherence rate is low. The MRCI and MPR modestly improved prospective utilization predictions, although the effects are not significant for models using the ACG risk scores.

Clinic Characteristics Associated with Screening for Social Determinants of Health

Miguel Marino, PhD1, Jorge Kaufmann, MS1, David Ezekiel-Herrera, MS1, Dagan Wright, PhD2, Erika Cottrell, PhD1,2, Rachel Gold, PhD, MPH2,3

1Oregon Health & Science University, Portland, OR; 2OCHIN Inc., Portland, OR; 3Kaiser Permanente NW Center for Health Research, Portland, OR

Introduction: There is a growing national emphasis on documenting patients’ social determinants of health (SDH) data in electronic health records (EHRs).1-2 Preliminary research suggests that EHR-documented SDH data can inform care teams about patient needs, facilitate referrals to local resources, and track referral outcomes.3-4 However, some healthcare systems may lack the capacity and / or infrastructure needed to implement systematic, EHR-embedded SDH screening, or to respond to patients’ documented SDH-related needs.5 The need for standardized SDH data collection and response is greatest in ‘safety net’ community health centers (CHCs), whose vulnerable patients have higher disease burden and worse health outcomes than the general US population.6 In 2016, OCHIN (the nation’s largest network of CHCs on a single EHR system) developed and rolled out SDH documentation tools in an EHR shared by 440 CHCs. To evaluate factors associated with the uptake of EHR-based SDH documentation, we estimated clinic-level prevalence of use of this tool, and practice characteristics associated with its adoption.

Methods: We used data from 440 primary care CHCs that were using OCHIN’s networked EHR by 6/24/2016. OCHIN, Inc., is a non-profit health center-controlled network that hosts an Epic© EHR and manages its data, including regular validation and cleaning. Data for these analyses were extracted at OCHIN. The study population includes N=345 clinics that were active OCHIN members throughout the two-year study period (6/24/2016-5/17/2018). The primary outcome of interest was a binary indicator denoting if the clinic had ever screened a patient using the EHR’s SDH tool (yes vs. no). Clinic-level independent variables of interest included clinic type and rurality. Additionally, we measured characteristics of the clinics’ patient panels, to produce clinic-level percentages of the distributions of the following characteristics for inclusion in analyses: sex, race/ethnicity, language, age, healthcare utilization, federal poverty level, and insurance. These variables were selected as potentially influential on clinics’ choice to conduct SDH screening. We used logistic regression to model SDH tool use by clinic-level characteristics and produce odds ratios and corresponding 95% confidence intervals.

Results: Among the 345 clinics that had access to the EHR-based SDH tool over the two-year study period, 41% had ever used the tool to document SDH among their patient population. Overall, CHCs serving patients in the general community had higher odds of SDH documentation than school-based health centers (p=0.009). We observed no differences in SDH documentation by clinic rurality, percentage female, or racial/ethnic distribution of the clinic’s patients. Clinics with older patients had increased odds of SDH screening compared to those with younger populations (odds ratio [OR] = 1.046, p=0.045). Clinics that had higher rates of missing data on patients’ federal poverty levels had decreased odds of SDH screening (p<0.001). Last, clinics with higher percentages of Medicaid or uninsured visits showed lower odds of SDH screening (Medicaid: OR=0.974, p=0.051; Uninsured: OR=0.948, p<0.001).

Discussion: With national calls to document patient’s SDH in EHRs, it is important to consider whether and how such screening varies across different kinds of clinics. This study reports on adoption of an EHR-based SDH documentation tool in the two years after it was rolled out in hundreds of CHCs. Under half of these CHCs used the SDH tool at all, and several clinic characteristics were associated with the odds of SDH screening tool use. These results suggest that national initiatives seeking to encourage increased EHR-based SDH documentation may need to account for the clinic characteristics that may serve as barriers or facilitators to adopting this practice change. Such context may indicate the need to provide additional, tailored support to certain clinics, to ensure increased adoption of EHR-based SDH documentation.

An Analysis of the Lexical Structure of Documented Communicative Information Surrounding the Abdominal Roentgenogram Ordered in the Neonatal Intensive Care Unit

Jacob McPadden, MS, MD\textsuperscript{1,2}, David Chartash, PhD\textsuperscript{1}, Kelson Zawack, PhD\textsuperscript{1}
\textsuperscript{1}Yale Center for Medical Informatics, Yale University School of Medicine, New Haven, CT; \textsuperscript{2}Department of Pediatrics, Yale University School of Medicine, New Haven, CT;

Introduction
Communication between clinical teams and radiologists, results in structured reports which offer a record of the remote diagnostic task of a read by the radiologists, and support the effective transmission of information.\textsuperscript{1} This communication is not a unidirectional transmission of information from the radiologist to the clinical team, rather, it consists of a study request (order) with clinical indication which prompts the subsequent report from the radiologist. To analyze the linguistic data within these reports, the communication between the clinical team and radiologist can be viewed as a conversation consisting of a question in the form of the clinical indication and an answer in the form of the radiology impression. This question and answer pair is not formulated as the typical wh-question structure, rather, consists of a clinical statement which entails the radiological answer. For example, in the case of pneumonia, a patient’s indication describing a cough results in a chest roentgenogram, which has an impression which includes the finding of a lobar consolidation concerning for infection. In this instance, it can be stated that cough entails pneumonia, by way of lobar consolidation.

In neonatal intensive care, it is commonly stated that there are a reduced set of health problems encountered. It follows that the majority of abdominal roentgenograms are obtained for a smaller subset of clinical indications. This results in the hypothesis that indication and impression pairs fall into a reduced smaller subset of categories. The presumption is that radiologists actively respond to the indication leading to related categories in response.

For a set of neonatal abdominal roentgenograms, this study aims to examine: 1. The content-completeness of communication between the clinical team and radiologist, as modeled by the language in the indication and impression. 2. The categorization of neonatal indications for a radiology study, and the correlation between these categories and impression categories.

Methods
Abdominal roentgenograms reports were obtained from all patients admitted to the Yale Neonatal Intensive Care Unit (NICU) from January 2011 to August 2018. This produced a dataset of 5149 reports. Neonates were 56.1% male with an average gestational age of 35.8(23-42). The high-level report segments defined by the consensus of the Radiological Society of North America\textsuperscript{2} were extracted. The indication gives the reason for the test and the impression gives the summary of its result.

Each extracted note segment was processed by MetaMap, extracting Unified Medical Language System (UMLS) Concept Unique Identifiers (CUIs) and semantic Type Unique Identifiers (TUIs). The CUIs and TUIs in the indication and impression pairs were analyzed for internal non-exclusive consistency from indication to impression to address whether the concepts in the indication were addressed by the radiology read.

$\chi^2$ tests of association were used to test between the impression categories generated by PCA and the coded indication
categories. One test was done to identify associations between indications and impressions categories generally. A second set of tests were done between each combination of indication and impression categories.

Hierarchical clustering (using a Euclidean distance metric) was performed on the matrix of coded indication categories and impression PCA constructed categories. This was performed to analyze the separability of indications given impression categorization.

Results

Analysis of CUIs showed that only 7.7% of CUIs in the indication were referenced in the impression. By generalizing to semantic type, 44.6% of TUIs in the indication were found in the impression.

Visual inspection of PCA results initially indicated that the CUIs within impressions could be optimally grouped into between three and six classes, with the constructed dimensions adequately separating roentgenograms. \( \chi^2 \) tests demonstrated statistically significant association at four, five, and six \((\alpha<0.05)\) categories with three not having statistically significant separation. Examination of the \( \chi^2 \) test of category-category association showed significance between multiple groups. However the significance was largely driven by strong associations of the "Confirm line/device placement or positioning" categories. Analysis of dendrograms identifies optimal categorical separation off of the root node between five and six categories. These results implied six categories intrinsic to the data.

Discussion

The low overlap of CUIs between indication and impression pairs and the relative increase in the association of TUIs could be explained by the granularity of lexical concepts. This is further explicated by the mismatch between disease and radiologic finding concepts: e.g. concern for necrotizing enterocolitis vs no free air, pneumatosis, or dilated bowel loops.

The significant association between classified indications and PCA categorized impressions suggests that a conversation may be taking place. The most significant findings involved the clinical classification of devices suggesting that there was notable communication around these devices. However, this signal may be amplified by the radiologist noting the finding of a new device with or without the question being stated. It is rare in clinical experience for a radiologist not to comment on a present device and device placement confirmation is a frequent request in neonatology. Contrarily, some known information is withheld in radiology reads. A repeat roentgenogram may not repeat the unchanged findings from the previous study. This would have the effect of weakening the association.

While there may be true communication, further investigation is warranted. The difference in number between clinical categorization and PCA derived categories may indicate an sub-optimal clinical categorization. Restructuring clinical categories into more inclusive groups may improve evidence of communication. Additional approaches planned for the future analysis include textual entailment detection and topic modeling.

Reasons, Information, and Time: Exploration of Dental Clinician-Initiated Medical Consultations

Jayanth Kumar Medam, MS, BDS1,2, Karmen S. Williams, DrPH, MBA3,4, Jay Patel, MS, BDS1,2 Theresa Gonzalez, DDS2, Thankam P. Thyvalikath, DMD, MDS, PhD1,2,4

1Indiana University School of Informatics and Computing, Indianapolis, IN, USA; 2Indiana University School of Dentistry, Indianapolis, IN, USA; 3Indiana University Fairbanks School of Public Health, Indianapolis, IN, USA; 4Regenstrief Institute, Indianapolis, IN, USA

Introduction

Advancements in medical research have led to improved life expectancy worldwide.1 However with this improved life expectancy, approximately 26 percent of the US adult population have multiple medical conditions.2 As a result, dental clinicians are seeing an increase in patient populations with multiple medical conditions, which require both an assessment of patients’ medical information for treatment, and consideration of impacts of conditions and medications on patients’ oral health.3,4 Access to up-to-date medical information can assist in both avoiding unnecessary adverse events, such as excessive bleeding from medication, and preventing delays in oral health care. Currently, medical information is gathered in two ways—through patient-reported medical histories and medical consultations provided by the patients’ medical provider. The most common way is patient-reported medical histories; however, studies show patient-reported information has low rates of congruence between electronic dental records and electronic medical records.5 To confirm and verify patient information, dental clinicians may request medical consultations through a structured or unstructured consultation form. Although more than 90 percent of dental and medical providers use electronic dental or medical records, and there is the ability to use regional Health Information Exchange (HIE) organizations, consultations are still printed and faxed. This can cause delays in patient care and treatment. There is a pressing need to determine the challenges that delay the delivery of comprehensive oral health care by dental clinicians. Few studies have investigated the impact of medical consultations on dental treatments, importance of structured forms of medical consultations, and the characteristics of patients who require medical consultations. However, scant information exist regarding the reasons for dental clinicians to seek medical consultations despite obtaining patient-reported medical histories and to what extent providers respond to the dental clinicians’ questions. Using the Indiana University School of Dentistry structured, medical consultation forms, the objective of this study was to examine: 1) the reasons for dental clinician-initiated medical consultations, 2) the information requested and returned, and 3) days taken to complete the medical consultation process. The results of this study will inform how dentists can leverage regional HIEs to access patient medical information, such as labs and medicine.

Methods

Based on prior studies and medical consultations, two researchers drafted an initial annotation guideline. Four team members used guidelines to review the same 5 consultations with a moderate inter-reviewer agreement (Fleiss kappa-0.50). The guidelines were reviewed and finalized based on discussion and consensus. A convenience sample of faxed and returned medical consultations were selected for patient encounters between January 1, 2015 and December 31, 2017. Of these 4,586 medical consultations, 240 were reviewed for 179 unique patients. The annotation guideline characterized the reasons for the initiation of the medical consultations and type of information requested by dental clinician and provided by medical provider (Table 1). Descriptive statistics were used to analyze gender and age group. Summaries were used to determine the top reasons for initiation of medical consultation, medical information requested and received, and days of process completion.
Table 1. Sample of type of information requested by dental clinician and provided by medical provider

<td>HbA1c, WBC count, RBC count, complete blood count, viral load, etc.</td>
</tr>
<tr>
<td>Recommendations</td>
<td>When dental clinician requests recommendations or precautions or contraindications for the planned dental treatment.</td>
<td>antibiotic prophylaxis, anticoagulant medication, local anesthesia with vasoconstrictor, any contraindications, etc.</td>
</tr>
</tbody>
</table>

Results

Among the 240 medical consultations (179 unique patients), approximately 52 percent were men, followed by 47 percent women, and less than one percent listed as other. The mean age was 61 years (±15.25 standard deviation). The most common reason for dental clinician-initiated medical consultations was needing more information from medical provider (136), followed by confirmation of medical condition or treatment (103). The information requested by dental clinicians was laboratory values and diagnostic reports (219), recommendations (150), medication information (62), and the current status of medical conditions (57). However, of the 219 requests for laboratory values sent by dental clinicians, only 76 consultations returned by medical provider, followed by recommendations in 98 of 150 sent. However, medical providers returned more than requested information for medical status (85) and medication information (83), even when dental clinicians did not request. Just over half of the medical consultations were returned within 10 days with an overall mean of 15.6 days. Although, only seven were returned after 100 days, almost 15 percent of the medical consultations were sent after 30 days.

Conclusions

Although viewing a small sample size, challenges in the medical consultation process are clear. Despite studies to improve the medical consultation process, results still show gaps and delays in information medical providers share with dental clinicians. The lack of standard protocols for initiated consultation leads to duplicated efforts and delays in treatment, which affects overall health of patient. We propose that the need for medical consultations would decrease if dental clinicians had access to patients’ medical records. Access to patient medical records through regional health information exchanges and interoperability networks, such as Carequality and Common Well Health Alliance, would reduce the burden for dental and medical providers. Thus, medical consultations could be utilized to address more important questions regarding patient management. With an increase of dental patients with multiple chronic conditions, efficiently gathering medical information to deliver comprehensive oral health care is critical.

Automating new-user cohort construction with coarsened exact matching and
ingication embeddings

Rachel D. Melamed, PhD

1University of Chicago, Chicago, IL

Introduction

Comparative cohort studies are a major tool for assessing drug safety, but these studies require appropriate adjustment for confounding variables. Propensity score methods adjust for confounders by estimating the effect of these confounders on treatment assignment. One of the challenges of applying these methods to health care data is the high dimensionality of the health record, with tens of thousands of potential confounders. Thus, recent studies have proposed improvements to the propensity score, including large-scale regularized estimation, and automatic determination of relevant confounders. Fewer studies have focused on the selection of patient cohorts, a necessary step preceding the application of the propensity score. This step is usually designed by experts, limiting the throughput of comparative cohort studies. Including non-comparable patients can add bias and noise to effect estimates. For example, Weinstein, et al, showed that people with a history of gastrointestinal bleeding are unlikely to be prescribed paracetamol rather than ibuprofen. In order to more rapidly conduct cohort studies, we develop an automated approach to choose comparator cohorts for a treated population.

Methods

Our study uses the IBM MarketScan claims data, containing age, gender and week for coded prescriptions, diagnoses, and procedures, comprising 30,000 non-rare event types. Encoding these events results in a high-dimensional, sparse, and low-information feature vector: for example, the feature vector for a person with a diagnosis code for diabetes is not any closer to that of someone prescribed insulin than to that of a person taking Prozac. One way to create a more informative representation of medical history is with embeddings. Unlike other medical embeddings, we develop embeddings to specifically represent the medical context for new drug prescription, which we term indication embeddings. These embeddings are designed such that history events that precede the same prescription (indications) will have similar vectors to each other; correspondingly, so will drugs that occur in a similar history context.

Given any drug of interest, our method uses three steps to identify a comparator population similar to the treated population. The first step uses the drug embeddings to identify comparator drugs prescribed in the most similar medical contexts, among those drugs with the same therapeutic purpose (as annotated in UMLS). Each of these comparator drugs defines a pool of possibly comparable people. In the second step, we select from these pools of people exposed to either drug using Coarsened Exact Matching (CEM). We define coarsened bins as: gender; calendar year of prescription; age in bins of: 0-5, 6-10, 11-15, 16-25, 26-40, 41-55, 55-70; and number of unique drugs prescribed to that person. For each comparator person, that person is only kept for further analysis if that person falls into a bin containing a treated person. Third, we match patients within treated bins. Using the indication embeddings we create a low-dimensional and dense representation of patient state at the time of exposure. We match treated patients to comparator patients in each bin using the Mahalanobis distance of these vectors. Finally, to evaluate how comparable our populations are, we use the same data (demographics, medical history), to fit high-dimensional,
sparse models to predict treatment (propensity scores). We examine the propensity score overlap across the cohort definitions.

**Results**

We evaluate how comparable a pair of cohorts is using the propensity score overlap. If the propensity scores of the treated and comparator populations have high overlap then the patients have a reasonable probability of receiving either drug, that is, they are more comparable. Equivalently, propensity score models for comparable populations have a low area under the ROC curve (AUC). Drugs prescribed in similar medical contexts should have similar embeddings. First, we show that similar embeddings indeed point to more appropriate comparator drugs for a given treatment, even in the complex case of neuropsychiatric drugs (Fig. 1). Then, we assess performance of the last two steps of our method, which identify comparable populations given a drug pair. We roughly follow three published cohort studies, where the cohorts were defined by experts (Fig. 2). In each of these, we examine the overlap in the two treatment-defined populations before any matching (Fig 2, left columns); then after the CEM step (middle column); and after matching both on coarsened demographics and on history vectors (right columns). In all cases, the populations become more comparable.

**Conclusions**

We have shown that automating cohort selection has the potential to improve upon expert-defined comparator cohorts. As well, we have promising results in automatic selection of comparator drugs. This will enable cohort studies without relying on clinicians to design every study.

Feasibility of a machine learning based method to generate personalized nutrition goals for diabetes self-management

Elliot G. Mitchell, MA¹, Marissa Burgermaster, PhD², Elizabeth M. Heitkemper, PhD¹, Matthew E. Levine, BA³, Yishen Miao, MA¹, Esteban G. Tabak, PhD³, Arlene Smaldone, PhD⁵, David J. Albers, PhD⁶, Lena Mamykina, PhD¹

¹Columbia University, Department of Biomedical Informatics, New York, NY; ²The University of Texas at Austin, Dell Medical School, Austin, TX; ³California Institute of Technology, Pasadena, CA; ⁴Courant Institute of Mathematical Sciences, New York, NY; ⁵Columbia University, School of Nursing, New York, NY; ⁶University of Colorado, Departments of Pediatrics and Informatics, Aurora, CO

Introduction

Chronic diseases like diabetes are increasingly prevalent, with a high burden for individuals and the healthcare system, but this burden is not shared equally.¹ Low socioeconomic status and communities of color have more than 50% higher risk of developing obesity and diabetes compared to the overall population.² In type 2 diabetes (T2D), care involves modifying day-to-day lifestyle behaviors. Self-management is particularly challenging because of notable individual differences. In the case of nutrition and T2D, there are individual differences in glucose physiology after eating different foods, and the American Diabetes Association guidelines recommend setting individualized nutrition targets with a diabetes educator.³,⁴

Patient-generated health data (PGHD), collected through sensors and smartphone apps, offers an unprecedented view of individual physiology and behavior. Most personal informatics applications focus on visualization of PGHD, putting the burden on users to find insights that inform action.⁵,⁶ These applications require health literacy and numeracy to use, and therefore have the potential to deepen existing inequalities.⁷ When combined with machine learning (ML), PGHD can make predictions and find patterns in tasks where human cognition falls short. However, translating patterns discovered using machine learning into actionable information that could inform future choices is non-trivial, particularly when designing for populations with low literacy and low familiarity with technology.

GlucoGoalie

Here, we present the design and evaluation of GlucoGoalie, a system for individuals with T2D that recommends personalized nutrition goals to improve blood glucose (BG) control. To design GlucoGoalie we followed an iterative process that considered the data and ML methods available, expert input, a literature review of best practices in nutrition management for T2D, and early feedback from (N=3) users in the target population.

GlucoGoalie takes patient-generated data including meal logs and BG readings as input, and uses an ML-driven expert system to generate concrete and actionable suggestions for how to change eating behaviors. To deliver recommendations that are meant to inform behavior, GlucoGoalie uses goal setting, an effective behavior change strategy for diabetes self-management and mobile health.⁸,⁹ Each goal suggests changes to the macronutrient composition of meals to improve the impact on BG by specifying a direction of change and target amount. The target is presented in grams as well as “choices”, a unit used to help individuals identify portions of different foods with similar amounts of a specific macronutrient. For example, 1 carbohydrate choice is 15g, which could be 1 slice of toast or 1/3 cup of rice, while 1 protein choice is 7g of protein. See Table 1 for examples of goals generated by GlucoGoalie.

Methods

15 individuals with T2D participated in a controlled evaluation to assess whether recommendations were understandable and actionable. First, in a goal comprehension task, participants chose which of two meals followed a given goal based on meal photographs or nutritional labels. We assessed how often participants selected the appropriate meal. Second, in a meal choice task, participants were asked to assemble meals with cutout food images at a “virtual buffet.” Participants started by selecting a meal that is closest to what they would normally eat, and then were presented with two goals that asked them to vary from their baseline behavior and assemble three meals for three days in a row with
Type | Title | Goal description
--- | --- | ---
Decrease | Decrease your carbs to 2½ carb choices | For high carb lunches, decrease your carbs to be about 2½ carb choices (38g). An example of 1 carb choice is 1 slice of whole wheat toast, ⅓ cup of plantain, or ½ cup of brown rice.
Increase | Increase your protein to 3 protein choices | For low protein dinners, increase your protein to be about 3 lean protein choices (21g). An example of 1 lean protein choice is 1 ounce of lean ground beef, ½ cup of tofu, or 1 ounce of chicken breast.

Table 1: A selection of personalized nutritional goals output by GlucoGoalie

the chosen goal in mind. The procedure was repeated for breakfast, lunch, and dinner meals. We assessed how often composed meals were consistent with the direction of the chosen goal as a percentage, and tested for significance with a binomial test. In addition, we measured the variability in meeting the goal target with mean absolute error, measured in “choices”, which provides a standard unit to compare goals for different macronutrients.

Results

For the goal comprehension task, when choosing which of the two nutrition labels met a given goal participants were correct 89% (SD = 21%) of the time. When choosing between two meal images, however, participants chose the correct meal only 49% (SD = 25%) of the time. For the meal choice task, participants composed meals that were consistent with the direction of their chosen goal 67% of the time, which was statistically significant with a binomial test ($p < 0.001$). There was no difference by meal type, macronutrient, or direction of goal. While most of the chosen meals were in the correct direction, there was a high degree of variability in precisely meeting the goal target. Meals were an average of 0.83 (SD = 0.56) macronutrient “choices” away from the goal target. For example, participants were an average of 4/5 carb choices (12g), from the target.

Discussion and Conclusion

We designed, implemented, and evaluated GlucoGoalie, an ML-based expert system to generate personalized nutrition goals for individuals with T2D. Our evaluation demonstrated the preliminary feasibility of algorithmically generating nutritional recommendations from PGHD. This is important, because GlucoGoalie can help personalize self-management without requiring users to analyze their own records, or rely on their healthcare providers to identify meaningful patterns and recommend changes in behavior. However, our results indicated mixed success in participants’ ability to fully understand and follow goals, which suggests that additional work is necessary to design data-driven nutrition recommendations that are easy to incorporate into daily self-management practices.

Abstract

In recent years, the use of extracorporeal membrane oxygenation (ECMO) therapy has been increasing. Despite many published studies, there are no commonly accepted therapy guidelines. To address this gap in knowledge, we have developed a retrospective study of almost 900 ECMO patients to outline meaningful indications, provide clinical decision support where evidence-based recommendations can be established, and effectively counsel our patients and their families regarding the morbidity and mortality associated with this therapy.

Introduction

The number of patients with refractory cardiac or respiratory failure that receive extracorporeal membrane oxygenation (ECMO) therapy is growing. This is an expensive and life-saving technology that comes with significant morbidity and mortality. Limitations in data governance, standardization, curation, and in IT infrastructure have reduced our ability to fully utilize this information in improving healthcare delivery to ECMO patients and drive the research agenda. This project aims to streamline, standardize and integrate data from over five years of Duke experience to maximize patient sample size, clarify the proper patient selection for ECMO, better understand clinical outcomes, develop clinical guidelines for ECMO therapy, and facilitate registry submission (ELSO).

Methods

The ECMO Repository integrates data from the Duke Heart Center, the electronic health record (EPIC/Maestro Care), as well as manually curated data from REDCap on all Duke patients receiving ECMO from June 23, 2013 to October 31, 2018 (see Figure 1). The repository contains demographic information, medical history, diagnoses, medication history, medication administration, details of ECMO cannulation, pre and post ECMO lab values, vital signs, heart catheterization reports, echocardiogram reports, perfusion data, ventilation parameters, ECMO-specific risk scores, consult orders, functional assessments and transfusion requirements. The ECMO repository is built in a PostgreSQL environment and available to collaborators for analysis with appropriate approval.

Results

The current iteration of data contains 899 patients that received venoarterial (VA) or venovenous (VV) ECMO support from June 2013 through October 2018. The average age is 41.7 years of age (range neonate – 82 years of age) and 59.3% of the patients are male. The overall inpatient mortality during index hospitalization is 41.3% in the pediatric population (N=175, age < 18 YO) and 43.5% in the adult population (N=680, age >=18 YO). In the pediatric population, the most common hospital associated diagnosis was liveborn (28.9%), congenital anomalies (25.7%), related to infectious causes (15.7%), and respiratory disease (13.2%). In the adult population, the most common hospital associated diagnoses were related to pulmonary/respiratory disease (26.5%), associated with...
surgical procedures or devices (18.3%), related to infectious causes (15.1%), and complications of acute coronary syndrome (14.6%)^2.

There have been many challenges in data acquisition, cleaning, and integration of clinical data. Notably, poor clinical documentation, lack of regulatory coding schema, and clinical complexity of critically ill patients. The process of cleaning and integration is ongoing. After the complete repository is available for analysis, we plan to construct a durable pipeline to facilitate ongoing evaluation of ECMO data by automating repository updates from each clinical source every three months.

**Discussion**

This repository will allow for extensive study of ECMO therapy in Duke patients. To date, our repository is one of the most extensive and largest single-center studies of ECMO patients. We plan to use traditional (regression-based) methods and machine learning algorithms as analytic tools to build predictive models and clinical decision support systems for morbidity and mortality. This extended dataset will help us better understand which groups of patients benefit the most from ECMO therapy, the appropriate timing of ECMO therapy, and to better characterize complications of patients that have received ECMO therapy. The repository will also be available for retrospective review of ECMO patients for Duke investigators that obtain IRB and ECMO Oversight Committee approval.

Complementing Observational Signal with Distributed Representations for Drug Side-effect Prediction

Justin Mower\textsuperscript{1}, Trevor Cohen\textsuperscript{2}, Devika Subramanian\textsuperscript{1}

1. Department of Computer Science, Rice University, Houston, Texas
2. Biomedical Informatics and Medical Education, University of Washington Medicine, Seattle, Washington

Introduction:
Contemporary approaches to identification of potential on-market adverse drug effects (ADEs) depend upon aggregation of many data sources, including spontaneous reporting systems (SRSs) and the biomedical literature. Due to inherent scale and complexity, information from these data sources require robust and scalable methods. The aim of this research is to leverage relational information extracted from the biomedical literature in direct complement to observational signal extracted from the FDA Adverse Event Reporting System (FAERS, a SRS) using representation learning and composition with downstream supervised learning for drug safety monitoring.

Methods:
Distributed semantic vector representations of UMLS concepts were derived from around 90 million concept-relationship-concept triples (semantic predications) extracted from the biomedical literature, available via SemMedDB\textsuperscript{1}. Representations were generated using a neural-probabilistic technique: Embedding of Semantic Predications (ESP)\textsuperscript{2}. Representations for drug-ADE pairs from the Observational Medical Outcomes Partnership (OMOP) and the Exploring and Understanding Adverse Drug Reactions (EUADR) reference standards\textsuperscript{3,4} were composed from these concept vectors to generate abstract “relational embeddings”, shown previously to hold promise for pharmacovigilance research\textsuperscript{5}. Additionally, disproportionality measures were extracted from Harpaz et al\textsuperscript{1} and Banda et al\textsuperscript{6} for each of the drug/side-effect pairs in the reference standards (respectively). Using each data source (FAERS and literature) individually and combined - directly as concatenated features - cross-validated average precision scores at varying training set sizes were calculated for L1-regularized logistic regression (L1LR) models. These scores were then organized into learning curves for each model/data-source combination. Additionally, an ensemble configuration was generated by training two L1LR models - one on disproportionality data alone and another on literature data alone - and calculating a weighted average. Average precision was calculated at various thresholds of literature contribution for final classification.

Results:
Across all models, incorporating information from both the disproportionality and literature data sources resulted in the highest performance, with average precision of \(-0.95\) for training sizes of \(>35\%\) of each data set, a 12-19\% relative increase over the best performing SRS-based models. Compared to literature-based models, the combination models resulted in a modest but consistent \(-2\%\) point absolute increase. For the ensemble models, the best performance of the thresholds tested was at equal contributions of the outputs of both models (that is, both literature and disproportionality models were weighted equally; a true average). At a weighted contribution of 20\% literature and 80\% disproportionality, an uplift of \(-20\%\) over utilizing disproportionality-based models alone is observed.

Discussion:
Integrating signal from the SRS and information from the literature results in improved performance over a single data source alone, demonstrating their complementation in a supervised machine learning setting. These results exceed the previous state of the art on the reference standard tested, besting the previous state of the art (even accounting for methods which consider SRS, literature, product label, and other sources of data)\textsuperscript{6}. More importantly, models presented here can be trained with varying degrees of literature contribution, allowing a user-defined level of grounding in SRS-based measures. In a conservative setting, allowing only 20\% contribution from the literature, this approach still has substantial gains over utilizing SRS-based disproportionality measures alone, the most commonly leveraged form of post-market surveillance measures.
Average cross-validation average precision scores at various training set sizes, plus or minus the standard error of the mean across multiple cross-validation runs, for disproportionality only based models (orange), literature only (green) and combined literature-disproportionality based models (blue), on the OMOP reference standard.

Framework for Clinical Decision Support and Structured Reporting in Radiology

Sujith K. Nair, B-Tech1, Mike S. Tilkin, MS2, Laura P. Coombs, PhD3
1American College of Radiology, Reston, VA; 2American College of Radiology, Reston, VA; 3American College of Radiology, Reston, VA

Abstract
Radiologists often look into standard guidelines while they dictate a case, but these guidelines are outside their dictation system, which contribute to an inefficient workflow at the point of care. ACR Assist is a clinical decision support framework designed to provide structured clinical guidance to radiologists into their workflow, also fixes the downside of narrative-based radiology reporting and ensures that every report captures information essential to patient care and valuable for analysis.

Introduction
The American College of Radiology (ACR), headquartered in Reston, Va., is a nonprofit professional society with more than 38,000 member radiologists, medical students, medical physicists and radiation oncologists. The ACR Core Purpose is to serve patients and society by empowering members to advance the practice, science and professions of radiological care.

ACR Assist is a clinical decision support framework designed to provide structured clinical guidance to radiologists in a manner that allows this content to be incorporated naturally into the radiology workflow. The ACR Assist framework includes raw clinical content, an encoding schema that allows this content to be consumed by commercial applications, and a communication framework that facilitates content delivery.

Methods
The American college of Radiology developed an open authoring for point-of-care clinical decision support tools integrated into the radiologist reporting environment referred to as the computer-assisted reporting and decision support (CARDS)1, 2 framework. The CARDS, described herein, includes: (1) a definition format for representing radiology clinical guidelines as structured, machine-readable Extensible Markup Language documents and (2) a user-friendly reference implementation3 to test the fidelity of the created definition files with the clinical guideline. The proposed definition format and reference implementation will enable content creators to develop CARDS tools that voice recognition software (VRS) vendors can use to extend the commercial tools currently in use. In making the definition format and reference implementation software freely available, we hope to empower individual radiologists, expert groups such as the ACR, and VRS vendors to develop a robust ecosystem of CAR/DS tools that can further improve the quality and efficiency of the patient care that our field provides.

A sample CARDS module creation has been explained with a figure reference (Figure 1); which shows the full cycle (1) creation of a computer readable clinical guidance (2) how a voice recognition dictation software renders it and (3) how this produce a radiology report. The framework also makes it easy to integrate AI into the workflow where any of these elements on the clinical decision support content could be filled by an AI algorithm.

Results
The framework has been adapted by prominent radiology reporting software vendors and integrated on their dictation workflow.

Figure 1. A clinical guidance converted to an XML file is rendered on a voice recognition dictation software produces radiology report.
Decreasing unnecessary variation in radiology reporting and producing guideline-concordant reports helps with the success in value-based payment models and good for patient care. ACR has been converting College’s clinical content, including the Incident Findings Committee White Papers, available for decision support tools based on the CARDS framework.

**Conclusion**

A need for a clinical decision framework for radiologists to use the clinical guidance integrated on their radiology workflow at the point of care will make them more efficient. The need for having structured radiology reports in order to help the referring physician to understand the diagnosis improves the patient care plan. Last but not the least, data sharing for registries and research will help to improve the patient care over the period of time and an open framework which facilitates the data-sharing is critical. (see: www.icmje.org/index.html).

QUICK: A FHIR Logical Model for Clinical Decision Support and Clinical Quality Measurement

Claude Nanjo, MPH, MAAS,1 Guilherme Del Fiol, MD, PhD,1 Douglas K. Martin, MD,1 Richard L. Bradshaw, PhD,1 Bryn Rhodes,2 Floyd Eisenberg, MD, MPH,3 Kensaku Kawamoto, MD, PhD, MHS1

1University of Utah Department of Biomedical Informatics, Salt Lake City, UT, 2Dynamic Content Group, Orem, UT, 3iParsimony, Washington, DC

Introduction

The Health Level Seven International (HL7) Fast Healthcare Interoperability Resources (FHIR) data interface standard holds great potential for improving health and healthcare. FHIR is a standard for the electronic exchange of healthcare information which defines a metamodeling language, an extensible clinical information model, and a resource-oriented RESTful API.1 However, use cases such as clinical decision support (CDS), electronic clinical quality measurement (eCQM), electronic phenotyping, and cohort identification face important challenges when using FHIR directly as a target model. Specifically, CDS and eCQM systems need a consistent logical view of information (known as a logical model) that is optimized for reasoning and computation, hides unnecessary implementation details, is stable over time, and can be easily converted to and from the targeted information transport format. Here, the authors – who are leaders in the HL7 community – identify requirements for an ideal logical model for CDS and eCQM. We then propose a FHIR logical model known as the Quality Improvement and Clinical Knowledge (QUICK) model as the solution, and we evaluate QUICK and native FHIR against the identified requirements.

Methods

To develop and evaluate QUICK, we convened a panel of experts in the development and implementation of health IT standards for CDS and eCQM. The panel members serve or have served as co-chairs of the HL7 CDS Work Group (KK, GDF, BR), co-chair of the HL7 Clinical Quality Information (CQI) Work Group (FE), co-chair of the HL7 Clinical Information Modeling Initiative (CIMI) Work Group (CN), and members of the HL7 Board of Directors (KK, FE). Moreover, the panel members have been deeply engaged in current and prior efforts to develop and leverage standard logical models for CDS and eCQM, including the National Quality Forum Quality Data Model (QDM), HL7 Virtual Medical Record (vMR), the initial HL7 QUICK model, and the HL7 FHIR Quality Improvement Core (QI-Core) profiles. They have used FHIR and several logical models in the authoring of knowledge artifacts and in CDS applications deployed in production.

Drawing upon these experiences, as well as a detailed analysis of challenges associated with using FHIR directly as the logical model for CDS and CQI, the panel members developed requirements for an ideal logical model for CDS and CQI through multiple joint meetings of the HL7 CDS, CQI, and CIMI Work Groups in 2017 and 2018. QUICK was targeted for a redesign to fulfill these requirements, and it was proposed at the January 2019 HL7 Work Group Meeting as the future direction for a logical model for CDS and CQI. The approach was endorsed by the HL7 CDS, CQI, and CIMI Work Groups, and detailed data modeling based on this approach is currently underway. Moreover, to assess implementation feasibility and model fitness for purpose, the University of Utah is currently conducting a pilot study on the definition and use of declarative bi-directional FHIR-to-QUICK transformations for the automated generation of Java libraries to convert FHIR DSTU2, STU3 and R4 instances to QUICK and back for use in CQL-based, Java-based, and Drools-based CDS services. The QUICK logical model and pilot results will be submitted as a For-Comment Ballot in January 2020 by the HL7 CQI Work Group.

Results

Table 1 lists the logical model requirements developed by the HL7 CDS, CQI, and CIMI Work Groups along with the corresponding approach used by QUICK to address each requirement.
## Table 1. CDS-eCQM Logical Model Requirements and QUICK Approach to Addressing Need

<tr>
<td>Translation to FHIR</td>
<td>Platform independent model reversed engineered from current FHIR model to reduce transformation costs between QUICK and FHIR. Collaboration with HL7 Working Groups to improve cross resource consistency and better align FHIR to QUICK.</td>
</tr>
</tbody>
</table>

## Discussion

QUICK is designed to provide an implementable logical representation of the FHIR model for the health quality domain. The approach taken is strongly influenced by current object-oriented paradigms which are nearly ubiquitous in industry today, and it is based on substantial implementation experience in this space.

While QUICK addresses many of the implementation challenges identified over the years, it does not address all limitations equally gracefully (e.g., for the handling of FHIR “choice types”), deviates from FHIR in some areas (e.g., in the handling of modifying attributes), does not cover the entire FHIR resource space at this time, and requires restructuring transformations to and from FHIR in some cases. This inability to optimally meet all requirements relates to the inherent tension between some of the requirements in Table 1. For instance, approaches taken to enhance model semantic consistency and intuitiveness may lead to deviations from the FHIR model that complicate translations to and from FHIR. Ideally, some of the weaknesses present in the FHIR model with regard to the requirements in Table 1 will be addressed over time. In particular, the authors are engaged in a collaborative effort with other HL7 Work Groups to address structural and semantic inconsistencies in FHIR directly within the base FHIR standard. However, as the requirements for implementation models such as FHIR and logical models such as QUICK can and will differ, we anticipate a continuing need for QUICK.

## Conclusion

While FHIR aims to standardize the service interface, the need for a corresponding logical model in the quality space that lies behind the service interface has become more salient. QUICK is an attempt to present a common logical representation of the FHIR model based on implementation experience that supports both knowledge authors and CDS implementers.

A new representation of disease conditions and treatment pathways accurately predicts mortality and chronic diseases

Che Ngufor, PhD¹, Pedro Caraballo, M.D.¹, Thomas J. O Byrne¹, David Chen, Ph.D.¹, Nilay D. Shah, Ph.D¹,
Michael Steinbach, Ph.D², Gyorgy Simon, Ph.D²
¹Mayo Clinic, Rochester; ²University of Minnesota, Minneapolis

Introduction

The number of individuals in the U.S. suffering from multiple chronic conditions (MCC) has increased substantially and continues to rise. Patients with MCCs require significantly more health care resources, incur high cost of care, and face greater mortality, functional decline, and worse quality of life. At the basic level, the distinct MCCs act as competing risks, and co-occur either by chance, through causal relationships, or by common underlying risk factors. Consequently, interventions that address one comorbidity without reducing the severity of the others will offer limited benefit in terms of quality of life and mortality. Because slowing the progression of one comorbidity may hinder the progression of others, understanding the interactions among MCCs and treatment pathways offers the opportunity to strengthen intervention strategies. However, identifying these relationships or ascertaining the likelihood of adverse health outcomes have been hindered by the marked complexity and heterogeneity of patients with MCC.

Predictive analytics based on longitudinal data can provide crucial information for making better clinical decision about MCC patients. However, it also raises an important question about the appropriate representation of MCCs for predicting health outcomes. Numerous comorbidity measures have been developed for research using electronic health records (EHR) and administrative claims data such as the Charlson and Elixhauser Comorbidity Index (CI) and the Agency for Healthcare Research and Quality’s (AHRQ) Clinical Classification Software (CCS). Current Comparative Effectiveness Research and Evidence Based Practices (EBP) tend to focus on inefficient comorbidity representations such as simple summaries (e.g. counts, sum, frequencies, any or last observed) of individual conditions or aggregate measures of the CI and CCS within a specific observation window. However, these representations do not reflect an individual’s comorbid disease history and severity, and do not account for interactions with other risk factors or the different treatment pathways that a patient may take. This thus leaves a large gap in our knowledge about how to optimally manage individuals with complex MCCs. Different subpopulations of patients can exhibit different relationships between patient characteristics and outcomes. Thus information about the interactions and subgroups that maximally capture heterogeneity in MCCs and treatment pathways can facilitate diagnosis, enhance preventive strategies, improve quality of life, and help create smart EBP guidelines.

To address this critical knowledge gap, in this study, we introduce a novel representation of patient data called Disease Severity Hierarchy (DSH) that explores specific diseases and their known treatment pathways in a nested fashion to create subpopulations in a clinically meaningful way. As the DSH tree is traversed from the root towards the leaves, we encounter subpopulations that share increasing richer amounts of clinical details such as similar disease severity, illness trajectories, and time to event that are discriminative, and suitable for learning risk stratification models.

Methods

Study population: We used data for 15,391 adults, age 45 – 85 years, included in the Rochester Epidemiology Project (REP) database who received primary care at Mayo Clinic in 2004-2015. Subjects entered the study at their age in Jan 1 2004 and were still alive on Dec 31 2010. Patients were then followed until Dec 31 2015. Primary outcomes considered include all-cause mortality and major cardiovascular event (MCE) in 2011 - 2015. DSH construction: We focus on four common diseases: type 2 diabetes mellitus (T2DM), hypertension, hyperlipidemia and obesity and constructed their DSH for comparison with traditional representations. We included all primary care patients with or without an indication of these conditions at any time during the study period. We developed models based on features taken in 2004-2010 to predict mortality and MCE in 2011 - 2015. Specifically, for each patient, we collected demographic data, time-stamped diagnosis of the four disease conditions, medications, and laboratory results measured in 2004-2010 and use these to construct the DSH trees for each disease. For most disease conditions, associated laboratory tests exist, and medications indicated for these conditions are also known. However, most existing representation techniques ignore these relationships, thus eroding the interpretability and clinical applicability of the results. DSH is designed to account for known relationships in EHR by encoding disease severity. At each time point (hospital visit), DSH considered the full clinical context of a disease at several nested levels of details. Starting at the population level (root) we determined if a patient had a disease condition or not (e.g T2DM). If the patient is diseased, we looked for any information regarding whether the condition was treated (e.g. prescription of Metformin); next we consider the
aggressiveness of the therapy (first-line / last-line drug); and finally whether the patient was under control or not. A patient is under control, if the lab result or vital sign associated with the condition was within its predefined normal range. This nested or hierarchical representation of information helped us to assess the severity of the disease. Figure (a) shows the DSH for T2DM, where the leaves indicate if the patient is in control or not based on hemoglobin A1c. Notice that the structure of DSH is a binary tree, where each node has at most two children. Further, any branch on a right child leads to intensification of the disease severity. We used this property to quantitively represent the information embedded in DSH. Specifically, we assigned “risk” scores to the nodes, where the score of the right child doubles that of its parent. The risk score of the root node is either 1 (diseased) or 0 (disease free).

Training and validation: We developed age specific survival models, where instead of the traditional time-on-study, we used the subject’s age as the time scale to predict the risk of death and MCE at age 60, 65, 75, and 80 years based on the DSH, while adjusting for sex and race. The use of age time scale provides an expressive and flexible way to control the effect of age especially for older adults. It also provides a relatively meaningful basis on which to examine how risk varies over time.

We trained the random survival forest (RSF) model through a 5-fold cross-validation procedure.

Results

The median age of the study population in 2004 was 47.6 years, with 57.7% female and 88.5% white. 3.3% of the patients died during the follow up period (2011-2015), while 25.7% had MCE. Figure (b) presents the AUC, Sensitivity, and PPV of the RSF model trained using DSH risk scores and standard representation of the four comorbid conditions. Specifically, we considered three formats for the standard representation: a diagnosed condition persisted throughout 2004-2010, most frequent value (yes/no) of the condition, and the last observed value of the condition in 2004-2010. We also included indicators of medication use in 2004-2010. The figure clearly shows that the performance of RSF based on DSH risk scores significantly outperformed the traditional representation of comorbidities.

Conclusion

The proposed DSH risk scores effectively and accurately predict the age at which a patient maybe at risk of dying or developing MCE significantly better than traditional representation of disease conditions. DSH utilizes known relationships among various entities in EHR data to capture disease severity in a natural way and has the additional benefit of being expressive and interpretable. This novel patient representation can help support critical decision making, development of smart EBP guidelines, and enhance healthcare care and disease management by helping to identify and reduce disease burden among high-risk patients.

Measuring the impact of screening automation on meta-analyses of diagnostic test accuracy

Christopher Norman, M Sc,1,2 Mariska Leeflang, PhD,2 Raphaël Porcher, PhD,3 Aurélie Névéol, PhD1

Introduction

The large and increasing number of new studies published each year is making literature identification in systematic reviews ever more time-consuming and costly.1 Technological assistance has been suggested as an alternative to the conventional, manual study identification to mitigate the cost, but previous literature has mainly evaluated methods in terms of workload reduction recall, i.e. the number of references missed.2 There is a need to also evaluate whether screening prioritization methods leads to the same results and conclusions as exhaustive manual screening. In this study we examined the impact one screening prioritization method based on active learning would have had on estimates of sensitivity and specificity in systematic reviews of diagnostic test accuracy.

Methods

We simulated the screening process in 48 Cochrane reviews of diagnostic test accuracy, and re-ran 400 meta-analyses based on at least 3 studies. We evaluated prioritized screening with candidate references ranked in descending order of likelihood of being relevant, trained using active learning with logistic regression on n-grams trained with stochastic gradient descent. We compared the prioritized approach with randomized order, equivalent to conventional practice for screening in systematic reviews. We examined if the screening could have been stopped before identifying all relevant studies while still producing reliable summary estimates (points estimates of the sensitivity and specificity of the diagnostic test). For all meta-analyses, we also examined the relationship between the total number of relevant studies and the reliability of the final estimates.

Results

The main meta-analysis in each systematic review could have been performed after screening an average of 30% of the candidate articles (range: 0.07% to 100%) (fig. 1). No systematic review would have required screening more than 2,308 studies, whereas manual screening would have required screening up to 43,363 studies. Despite an average 70% recall, this procedure would have changed the estimates by only 1.3% on average (fig. 1).

We found a moderately strong correlation (Pearson $r = 0.60$) between the total number of studies included in a meta-analysis and the observed uncertainty of the meta-analysis. We estimated the maximum estimation error in the reported meta-analyses to be approximately 50% point when based on 3 studies, 16% point when based on 5 studies, and 4% point when based on 10 studies.

Discussion

By monitoring the moving average of the displacement we were able to estimate the current precision of the diagnostic test accuracy estimates through the screening process. However, the meta-analyses of diagnostic test accuracy were accurate within 2% only for meta-analyses including at least 20 studies. In many cases the screening could be stopped prematurely while bounding the estimation error within prespecified limits (Fig. 1).

Future Work

Future work will evaluate the validity of these results in prospective settings. We also plan to use Bayesian methods to estimate final meta-analysis accuracy from the study data accumulated through the screening process. We will also aim to extend this approach to other study types beyond diagnostic test accuracy, such as intervention studies.
Conclusion

Screening prioritization coupled with stopping criteria in diagnostic test accuracy reviews can reliably detect when the screening process has identified a sufficient number of studies to perform the main meta-analysis with an accuracy within pre-specified tolerance limits. However, many of the systematic reviews did not identify a sufficient number of studies that the meta-analyses were accurate within a 2% limit even with conventional, exhaustive manual screening.

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 676207.

Figure 1: The impact of screening prioritization and stopping criteria as the difference in meta-analysis results for the largest meta-analysis in 38 systematic reviews. Ten systematic reviews did not include any meta-analysis based on three or more studies in PubMed and were therefore excluded from the results. Effort denotes the fraction of candidate references screened. Recall denotes the fraction of identified relevant studies. Blue data points correspond to the simulated results using early stopping. Red data points correspond to results without early stopping, i.e. equivalent to current practice (which would have 100% effort and 100% recall).

Reduction in Severe Ordering Errors of Blood Products in Pediatrics through Formative and Summative Usability Testing

Evan W. Orenstein, MD1,2, Jeanne Boudreaux1,2, MD, Margo Rollins, MD1,2, Jennifer Jones, RN2, Christy Bryant, RN, BSN2, Dean Karavite, MS3, Naveen Muthu, MD3, Jessica Hike, MPH2, Herb Williams, BA2, Alexis Carter, MD1,2, Cassandra D. Josephson, MD, 1,2

Introduction: Electronic order sets have the potential to improve adherence to evidence-based practices, reduce variation in care, and minimize cognitive load. However, poorly designed order sets can also change practice patterns unintentionally1 or lead to medical errors.2 In pediatric medicine, ordering blood products for transfusion is a complex task as providers must consider multiple factors, including but not limited to the transfusion itself (e.g. the appropriate blood product, volume, and rate of transfusion), patient factors (e.g. conditions requiring special preparation by the blood bank such as irradiating or washing blood products), and workflow factors (e.g. preparing blood on hold for surgery or future transfusion vs. blood to be prepared and administered immediately). During a Failure Modes and Effects Analysis (FMEA), our institution identified the blood product ordering process as high risk for serious transfusion-related errors. To mitigate this risk, we used user-centered design principles to standardize blood product ordering across a large pediatric healthcare system and evaluated order set designs using formative and summative scenario-based usability testing.

Methods: We re-designed the blood product ordering process at Children’s Healthcare of Atlanta in three phases. 1) Identification of stakeholders across clinical, laboratory, and information technology departments and assembly of a multidisciplinary guiding coalition. This group used FMEA to identify the users involved in blood product administration and nuances of blood ordering tasks by clinical department and patient context. 2) This group performed a heuristic review of existing blood bank order sets and proposed adjustments to a single common blood product ordering process. 3) Formative usability testing using a think-aloud protocol, in which providers ordered blood with the proposed order set in their usual clinical workspace using a realistic scenario appropriate to their clinical specialty. Based on observed errors and direct feedback, iterative adjustments were made to the proposed order set between participants. These processes were completed from July – December 2018.

Usability of the re-designed order set was evaluated and compared to the original version through summative testing of the effectiveness, efficiency, satisfaction, and educational value of each approach (Figure 1).

We recruited front-line ordering clinicians in their usual clinical setting from a purposeful sample of clinical specialties. Participants first answered 5 multiple choice quiz questions asking about which special processing requests would be appropriate in a complicated clinical scenario, created and validated by a pediatric hematologist (JB) and two transfusion medicine specialists (MR, CJ). Participants were then randomized in blocks of two to use either the original or re-designed order set to order blood products for 4 standardized scenarios in a non-production electronic health record (EHR) environment. Participants used the same order set version for all 4 scenarios. The scenarios were developed based on a combination of known safety events and errors observed during formative usability testing. Order set appearance and functionality based on age and weight of the patient were identical to the production EHR environment. However, clinical details of each scenario were read to the participant directly and not present within the simulated patient’s chart. For each scenario, participants were timed from the end of the scenario prompt until the orders were signed. Additionally, an observer noted any severe or moderate ordering errors, defined as follows:

1423
Severe error: Orders that, if followed exactly by both the blood bank and the nurse, would lead to over-transfusion (higher volume of blood or faster rate of infusion than intended reaching the patient), under-transfusion, or missed special processing request (e.g. non-irradiated blood in a scenario in which the patient has T-cell dysfunction).

Moderate error: Orders that, if followed exactly by both the blood bank and the nurse, would lead to an unnecessary special processing request (e.g. order for CMV-negative blood in a patient who does not require it) or a delay in transfusion (e.g. missing transfuse order for the nurse).

After completing all 4 scenarios using either the original version or the re-designed version, participants re-took the same 5 question quiz with the question order and answers shuffled. They completed one additional scenario with the opposite design (i.e. if they did the first 4 scenarios with the re-designed order set, scenario 5 was with the original order set). Finally, participants rated their preference between the order sets, perceived ease of use, usefulness, and efficiency of the new order set (adapted from the Technology Acceptance Model3) and overall evaluation of the new order set. All differences between the two groups were compared using two sample t-tests in R version 3.5.2. This work was deemed non-human subjects research by the IRB of Children’s Healthcare of Atlanta.

Results: Twenty-nine stakeholders were identified across clinical, laboratory, and information technology departments. After heuristic review, the standard blood product order set was restructured from groupings by similar order type into a decision tree based on the different clinical settings identified. Defaults were also adjusted based on discussion with the stakeholder group, and questions in the “prepare” and “transfuse” orders were redesigned.

Formative usability testing was completed with 27 providers from 7 specialties with 30 unique scenarios and a total of 70 tests. Key error types targeted during formative testing included transfusion volume ordering errors, errors in selection of special processing requests, and errors in communication when preparing and transposing 2 separate aliquots of blood product from the same donor unit. During formative testing, 18 design changes were made, 12 of which were considered major (e.g. changing order question logic, changing order set structure) and 6 minor (changing wording, allowing multi-select on order questions).

Fifteen front-line ordering clinicians participated in summative testing and completed 4 scenarios each for a total of 60 scenarios, with 8 participants randomized to the re-designed order set (32 scenarios) and 7 to the original order set (28 scenarios). There were no significant differences in specialty distribution or experience between the groups.

Task completion without errors and the rate of severe errors were significantly improved with the re-designed order set, while the frequency of moderate errors and time per scenario were no different (Table 1). There was a slight trend towards greater improvement in quiz grade for those using the re-designed version, but this was not significant. On a scale of -1 (completely prefer original order set) to +1 (completely prefer re-designed order set), participants preferred the re-designed order set with a mean score of 0.56 (95% CI: 0.23 – 0.89). Overall, 71% of participants agreed or strongly agreed that they were satisfied with the new system, 79% that it was easy to use, 71% that it allowed efficient task performance, and 79% that it was useful.

Discussion: In the setting of a complex, high-risk ordering task, scenario-based usability testing performed in the clinical setting demonstrated a high rate of severe ordering errors despite stakeholder heuristic review, leading to substantial changes in order set design during formative usability testing. This method of in-situ testing and immediate adjustments based on observed errors was low cost and could be performed by a small, skilled team within 1-2 weeks. Summative testing in a simulated environment demonstrated that this approach reduced (but did not eliminate) severe ordering errors in simulation with no change in ordering efficiency. While there was a modest trend towards improved learning that our study may have been underpowered to detect, reductions in severe errors appear largely independent of changes in provider knowledge about appropriate special processing requests for blood products. While we have yet to demonstrate the clinical impact of these design changes, further research after implementation in production will determine if this effort yields a true patient safety benefit.

Decision-Support Needs of ECG Technicians in Inpatient Settings

Mustafa Ozkaynak, PhD1; Andrew E. Levy, MD2; Juliana Barnard, MA1; Sharon Pincus, MA1; Michael Ho, MD, PhD1,3
1University of Colorado, Aurora, CO; 2University of Colorado Hospitals, Aurora, CO; 3VA Eastern Colorado Health Care System, Aurora, CO

Abstract
Ancillary service performance affects organizational and patient outcomes. This study aims to identify decision-support needs of ECG technicians, a critical ancillary service in inpatient settings. We devised a mixed methods study including staffing data, ECG records (request time, completion time, priority) and technician semi-structured interviews/observations. Results suggest ECG completion times fall below recommended clinical times, a suboptimal result influenced by work system elements. Decision-support tools may streamline the process and significantly shorten ECG technicians' completion times.

Introduction
Timeliness is a critical component of many ancillary health services in the hospital setting.1 For instance, delays in electrocardiogram (ECG) acquisition contribute to delayed diagnosis and treatment of such critical conditions as ST-elevation myocardial infarction (STEMI).2 Decision-support tools have previously been shown to improve efficiency and workflow for providers, nurses, and other professionals3. Decision support can potentially improve ancillary services with planning and scheduling,4 but the precise decision-support needs of ancillary services (such as ECG technicians) has not been fully explored. Previous studies on decision support, highlighted the importance of congruence of technology with work system elements (e.g., person, organization, task, environment, and tools/technologies).5 The purpose of this study is to identify decision-support needs of ECG technicians, a critical ancillary service in inpatient settings. We focused on work system elements that should be considered in technology development.

Methods
We collected quantitative and qualitative data. Quantitative data included all ECG orders between 1/1/2017 and 10/31/2018 at a single academic hospital with about 700 beds. Each record included unit name, order time, completion time, and priority level (STAT, Now, Routine; maximum completion times are 15, 60 and 120 minutes respectively). We also examined staffing data. Semi-structured interviews were completed with ECG technicians (N=14, from both day and night shifts) until saturation was achieved. Interview questions focused on ECG completion processes, team communication, and work flows with probing to contextualize and explain the quantitative data. Quantitative data were analyzed to identify ECG request patterns by time of day and patient location. Qualitative data were analyzed using content analysis and frequent team debriefings to identify emerging themes.

Results
We studied 53,274 ECG orders. The 95th percentile of ECG requests each hour across the day varied between four (4-5 AM) and 12 (6-7 AM) during the weekdays. Among all non-scheduled ECGs, 39% were ordered with STAT priority. Although average ECGs completion times (about 14 minutes) could be reasonable, a significant percentage of ECGs had delayed completion times, according to current hospital standards. STAT delays (>15 min) varied slightly (23% to 33%) across unit groups while overall delays did not vary by time of day (13%-18%). Qualitative findings included (a) variability in how staff decided prioritization of multiple STAT ECG orders across a large hospital, (b) inappropriate use of STAT label for non-clinically urgent ECGs, (c) duplicative ECG orders causing technician confusion and frustration, (d) lack of alerts to notify technicians when they completed a STAT ECG outside of expected time frames, and (e) staffing issues (e.g., short staffing and demanding pace with limited breaks). Interview data supported some of the underlying work system elements highlighted in the quantitative findings. We organized these elements using systems engineering initiative for patient safety (SEIPS) model5 in Table 1.
Discussion

We describe five interrelated work system elements related to ECG acquisition and technician work. Some of these elements can be modified (e.g., priority policies or staffing levels); however, some of the elements are not feasible to modify (e.g., two-tower structure of the hospital). Informatics interventions aimed at the modifiable components should be designed in consideration of the non-modifiable elements to prevent unintended consequences.

ECG completion times can be improved through clinical decision-support systems in three ways. First, a dashboard that shows the timeliness of ECG orders and various staffing variables could be developed for administrators for better managerial planning (e.g., staffing levels). This type of decision support can assist administrative staff in decisions related to scheduling, capacity planning and policy level decisions. Second, decision-support tools embedded into electronic health records can assist clinicians in prioritizing ECG orders. This type of decision support will allow clinicians to assign an ECG order the most appropriate prioritization based on the patient’s health status and hospital policies. Third, ECG technicians, who travel between units a majority of their shifts, can be assisted by mobile decision-support tools when there are multiple, competing orders at the same time. This type of decision support systems will guide technicians which ECG order should be fulfilled first and help coordination between multiple technicians and nurses when there are competing orders.

Conclusion

Decision-support systems have the potential to improve ECG technician performance and ECG completion times if the development of these systems are informed by work system elements. These improvements can enhance patient safety and quality of care in the inpatient settings.

Objective measures for Medical Education from the Electronic Health Record

Sarada S. Panchanathan, MD,MS\textsuperscript{1}, Andrew Muth, MD\textsuperscript{2}, Pamela Garcia-Filion, PhD\textsuperscript{1}
\textsuperscript{1}University of Arizona, Phoenix, AZ; \textsuperscript{2}VA Central Iowa HCS, Des Moines, IA

**Introduction**
Hospitals nationwide have adopted electronic health records (EHRs) over the past decade. These have served as a valuable repository of information beyond their daily use by physicians for patient care. Clinical researchers use the patient data contained in the EHR, and quality officers use information about providers and their patients to create tracking dashboards for process and outcome metrics. EHR systems also provide use data for learners at all levels of medical education; this underutilized section of data provides a unique opportunity to objectively measure outcomes of both individual residents and Graduate Medical Education (GME) programs.

The Accreditation Council for Graduate Medical Education (ACGME) describes six competencies that develop from the learner stage to expert: patient care, medical knowledge, systems-based practice, practice based learning and improvement, professionalism, and communication. Recently, the ACGME recognized the need for metrics to track and improve medical education outcomes\textsuperscript{1}. To this end, medical educators are seeking objective measures for competency-based progression in lieu of solely time-based progression. Use of EHR data to guide GME training has recently been reported. In 2017, Boston Children’s Hospital reported the use of a resident dashboard with automated training metrics\textsuperscript{2}. At Phoenix Children’s Hospital, we are developing a similar resident dashboard\textsuperscript{3}. Herein we describe the use of EHR metadata from pediatric residents to create objective metrics corresponding to ACGME competencies for patient care and professionalism.

**Methods**
From an EPIC platform, 6 years of metadata were extracted for all ambulatory clinic notes authored by pediatric residents. Note types were history and physical, progress, consultation, and procedure notes. Data for unique visits and patients, as well as patient age and gender, were captured to provide the volume and measures of continuity of patient care. ICD-10 diagnosis codes for each encounter were captured to classify disease type, as an indicator of variety and volume of resident clinical experiences. Time to note completion was calculated and used as a measure for attention to professional duties. Data visualizations were created such that an individual resident can evaluate their current clinical experience, and compare themselves to their class and with graduated classes (target benchmark).

**Results**
**Patient Care:** Aggregate resident data by class on clinical experiences were visualized using a radar graph projection. To account for the finding that different diagnoses were seen in vastly different volumes, the raw data were normalized such that 100\% (red line) on the radar chart (Fig. 1) represents the target benchmark, i.e. the clinical experiences of graduated residents. Resident data are presented as percentages.\textsuperscript{†}

**Fig 1.** Patient Care: This radar chart represents the current status of clinical experiences for resident classes compared to graduated residents (100\%).
**Professionalism:** Individual resident note completion rates for the previous 3 months were calculated as the percent of notes completed within the clinic expected time period of 3 days. The average for all residents in the clinic was 71% (Fig. 2). We selected a three month time frame to capture behavior changes at each quarterly report.

![Percent notes completed within 3 days](image)

**Fig 2:** Resident data on timeliness of note completion for a 3 month period is benchmarked to the overall average of 71% for all pediatric residents (n=49). Each resident is represented by one bar.

**Discussion**
This project demonstrates the use of note metadata to develop objective measures for pediatric resident learners and educators. Individual resident data can be inserted to benchmark their clinical experiences and performance against aggregate class data. In July 2019, these data were provided to individual residents with comparison data for the first time, and will be repeated every three months to allow for data-informed goal setting. The impact of this method on resident individualized learning plans will be examined.

In addition to the immediate effects on residents, we plan to further analyze the retrospective data of graduated residents, to determine if there is a correlation between the development of expertise over time and differences in volume and variety. This method may be extended for use by other GME programs, and is a promising mechanism for comparisons within and between programs.

There were a few additional results to highlight. We observed an underrepresentation of data for diagnoses for which no testing or prescriptions are required. We expect the representativeness will improve as residents recognize that clinical experiences are measured by the appropriate use of ICD10 coding. We were also able to observe true shifts in the clinical trends, as seen by the increase in diagnoses of anemia which reflected an underlying change of the population demographics in the last 3 years (i.e. rise in refugee rates).

**Conclusion**
We developed an education report for learners and educators to obtain objective data and develop specific learning goals across the continuum. We plan to work next to combine data from disparate EHRs (Cerner, AllScripts, and Epic) within our program to capture all of our sites. We are confident that such objective measures will enable individual learners, educators, and programs to improve both undergraduate and graduate educational outcomes.

**Acknowledgments**
We would like to express our gratitude to Mark Moehling, for his tireless work on the numerous versions of the educational reports.

A deep learning-based survival model for prediction of progression in late Age-related Macular Degeneration (AMD) from color fundus photographs

Yifan Peng, PhD¹, Tiarnan Keenan, BM BCh, PhD², Qingyu Chen, PhD¹, Elvira Agrón, MA², Wai T. Wong, MD², Emily Y. Chew, MD², Zhiyong Lu, PhD¹

¹National Center for Biotechnology Information (NCBI), National Library of Medicine (NLM), National Institutes of Health (NIH), Bethesda, MD, United States; ²National Eye Institute (NEI), National Institutes of Health (NIH), Bethesda, MD, United States;

Introduction

Age-related macular degeneration (AMD) is a common eye condition and a leading cause of vision loss among people aged 55 and older. Based on clinical features, the disease is classified into early, intermediate, and late stages. In some people with non-late AMD, the disease progresses to the late stage slowly; in others, it advances faster and may quickly lead to loss of vision in one or both eyes. Therefore, there is a critical need to predict progression to late AMD, in order to provide useful prognostic information for patients and clinicians.

Currently, the standard clinical method of predicting progression to late AMD uses the Simplified Severity Scale, proposed following the Age-Related Eye Disease Study (AREDS)¹. A score of 0-4 is generated for the individual by grading the presence of two risk factors (large drusen and pigmentary abnormalities) in the central retina of each eye, based on color fundus photographs (CFP). Each step on the scale is mapped to a 5-year probability of progression to late AMD (in either eye). For example, if the individual has a score of 1 on the scale, the 5-year probability of progression to late AMD is 3.0%. However, using this scale requires trained specialists and is subject to human errors. Furthermore, this method is unable to incorporate other factors such as demographic/clinical information, which is recognized as important in predicting late AMD. Therefore, there is currently an unmet need for algorithms that can perform automated prediction of late AMD from CFP.

In this project, we propose a novel framework to automatically predict progression to late AMD from CFP of both eyes. Unlike previous methods², our approach takes advantage of deep learning and survival analysis in a unified framework, which, to the best of our knowledge, has not been done in the ophthalmology domain. More importantly, our model is ‘explainable’: it mimics the human grading process by detecting individual risk factors in each eye. Thus, our model closely follows the clinical decision-making process. Unlike “black-box” approaches, it allows an ophthalmologist to inspect an interpretable result.

Methods

Our framework comprises two parts (Figure 1). The first part consists of two deep learning models to classify drusen size and pigmentary abnormalities from CFPs of both eyes. Recently, the performance of deep learning has been intensively demonstrated in clinical imaging³. In our framework, we utilized DeepSeeNet, a convolutional neural network-based model that has achieved state-of-the-art performances on automated classification of AMD severity from CFP⁴. Its drusen-net detects drusen in 3 size categories (small/none, medium, and large), and its pigment-net detects the presence or absence of pigmentary abnormalities. The second part is a Cox proportional hazards model to estimate time to late AMD⁵. The purpose of the Cox model is to evaluate simultaneously the effect of several factors on the probability of a particular event. In our case, the event is progression to late AMD and the factors are (i) drusen and pigmentary abnormalities of both eyes, and (ii) demographic/clinical information of the patient.

This study used the AREDS dataset¹† collected from a 12-year multi-center, prospective cohort study of the clinical course, prognosis, and risk factors of AMD and age-related cataract. CFPs from both eyes were obtained at the

---

¹These authors contributed equally to this work.
study baseline, the 2-year follow-up visit, and annually thereafter. The gold standard annotation (severity scale score, drusen, and pigmentary abnormalities) was performed by expert human graders at the Reading Center (University of Wisconsin). Data on all participants without late AMD in either eye at study baseline/year 0 (2,246 participants) were extracted from the AREDS dataset. Of these, 434 (19%) participants progressed to late AMD by 5 years. The overall survival is thus calculated from the baseline to the year when the participant is in the late AMD stage, or censure point if still in the non-late AMD stage.

DeepSeeNet was trained on the images of the participants in the training set (59,913 images) and tested on the images of the participants in the testing set (1,396 images). All images were cropped to generate a square image field encompassing the macula and resized to $224 \times 224$ pixels. The hyperparameters were learning rate 0.0001 and batch size 32. The training was stopped after 5 epochs once the accuracy no longer increased.

The c-index was used to evaluate the performance of our framework\(^6\). It is a generalization of the AUC and ranges from 0.5 to 1, with 0.5 indicating random predictions and 1 perfect predictions.

**Results**

We first evaluated the performance of DeepSeeNet on detection of drusen and pigmentary abnormalities (Table 1). We then compared one baseline approach and two survival models. The baseline approach mapped the severity scale from the retinal specialists to the 5-year risk from AREDS report 18\(^1\). The second approach used the framework described above, and the third approach included two additional patient factors: age and smoking history. Table 2 shows that the deep learning-based survival model achieved superior performance to traditional 5-year rates with retinal specialists (0.896 vs 0.878). Our results also demonstrated that age and smoking information are helpful in the prediction (0.903 vs 0.896).

**Discussion**

To our best knowledge, this work represents the first attempt to combine deep learning with survival analyses in ophthalmology. From the deep learning perspective, we demonstrate that DeepSeeNet can achieve state-of-the-art performance for detecting drusen and pigmentary abnormalities from color fundus photographs. The subsequent survival analysis supports the idea that deep learning can enhance the accuracy of predictions of progression to late AMD. Taken together, this work demonstrates the potential of our framework to assist decision-making in both clinical practice and research environments. In future, we plan to compare our model with other traditional methods such as logistic regression and random forests.

Get on the Same Page: Negotiating and Aligning Knowledge and Expectations between Patients and Providers through Self-Tracking Artifacts

Adrienne Pichon, MPH¹, Megan Houterloot¹, Kayla Schiffer², Emma Horan¹, Noémie Elhadad, PhD¹

¹Columbia University Department of Biomedical Informatics, New York City, NY; ²Barnard College, New York City, NY

Introduction

Patient-generated data (PGD) are emerging as the cornerstone of chronic disease management. Self-tracking tools have shown promise in supporting patients with their self-management needs, as many occur outside of doctor visits and throughout patients’ daily lives. There is limited work, however, on the use of self-monitoring and self-tracking data as means for building trust, ensuring shared decision making between patients and providers, and ultimately improving patient-centered care. There is further limited knowledge for complex chronic diseases without clear treatments guidelines and with different types of providers engaged in care. We ground our work in management of endometriosis, a multi-factorial, systemic condition impacting an estimated 6-10% of women. Endometriosis providers form multi-disciplinary care teams and patients experiment with several self-management strategies on their own. Endometriosis is an enigmatic condition with an often-debilitating impact on patients: there are no bio-markers for providers to monitor patients’ status, treatment response varies across individuals and is difficult to predict, and patients are dissatisfied with the lack of success in their care.

In prior work, we have designed and built the Phendo app (Fig 1) for endometriosis patients to self-track their symptoms, functional assessment of health status, treatments, and self-management strategies through time. The rise of FHIR technologies provides new opportunities to inform the design of self-tracking artifacts, such as interactive visualization of self-tracked data, for the goal of shared-decision making. We explore endometriosis specialists’ perceived opportunities and challenges for using these tools. In particular, we (1) identify convergent and divergent needs across medical specialties for successful encounters; (2) assess from the providers’ perspective, the ways in which they negotiate and align goals and expectations with patients, especially when both patients and providers have relevant knowledge; and (3) elicit perceived potential and limitations of self-tracking artifacts at the point of care.

Methods

Semi-structured interviews (n=10) were conducted with endometriosis specialists (2 gynecologists, 3 surgeons, 2 physiatrists, 2 pelvic physical therapists, and 1 pain specialist). Two endometriosis personas and corresponding vignettes (chronic and acute chief complaints) were described to facilitate discussion. Providers were first probed about their approach to a typical visit with endometriosis patients, perspective about shared decision making in practice, and their attitude towards using PGD at the point of care. In the second part of the interview, two prototypes for conveying self-tracked data at point of care were provided (interactive timeline and a semi-structured graphical and text summary) (Figs 1 and 2). The prototypes operate over data collected in the Phendo app. Themes were created using inductive coding of the interview transcripts. All study activities were approved by Columbia University’s IRB.

Results

A number of key themes were identified: (1) complexity of assessing patient status and goals (e.g., methods to elicit broad symptom experiences; goals of patient-specific functional activities or reduction in pain), (2) factors and strategies underpinning or hindering communication and relationship building (e.g., roles a provider can take including coach or cheerleader; patient traits including motivation and mindset), (3) approach towards treatment and selecting specific or general treatment modalities, (4) negotiation and alignment of endometriosis knowledge and expectations around treatment and outcomes between patients and providers, and (5) features of provider and information workflow to promote a successful encounter (e.g., insurance requirements and documentation; electronic health record functionalities to upload PGD). Implications of self-tracking artifacts emerged across all themes, with their potential for grounding the clinical encounter, facilitating visit structure, reviewing past treatment choices, supporting monitoring and assessment of symptoms and goals, and aligning expectations. Across specialties, providers exhibited
differences in information needs and their granularity through time (e.g., surgeons wanted the most concise summary over a large period of time and physiatrists wanted granular, daily measures).

Provider needs and perceived benefits may inform how patients engage with self-tracking. While some providers worried about continued use of self-tracking for patients, several suggested discussing "self-tracking prescriptions" as a potential encounter outcome. The tools were seen as potentially useful to build trust by validating patients’ experience and suggesting a common language for patients and providers. Our ongoing research is exploring patient needs, the interpersonal dynamics of the patient-provider relationship, and how technology may support collaboration.

Discussion

Management of chronic conditions is challenging. The enigmatic nature of endometriosis, disparate knowledge amongst different specialties, providers, and patients, and current limited guidelines for care further complicate the provision of quality care and treatment. Self-tracking data, which depict a specific patient trajectory, have the potential to help providers in their care and to act as tools for shared decision making. Our work confirms that self-tracked data can act as powerful evidence to re-align knowledge and expectations between patients and providers. The interviews can inform the design of self-tracking artifacts in the context of the patient-provider encounter.

Breast Cancer Screening Rates Among Family Members of Affected Relatives

Fernanda C. G. Polubriaginof, MD PhD1, Silis Y. Jiang, PhD1, Nicholas P. Tatonetti, PhD2, David K. Vawdrey, PhD1,2

1 Value Institute, NewYork-Presbyterian Hospital, New York, NY
2 Department of Biomedical Informatics, Columbia University, New York, NY

Abstract

Delayed diagnosis of breast cancer can increase patients’ morbidity and mortality. We used a novel algorithm to identify 9,001 family members of breast cancer patients. We found that 38.5% of patients did not receive screening as recommended by guidelines and 75.2% of women over 40 with a first-degree relative with breast cancer diagnosis were not screened. Informatics methods can be used to identify patients at risk for disease development, and therefore support clinical care.

Introduction

Breast cancer is a prevalent disease, affecting 1 in 8 women in the United States. In 2019, 268,000 new cases of breast cancer are expected in the United States.1 Breast cancer is one of the leading causes of death among women. Early diagnosis and treatment is critical to reduce mortality and morbidity in this patient population. Identification of early stage tumors without metastasis leads to better outcomes. Given the high prevalence and importance of early diagnosis, the American Cancer Society2 recommends women with an average risk of breast cancer receive disease screening with mammograms starting at age 45 while the U.S. Preventive Services Task Force (USPSTF) recommends biennial mammography screening starting at age 50.3 Women considered to be at a high risk should receive early screening starting at 40 years old and, in some cases, receive additional screening with an MRI.

With the wide adoption of electronic health records (EHRs) and increased availability of clinical data in electronic format, existing clinical databases can be used to monitor overall screening rates among women and among high-risk populations. However, there has been limited work on clinician adherence to this recommendation in large academic medical centers. We undertook this study to determine the rates of breast cancer screening among women and among women with known a family history of breast cancer.

Methods

With approval from the Institutional Review Board of Columbia University Medical Center, we conducted a retrospective analysis of family members of patients diagnosed with breast visiting NewYork-Presbyterian Hospital/Columbia University Medical Center from June 2007 to March 2019. Patients with a diagnosis of breast cancer were identified using billing and procedure codes. To identify family history in electronic health records, patients’ relatives were identified using RIFTEHR (Relation Inference from the Electronic Health Record),4 a novel, validated method that used the first name, last name, phone number and ZIP code of patients’ emergency contacts to identify familial relationships. Once the relationships were identified, RIFTEHR inferred additional relationships according to family structure. The identified relationships were previously validated using both clinical and genetic data in three distinct institutions.4

Once the cohort of family members was identified, we extracted demographic information such as sex, age, race, and ethnicity from the EHR. We measured breast cancer screening rates for the overall cohort by identifying women over the age of 50 that had at least one mammogram or breast MRI. Additionally, we built a high-risk cohort by identifying women that had at least one first-degree relative (e.g., parent, child, sibling) with breast cancer diagnosis. We measured breast cancer screening for the high-risk cohort by identifying individuals that had at least one mammogram or breast MRI after the index case diagnosis date. We present descriptive statistics of the identified cohorts, along with the rate of breast cancer screening.

Results

Overall, we identified 2,368 patients with breast cancer and with familial relationships extracted by RIFTEHR. These patients had 9,001 family members in our database representing 2,237 families. This cohort of patients was composed of 11,083 (89.9%) females, with an average age of 44 years old. Among patients with breast cancer diagnosis, 97.2% where female, with an average age of 61. A total of 67 men from 54 families were diagnosed with breast cancer, demonstrating an increased risk of disease among close relatives in these families. When assessing overall screening
rates for the cohort among women over the age of 50, 61.5% received mammography screening. Among women over age 40 who had at least one first degree relative with breast cancer diagnosis, 24.8% received at least one screening test.

**Discussion**

Secondary use of EHR data can facilitate clinical research by providing not only the medical history of patients, but also their family medical history. Many EHR implementations do not store family history information in a centralized or standardized fashion. Family medical history data is often collected and stored as free-text as part of clinical notes, which makes using this information challenging. Additionally, uncertainty about the medical history of family members, as well as inaccuracies in patient recall, compound the challenge of obtaining accurate family history data.5

Our study employed a novel method for identifying families and gathering corresponding medical histories through patient-provided emergency contact information stored in the EHR. This method could be used to identify patients at risk for disease development that are eligible for additional testing. Previous research suggests similar findings for a myriad of different diseases, most notably in relation to cancer screening.6 In our study, 38.5% of patients were not screened for breast cancer, even though early diagnosis is known to decrease morbidity and mortality. Potential explanations for the low adherence to breast cancer screening may include lack of family history documentation and physicians’ choice to not pursue screening. The fact that family history is often unavailable or stored in clinical notes presents barriers to using this data in clinical encounters,7 which may ultimately result in poor screening rates. Clinicians may consciously choose to not screen certain patients; however, due to the low rate of screening adherence, we believe this explanation alone to be less probable. Future work should focus on the use of informatics solutions, such as RIFTEHR, to identify high-risk patients eligible for screening, and alert physicians of such eligibility during the clinical visit.

There are privacy issues regarding the use of the RIFTEHR method for clinical practice, and tradeoffs must be made between providing optimal care and safeguarding the privacy and confidentiality of family members’ health information.8 Notwithstanding the ethical considerations, the use of RIFTEHR for identifying familial relationships using EHR data unlocks new opportunities for secondary use of data to facilitate identification patients at high risk for disease development and support appropriate monitoring of prevention strategies such as disease screening.

Improving Delivery of Chronic Opioid Therapy (COT) in a Primary Care Internal Medicine Clinic: Quality Improvement Study

Sravya Ponnapalli\(^1\); Andrew Johnson, MS\(^1\); Stephen LaCour, MS\(^1\); Barbara Ruddy, MD\(^2\); Heather Fields, MD\(^2\); Anita Murcko, MD\(^1\); Adela Grando, PhD\(^1\); Patricia Davis\(^2\); Mark Wallace, MD\(^2\)

\(^1\)College of Health Solutions, Biomedical Informatics, Arizona State University, Scottsdale, AZ; \(^2\)Mayo Clinic, Division of Community Internal Medicine, Scottsdale, AZ

**Introduction:** According to the Centers for Disease Control and Prevention (CDC), the rate of death from prescription opioid overdose has increased by nearly fourfold (1.5 to 5.9) from 2000 to 2014.\(^1\) Misuse of prescription opioids is a significant factor as over 20% of misusers report obtaining opioid prescriptions from a physician.\(^2\) In 2016, the CDC released recommendations to mitigate risk of misuse and overdose in opioid-based treatment of chronic pain, including prescribing the lowest effective dose of morphine milligram equivalents (MME), evaluating patients every three months, checking state prescription drug monitoring program (PDMP) databases, and obtaining urine drug screening at least annually.\(^3\) This study aims to evaluate the implementation of an evidence-based chronic opioid therapy (COT) program in a primary care setting.

**Methods:** Guidelines for managing adult patients receiving chronic opioid therapy (COT) were created based on CDC recommendations, guidelines were socialized and implemented at an academic medical center primary care internal medicine clinic in September 2017. This COT program included use of an enterprise controlled substance agreements (CSA), opioid risk tool\(^4\) (ORT), standardized opioid risk assessments, quarterly office visits, annual urine drug screening (UDS), documented review of the state PDMP database at each office visit and the assignment of a primary prescriber for each patient using COT as part of personalized treatment plan. Before each visit, the Brief Pain Inventory (BPI)\(^5\) and Quality of Life (QOL)\(^6\) questionnaires were administered to assess level of pain, quality of life, and functional status using a 10-point scale. Clinician and allied health staff (AHS) satisfaction, attitudes and beliefs were assessed quarterly using a 16-item questionnaire addressing the safety, efficacy, efficiency and satisfaction regarding COT care delivery. Staff survey participants represented stakeholders throughout the clinic care delivery process, including call center representatives, medical practice secretaries, medical assistants, licensed practical nurses, team nurse leads, care coordinators, administrators, nurse practitioners, physician assistants and physicians. Physicians in training (medical residents) were excluded due to limited or no office visits with COT patients. The questionnaire employed Likert scale response categories of “Strongly Agree”, “Agree”, “Neutral”, “Disagree” and “Strongly Disagree”. For analysis, “Strongly Agree” and “Agree” were coded agreement while “Disagree” and “Strongly Disagree” were coded as disagreement. The change was tested for significance using a logistic generalized estimating equation. To evaluate changes in patient self-reported outcomes, response data from patients completing at least four rounds of questionnaires were analyzed using Friedman’s test for repeated measures. To measure the rates of adherence with the guidelines and changes in resource utilization, the institution’s Unified Data Platform (UDP), a business data warehouse which aggregates and standardizes data across systems, was queried. Queries for adherence evaluated compliance with quarterly follow-up visits (based on patient questionnaire completion), urine drug screening at least annually, completion of the (ORT), and completion of a CSA for the cohort of 217 patients enrolled in COT between Sept. 1, 2017 and Oct. 1, 2018.
Results: Fifty-one clinicians and AHS completed the baseline survey prior to implementation of chronic opioid therapy guidelines. Twelve of the sixteen questions had a significant increase in agreement across all survey intervals (p < 0.05). All five of the questions in the patient safety domain had a significant increase in respondent agreement. After guideline implementation, more staff agreed that delivery of COT was effective and patient understanding of the opioid prescription renewal process improved. There was improvement in the level of confidence in identifying patients at risk for diversion, however most respondents still felt this remained a difficult task at 12 months after guideline implementation. Regarding guideline adherence, the highest rate was seen with execution of the (CSA) (90.8%), followed by use of the ORT (80.2%) and obtaining a UDS (73.7%). However, the attainment of quarterly COT office visits, based on completion and BPI and QOL was only 37.8%. Comparing patient self-reported outcomes (BPI & QOL) before and after the COT program, there were no significant change in mean pain scores (5.87 to 5.61), quality of life (6.12 to 5.80), and functional status due to pain (5.84 to 5.96). Finally, early evaluation of utilization among a subset of 174 patients enrolled between September 1, 2017 and March 1, 2018 demonstrates that emergency department visits in the twelve months preceding initial COT visit compared to twelve months following that visit decreased from 59 to 39 (p < 0.05). There was no significant change in hospitalizations during the same observed interval.

Discussion: This observational study of a COT guideline implementation in a single-site, primary care internal medicine academic medical center practice is unique based on the concurrent assessment of staff perceptions, adherence to guidelines and patient outcomes. Clinical and support staff perceived positive changes in the safety, efficacy, efficiency and satisfaction regarding their role in the COT care delivery processes after the implementation of guidelines and the standardization of processes for local COT delivery. Although patient adherence to quarterly visits was low, post-program implementation adherence as measured by specific guideline components by providers was excellent. Guideline implementation was less impactful on the patient experience, specifically, self-reporting did not identify improvement in levels of pain, quality of life, or functional status. The decrease in the number of emergency department visits observed in the subset of patients enrolled for more than twelve months after guideline implementation is provocative. Continued monitoring, analysis, application to the full cohort and review in the context of other measures is needed. Major limitations of this study are the observational nature, lack of a control group, and observation of a single practice. This study may not be generalizable to COT delivered outside a primary care academic medical center.

Conclusion: This observational study demonstrates that implementing a standardized, evidence-based approach to COT care in an academic primary care internal medicine clinic is associated with improved staff satisfaction and an overall positive impact on COT safety, efficacy, efficiency. Early data suggest improved patient service utilization. Future work includes incorporating new clinical decision support packages, digitized patient reported outcomes and other data sources to evaluate impact on opioid-related outcomes over time.

Testing the Feasibility of an Academic-State Partnership to Combat the Opioid Epidemic in Tennessee Through Predictive Analytics

Christopher Puchi, B.S., Vanderbilt University School of Medicine, Nashville TN; Ben Tyndall, Ph.D., Tennessee Department of Health (TDOH), Nashville TN; Melissa McPheeters, Ph.D., M.P.H., TDOH, Nashville, TN; Colin G. Walsh, M.D., M.A., Vanderbilt University Medical Center, Departments of Biomedical Informatics, Medicine and Psychiatry, Nashville TN

Introduction: The state of Tennessee has partnered with Vanderbilt University Medical Center (VUMC) to form the TDOH-VUMC Experience (Principal Investigators: TN, McPheeters; VUMC, Walsh). This academic-state collaboration leverages TDOH public health, analytic, and epidemiology expertise with clinical applied predictive modeling expertise at VUMC to combat the opioid epidemic killing an average of three to four Tennesseans every day. It includes a Memorandum of Understanding and Data Use Agreement for de-identified data sharing developed over the course of one year to support analytic work as well as learning experiences and regular meetings across sites.

This study presents a preliminary predictive model to predict fatal opioid-related overdose to test this collaboration and its feasibility for data sharing and scientific collaboration. This model aggregates de-identified data including: > 110 million prescriptions in the Controlled Substance Monitoring Database (CSMD), Tennessee’s Prescription Drug Monitoring Program (PDMP); vital statistics including Medical Examiner certified cause of death; demographic data; pharmacy/provider data. We also bridge external data sets like the Area Deprivation Index Data (ADI) to improve potential for analytics to identify those at highest risk of overdose before harm occurs.

Methods: Retrospective case-control study. Data were collected from various TDOH data sources from January 2012 to December 2017: Prescription-level data from the CSMD; Hospital discharge data from state databases; State vital statistics and mortality data including Medical Examiner-certified causes of death. A major challenge at this scale remains disambiguation of patient identifiers in the CSMD. Like other PDMP’s, pharmacists type information manually for each prescription. Ongoing TDOH efforts have shown notably improved accurate patient identification, but the iterative nature of this work resulted in a subset of charts that were difficult to disambiguate. We selected only those with clear identifiers that matched across all study datasets and opted not to include those records not yet fully disambiguated for this feasibility study.

Fatal opioid overdose cases were defined as decedents in the year 2017 with drug overdose as an underlying cause of death on the death certificate (ICD-10 codes X40–X44, X60–X64, X85, and Y10–Y14) with any opioid as a contributing cause of death (ICD-10 codes T40.0–T40.4, T40.6). Control candidates were defined as those with any opioid prescription in 2017 who did not have a recorded opioid overdose death. Demographic information was obtained from death certificate data for cases and the TDOH Hospital Discharge Data system for controls. Address of residence data were obtained from the CSMD. Exclusion criteria were: 1) no demographic data; 2) no Tennessee address; 3) incomplete prescription data; and 4) multiple records of death occurring in different years.

The validation strategy split study data into random partitions of 60% for training, 20% for validation, and 20% for a holdout testing set. An optimal ratio of 1 case to 8 controls was determined empirically by evaluating model performance on validation data. Predictors were extracted from individuals’ 2017 CSMD opioid prescription records and from demographic data (Figure 1). Median ADI and county fatal overdose rate were determined using each of an individuals’ Tennessee zip codes listed in the CSMD. Age was calculated as a continuous variable reflecting age at day of death for cases and age on December 31st, 2017, for controls. Buprenorphine prescription data was obtained from the CSMD. Predictions were calibrated using logistic calibration. Relative variable importance was measured through node impurity. The experimental setup included R version 3.5.1 and packages caret and rms.

Results: We identified 1,330 opioid overdose decedents in 2017 (1,268 of these individuals had Tennessee as their state of residence on the death certificate). Of these 1,330 decedents, 858 filled opioid prescriptions in 2017. 160 individuals were excluded because their records were not fully disambiguated. 1 individual was excluded due to multiple death records. 11 individuals were excluded because their prescription records were incomplete, and 21 were excluded because they did not have a Tennessee zip code listed in the CSMD. We identified 1,977,281 individuals with opioid prescriptions in 2017 who did not have a recorded opioid overdose death. 852,066 of these individuals were excluded due to lack of demographic data, and 255,086 individuals were excluded because they did not have a

* Because of the preliminary nature of these analyses, prevalences presented might not match exactly the published Prescription Drug Overdose Report previously published by the state of TN DOH.
Tennessee address listed in the CSMD. The dataset used for model training, validation, and testing consisted of 665 cases and 5,320 randomly sampled controls from the pool of 870,129 candidates. 47 cases (7.1%) and 229 controls (4.3%) filled buprenorphine prescriptions in 2017.

A random forest model with 50 trees outperformed logistic regression on the validation set. The Area Under the Receiver Operating Characteristic Curve (AUC) was 0.83 for random forest and 0.81 for logistic regression – though formal hypothesis testing was not performed for this pilot study. Brier scores were 0.07 and 0.08 for random forest and logistic regression, respectively. A random forest model was tested on the holdout set. The AUC was 0.81 with a Brier score of 0.08. Relative variable importance is summarized in Figure 1. Logistic calibration on random forest predictions yielded an AUC of 0.837 and a Brier score of 0.08.

Conclusions: We tested the feasibility of the data sharing and modeling pipeline for the TDOH-VUMC Experience and were able to validate promising initial predictive models of fatal opioid-related overdose risk. In this example, PDMPs offer promising data repositories to identify risk factors for and risk of opioid-related overdose. Using machine learning on PDMP data may support automation of screening for risk of fatal opioid overdose. Future directions include development using larger cohorts from the PDMP, refinement of feature selection and inclusion of larger numbers of relevant predictors (e.g., buprenorphine therapy), validation of these findings on out-of-sample Tennessee data, inclusion of other external data sets such as the Community Health Service Indicator Data6, and testing other algorithmic assumptions empirically, e.g., other parametric/non-parametric algorithms, and deep learning. Simultaneously, we are understanding current clinical processes for intended implementation of this methodology with state collaborators. If effective, these findings might apply to other states using a PDMP, and we believe this collaborative model generalizes to other states willing to reach a data use agreement, to align around an educational initiative, and to consider ethical and legal issues as they arise. As the TDOH-VUMC partnership evolves, identification of objective criteria could help drive evaluation and continuous improvement efforts. The collaborative methodology described has a wide range of potential applications, from screening high-risk individuals for earlier intervention, to providing decision-support for opioid prescribers. The partnership approach also has the potential to provide rapid collaborative opportunities to address future public health challenges.

Extracting Drug Exposure Epochs and Drug Response Outcomes from Electronic Health Records

Andrea H. Ramirez, MD, Yaping Shi, MS, Elliot Fielstein, PhD, Jonathan Schildcrout, PhD, Henry H. Ong, PhD, Josh C. Denny, MD, Josh F. Peterson, MD
Vanderbilt University Medical Center, Nashville, TN, USA

Abstract

Estimating drug exposures and defining their temporal relationship to drug response outcomes is challenged by incomplete prescription data and lack of reconciliation between drug exposure records. We devised a method to visualize all sources of medication data, including concept matched drug mentions, e-prescribing records, and manually curated drug lists, maintaining temporal relationships, and annotating with drug response phenotypes. The method has utility for empirically creating rules to define drug exposure epochs for each patient.

Introduction

Ascertaining medication exposure and defining temporal relationship to drug response outcomes from EHR data is challenging due to incomplete data capture from prescribers outside the system and lack of integrated pharmacy fill information. Often a simple binary classification is used for drug exposure where a patient is defined as exposure given any drug mention prior to the phenotype of interest. This simplistic approach leads to high rates of misclassification as the complex time varying nature of drug exposure and dose relative to outcome events is lost.

As part of our work with the Implementing Genomics in Practice (IGNITE) network to study the pharmacogenomic relationship of adverse events from long-term proton pump inhibitor (PPI) therapy we developed a model to represent complex drug exposure data. Defining PPI exposure is especially challenging as the drug is available over the counter as well as by prescription. Research has shown that PPI use is associated with Clostridium difficile colitis (C. diff), pneumonia, acute kidney injury (AKI), and chronic kidney disease (CKD). To characterize the additional risk of these events to patients who metabolize the drug poorly due to their CYP2C19 genotype it is important to accurately classify which subjects were most likely to be on PPI, at what dose, and at what time.

This work describes a longitudinal method for describing drug exposure relative to outcome events that was developed and built into a reusable R function including graphical representation and production of files for further analysis. Demonstrated here, using as much information as possible allows accurate exposure ascertainment, less misclassification, and improved analyses.

Methods

Data from the VUMC Pharmacogenomic Resource for Enhanced Decisions in Care and Treatment (PREDICT) project including CYP2C19 genotyping for approximately 15,000 patients and their clinical data was used to study how metabolizer status impacts adverse events associated with long-term PPI usage. Computable phenotypes were implemented for C. diff, pneumonia, AKI, and CKD including extracting date(s) of events. PPI drug name, date of mention, and dose were extracted using MedEx, a natural language processing (NLP) system that recognizes medication information from any free-text record. In this example, we used problem lists as the source of our drug information.

To handle missing dose information in drug data, we used last observation carried forward (LOCF) to impute missing dose with the following schema: 1) Use LOCF to impute dose for subsequent mentions with no dose; 2) If there are mentions with no dose before the first ever observed dose, a default dose of 20mg was assigned. Drug exposure epochs are defined as periods of time during which a patient was exposed to a drug at a given dose. We
defined the start of an epoch as the date of a new PPI mention and the end of an epoch as either: 1) The date of a subsequent mention with a different dose OR 2) No mention of PPI in subsequent problem lists. At the end of a patient’s record, the last epoch is extended by 3 months from the last mention with dose or imputed dose.

Patient ID and demographics, phenotype event date, and epoch start/end dates with dose serve as inputs for our R function that will generate a graph and other files such as table of case counts with PPI exposure. A simulated graph is shown in Figure 1 with annotations to explain salient features.

Results

Two example plots are shown below in Figure 2. In the bottom row, all three events are labeled as on drug. The top row has a pneumonia event labeled as on drug, while the C. diff event is labeled as off drug. This difference is notable as the C. diff event would have been labeled as on drug when using a traditional binary definition of exposure.

Discussion

This abstract describes a method to visualize information regarding drug or other exposures to outcomes for study of association such as drug metabolizer status. While the absolute numbers of exposed subjects may decrease, the certainty of the exposure is higher. This approach also facilitates sensitivity analyses to better understand the threshold around any found signal. Also, by creating simple imputation rules, more dose information may be used, as many drug-outcome associations are sensitive to dose thresholds but tracking of dose is inconsistent across the EHR. Many medications have a known starting dose, and reasonable minimum and maximums expected. While the sample demonstrated uses data extracted by the Medex NLP program, other sources of exposure for medication or other variables may be used as shown in the input format example. Other data such as insurance fill data and pharmacy fill records exist, though unfortunately this information is not routinely shared to the research community nor has proper permissions in place to reassociate with clinical notes and outcomes. Additionally, drugs such as PPI which are easily taken over the counter are better captured in provider encounters than other sources. This method is an important step forward in improving the specificity of exposed case and control assignments, and will avoid the misclassification and loss of power from simpler methods of assigning drug exposure.

Multi-technology Meta-Analysis Identifies Bacterial Signatures Delineating Clinical Response to Immune Checkpoint-Inhibitor Therapy in Melanoma Cohorts

Jayamary Divya Ravichandar, Cheryl-Emiliane Chow, Connor Skennerton, Dhwani Haria, Erica Rutherford, Helena Kiefel, Joanna Dreux, Kareem Graham, Kathryn Iverson, Lynn Yamamoto, Michelle Lin, Michi Willecoxon, Nicole Narayan, Paul Loriaux, Roberta Hannibal, Sabina Lau, Shoko Iwai, Sunit Jain, Thomas Weinmaier, Yonggan Wu, Yuliya Katlinskaya, Toshikko Takeuchi, Karim Dabbagh, Todd DeSantis
Second Genome Inc., South San Francisco, California.

Introduction
The gut microbiota has emerged as an important player in cancer pathology and a growing body of evidence supports its influence on clinical response to cancer therapy, especially in the context of immune checkpoint inhibitors (ICI). While several studies present insight into the landscape of bacteria differentially abundant in responders and non-responders to ICI, they are limited by biases arising from variations in the cohorts, manner in which data is procured, processing workflows, and analysis pipelines. Further, bacterial species signatures are rarely concordant across independent datasets, which can limit therapeutic development.

In this context, microbiome-based discovery of an enhancer of clinical response to ICI rests on identification of bacterial functions conferring a host benefit. Mining the genomes of differentially-abundant bacterial strains or differentially-abundant proteins in metagenomes enables identification of such functions and presents a promising approach to discover novel bacterial-derived therapeutic molecules. Herein, existing published datasets which investigated links between the gut microbiome and response to ICI were re-analyzed and integrated via a multi-technology meta-analysis (MTMA) to identify strains and proteins separating responder and non-responder populations in melanoma that are concordant across cohorts. Bacterial polypeptides derived from these response-associated signatures were screened for immune cell binding using phage display to identify polypeptides, followed by chemical synthesis of binders and evaluation in vitro for therapeutic potential to enhance clinical response to ICI.

Methods
We performed a literature survey to identify studies investigating the effect of the baseline gut microbiome on clinical response to ICI (anti-PD1) in melanoma patients. Studies were included in the analysis if both metadata and sequence data was available in public repositories. Three studies that had analyzed the microbiome associated with stool collected from discrete melanoma cohorts prior to ICI therapy were selected. Metadata was evaluated for accuracy and manually re-annotated using a controlled vocabulary, allowing for direct comparison between studies. Samples were sequenced on one or more technologies (16S NGS and shotgun metagenomics: a total of five datasets) and FASTQ files were downloaded from public repositories, quality filtered and matched to our in-house strain database (StainSelect: secondgenome.com/platform/data-analysis-tools/strainselect) to obtain strain-level annotations. For shotgun metagenomic sequencing datasets, we de novo assembled genes and predicted proteins. Based on the distribution and sparsity of each dataset, normalization and statistical tests were applied to identify strains and proteins whose abundance differed significantly between responders and non-responders. A random-effects model was used to integrate strain- and protein-level differential abundance results from all datasets. Significance is defined at adjusted p-value < 0.05. Proteins were predicted from the genomes of response-associated strains and pooled together with those significantly enriched in responder metagenomes. Proteins longer than 50 aa were broken down into smaller fragments in silico to obtain polypeptide fragments 8-50 aa long to enable efficient incorporation into phage libraries, where these polypeptides were expressed as a fusion protein on phage virions. These libraries were panned against multiple immune cell types to identify peptides that bound specifically to the target immune cells.

Results
Leveraging our multi-faceted bioinformatics platform, which enables appropriate technology-specific quality filtering and statistical testing, we identified differentially abundant bacteria at the strain-level. A range of 50 - 900 strains were identified in analysis of each dataset. No overlap in significantly differentially abundant strains was observed across cohorts or even between datasets from the same cohort sequenced on different technologies. From the de novo assembly, a range of 2-3M proteins were identified in each dataset. Of those, a few thousand proteins were significantly enriched in responders in each dataset. We performed a cross-cohort multi-technology meta-analysis (MTMA) to identify strains and proteins that were concordantly enriched in responders across datasets. Figure 1
demonstrates the power of the MTMA approach to identify strains with consistent effects across multiple datasets while eliminating strains with discordant or otherwise inconsistent effects. The strain signatures identified by MTMA were not previously reported in the analysis of these datasets in their publications1-3. The MTMA approach identified 37 strains and 1,000+ proteins as concordantly enriched in responders across cohorts. From these response-associated strains and proteins, we identified 50,000+ proteins and polypeptide fragments.

**Figure 1.** MTMA identifies concordant microbiome signatures delineating response to ICI. Significantly enriched strains (blue dots) in the responders or non-responder by individual-dataset analysis (grey dots) or MTMA (purple dot). Solid lines, supported by MTMA; dashed lines, supported by individual dataset analysis. Thick lines, significant findings; thin lines, non-significant findings. Red lines, enriched in non-responders; green lines, enriched in responders.

We hypothesized that an immunomodulatory-effector molecule that has the potential to modulate ICI-response would need to bind to immune cells associated with anti-tumor immunity. We established a phage display screening platform and screened the polypeptides against four immune cell types. Phage-panning selected for about 1% of the polypeptides as immune cell binders.

**Discussion**

Although individual datasets identify certain strains to be beneficial or detrimental with high confidence, it could be unduly biased by the cohort and platform4. The cross-cohort multi-technology meta-analysis presented here demonstrates the power of a robust bioinformatics platform to leverage publicly available datasets and systematically integrate microbial shifts (strains and proteins) to identify polypeptides with therapeutic potential. This MTMA approach on strains not only identifies concordance across cohorts, but also enables integration of datasets generated by different technologies at fine-grained bacterial identities (strain-level), resolving a key challenge with microbiome meta-analysis. Strains identified by MTMA, in addition to providing a starting point for identification of peptides with favorable therapeutic effects, could also serve as predictive biomarkers for response of melanoma patients to ICI. To our knowledge, this is the first time a phage display platform has been used to systematically screen peptides derived from bacterial signatures for immune cell binders. The platform presented here represents a novel approach to microbiome-based drug discovery, with a focus on bacterial-derived effector molecules rather than species as therapeutic targets. With the identification of concordant strain biomarkers for response to ICI and polypeptides with therapeutic potential to enhance response to ICI, this works presents a paradigm where administration of therapeutic polypeptides could be determined by the differential abundance of these bacterial signatures.

Learning Disease Phenotypes with Semi-Supervision

Victor A. Rodriguez, MPhil, Adler Perotte, MD, MA
Department of Biomedical Informatics, Columbia University, New York, NY

Introduction

In this work we propose the Semi-Supervised Mixed Membership Model (SS3M), a probabilistic graphical model which utilizes a relatively small number of disease labels to learn multiple disease-specific phenotypes from clinical data. SS3M does not require that all patients have labels for all diseases. Thus, SS3M reduces the amount of labeled data needed to train effectively, addressing a major limitation of fully supervised phenotyping methods. Furthermore, SS3M establishes a one-to-one relationship between disease labels and disease phenotypes. Thus, unlike with fully unsupervised phenotyping methods, SS3M may be guided toward learning specific phenotypes desired by the user.

Methods

SS3M is a model for multisource bag-of-words data accompanied by a set of instance specific labels. It is closely related to the popular topic model Latent Dirichlet Allocation (LDA)\(^1\), as well as its multisource\(^2\) and supervised extensions\(^3\).

Model Description: Let \( D, S, \) and \( P \) be the number of patients, clinical data sources and phenotypes. Each patient, \( d \in \{1, \ldots, D\} \) is associated with a set of clinical observations \( \{w_{sdn}\}_{n=1}^{S} \), as well as a set of partially observed binary labels \( \{A_{dp}\}_{p=1}^{P} \). Each observation, \( w_{sdn} \), is accompanied by a latent assignment \( z_{sdn} \) which specifies which phenotype-token distribution, \( \phi_{sp} \), the observation was drawn from. Assignments for patient \( d \) are drawn from a patient-phenotype distribution, \( \theta_{d} \). A patient’s label set directly impacts her patient-phenotype distribution, and thereby all her assignments. When \( A_{dp} = 1 \) the phenotype \( p \) is “on” for patient \( d \); the model uses \( B_{p} \) to calculate \( \theta_{d} \). When \( A_{dp} = 0 \), the phenotype is “off”, and the model uses \( B^{*} \) instead. Since \( B_{p} \) is generally much larger than \( B^{*} \), setting \( A_{dp} = 1 \) encourages \( \theta_{d} \) to allocate more probability mass for phenotype \( p \).

Label sets are partially observed. If a specific label, \( A_{dp} \), is observed, then its value is held fixed. If \( A_{dp} \) is unobserved, then the model learns its value during inference. In this latter case, \( A_{dp} \) is modeled as a binary variable drawn from a distribution parameterized by \( C_{p} \) – a latent variable controlling the likelihood of phenotype \( p \) being “on” within the patient population. Note that the partial observation of labels is what makes SS3M a semi-supervised model.

Inference: We implement a collapsed Gibbs sampler to obtain posterior estimates of our model’s latent variables. We integrate the \( \{\theta_{d}\}_{d=1}^{D}, \{\phi_{sp}\}_{s=1, p=1}^{S,P} \) and \( \{C_{p}\}_{p=1}^{P} \) out of the joint distribution. The complete conditional distributions for the \( \{z_{sdn}\}_{n=1}^{N_{sd}} \) and \( \{A_{dp}\}_{d=1, p=1}^{D,P} \) in the collapsed joint are sampled from directly. We use Hamiltonian Monte Carlo to sample from the complete conditionals of the \( B_{p} \) and \( B^{*} \). Setting the path length \( L = 100 \) and step size \( \epsilon = 10^{-3} \) yielded stable trajectories with high acceptance rates in preliminary experiments.

Dataset: We train our models using clinical notes, labs, and medications for 46,520 patients from the Medical Information Mart for Intensive Care version III (MIMIC-III)\(^4\). Patients’ label sets are derived from the 50 most common ICD9 diagnosis codes. The corpora and labels were split into training and test sets containing data for 80% and 20% of patients respectively.
Experiments: We train SS3M and a closely related unsupervised model, the Multi-Channel Mixed Membership Model (MC3M), setting $P = 70$. For SS3M this results in 50 labeled and 20 unlabeled phenotypes. Preliminary studies indicated inclusion of some unlabeled phenotypes resulted in better performance for SS3M.

Qualitative Evaluation: A clinical expert assessed the quality of SS3M phenotypes relative to MC3M phenotypes by evaluating their coherence, granularity, and label quality. Coherence and granularity were assessed as described in Pivovarov et al. To assess label quality, the expert was asked to rate how well a SS3M phenotype’s true label appeared to match the learned phenotype using a 5-point scale (1-no match, 5-perfect match).

Quantitative Evaluation: For SS3M, we estimate each test patient’s posterior likelihood for each disease label. We evaluate AUROC and AUPRC against logistic regression (LR) and naive Bayes (NB) models trained with raw tokens or patient-phenotype distributions, $\{B_d\}_{d=1}^D$, learned with either MC3M or SS3M trained without labels (MC3M with a structured prior – MC3M-SP). Because SS3M is highly sensitive to the relative values of the $\{B_p\}_{p=1}^P$ and $B^*$, we train our model in two modes: (1) sample these variables freely and (2) hold them fixed.

(e) Quantitative Results Summary

Discussion

SS3M is a model for semi-supervised learning of disease phenotypes from clinical data. We exposed SS3M to MIMIC-III clinical data and derived phenotype labels from common ICD9 diagnosis codes. In quantitative evaluations, SS3M was generally outperformed by baselines in predicting disease labels on held out patient data. Meanwhile, in qualitative evaluations conducted by a clinical expert, SS3M phenotypes were judged to be more coherent, and more granular than phenotypes learned with a closely related unsupervised model. These results suggest that despite its weak performance on label prediction, SS3M does indeed appear capable of learning interpretable, disease-specific phenotypes from clinical data. Ongoing work is focused on improving SS3M’s predictive performance and acquiring higher precision labels than the ICD9 codes used here.

Developing Cancer Informatics Tools to Support the Implementation and operation of a Cancer Care Navigation Program across Eight VA Facilities

Traudi Rose RN, MBA1, Jianji Yang PhD1, Judy McConnachie MPH2

1VA Portland Healthcare System, Portland, Oregon, USA
2Providence Health & Services, Portland, Oregon, USA

Introduction
The concept of patient navigators in cancer care started in 1990 with a program developed by Dr. Harold Freeman at Harlem Hospital [1]. Since the 90s, cancer navigator programs have continued to grow throughout the United States [1]. Since 2012, Patient Navigation Process is a standard of care for all programs accredited by the Commission on Cancer [2]. In October 2013, the VA Integrated Service Network (VISN) 20 Cancer Care Navigation Team (CCNT) was initiated as a pilot program across eight VA facilities. CCNT is a multidisciplinary team approach that focuses on identifying and eliminating barriers to care and coordinating care to assure that patients have timely access to care and needed psychosocial support. VISN20 covers a broad region including Alaska, Idaho, Oregon and Washington. There is a CCNT at each of the eight facilities, with all of the teams forming a VISN20 CCNT network to support Veterans traveling across the system for cancer care. Due to the unique technological barriers which include separate Computerized Patient Record System (CPRS) at each facility and need for system-wide patient tracking and communication, it was determined that informatics would be a critical component in supporting navigation. To assure close collaboration with the informatics team, the VISN20 CCNT RN Program Manager was embedded with the informatics team during CCNT program implementation and participated in every step of the cancer informatics tool development lifecycle.

Methods
Collaboration with stakeholders: An important part of the CCNT program implementation was development of cancer informatics tools. An integrated team approach enabled the embedded CCNT Program Manager to establish close relationships with the informatics team and serve as the liaison between the developers and end users. This model ensured the team had ready access to the Program Manager during the agile development process. The Program Manager also regularly updated the team on CCNT program activities and real-time feedbacks, promoting ownership and pride amongst the informatics team. The relationship established during this development process highly benefited the ongoing support and maintenance of the applications, due to team engagement and ownership.

Tool development: The Program Manager worked closely with the developers through all stages of requirement gathering, prototyping, development, usability testing, data validation, and end user training. Tools are developed using an agile approach and iterative cycles that depend on timely user feedback, facilitated by the Program Manager.

Implementation of tools: Once the clinical tools were available, training and further information was provided to the CCNTs, feedback and questions were sent through the Program Manager who serves as the interface between the clinical staff and the informatics team.

Monitoring and evaluation: CCNT’s use of tools is monitored to determine effectiveness, identify further needs, and identify under-utilized elements for removal. Information from tools is also used for the overall CCNT program evaluation and presentations to leadership and key stakeholders.

Results
Various tools have been developed and/or customized to support the operation of the CCNT program. Table 1 shows challenges to navigation and tools to meet these needs. With these tools, CCNT has now supported over 11,586 Veterans with cancer and their caregivers/loved ones (Nov. 2014- June. 2019).

Program Implementation
Care Management Tool (CMT): Web-based task management tool to support CCNT team-based care across VISN for complex patient needs. Figure 1 depicts the heavy usage of the CMT by CCNT in six facilities actively using the tool.
Standardized Documentation: CPRS consult, note titles, and templates developed and standardized for CCNT use across VISN20. Health Factors which are customized data elements to capture clinical information are embedded in templates. New Cancer Findings Report: Application pulls data daily for all facilities, to display new malignancies from pathology reports for CCNT review. VISN20 Resource Directory: Provides service-level, clinic-level and individual staff contact information across the VISN to support CCNT communication needs.

Program Evaluation
Activity Hub: A real-time data dashboard of CCNT activity. The dashboard pulls information for all CCNTs from standardized note titles, consults, clinics and CMT. Program Outcomes Data: Program Manager designed,
implemented and analyzed studies with informaticians to evaluate program objectives and impact, as well as report to VISN leadership.

Discussion
Navigating Veterans across multiple facilities is a challenge due to system-wide technological barriers. Our model of having the CCNT Program Manager embedded within a clinical informatics team has allowed for integration, development, and timely enhancements of clinical informatics tools, which has supported the reduction in barriers to care at both a system-wide and individual level. One of the challenges we faced is that the documentation tools depended on CACs to load them at each facility which caused some delays. We also found that there are varying degrees of adoption and use of tools across sites. Further data and assessment are needed to better understand the impact the navigation program and supporting cancer informatics tools have on timeliness and access to cancer care.

Table 1. Identified barriers/challenges to system-wide navigation, tools developed/customized to support these needs and specific navigation activities supported.

A Visual Consideration of Sepsis Deaths and Non-sepsis Deaths with a Finely Graduated Measure of Patient Acuity: Should We Just Focus on Who is Sick?

Michael J. Rothman, PhD a; Kathy Belk, BA a; Robert Fogerty, MD b

Affiliations: aPeraHealth, Inc., Charlotte, NC; bYale New Haven Health System, New Haven, CT

Introduction
Two widely publicized numbers have had profound influence on initiatives to improve the quality of care in hospitals. The first is the statement that 30% of US hospital deaths are associated with sepsis [1]. The second states that each hour of delay after the inception of septic shock in initiating effective antimicrobial therapy increases mortality rates by 7.6% [2]. The first establishes sepsis as a major problem. The second is a call to action: early intervention can reduce mortality. We posit that these numbers have been misunderstood. Even though sepsis is a problem, a more effective approach would be to simply focus on sick patients. Although patients who arrive at the hospital with sepsis are sicker than those who do not [3], those who die of sepsis are those who arrive in poor physiological condition, just as non-sepsis patients who die are those who arrive in poor physiological condition. The Rothman Index (RI) is a finely graduated general measure of patient acuity based on empirically derived univariate relationships between 1-year post-discharge mortality and each of 26 clinical measurements and has been validated in many studies [4]. It is applicable across all diseases and settings.

Methods
Clinical data covering 27,453 inpatient visits over a 4-month period (4/16 – 8/15/2018) were extracted from the electronic medical records of three sites which are part of the Yale-New Haven Hospital System. These data included the initial RI score for each visit, along with the ICD-10 codes, and the patient’s discharge status. Univariate comparisons between septic and non-septic patients were analyzed using Chi-square tests. Comparative cumulative percentage histograms were generated for sepsis present on admission (POA) and non-sepsis POA patients discharged alive, and for sepsis POA and non-sepsis POA patients who died. Mean and standard error were computed by bucketed RI (0-20, 20-40, 40-60, 60-80, 80-100) for mortality in sepsis POA patients and non-sepsis POA patients. One and two variable logistic regression (LR) models were created, using initial RI, and then adding a sepsis POA flag. IRB approval was granted.

Results
Of 27,453 inpatient visits, 974 did not have an RI score and were excluded from the analysis. Of the remaining visits, 1,894 were designated septic POA using ICD-10 codes. The mortality rate for septic POA patients was 8.6% compared to 1.4% for non-septic POA patients (p<.001). For non-septic POA patients who were discharged alive, 20% arrived with a RI below 65 versus 55% of septic POA patients. For those who expired, the percent of non-septic POA patients with an initial RI below 65 was 86% versus 89% for septic POA patients. LR AUCs for one and two variable models were 0.907 and 0.909, respectively. The graph of mean mortality +/- 2SE vs. mean bucketed RI was similar for septic and non-septic patients (Fig. 1).

Discussion
To calibrate the reader, an RI value of 100 represents “unimpaired”. A value of 65 represents the acuity of a patient discharged to a skilled nursing facility, a value of 40 would warrant consideration for ICU transfer. Mortality rates for patients whose scores fall below 20 are about 25%, and who fall below 0, 50%. Viewing histograms in Fig. 1 we see a marked contrast in the initial RI score between septic and non-septic patients who are discharged alive. However, when considering patients who expired in the hospital that difference disappears. Non-septic patients who expired arrived at the hospital looking just like septic patients who expired. This observation is reinforced by the LR results, where initial RI alone is an excellent predictor of mortality and adding an indicator of sepsis POA provides no improvement. The graphs of mortality vs. initial RI further confirm that initial acuity, how sick the patient is, determines likelihood of death. Sepsis is largely irrelevant. In other words, to address hospital mortality rates, focus should be on patients who arrive in poor physiological condition. A recent paper by Rhee [5] goes further. After reviewing charts of septic patients who expired, they found that more aggressive treatment, specifically the measures in the sepsis bundle, would only have prevented 4% of deaths. Reducing mortality is difficult, but rather than a focus
on sepsis, a more general approach, addressing those patients who arrive at the hospital in poor physiological condition, is more likely to produce significant results. [6]

REFERENCES

Figure 1 – Top left: cumulative comparative histogram shows the distribution of initial RI scores for non-sepsis vs. sepsis patients discharged alive, top right: for patients who expired. Graph on the bottom shows mean mortality and 95% CI versus mean bucketed RI for patients with sepsis at admission and without sepsis at admission.
More Than Copy-Paste: Content-Importing in Clinical Documentation

Adam Rule, PhD\textsuperscript{1,2}, Michael F. Chiang, MD\textsuperscript{1,2}, Michelle R. Hribar, PhD\textsuperscript{1,2}

\textsuperscript{1}Department of Ophthalmology, \textsuperscript{2}Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR

Introduction

Content importing technologies such as copy-paste, text-importing phrases, note templates, and data-links provide an efficient way to document clinical encounters but can unnecessarily lengthen notes and propagate errors\textsuperscript{1}. A crucial step in weighing the risks and benefits of content importing technologies is understanding their current use and impact on clinical documentation. While there is growing evidence about the widespread use and safety risks of using of copy-paste\textsuperscript{2-5}, other methods of content importing and their impact on documentation have been largely overlooked with only a few studies reporting the percent of note text that has been imported, copied, or manually entered\textsuperscript{4,5}. The aim of this study is to demonstrate a method of using Electronic Health Record (EHR) activity logs to examine use of content importing technologies in greater detail.

Methods

This study was approved by the Institutional Review Board at Oregon Health & Science University (OHSU), which granted a waiver of informed consent for analysis of EHR logs. OHSU is a large academic medical center in Portland, Oregon. This study was conducted at the Casey Eye Institute, OHSU’s ophthalmology department, which includes over 50 faculty providers who perform more than 130,000 outpatient examinations each year. In 2006, OHSU transitioned to an institution-wide EHR (EpicCare; Epic Systems, Verona WI) and documentation at Casey Eye Institute is performed in an ophthalmology specific module (Kaleidoscope).

Our institution’s EHR tracks use of several content-importing technologies, including \textit{text-importing phrases} which import preset text into the note and \textit{data-links} which import structured data from other parts of the patient’s record. For example, typing the “.SIGN” phrase into a note and hitting enter might import a pre-set signature line. Alternatively, invoking “.VITALS” might import a patient’s most recent vital signs, using a data-link embedded in the phrase’s definition (e.g., @LASTVITALS@) to retrieve and place vital sign values into the note. Text-importing phrases in our institution’s EHR may also have embedded \textit{manual entry flags} (i.e., ***) that make it easy for providers to tab between specific locations in the note so they can manually enter text, such as exam findings or their plan.

We collected data on all text-importing phrases used while documenting office visits to 48 providers at Casey Eye Institute between Jan 1, 2017 and Dec 31, 2018. We manually coded each unique phrase as generating either 1) a full-note template, 2) a signature or attestation line, or 3) serving some other purpose. We counted the number of data-links and manual entry flags embedded in each phrase. To inspect text imported by data-links in more detail, for each of the 50 most frequently used data-links we randomly selected 100 notes generated using a text-importing phrase with that data-link embedded within it and manually counted the number of words imported by that data-link. All analyses were performed in Python (v. 3.7).

Results

Of the 200,695 office visits in 2017-18 to the 48 study providers, 96% had at least one text-importing phrase used during the visit. There were 5,810 unique phrases used 647,524 times across all visits. Full-note templates and signature lines were a small portion of unique phrases (11% and 8% respectively), but together made up more than half of all phrases usages during the study period (27% and 28% respectively).

The median office visit used three text-importing phrases, one full-note template, one signature line, and one importing text for some other purpose. These other phrases served many purposes including inserting a short phrase (e.g., “right eye”), inserting a long phrase (e.g., standard findings for a review of systems), inserting a note subsection template (e.g., a template for results of a specific exam), generating patient education materials, or generating a letter template. Phrases generating full-note templates were used at 82% of office visits. Whereas the median other phrase had 4 words of static text and the median signature phrase was 22 words, the median full-note had 81 words. Moreover, whereas the median other and signature phrases had no data-links or manual entry flags, the median full-note template had 18 data links and 4 manual entry flags. See Figure 1 for an example of part of one full-note template generated by invoking a text-importing phrase.
Figure 1: Portion of a full-note template with inline data-links (e.g., @NAME@) and manual entry flags (i.e., ***).

There were 301 unique data-links embedded in the 5,810 text-importing phrases and the amount of text imported by data-links varied significantly both within and between links. For example, whereas the links for the patient’s @AGE@ and @SEX@ only ever imported one word, the link for their @MEDS@ imported 100±77 words, sometimes importing no text and other times importing over 350 words.

Discussion

This study has three key findings: 1) content importing phrases are used during the vast majority of office visits, 2) phrases that generate full-note templates are used at the majority of office visits, and 3) full-note templates include many data-links to automatically import text. These findings highlight the frequent use of text-importing phrases to generate documentation and reliance on full note templates to automatically populate large portions of the note, rather than build it up piece by piece with several smaller phrases. These findings have implications for the design of EHRs as well as the management and use of content-importing technologies. They show the impact template design can have on note usability, with a few phrases generating templates being used for documentation at the majority of office visits. Moreover, they reveal documentation practices that resemble programming in that providers manipulate a few abstract symbols representing large blocks of text rather than writing that text out manually.

This research demonstrates using EHR activity logs to investigate use of content-importing technologies for clinical documentation. Future work can provide further guidance for the design and use of content-importing technologies by investigating the impact of specific phrases and data-links on documentation length, quality, and usability. Clinicians and administrators should think carefully about the design and use of note templates, particularly ones that include long strings of boilerplate text or large tables automatically populated with information from the patient record such as medication lists. Such templates should be designed with an eye towards what is clinically relevant and strike a balance between freedom for clinicians to generate their own templates while providing guidance and governance to help templates embody best practices.

Complexities of Finite State Machines to Streamline Inpatient Sepsis Management
Sameh Saleh, MD, Samuel McDonald, MD, Mujeeb Basit, MD, MMSc
UT Southwestern Medical Center, Dallas TX, US

Introduction: Sepsis is the dysregulated response to an infection that can lead to life-threatening multi-organ dysfunction. It has an annual incidence of 1.7 million cases claiming 270,000 lives and costs US hospitals nearly $25 billion per year (1,2). Despite previous research to gauge sepsis risk, the heterogeneity of sepsis makes it a difficult process to predict and preempt. Previous sepsis prediction models have had limited real-world use due to a lack of a flexible design implementation framework. These models either do not integrate into the electronic health record (EHR) or do not provide real-time recommendations that harmonize with a physician’s workflow and decrease cognitive load (3,4).

A finite state machine (FSM) is a mathematical model that defines a set of states with logical transitions linking them. FSMs are one design solution that have been often used in computing and have been successfully applied to other medical computing domains (5,6). FSMs can serve as a discretized, simple framework to define risk using a prediction model where the risk strata from the prediction model serve as the FSM transitions. The FSM can then be easily adjusted for different prediction models and use cases while directly comparing model performance and providing integrated, pertinent recommendations, both in real-time. We extend on our previous work of using an FSM to model sepsis risk in the emergency department (7) by tailoring the FSM with the same prediction model applied to the inpatient setting. We then evaluate the prediction model’s performance of sepsis to the previously used Systemic Inflammatory Response Syndrome (SIRS) criteria.

Methods: We conducted an observational study of adult (≥18 years old) inpatient (including intensive care unit) hospitalizations (>48 hours) from October 2018 to February 2019 at a single tertiary care hospital in north Texas. The finite state machine stratifies risk into Low, Medium, and High risk before and after administration of broad-spectrum antibiotics. We implement a previously validated logistic regression prediction model developed by the electronic health record (EHR) vendor Epic into our EHR to produce model output in 15-minute intervals for every patient (Figure 1). The model outputs serve as the transitions between states and are compared with standard SIRS criteria at the same interval. We first analyzed the descriptive statistics of the High state in our population and examined the amount of time patients stayed in the High state. We then focused on the High to the High + Antibiotics transition by analyzing the first transition to a High state in a given admission. The primary outcome was the positive predictive value (PPV) of that first High transition for treatment of sepsis, which was defined by the use of broad-spectrum antibiotics that are started within 24 hours of the High transition and are continued for more than 72 hours. We also calculated the negative predictive value by evaluating the Low to Low + Antibiotics transition. We initially verified the veracity of this treatment of sepsis definition in a subset of 40 patients per transition evaluated and plan to automate the process for all other admissions.

![Finite State Machine Diagram](image1)

**Figure 1.** Our finite state machine for sepsis risk for an admitted patient using a previously validated logistic regression prediction model developed by the electronic health record (EHR) Epic to define transitions. As a comparison, we use the same FSM framework, but use SIRS to define transitions. The focus is on the grayed transitions for the current study.
Preliminary Results: For 7,946 unique admissions, there were 4.85 million transitions, of which only 0.16% were from a lesser state to a High state. There were 5,016 admissions that only had Low to Low transitions throughout the entire hospitalization, while 1,421 admissions had at least one transition to a High state. Figure 2 shows a histogram of the continuous time spent in the High state every time a new High state was encountered; a vast majority exited the High state quickly within less than 4 hours. Initial chart review of 40 high-risk patients showed a 97.5% PPV for sepsis treatment when using the Epic model compared to 67.5% when using ≥ 3 of 4 SIRS criteria and 90% when ≥ 2 of 4. Negative predictive value (NPV) for a subset of 40 low-risk patients was 92.5% with the Epic model versus 40% with < 2 of 4 SIRS criteria.

Conclusions: We are able to easily extend a workable, live FSM from the emergency department to the inpatient setting. Preliminary results comparing the EHR prediction model versus SIRS criteria show clear overall gain in discrimination with improvement of both PPV for high-risk patients and NPV for low-risk patients. We expect these results will be sustained as they are validated on the full dataset.

Only a small percentage of patients enter the high-risk state and only a minority of those persist there for more than 4 hours. Establishing trend signatures that pre-date a transition to a high-risk state may help identify the risk of sepsis earlier. Determining which patients persist in the high-risk state versus those who are only transiently there will be a key future insight into what drives a septic process as well as appropriate sepsis treatment in the inpatient setting after they have received antibiotics.

Overall, FSMs allow for robust interpretability and modeling flexibility as well as real-time analysis and clinical decision support of sepsis risk in the inpatient setting. In doing so, they can decrease cognitive load and streamline workflow for physicians.

A Digital Biomarker for Detection of Benign Childhood Epilepsy with Centrotemporal Spikes (BECTS)

Aarti Sathyanarayana, PhD1,2, Rima El Atrache, MD3, Michele Jackson, BA3, Ivan S. Fernandez, MD3, Kenneth D. Mandl, MD, MPH1,2, Tobias Loddenkemper, MD1,3, William J. Bosl, PhD1,2,4

Introduction

Benign childhood epilepsy with centro-temporal spikes (BECTS), also known as Rolandic Epilepsy, is one of the most common forms of focal childhood epilepsy. Despite its prevalence, it is often misdiagnosed or missed entirely. While most research has focused on early warning signs of seizure onset, a more difficult challenge is to monitor brain electrodynamics in order to detect functional characteristics - biomarkers - that indicate the brain has entered a dynamical state in which seizures are likely to occur. This has the potential to predict clinical outcomes. Our methodology uses nonlinear analysis to identify a digital biomarker for BECTS at the population level. This biomarker appears to have properties necessary for a clinically effective screening method on an “awake” EEG.

Seizures associated with BECTS occur most frequently during sleep. They present with unilateral tonic and clonic features, and at times generalized tonic clonic seizures. Because these seizures occur during sleep, BECTS often goes undiagnosed. Moreover, BECTS usually remits before the age of 18. Due to the high rates of remission during adolescence as well as the long-term effects of anti-epileptic medication, children diagnosed with BECTS often go untreated. Despite the name, this benign epilepsy has been repeatedly associated with developmental delays. The decision of whether to treat BECTS with anti-epileptic drugs or not remains unclear.

Methods

Our methods leverage nonlinear EEG signal features extracted from multiscale entropy and Recurrence Quantitative Analysis (RQA) on the EEGs of 22 BECTS patients, and 22 controls, to find reliable predictors of BECTS diagnosis.

Study Population: All patients were seen at a tertiary epilepsy center in the Division of Epilepsy and Clinical Neurophysiology, Department of Neurology, Boston Children’s Hospital (BCH). Twenty two BECTS patients between 4 and 16 years old were retrospectively chosen from the BCH Epilepsy Center database after BECTS was confirmed via clinical history and the EEG findings of an experienced neurologist. Twenty two age-matched controls with normal EEG (i.e. no diagnosis of epilepsy) were selected from the same clinical database.

Data Collection: Thirty second EEG samples were selected for both the BECTS cases and the controls. On the BECTS cases, the 30-second samples were selected such that they contained no spikes or evidence of epileptiform activity from awake EEG data. Each sample was collected on 19 channels located according to the standard 10-20 system. These segments were classified as ‘awake” by an experienced EEG technologist and reviewed by a resident neurophysiologist. All EEG samples that were chosen from awake subjects, both BECTS cases and controls, appeared normal to the neurophysiologist on visual inspection. Some of the BECTS case sleep segments contained nocturnal epileptiform spikes. No other filtering was performed on the EEG signals.

Signal Processing: Two key sets of dynamical values were computed from the EEG signals: Multiscale Entropy and Recurrence Quantitative Analysis. Multiscale entropy is a nonlinear method that has been used for analyzing biological signals and distinguishing healthy from pathological states. Another approach to computing nonlinear time series properties is recurrence quantitative analysis (RQA). RQA is an empirical approach to analyzing time series data and is in principle capable of characterizing all of the essential dynamics of a complex system including real-world, noisy, high dimensional data. In principle, RQA is capable of detecting significant state changes in a dynamical system, which suggests that it may be appropriate for detecting BECTS. All nonlinear features used in this study were computed on multiple frequency bands using publicly available methods and tools.
Results
Statistically significant group differences between BECTS patients and controls were found for several nonlinear features, particularly determinism, \( p < 10^{-4} \) for all frequency bands. Determinism is a measure of dynamical stability and non-randomness, which has been hypothesized to be related to seizure risk. The below heatmap illustrates the area under the curve (AUC) of a multiscale curve for determinism, on the awake brain of a BECTS patient versus a control. The irritative zone indicates the region of the brain that BECTS patients have identifiable epileptiform activity at night. The BECTS patients have no identifiable epileptiform activities when awake.

**Figure 1:** Brain Dynamic Effects on a 10-20 System Modeled by Determinism

Discussion
Our results suggest that although BECTS patients are most likely to seize at night, that significant dynamical differences can be detected as digital biomarkers even when awake. Our findings suggest that our nonlinear signal analysis approach may be able to enable routine clinical EEG measurements during awake interictal periods, to screen for BECTS.

Optimizing Workflows in the Patient Portal to Incorporate Patient-Reported Outcomes in Clinical Practice

Courtney Segal, BA¹, Elizabeth Austin, MPH¹, Denise Chang, MD¹, Eliza Sutton¹, MD, Danielle Lavallee, PharmD, PhD¹
¹University of Washington Medicine, Seattle, WA

Introduction

Patient-reported outcomes (PROs), or data reported directly by patients about their health and quality of life, are used in a variety of clinical settings to provide insight on patients’ health experiences and their perspectives on health outcomes. Health systems are increasingly looking to leverage digital tools to efficiently use PROs and drive healthcare delivery, yet paper-based approaches remain the mainstay of collecting data from patients. Engaging patients outside the care setting using patient portals can introduce workflow efficiencies, improve response reliability, and enhance data quality through long-term follow-up between clinical encounters. However, little evidence exists to guide care processes and ensure appropriate clinical follow-up of PROs when using patient-facing technology, like portals. This study reports on learnings from three pilots to collect PROs via the patient portal for Medicare Annual Wellness Visits (AWV), depression screening in primary care, and symptom tracking for depression management.

Methods

The three prospective pilots took place 2017-18 at 20 primary care clinics within Seattle, WA and its surrounding suburbs (Table 1). A multidisciplinary team compromising clinicians, clinic support staff, IT programmers, population health managers, and researchers established standards and technical configurations in the EHR (Epic) to collect and report the HRA and PHQ using the portal (MyChart). The project goal focused on creating tools that facilitated more integrated data collection and efficiencies in the clinical workflow processes. We utilized quality improvement methodology (Plan Do Study Act, or PDSA) to continuously evaluate current state and rapid cycle implementation of PRO workflows. The HRA and PHQ pilots were conducted sequentially, which allowed for iterative translation of learnings through the PDSA cycle. Qualitative interviews (n=15) with patients provided user feedback on completing the assessments in the portal, including usability of the questionnaire in the portal and impact on care experience. Additionally, the team sought feedback on usability and workflows from clinic teams (n=4) via in-person meetings.

Over the course of the HRA pilot, 260 patients (ages 49-103) received the HRA at three clinic sites. Sixty-nine percent of patients opened the E-mail alerting them to the questionnaire, and 45% of patients submitted the HRA prior to their AWV, with no patterns of data missingness. One clinic site participated in the depression screening and management pilots, and providers from 7 additional clinics used the PHQ for depression management with their patients. During the pilot, 232 patients received the PHQ via the depression management workflow, which had a higher response rate (37%) compared to the depression screening workflow (22.3%), which was sent to 1,478 patients.

Feedback from patients who were sent the HRA highlighted that it was easy to use and helped them better prepare for their appointment, yet recommended more targeted reminders for questionnaire completion. For the PHQ, patients highlighted that completing the PHQ streamlined their appointment allowing for more time to discuss responses with their provider. Due to the sensitive nature of answering questions about depression symptoms, patients raised the importance of communicating the purpose of depression screening in primary care, as well as personalized correspondence from a known provider for depression management.

Feedback from clinical teams using the HRA emphasized that portal workflow significantly increased clinic efficiency and allowed providers to proactively identify care needs, yet recommended more intuitive tools to track submissions. Feedback from providers participating in the depression screening and management pilots emphasized the need for clearly defined roles and clinical pathways to respond to PHQ submissions, particularly for high risk responses. Validation of the portal screening and management workflows was also important to clinical teams to ensure that PHQ data was appropriately reviewed and stored for population-based management and contractual reporting purposes.

Discussion

Our pilots of HRA and PHQ collection in the portal demonstrated feasibility for obtaining and integrating patient data prior to and between clinical encounters that supports workflow efficiency and improved patient-provider engagement. The differences in PRO response rates across the three workflows (45%, 22%, and 37% respectively) highlights the variation introduced by local clinical workflows (e.g. staff available to deploy and track questionnaires) and patient populations (e.g. preference and comfort to use the portal). Through PDSA we were able to identify changes in the technical workflow and staff training that led to increased response rates (e.g., adding E-mail reminders). Response rates may further increase with targeted and personalized reminders, as well as tools to track questionnaire completion for providers and clinic staff that check-in and room patients for their appointments. Patients in the depression care setting also emphasized the importance of communicating the purpose of screening and use of PHQ results. Additional barriers to adoption of the workflows included fitting the PRO data flow into existing and familiar clinical tools, as well as the appropriate data storage location that meet the various clinical follow-up and administrative reporting needs. Providers also desired clinical decision support to triage submissions, particularly for high risk responses. During the pilot monitoring, additional metrics were identified that would be important to track in future implementations to understand population reach, workflow efficiency, and variation in clinical pathways.

Conclusion

While promising, there are several key functionality challenges to consider when PRO tools are brought to scale across the health system, highlighting the importance for continuous monitoring of questionnaire completion status, data documentation across care teams, and user feedback. Integrating process metrics and end-user feedback ensures that technical solutions are optimized to meet the information needs of diverse stakeholders as well as quality improvement and care delivery goals. Future work to understand how tailored EHR-enabled strategies can further reduce the time burden on both patients and their clinical care teams may facilitate improved response rates and adoption in practice. Assessing the implications for building PRO collection tools in the portal allowed us to forecast potential scalability limitations that would affect our ability to execute HRA and PHQ in the portal at the systems level. These findings provide foundational information for the next implementation phase to spread HRA to additional clinic sites and enhance PHQ functionality to support population-focused panel management.
National Prevalence and Hospital Characteristics Associated with Use of Health Information Exchange Following Discharge from Inpatient Psychiatric Units in Acute-Care Hospitals

Morgan Shields, M.Sc., M.A.,1 Grant A. Ritter, Ph.D.,1 Alisa B. Busch, M.D., M.S.2,3
1Heller School for Social Policy and Management, Brandeis University, Waltham, MA; 2McLean Hospital, Belmont, MA; 3Department of Health Care Policy, Harvard Medical School, Boston, MA.

Introduction
Psychiatric illnesses are prevalent and often associated with higher rates of co-occurring medical conditions.1,2 Acute-care hospitals with dedicated inpatient psychiatric units are important providers for patients with severe psychiatric illnesses: nearly 79% of US acute-care hospitals provide mental health services, and psychiatric units in them account for 71% of Medicare inpatient mental health discharges.3,4 New forms of treatment and payment models, such as accountable care organizations (ACOs) and integrated primary and mental health care, aim to better serve individuals with psychiatric illnesses.5–8 These new models will require robust use of electronic health information exchange (HIE) to manage transitions from inpatient to outpatient care.9 In 2016, 88% of U.S. non-federal acute-care hospitals electronically sent information to providers outside of their health system.10 However, HIE from inpatient psychiatric units in acute-care hospitals may not be as prevalent as it is from other inpatient units in these same hospitals. In part, this could be because psychiatric illnesses typically are accompanied by heightened privacy concerns from patients and more stringent federal and state privacy laws and regulations,9,11,12 which can influence how or whether health information is shared across providers. Despite the importance of HIE at discharge from inpatient psychiatric care in order to better manage severely ill and complex patients, no prior research has examined HIE to outside providers from psychiatric inpatient units in acute-care hospitals. Using national data, this study examines the reported use of HIE at transitions of care from acute-care hospital inpatient psychiatric units in 2016, and the hospital characteristics of these psychiatric units that are associated with HIE.

Methods
This is an observational cross-sectional study that merged facility-level data from 2016 the Centers for Medicare and Medicaid Services (CMS) Inpatient Psychiatric Facility Quality Reporting (IPFQR) program with data from the American Hospital Association (AHA) 2016 Annual Survey. The outcome of interest was whether an inpatient psychiatric unit within an acute-care hospital reported to the IPFQR whether it used an EHR to send HIE at times of transition in care. Logistic regression models were fit to examine characteristics associated with HIE from inpatient psychiatric units in acute-care hospitals (N=1,085, 99.8% of hospitals in the IPFQR; N=2 hospitals excluded because they were not in the AHA database of hospitals). Individual hospital characteristics in these models included overall hospital-bed size (<100, 100-399, ≥400), psychiatric-bed size determined by tertiles (3-8, 19-37, ≥37), teaching status (major teaching versus not), ownership (for-profit versus nonprofit and government versus nonprofit status), percent Medicaid bed days, urbanicity (metropolitan versus rural and micro areas), whether the hospital was part of a network, and whether it participated in an ACO. State level variables in the models included the overall state-level rate for electronically sending patient care summaries at discharge to any provider13 and a dichotomous variable denoting whether a state required patient authorization for sharing mental health information for treatment purposes.14 Multiple imputation was performed for item-level missingness on variables of HIE (12 missing), ACO (235 missing) and network (178 missing), with 5 iterations and assuming missing at random.

Results
In 2016, out of the N=1,073 acute-care hospital inpatient psychiatric units that responded to the HIE question in the IPFQR, 56.3% (N=604) reported they sent HIE from their EHRs to providers at the transition of care. Hospital characteristics associated with sending HIE from their inpatient psychiatric units were: large hospital bed-size (≥400 vs. <100: OR[95%CI]=2.46[1.46-4.15]) and hospital participation in an ACO (1.37[1.01-1.86]).

Conclusion
Sending electronic HIE from inpatient psychiatric units of acute-care hospitals lags far behind HIE use-rates that are happening more generally from the hospitals that “house” these psychiatric units (i.e., 56.3% vs. 88%). Hospital size

1457
and participation in ACOs—but not participation in a network—were associated with sending HIE from inpatient psychiatric units of acute-care hospitals. State mental health laws more stringent than HIPAA (that is, requiring patient authorization for sharing of mental health information for treatment purposes) were not associated with electronic HIE from inpatient psychiatric units of general hospitals. More research is needed to better understand characteristics associated with HIE from inpatient psychiatric units of acute-care hospitals. For example, whether outpatient provider EHR adoption rates or provider culture influence HIE from inpatient psychiatric units. Also, more research is needed to understand the potential role of alternative payment models to facilitate electronic HIE from inpatient psychiatric units in acute-care hospitals.

Validation of a Computable Phenotype for Site-Specific Cancer Treatment

Evan T. Sholle, MS1, Orrin S. Belden, BS2, Jaclyn D. Rosenzweig, MD2, Jennifer Levine2, MD, Joseph Kabariti, BS1, Thomas R. Campion, Jr., PhD1,2,3, Jyotishman Pathak, PhD3

Introduction

While widespread adoption of the electronic health record (EHR) has ushered in an era of unprecedented availability of patient data, challenges remain in secondary use of clinical data, including the translation of clinical concepts into concrete, machine-interpretable query algorithms represented using reference terminology and structured data points. To address this issue, the informatics research community has advanced the idea of a “computable phenotype” – a structured, machine-interpretable query algorithm that can be used for patient cohort identification using EHR data. Computable phenotyping has driven advances in the use of EHR data to study diverse conditions including diabetes, autism, and many others. Existing knowledge bases such as PheKB (1) also allow investigators to share locally-developed phenotype algorithms and make use of algorithms developed elsewhere.

While these efforts have yielded significant benefit towards defining patient cohorts, they have primarily centered on identifying phenotypes that relate solely to the patient’s physical state. However, at our institution, many patients who receive a structured diagnosis of cancer are receiving treatment for unrelated conditions and receive cancer care elsewhere. While these patients might meet the criteria for a “cancer” phenotype, their lack of cancer-specific data points would render them unsuitable for inclusion in research studies that depend on their receiving cancer care at our institution, as their EHR data would not contain any of the elements required to conduct retrospective research on oncologic outcomes. To remedy this issue, we sought to develop and validate a computable phenotype for a patient cohort defined not purely by clinical criteria, but also by healthcare-process-specific criteria: patients receiving cancer treatment at our institution, as distinguished from patients receiving cancer care at another institution but seeking care from our institution for other conditions.

Methods

We first developed a manually-annotated gold standard of patients who were receiving cancer treatment at our institution, Weill Cornell Medicine. This process included identifying a sample of 902 patients diagnosed with Hodgkin’s lymphoma at encounters when they were 15-39 years of age, as defined by the presence of an ICD-9 or 10 code anywhere in the electronic health record, including patient self-reported history, billing diagnoses, and problem list entries, as well as encounter diagnoses. We then annotated each patient with a binary classifier for either receiving or not receiving cancer care at our institution. Annotation was based on subjective clinical judgement, as we sought to determine the extent to which each phenotype criteria or combination thereof matched clinician adjudication.

After developing the gold standard, we applied three distinct criteria, along with their combinations (see Figure 1), to classify these patients as either receiving or not receiving cancer treatment at our institution.
The first criteria was whether or not the patient had 2+ encounters with an oncologist. The second was whether the patient had an order for a medication of the “antineoplastic” drug class as defined by the National Drug File - Reference Terminology (NDF-RT), and the third was an encounter diagnosis associated with an ICD-10 code for neoplasia. Using existing infrastructure for secondary use of electronic patient data (2), we then queried the EHR to determine whether each patient met each of these criteria. We compared the results of each criteria alone and in combination, to determine their performance relative to the gold standard by calculating precision, recall, and F-score for each.

**Results**

As detailed in Table 1, the various approaches yielded differing results, with the combination of all three criteria showing the highest specificity and the lowest recall. Overall, as determined by F-score, combining antineoplastic orders with either diagnoses or encounters demonstrated the best performance, with an F-score of 0.72.

**Discussion**

The relatively poor performance of ICD-10 codes alone (as demonstrated in Table 1) as a proxy for ascertaining whether or not patients received site-specific treatment for a given condition is a major limiting factor in identifying patient cohorts for clinical trials, as well as retrospective research. Since patients with diagnosis codes alone may have the conditions in question, but did not receive care at the institution, they likely lack many of the data points required to support the research question for which their inclusion was determined. This often necessitates painstaking manual review to exclude and filter out patients from a cohort ostensibly matching study inclusion criteria. Similarly to the existing support biophysical computable phenotypes provide in identifying patients with given clinical characteristics, this technique may help researchers better characterize patients seeking care for a given condition at a specific institution, obviating the need for manual review to exclude patients without sufficient condition-specific data.

Healthcare fragmentation is a well-documented phenomenon (3), and it is possible that our relatively young cohort may be less subject to this issue than an older group of patients, artificially deflating the count of true negatives in our gold standard. However, we deemed the relatively higher availability of longitudinal cancer-related treatment in this younger, lower-mortality cohort to be a worthwhile tradeoff – future research may expand the utility of the classifier in older populations and other disease areas. Additionally, incorporation of data from collaborative research networks, such as New York City’s INSIGHT Network, may provide an opportunity to better characterize site-specific treatment.

Sonoma County Empowering Caseworkers to Better Serve the Most Vulnerable

Jane L Snowdon PhD\(^1\), Barbie Robinson\(^2\), Carolyn Staats\(^2\), Kenneth Wolsey\(^3\), Thomas Strasheim\(^4\), William Kassler MD MPH\(^1\), Gretchen Jackson MD PhD\(^1\)

Abstract

Sonoma County government agencies employed advanced health information technologies, artificial intelligence (AI), and inter-agency process improvements to transform health and healthcare for socially disadvantaged groups and other displaced individuals. This unique application of innovative care-management tools, which created a bridge between social and clinical determinants of health, helped 77 individuals who were at risk and experiencing a crisis through coordinated care plans and access to services in their time of need.

Introduction

State and local government agencies are faced with budgetary, organizational, and legislative constraints as well as increasing demand for services. Typically, agencies are separately funded, staffed, and operate in “silos of service” with limited inter-agency integration. Recognizing an unmet need for a better way to support their most vulnerable citizens, Sonoma County, California prioritized their safety net system in early 2017. While initiating the workplan to support improving their safety net system, the Sonoma County Complex fires hit burning more than 36,000 acres, killing 22 people, and destroying 5,636 homes and buildings.\(^1\)

Sonoma County has an estimated population of 500,000, is largely rural, and exhibits significant disparities in health, living standards, and educational attainment.\(^2\) Demographically, whites are the largest racial group. Latino or Hispanic persons represent the second largest and fastest growing group over the past decade with 27% of the total population. Sonoma County is challenged by a high cost of living, limited housing, and a homeless crisis that was exacerbated by the 2017 fires.\(^3\) In the aftermath of the wildfires, many vulnerable citizens already living in shelters needed ongoing shelter, while others who required shelter were faced with dwindling supply. Sonoma County sought to design and deliver better coordinated service delivery for its citizens, particularly for individuals experiencing one or more complex needs including unemployment, housing insecurity, homelessness, behavioral health issues, substance abuse, and incarceration. Sonoma County’s siloed departments (e.g., Health Services, Human Services, Community Development Commission, Child Support Services, Probation and others relating to criminal justice) collaborated through advanced care-management tools to decrease fragmentation of care for shared clients; reduce duplication of services; and create an effective, efficient care management plan.\(^4,5\)

Methods

Sonoma County implemented a three-step approach for achieving their objectives. First, a new program called Accessing Coordinated Care and Empowering Self Sufficiency (ACCESS) Sonoma County was established to identify the most vulnerable residents and match them with services to help improve their well-being and self-sufficiency, increase service utilization, reduce duplicate services, and lower expenditures per client or family. Second, Sonoma County created an Interdepartmental Multidisciplinary Team (IMDT) to generate and deploy coordinated cross-departmental services to address individuals experiencing homeless or housing insecurity needs and to inform the strategy of technology to support IMDT care coordination requirements. Third, a data integration hub (DIH) and care management and coordination system (CMCS) were implemented. The DIH brought together data from a variety of sources and created a single, integrated, current master data index resulting in a golden record for every individual. More than 91,000 resident records were loaded from across four sources (CalWIN for eligibility operations, SWITS for drug and alcohol dependency, Avatar for mental health, and IJS for proprietary justice data) into the DIH. The CMCS was built on a Health Insurance Portability and Accountability Act (HIPAA)-enabled, cloud-based platform that can aggregate data and connect agencies, payers, and community service providers, helping to support the design, coordination, and delivery of individualized care plans and services to

1461
manage the whole person. Across multi-disciplinary teams, care managers, social workers, and treatment providers optimized workflow for activities such as scheduling, developing individualized care plans, managing budgets, selecting providers, and enabling care. The CMCS uses one care plan to coordinate care across a multi-disciplinary team for a person’s mental health, physical health, and social service needs, such as palliative care, chronic disease management, personal budgets, and substance use management. The CMCS is able to apply best practices (e.g., management of comorbid conditions such as diabetes, heart failure, chronic obstructive pulmonary disease, hypertension) through structured programs built in alignment with evidence-based medicine, quality standards, and regulatory requirements. Individuals can engage with their care team and collaborate on their care plan through their own responsive application. Given client consent and local rules regarding the user’s role in the organization and eligibility to view the data, the CMCS enabled secure and systematized data collection, storage, and access. The CMCS provided the IMDT with a cloud-based 360° view of a client’s health, behavioral, and social factors and the ability for client-centric, goal-driven care planning with the aid of an AI component for automatically extracting and surfacing social and clinical determinants of health terms in large volumes of care management notes to practitioners.\textsuperscript{5-6} The CMCS allowed the IMDT to create and care manage a new fire-displaced cohort, perform assessments, record case notes, set care plans and actions, and match client needs with community providers.

Results

Caseworkers, clinicians, housing specialists, and other community partners coordinated services for the highest risk clients. More than 4,000 fire victims were initially housed in the shelter. After week two of the disaster, the number of individuals who did not have resources to leave the shelter for secure housing was about 300. Of 127 individuals representing 95 households that remained in shelters two weeks after the fires, approximately 42 percent were identified as precariously housed and approximately 26 percent were homeless prior to the fires. Over the ten-month period from April 2018 to February 2019, the IMDT managed 77 clients with multi-dimensional, complex needs. The median age was 54.5 years (range 29 to 84 years), and 58% were female. Care managers identified goals for each client (e.g., stabilize client by addressing emotional trauma and financial distress, rehouse client, and engage other collaborative care providers to address health and safety concerns). In some cases, care managers were unable to establish or maintain contact with the client. The average number of times IMDT formally discussed cases was 2.9. As of February 2019, 34 cases were stable and intermittently monitored and 43 were being actively managed.

Discussion

Care management tools have traditionally been applied in chronic disease or primary care settings. This innovative care-management solution transformed health and healthcare for socially disadvantaged groups and those displaced by a natural disaster. With the integrated DIH and CMCS solution, Sonoma County’s IMDT is now able to enter, aggregate and render near real-time information to caseworkers, clinicians, housing specialists, and other community providers. IMDT staff believe DIH and CMCS have resulted in productive care-planning meetings, information transparency, and enhanced access to coordinated care. With the assistance of DIH and CMCS, applications for food stamps, Section 8 housing, and Medi-Cal, California’s coverage for adults of limited means, were prepared and thoroughly reviewed by IMDT, reducing the burden on multiple staff. Advanced health information technologies can be instrumental in driving collaboration and access so that residents at risk and experiencing a crisis can be better served in their greatest times of need. Conceptually, the potential exists for replicating this program across other counties with possible operational efficiency and client outcome benefits.

1IBM Watson Health, 2IBM Research, Cambridge Massachusetts

Introduction

At the point of care, clinicians seek information to understand their patients such as ‘What is this person’s HbA1C goal?’ or ‘Did this person have an adverse reaction to metformin?’. Today, finding answers to these questions often requires foraging through progress notes from past encounters in Electronic Health Records (EHRs). Our goal is to improve the clinician’s understanding of their patient by making it easier to find answers to their prototypical questions [1]. We used a previously developed artificial intelligence natural language processing (AI-NLP) method [2] to extract relevant information from unstructured data in clinician notes. We present a user-centered design approach to support the creation of a user interface for a primary care clinician at the point of care.

In the past, mental models have helped cognitive psychologists understand how people accomplish complex tasks in varied domains such as navigation [3], electricity [4] and others. We hypothesize that physicians’ mental models of what’s needed to understand and treat a specific person drive the search for relevant information in that patient’s medical record. This information will form the basis of what is needed to design a software product that displays a patient’s medical information where and when it is needed.

Method

A mixed methods approach was used to identify both the nature of physician’s prototypical questions as well as the order in which they are asked. The IRB approved research was performed in partnership with Atrius Health (a medical practice group in Massachusetts). A convenience sample of physicians was recruited from the clinical staff at Atrius Health. In Study 1, think aloud protocols were collected from eight primary care physicians at Atrius Health as they reviewed four patient records. For each record, we asked the physician to act as if she had inherited the patient from a retired physician and was about to see the patient for the first time for a chronic disease management follow-up. A total of twenty-seven different reviews were recorded, transcribed and coded using a grounded theory approach. For each unit of speech, the coding system captured both the information category (e.g., “Medications” or “Labs and Vitals”) as well as the intent behind the search (e.g., “Understand the patient” or “Formulate an hypothesis”). Study 2 was an observational study in which two authors (JS, SM) shadowed nine primary care physicians before, during and after fifteen different patient encounters at five Atrius Health locations. Observations were captured in handwritten notes with a special focus on the questions that physicians asked, either implicitly or explicitly. The notes were also analyzed for themes relating to mental models and clinical workflow. Study 3 was composed of a series of feedback sessions with clinicians where we tested the usability of the improved interface in answering the clinician’s prototypical questions and providing the right information in context. During these feedback sessions, clinicians at Atrius Health interacted with increasingly refined versions of a high fidelity prototype using the Invision software product. Continued refinement of the clinicians’ mental models and, most importantly, the display was made possible by triangulating the results of each study.

Results

From Study 1, we learned that all clinicians spent at least 50% of their time in a patient’s record searching for information to better understand the patient (range from 54-81% of all information seeking codes). Typically, they were searching for information about the patient’s Problem List, Labs and Vitals, Person Story and Medications. From Study 2, we were able to collect a broad set of questions that physicians ask about each of these information types. Study 3 enabled us to continually optimize the interface for usefulness and ease of use.

To illustrate one of the mental models, we present a record review of a patient focused on Type 2 Diabetes (Figure 1). This physician goes through a process of searching for information then formulating a grounded hypothesis, setting an agenda for the visit and then repeating that process to refine the agenda. The green boxes highlight areas where AI-NLP can be used to quickly pull information from the EHR to create a clinically relevant insight.

Application to Interface Design

After we analyzed the information seeking behavior and prototypical questions the clinicians asked, we used the mental models to develop a user interface. The goal of the display was to minimize the information foraging and time needed to find answers to the clinician’s prototypical questions.

To develop the interface, first we took the questions to determine what information the clinicians needed and where that information can be found in the EHR. Recall that information can come from both structured (e.g., labs, medications and vitals) as well as unstructured data (e.g., physician progress notes).
Type 2 Diabetes is a chronic condition, measured by HbA1C, that is often treated with medications as well as lifestyle factors. In addition to understanding the person’s HbA1C and whether it is controlled or not and the medications they’ve been prescribed to control their condition, clinicians often want to know about additional labs, the person’s weight and weight goals and the control of their blood pressure. The resulting interface visualized all of this information along a common timeline.

Three information-seeking behaviors illustrated in Figure 1 could be answered by insights extracted by the AI-NLP service from the text in the physician’s note. In each case, the extracted insights would be presented in context within the interface. For example, the PCP6 statement that “A lot of times when you [increase the metformin], you start developing diarrhea” would be captured as an “Adverse Drug Reaction” and presented as an insight associated with the display of metformin on the date that it was documented by the physician. In such a case, clinicians would be given a visual cue that there was an NLP-based insight and they could hover over the location to read the relevant insight (Figure 2). As confirmed from the feedback sessions in Study 3, this resulted in reduced foraging through the patient’s record to find relevant information.

Figure 2: The left AI-NLP insight is an example of information that would appear when a clinician hovered over the blood pressure goal on the Hypertension page, while the right image shows a Medication Change insight.

Using Interactive Data Visualization to Drive Quality Improvement in Emergency Medical Services

Rachel A. Stemerman, MPH, NRP¹, Malvika Pillai¹
¹University of North Carolina, Carolina Health Informatics Program, Chapel Hill, NC

Introduction

In 2017, the National Emergency Medical Services Information System (NEMSIS) reported that 4,016 Emergency Medical Services (EMS) agencies responded to over 7 million EMS activations through the United States 911 system¹. EMS agencies vary significantly in the use of quality improvement programs due to resource limitations and data collection barriers². As a result, EMS providers may be unaware of opportunities to improve their care knowledge and skill. Measuring and comparing care quality against agreed-upon standards of practice or peer performance (audit) and providing results to healthcare professionals and or administrators (feedback) is a common quality improvement strategy³. Studies link audit and feedback to more accurate self-assessment of a health professionals’ performance³⁴. However, health professionals may overestimate their clinical performance and, in turn, fail to identify opportunities to improve their practice even if improvement is recommended. A number of studies have highlighted how dashboards had a positive effect on outcomes and may change individual provider behavior⁵. In this study, our objective was to develop and evaluate interactive quality improvement dashboards for EMS providers as guided by a user participatory design process.

Methods

We continued our work developing interactive visualization dashboards that displayed the EMS provider’s patient symptom assessment (or primary impression), their treatment intervention, and the resulting patient outcome. Scenario evaluations from the previous iteration found that these dashboards addressed system quality metrics, but not the individual needs of the EMS providers. Analysis of focus group data identified that burnout and lack of experience with specific populations such as pediatrics were of primary concern.

A user participatory iterative design process guided the development of two interactive dashboards created through D3.js. D3.js, an open source JavaScript library, was the primary software used and data analysis was performed with Python’s pandas library. One year of data was extracted from the Orange County Emergency Services (NC) EHR resulting in 300 - 450 patient contact per individual provider. Figure 1 shows a heat map calendar displaying the daily call volume for an individual EMS provider. Days with darker color indicate higher call volume. A tooltip on the individual calendar days displays the number of 911 calls the provider completed that day. When a day is clicked, a time series graph of their call volume appears at the bottom of the calendar (Figure 2) displaying the 911 call’s total length of time over their shift from 0600 until the next day at 0600 (y-axis).

The second dashboard displays all patient contacts the EMS provider had in 2018 as an interactive hierarchical bar chart (Figure 3). Each blue bar represents the total number of patient contacts categorized by the EHR data element “primary support system.” Clicking on a bar allows the user to drill down into the patient’s “primary support sign.” Another click on a bar populates the provider’s “primary impression” or their diagnosis of the patients’ active complaint condition. Clicking on the background will return the user to the previous bar chart until the home screen

Figure 1. Interactive heat map of EMS provider’s daily call volume

Figure 2. Time series line graph

Figure 3. Interactive hierarchical bar chart
is reached. This categorization allows the user to visualize the full scope of clinical patient contacts they evaluated that year highlighting low volume categories in red (< 10).

**Figure 3.** Hierarchical bar chart of clinical patient contacts for an individual EMS provider

Results

During a preliminary evaluation, all providers (N = 12) reported that this was their first exposure to their personal operational and clinical care data. As providers explored the calendar heat map, they expressed a better understanding of what was contributing to their feelings of burnout. Previously, providers perceived they had higher call volume, but were unaware of the total length of time of individual patient contacts. Evaluation of the interactive bar chart resulted in increased awareness of gaps in clinical patient contact types and a desire to pursue continuing education in areas of greatest need. Many providers also reported that, due to faulty memory, they underestimated the number of critical patient contacts (i.e., cardiac arrests) they experienced.

Discussion and Conclusion

We created visualizations that provided a method for EMS providers to rapidly and accurately analyze their individual operational and clinical care data resulting in actionable information. Interactive presentation of this information can engage users and generate new insights to inform training guidelines and address the quality improvement needs of the individual health professional. To the best of the researchers’ knowledge, no other studies were found using interactive data visualization in self-initiated quality improvement. Future work will explore how providers use and integrate the information provided by the dashboards into their decision making.

Engaging with MSK Engage: A Digital Platform for Monitoring Patient Reported Outcomes in Oncology

Peter D. Stetson, MD, MA; Era Bani1,2; Kevin Shannon1; Naga Akella1; Olga Strachna1; Monica Allison1; Rita Reynolds1; Judy Hagerty-Paglia1; John Philip1; Wazim Narain, PhD1; Julia Fu1; Kenneth Seier1; Donna Boccamazzo1; Suzanne Kelson1; MaryAnn Connor, RN1; Rori Salvaggio, RN1; Michael Eubank1

1Memorial Sloan Kettering Cancer Center, NY, NY; 2Mt. Sinai, NY, NY

Introduction:
Collecting and monitoring patient-generated health data (PGHD) is associated with improved patient survival in oncology [1,2]. Many electronic health records (EHRs) and patient engagement vendors have begun to enable remote monitoring and patient-reported outcomes (PRO) data collection. However, open Informatics questions remain regarding how to standardize and visualize actionable PGHD for the care team [3], what integration touchpoints are needed with EHRs to support clinician workflow, how to titrate appropriate notifications to the care team for alarm conditions, how to avoid patient “survey fatigue”, and what form and degree of clinician engagement confers benefit to patients being monitored. We report here on MSK’s ongoing efforts to engage with patients to support oncology care, and to broaden and deepen our phenotyping efforts for translational research.

MSK Engage is an Informatics solution embedded within our patient portal for PGHD collection and monitoring. It was launched in 2016 coincident with opening our ambulatory surgery center, and it is now live enterprise-wide for both standard of care and research patients. It automates the distribution and collection of numerous types of survey instruments, including PROs, medical history, structured family history, patient preferences, and patient experience. It integrates with our scheduling system, our EHR, and portal secure messaging. Instruments and questions are housed in libraries and structured using the emerging FHIR questionnaire standard [4]. Trigger notifications can be set in its rules engine at the question level (e.g. “severe” PRO-CTCAE symptoms[5]), and multi-lingual support is enabled. The design is responsive for desktop and mobile use by patients. Our patient-run advisory council (PFACQ) participates actively in the design and naming of MSK Engage.

Our objectives in this operational evaluation were to 1) understand system adoption by both patients and clinicians, 2) develop and implement user-centered workflow integration for notifications, documentation and ordering, 3) understand and establish best practices for governance, 4) develop prototype visualizations of PGHD from n=1 to cohort-level displays, and 5) incorporate PGHD into our deep-phenotyping efforts for translational research.

Methods:
Descriptive statistics were used to assess systems usage and adoption. Ethnographic observation, focus groups, and user-centered design approaches were used to develop workflow integration touchpoints and visualization dashboards. Dashboards were developed in Tableau with underlying data residing within our clinical data warehouse.

Results:
The portal adoption is 81% among patients under active treatment. As shown in Figure 1, 31 instruments are now live in MSK Engage across 359 participating clinics. 36,516 unique patients have completed 98,616 surveys with a median completion time of 3 minutes. 74% of surveys are completed at home, as opposed to onsite by iPad. Patient completion rates are increasing, currently at an average of 50% for Q1 2019. Patient completion rates vary by instrument. Not all instruments are configured to trigger alerts (e.g. routine medical history forms), but those that do have triggered 6,835 alerts on 3,236 unique patients associated to 59 physicians and 202 staff, who escalated the alert 25% of the time. Of the 31 instruments deployed to-date, 22 are standard of care, 2 are for research, and 7 are for both. 13 have a dedicated Tableau dashboard live or in development, 5 are imported directly into electronic documents in the EHR, and 1 generates automated referral orders (triggered when nurses review with the patient and save their linked note). Promotion to the legal health record, as a proxy for “provider attestation”, varied by instrument. An average of 2.7 instruments have been submitted per patient, enabling multiple time-point assessments for many patients.

Figure 2 demonstrates a user-centered prototype for cohort-level display of data in Tableau. Patient-level data views were developed as drill-downs. Additional enterprise dashboards have been developed in Tableau to monitor symptom alert triage and clinic compliance rates. At the individual survey response level, “advanced reports” have been developed for clinicians for 7 of the instruments, and for patients for 2 of the instruments.
To govern this process, we established an eForms Committee with multidisciplinary membership. It is staffed and run by Informatics, meeting twice monthly (working group; alternating with full committee). The committee is charged with avoiding duplicate questions and survey fatigue, as well as standardization of questions in the question library and triaging requests for alert triggers, documentation integration, and dashboarding requests. Patients who used the system generated new feature requests - most interestingly to add the capability to “ad hoc” report on symptoms even after the target cohort period was complete. An additional 15,000 structured family histories have been backloaded into Engage, with go-forward collection through Engage using the Family History Questionnaire for targeted research patients.

Discussion:
Patients and staff are adopting the platform for both standard of care and research, with increasing patient compliance. Patient and clinicians are using all the designed workflow integration tools, including direct import into documentation templates within our EHR, push notifications, and decision support. There is extensive and timely engagement by our nursing staff with MSK Engage data and triggered notifications on alarm symptoms. Opportunities exist to enhance physician engagement with the data. Significant oversight and governance with advanced visualization tools are required for success. MSK Engage has contributed multiple surveys per patient over time, which augments our clinical and administrative data sets for our ongoing phenotyping efforts. Future directions include enhancing the point-of-care display of this data for the clinical team, introducing tailored education information based on symptoms, and elicitation of patient treatment preferences.

Linear Algebra and Public Health: Identifying Areas of High Healthcare Needs through the Markov Chain Ranking Method

Abdul A. Tariq, PhD, Beatriz Ryan-Lora, MPH, Andres Nieto, MPA, David K. Vawdrey, PhD
1NewYork-Presbyterian Hospital, New York, NY, USA

Introduction

In recent years, increasingly larger quantities of data on the demographic, health, environmental and socioeconomic characteristics of communities are becoming available. While such data can paint a rich portrait of a community, it is unclear how to aggregate such disparate information into a single metric reflecting the overall “health” of a community. In this study we apply the Markov Method to aggregate multiple characteristics of a community into an overall fitness score. We apply the method to Census-tract level data on disease prevalence and health behaviors using a dataset from the Centers for Disease Control (CDC), to generate a healthiness ranking for areas in Manhattan: a large, ethnically and economically diverse borough in the city of New York. This score can be used by to pin-point areas where public health investments should be prioritized. The method is flexible enough to incorporate a variety of data types, and to build customized rankings based on different objectives.

Methods

The Markov Method is used extensively in rating and ranking, and among its most famous applications is PageRank, one of the earliest algorithms that powered Google’s search. We adapt it to our context and assume that we have \( i = 1 \cdots N \) communities, and each community has \( k = 1 \cdots M \) characteristics. For each of the community characteristics \( k \), we compute an \( N \times N \) voting matrix \( V^k \). In the voting matrix, each community casts a “vote” for every community that is better than itself (and there are \( N \times N \) such comparisons) on a given characteristic. In particular, the \( i \)-th entry of \( V^k \) is defined as follows: on a given characteristic \( k \) if community \( i \) is better than community \( j \), then \( V^k_{ij} = 0 \) (\( i \) does not cast a vote for \( j \)); or if \( i = j \). If community \( i \) is worse than community \( j \), then \( V^k_{ij} = 1 \) (\( i \) casts a vote in favor of \( j \)). If both are statistically indistinguishable (using some suitable test; we use the t-test), then \( V^k_{ij} = 0.5 \) (each community gets half a vote). We then row-normalize the voting matrix (each element is divided by the sum of all elements in that row). For rows having all zero elements (i.e. a community that beats all others on a given characteristic), we replace each entry with \( 1/N \). The resulting matrix is a stochastic matrix, and intuitively it reflects the probability of community \( i \) beating community \( j \) on a given characteristic.

Following the procedure above, we build a voting matrix for each of the \( M \) characteristics, and compute a final stochastic voting matrix as:

\[
V = \alpha_1 V^1 + \alpha_2 V^2 + \cdots + \alpha_M V^M
\]

Here \( \alpha_k \) is the weight assigned to the \( k \)-th characteristic, and all weights sum to 1. We then solve the eigensystem \( \lambda \mathbf{r} = \mathbf{r} \), where \( \mathbf{r} \) is the dominant eigenvector of the stationary distribution represented by the stochastic voting matrix \( V \). The \( i \)-th element of the dominant eigenvector represents the probability that community \( i \) will be better than all other communities, and we can use these values to compare communities with each other.

As an application, we rank different geographies within Manhattan on set of 23 health-related characteristics. We use census-tract level data from the CDC’s 500 Cities project, which provides the prevalence of a variety of chronic conditions and health-related behaviors for cities across the U.S. The 23 measures are bucketed into three overarching categories: health outcomes, unhealthy behaviors, and prevention.

Results

In Figure 1 we geo-code the rankings for the 2117 census-tracts in Manhattan for which data was available from the CDC. The rankings go from 0 (best) to 100 (worst), and are color-coded so that more red implies a worse score. The 23 health measures which comprise the ranking are provided in the bottom-left of the figure. To construct the ranking we use the crude prevalence of each of the 23 measures, as provided by the CDC. From examining the figures, two main points emerge: first, there is quite a bit of spatial heterogeneity in the overall health rank of areas within Manhattan. Even geographically contiguous areas can have vastly different health ranks, which underscores the need...
for geographically targeted public health interventions. Second, even the communities which are highly ranked overall, or in terms of health outcome measures, can sometimes fare poorly in terms of prevention measures. This highlights a potential disadvantage of aggregating multiple metrics into one (either through Markov or any other method), namely that it can potentially obfuscate areas in need.

**Conclusion**

We demonstrate a new method to aggregate a variety of community characteristics into a single ranking. Such a ranking can be used to prioritize areas in need for public health interventions, as well as provide an easily comparable summary of disparities across geographies.

Progressive Multi Class Predictive Modeling of Disposition Decision at Different Care Delivery Stages in an Emergency Department

M. Samie Tootooni, Ph.D. 1, Kalyan S. Pasupathy, Ph.D. 1, Heather A. Heaton, M.D. 1, Casey M. Clements, M.D., Ph.D. 1, Mustafa Y. Sir, PhD. 1  
1Mayo Clinic, Rochester, Minnesota, USA

Introduction

Boarding time in Emergency Department (ED) is defined as the time from the admission decision for a patient until the patient is placed in an inpatient bed. Higher boarding time is shown to be associated with many adverse outcomes such as mortality 1. Early prediction of the disposition decision, specifically potential inpatient admission, can facilitate timely initiation of the hospitalization process and therefore shorten the boarding time 2.

At the time that a patient arrives to an ED, only limited amount of information such as modality of transport, gender, and date of birth are usually available to the ED care team. While the patient receives care through different stages, the ED care team gets progressively more information about patient and consequently, prediction of disposition decision becomes increasingly accurate with the accrual of available electronic health records (EHR) data. Accordingly, we sought to develop, validate, and compare different multiclass classification models to predict the ED disposition decision (i.e., discharge home, admit to hospital, admit to intensive care unit, or ICU) for each patient at each major care delivery stage.

Recorded in the earliest stage of a patient’s visit, chief complaint affects several facets of a patient’s ED visit, i.e. nursing focus, initial medical assessment, prioritizing the treatment, determination of patient flow through the ED, and generation of different hypotheses for the final diagnosis 3. We recently developed a natural language processing approach (so-called CCMapper) to map these free-text data into a structured list so that they can be used in predictive studies. We evaluated whether incorporating chief complaint category improve the performance of the prediction models.

Methods

Three ED care delivery stages for visitors are identified: (1) patient arrival, when the registration clerk records the patient’s demographic data and chief complaint; (2) patient triage, when a nurse measures the height, weight, and other vital signs to determine emergency severity index (ESI level); and (3) first order bundle, when the first set of orders (medication, lab tests, etc.) is submitted by an ED Physician. We consider the first care delivery stage as time zero (T1 = 0). Table 1 shows the distribution for time to each care delivery stage as well as the disposition time.

The study cohort included all adults who visited the Mayo Clinic ED in Rochester, MN, between January 1st 2016 and December 31st 2017 (~140,000 encounters). In order to predict the final disposition decision, we trained, validated, and compared three types of predictive models: Logistic Regression (LR), Random Forest (RF), and Naïve Bayes (NB). All models used 10-fold cross validation with 21 months of data reserved for training the models and the remaining 3 months used for testing. By default all instances in the training data has equal weight for learning algorithm. To minimize the effect of unbalanced classes, we reweight the instances in a way that sum of weights for all classes of instances in the training data are equal.

Results
At each care delivery stage, we identified the significant variables that have high predictive power regarding the disposition decision. We found that patient transport categories such as *air ambulance* and *surface ambulance* are associated with higher risk of ICU admission while other categories, particularly *walk-in* is associated with lower ICU admission risk. Several chief complaint categories such as “accidental overdose” “blood pressure” and “rule out cerebrovascular accident” were found to be associated with ICU admission; in contrast with categories such as “lower/higher extremity pain” or “ear pain,” which had a negative relationship with ICU admission risk. Our analysis also showed higher age and male sex are associated with ICU admission.

Several patient factors associated with ICU admission are identified at the triage and first-order-bundle stages. For instance, *lower SPO2*, *higher acuity level (ESI)*, and ordering *lab-work, EKG, Radiology, CVT, etc.* are associated with ICU admission. Ordering medications such as *sodium, levofloxacin, vancomycin, piperacillin, and etomidate* are associated with higher ICU admission, in contrast with medications such as *ibuprofen, ketorolac, and lidocaine*.

All tested models had similar performance (e.g. predicting ICU admission at stage 3 (T3) with LR showed an Area Under the Receiver Operating Curve (AUROC) of 0.90 where RF and NB had AUROC of 0.89 and 0.86 respectively). However, LR slightly outperformed the other models in the majority of cases. Figure 1 demonstrates improvement of AUROC of the LR model from stage 1 (T1) to stage 3 (T3) on the test set. Also applying CCMapper and using its corresponding structured list of chief complaints categories not only provides insight about the general categorization of ED visit, but also improves the performance of the prediction models in all care delivery stages compared to not considering the chief complaint, or just consideration of the most frequent ones.

**Figure 1.** The AUROC of the developed progressive Logistic Regression model at each care delivery stage.

**Discussion**

The developed progressive predictive model uses the available information at each care delivery stage to predict the disposition decision. Barak-Corren et al. recently developed a binary class progressive logistic regression model to predict hospitalization in three defined timestamps in ED: within the first 10 min, within an hour and within 2 hours. We aim to predict disposition decision in three defined care delivery stages instead of time-since-arrival [due to the available EHR data may considerably vary between patients in similar time-since-arrivals].

The developed model can predict the disposition decision at earlier stage of patient ED visit with high performance. This model has potential to be adapted in ED settings in order to reduce the boarding time and eventually to improve the patient flow. Also certain patient-specific data such as clinical notes and system information data such as number of available physicians or number of patients in the ED were not considered in the current version of the model. These additional variables can improve the accuracy of the models reported above.

A Data-Driven Approach for Integrating Infant Mortality Prediction and Survival Time Estimate from Electronic Health Records

Fuchiang (Rich)Tsui, PhD1,2,3, Luge Yang, PhD1,3, Lingyun Shi, MS1, Lezhou Wu, PhD1

1Tsui Laboratory, Children’s Hospital of Philadelphia, Philadelphia, PA, USA;
2Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA, USA;
3Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, PA, USA

Abstract

We aimed to predict infant mortality and survival time from electronic health records. We collected 11 years of delivery data from one women’s hospital and birth/death certificates from a county office. We developed data-driven predictive models that provided mortality risk and survival time. Their AUCs ranged 0.88-0.94. To our knowledge, we are the pioneers merging predictive modeling and survival analysis. Our models can potentially identify moms or infants with high-risk infant mortality in practice.

Keywords: infant mortality, machine learning, survival analysis

Introduction

There is an unmet need of predictive models for identifying moms or infants with infant mortality risk. Infant mortality rates in the U.S. in general have gradually decreased from 6.84 in 2003 to 5.87 in 2016 per 1000 births1. However, the U.S. is ranked 55th for infant mortality given our highest healthcare expenditure in the world2-3. Current state-of-art approaches for infant mortality prediction leveraged available EHRs. These models’ performance measured by the area under the ROC curve (AUC) ranged from 0.62 to 0.945. Moreover, survival analysis is commonly applied in clinical trials but rarely applied to mortality prediction. Similarly, machine-learning based predictive models rarely provide individual survival time estimate.

In this study, we hypothesized that we can develop a data-driven predictive model that can predict infant mortality and survival time. The contribution of the study includes multiple predictive models with critical risk factors that impact infant mortality and survival time prediction based on the risk factors in a predictive model.

Methods

This section describes study datasets, predictive modeling, survival analysis, evaluation metrics and validation approach.

Datasets

We collected two datasets: 1) the Magee Obstetric Medical and Infant (MOMI) dataset from the UPMC Magee Women’s Hospital and 2) the death and birth certificates from the Allegheny County Department of Human Services (ADHS). The study period is between 2003 and 2013. MOMI dataset is a curated electronic health record dataset comprising 266 variables for all babies and moms during deliveries at the hospital.

Predictive modeling

We developed six machine learning methods: Naïve Bayes (NB), K2 Bayesian network (K2), Ridge regression (RR), elastic net (EN), gradient boosting machine (GBM), and random forest (RF). We developed a greedy search data-driven modeling approach from feature selection.

Survival analysis

We developed a Proportional Hazards (PH) model6, a classic method to study the relative risks of death, which is the foundation for an infant’s survival time estimate. Instead of using conventional approach of PH model building that may not be optimized for infant mortality prediction accuracy, we used the risk factors identified from our predictive model to build the PH model, \( h(t|X) = h_0(t) \exp(\beta_1 x_1 + \cdots + \beta_p x_p) \), where \( h(t|X) \) represents a PH model at time \( t \), \( X \) is a vector with \( p \) variables (features) identified from the ridge regression model, and \( h_0(t) \) is a baseline hazard function independent from the vector \( X \).

Evaluation

For predictive modeling, we used the area under the ROC curve (AUC) to evaluate predictive models’ performance. We used 10-fold cross validation to evaluate each model. For survival analysis, we used three metrics: concordance, integrated AUC (iAUC), and Kaplan–Meier weighted Brier score. Concordance measures the probability of agreement between predicted survival and observed survival7. iAUC measures AUC at time \( t \). Since infant death is a rare event, we selected Kaplan–Meier weight function6, a common function to adjust the case-control imbalance for Brier score. We used 5-fold cross validation to evaluate the PH model. We used restricted mean survival days for survival time estimate.

Results

We describes predictive models performance and survival analysis results followed by sample case outcomes.

1473
**Predictive models performance** After following data quality assessment (completeness, validity, consistency, and currency), we identified 102 variables for predictive and survival modeling. We identified 495 singleton infant deaths (infant died within one year of life) from the two linked datasets and 75,842 singleton births (controls; survived within the first year of life). Table 1 summarizes the performance evaluation for the 6 models with the number of features used in each model. Gradient boosting machine had the best prediction performance with 102 variables. Ridge regression had similar performance with only 29 variables. The 29 variables in the Ridge regression model include several categories: mom demographics, mom behavior, healthcare utilization, infant/mom diseases and symptoms.

Table 1. Predictive Model Performance. Each cell represents the performance of each algorithm measured by an area under the ROC curve (AUC) followed by a number of variables (features) in parentheses.

</tbody>
</table>

**Survival model performance** The PH model with the 29 variables identified from the Ridge regression model had 92.29% of concordance, 93.76% of iAUC, and 0.0035 of Kaplan–Meier weighted Brier score. To illustrate the integrated mortality risk prediction and survival time, we selected three sample study cases. Case 1 has risk factors including gestational age < 23.5 weeks, birth weight < 2500g, and African American mom. Case 2 has all the Case 1 risks with maternal narcotic addition. Case 3 has all Case 2 risk factors with mom’s high school or lower education.

Discussion and Limitations To our knowledge, we are the pioneers developing a predictive model that can provide both risk level and survival time as shown in Table 2. We built the survival model based on the risk factors (variables) used by a predictive model tuned for best risk prediction. Such integrated modeling not only can serve a clinical tool for clinicians and social workers to prioritize intervention and resources based on survival time but also an education tool for educating potential population in risk to better understand the impact of infant mortality given mom’s behavior. We chose Ridge model for building PH model since it only used 29 variables (instead of 102) with similar performance. The PH model demonstrated the capability of survival time estimate.

The limitations of this study include 1) the results were based on a single hospital data; 2) the MOMI dataset provides curated data at the time of delivery, which may limit the timeliness of risk estimate.

Future Work We are developing additional predictive models based on high impact symptoms/diseases identified from the Ridge model such as pre-term delivery for early prediction of mortality risk.

Conclusions In this study, we integrated machine-learning based predictive modeling with survival time estimate. We also developed six infant mortality predictive models. To our knowledge, we are pioneers in the innovative work.

Organizational Diagnostics: A Systematic Approach to Identifying Technology and Workflow Issues in Clinical Settings
Kim M. Unertl, PhD, Laurie Novak, PhD, Joyce Harris, MA, Christopher Simpson, MA, Nancy Lorenzi, PhD
Vanderbilt University Medical Center, Nashville, TN

Introduction
Healthcare organizations are under enormous pressure to improve ambulatory access, reduce expenses and optimize operational processes. Achieving peak efficiency and effectiveness is challenging, as healthcare organizations are highly complex sociotechnical systems. Making changes to optimize functionality in one area can lead to unintended negative consequences in other areas. As new health information technology (IT) comes into an organization, conflict can arise between out-of-date practices and process requirements related to new technology. An evaluation of current workflow and operational practices is critical to ensure that health IT can be smoothly integrated. However, there is limited research addressing how to rapidly diagnose organizational issues generated by the interaction between health IT and work practices in a structured manner and to identify solutions. Based on this methodology gap, the People, Organizations, and Technology Research Group at Vanderbilt University Medical Center (VUMC) developed an integrated set of assessment methods known as Systematic Iterative Organizational Diagnostics (SIOD). The purpose of this podium abstract is to report on the development of SIOD, to describe the outcomes of its initial application, and to explore how this approach can be applied in other organizations.

Design Process for Systematic Iterative Organizational Diagnostics (SIOD)
The goals of developing the SIOD method were to provide rapid diagnoses of operational issues with an emphasis on health IT and to identify evidence-based pathways for improvement. To accomplish these goals, the team developed a comprehensive diagnostic method combining social science methods with data analytics. SIOD consists of five main stages: Background Scan, Engagement Building, Data Acquisition, Data Analysis, and Reporting. The Background Scan stage focuses on collecting baseline data about the clinical environment (e.g., staffing model, patient load, throughput) and conducting open-ended key informant interviews to build rapport and identify contextual assessment goals. During the Engagement Building stage, the research group engages with the entire healthcare team by holding a series of design workshops based on concepts developed by W. Brendan Reddy to understand environmental and contextual factors. In the Data Acquisition stage, qualitative and quantitative methods are used to collect detailed data about clinic workflow, spatial design, and other contextual factors. In the Data Analysis stage, qualitative and quantitative data are initially analyzed separately, and then combined to identify gaps in the diagnostic process and to triangulate patterns across data sources. During the initial development of SIOD, qualitative data were analyzed using an iterative open-ended approach, which led to development of a codebook for application across data sets. As part of the Data Analysis stage, the team begins to identify potential improvements/solutions for issues identified in the data. These initial improvements/solutions are compiled and used in the final SIOD stage, Reporting, which involves reporting on our findings to multiple stakeholder groups. Reporting sessions provide a form of member checking, where the assessment team verifies data analysis with people from the clinical site. Major stakeholder groups include: the sponsoring organizational management representatives, clinical site leadership, and staff/providers from the clinical site. The Reporting stage serves three purposes: handing off recommendations to leaders with the experience and resources to implement change, determining which recommendations organizational and site leadership want to pursue, and sharing cross-organizational issues.

Internal VUMC SIOD Applications
As of March 2019, the POTR group has applied the SIOD approach in two ambulatory clinics and one multidisciplinary clinical center. In addition, components of the SIOD process were used during the group’s longitudinal evaluation of an organization-wide large-scale Epic implementation. Throughout all applications of the SIOD process, our team has focused on identifying what aspects of the methodology delivers the most benefits, determining areas for methodology improvement, and refining data collection instruments and data analysis process.

Over the course of applying the SIOD approach across multiple contexts, we have developed a coding schema grounded in the data, used for qualitative data analysis and integrated into presentations at the end of SIOD assessments. The schema includes five major categories, grounded in the data: Putting patients first, Reducing the chaos, Matching space to function, Technology making work harder, and Staffing is more than numbers. Putting Patients First focuses on the connections and gaps between the concept of patient-centered care and day-to-day
requirements of clinical work. **Reducing the Chaos** focuses on the concept that although adaptability and organizational resilience are strengths, rapidly changing contextual factors (e.g., new health IT features, new processes for collecting information) can lead to inefficient and confusing workflow. **Matching Space to Function** recognizes the fact that space, even in a large academic medical center, is a finite resource and that healthcare organizations need to optimize how available space is used. **Technology Making Work Harder** focuses on how technology or the implementation of technology increases difficulty in clinical work. Although health IT has potential to make clinical work easier and build connections across healthcare teams, in some cases health IT can increase workloads, disrupt work practices, and introduce communication challenges. Finally, **Staffing is More Than Numbers** focuses on the idea that staffing is not just about the number of people working in a clinical site, but rather how staff are deployed (e.g., scheduling), how staff roles are defined, and how satisfied staff are with the working environment.

For each SIOD application, we have identified multiple recommendations for improvements, which our team hands off to clinical and organizational leadership. Recommendations span a variety of topics, with some recommendations being clinic-specific and some recommendations potentially for application across the organization. Our data analysis process also identifies cascading chains of recommendations, where acting on a higher-level proposal would also resolve multiple smaller issues. Each recommendation is mapped onto a 2x2 grid with axes of implementation difficulty and potential benefit, allowing leadership to prioritize interventions aligned with available resources while maximizing benefit.

**Implications for Replication of the SIOD Process in Other Organizations**

Healthcare organizations spend millions of dollars implementing health IT systems, but without alignment to organizational requirements and integration into clinical workflow, these investments fail to deliver the intended benefits. The SIOD process connects academic biomedical informatics researchers embedded within the organization to organizational diagnostic needs. Such academic-operational integrations hold promise for future management projects that are evidence-based, data-driven, and integrated with health IT. Several key drivers of success were identified during application of SIOD to date, and are areas needed to transfer this approach to other organizations. Involvement of organizational leadership extended throughout the process, from identifying clinical sites in need of rapid diagnostics to recommendations hand-off. Identifying approaches to get everyone on the healthcare team involved in providing feedback was critical, given the holistic view of clinical functionality embedded in the SIOD process. Issues are not just related to a single role but to the full clinical ecosystem, including the health IT. The recommendation hand-off portion of the Reporting phase was especially important, as multiple clinical staff members discussed frustration with past process improvement efforts where they had provided feedback but no action was taken. Implementation of recommendations was beyond the scope of SIOD, which served primarily to diagnose issues and provide change recommendations, but we had to hand those recommendations off to people with the ability to take action. Understanding barriers to rapid assessment Conducting assessments in an organizational setting requires substantial coordination of activity and substantial time and effort from personnel. Proactively identifying assessment team members, providing training on data collection and analysis methods, and ensuring adequate resources for administrative aspects of SIOD implementation are all key components to overcoming barriers to applying SIOD to other clinical contexts.

**Conclusion**

Our team developed a rapid methodology to diagnose organizational issues generated by the interaction between health IT and work practices. After applying the SIOD approach multiple times in ambulatory clinical settings, we have identified common patterns related to technology-work mismatches, need for data-driven decisions on contextual factors such as staffing and space allocation, and gaps between the goals of patient-centered care and the requirements of day-to-day work. We are continuing to develop and apply SIOD to new clinical environments and are working to establish a toolset for use across organizations.

Expanding the Representation of Permissions and Deontic Roles in the Informed Consent Ontology (ICO)

Jonathan M. Vajda, MA1, J. Neil Otte, PhD2, Cooper Stansbury, MS3, Marcelline R. Harris, PhD3, Elizabeth Umberfield, BSN, RN3, Frank J. Manion, PhD3, Cui Tao, PhD4
1University at Buffalo (SUNY), Buffalo, NY; 2Johns Hopkins University Applied Physics Laboratory, Laurel, MD; 3University of Michigan, Ann Arbor, MI; 4University of Texas Health Science Center at Houston, Houston, TX

Introduction

The Informed Consent Ontology (ICO) is an OWL ontology that aims to represent the domain of informed consent, including the various processes involved in consent. Consent includes, for example, informing participants of the key elements of a research study and what their participation will involve, and ensuring that a patient’s participation is voluntary. The Informed Consent Ontology also represents the complex set of regulatory, legal, and policy processes involved in regulated research, and represents the permissions that may be granted to a research team and various governing bodies (including funders, institutions, and collaborating groups) as a result of the consent process, as well as the realization of those permissions in permitted actions. The specific use case driving the expansion of ICO is the sharing of biospecimens and associated data, especially in biobank repositories. This present work addresses a critical gap in representing permissions robustly, by enumerating deontic roles serviceable to different organizations across informed consent contexts, and by incorporating the Common Rule while considering use outside the United States.

ICO relies on the Basic Formal Ontology (BFO), imports the Information Artifact Ontology (IAO) and the Document Acts Ontology (D-Acts), and can extend the Ontology for Biobanking (OBIB) and the Data Use Ontology (DUO). BFO is a realist, upper-level ontology that has been successfully employed in hundreds of projects, including those ontologies of the Open-Biomedical Ontology (OBO) Foundry. Since BFO is a true formal ontology containing only high-level classes like ‘process’, ‘quality’, and ‘material entity’, it is suitable for use across domains and facilitates semantic interoperability with other ontologies that import it. The IAO is a mid-level ontology that imports BFO and represents information entities such as documents, data, and plan specifications. The D-Acts Ontology is a small mid-level ontology that imports the IAO and represents document acts (e.g. creating obligations through documents, such as a contract) and deontic roles – a role that inheres in an agent and which is externally grounded in normative expectations concerning how that agent should behave. OBIB extends the Ontology for Biomedical Investigations (OBI), and represents annotation terms relevant to biorepositories. DUO uses representations of consent codes to annotate data with usage permissions. The Common Rule Ontology (CRO), a related informed consent ontology project, represents the US Common Rule.

Methods

Developers performed a refinement and restructuring task known in the software development community as ‘refactoring’; our process involved exporting the label and definition of each resource in the existing Informed Consent Ontology into a spreadsheet and marking resources for revision and deprecation. Complex use cases—thirteen in total—were developed to assess whether classes in ICO were necessary and whether new classes were required to improve expressivity. Literature on informed consent was consulted, including regulations and best practices for obtaining patient consent and consent form creation. Blank consent forms with a diversity of presentation styles, participation descriptions, and procedure directives were annotated with ICO classes to demonstrate coverage and expressivity at different levels of granularity. Resources were marked for revision when they represented entities that were necessary but could be more appropriately labeled or defined. This often involved making classes more atomic in structure. Resources were deprecated if they fell outside the intended scope of a reference ontology for informed consent or did not adhere to BFO development principles (e.g., ill-formed genus or species terms, such as the process ‘explaining to participant about research investigation’). OWL reasoners, such as HermiT, checked for consistency throughout development. We compared the resulting resources in ICO against the thirteen use cases using diagrams expressing the complex relations involved and representation available in the ontology (e.g., a query for directives permitting research on samples from persons diagnosed with Parkinson’s disease). Collaborators from other ontologies (D-ACTS, OBIB, and DUO) provided feedback and corrections on the representation’s adequacy for use by application ontologies. CRO’s classes were deprecated, retained, or revised (often through generalizing a class), and then integrated into ICO. These updates were made with a view toward international regulatory contexts.
Findings

We expanded the representation of the most general entities in tandem with the imported ontologies. ICO originally asserted 669 classes and CRO asserted 1244; the new ICO asserts 1125 classes. Of those classes retained, 100 labels and 150 definitions were refined. We improved the representation of informed consent forms across phases of completion, and recast the relationships between documents and their parts. We elucidated how directives prescribe deontic roles, such as ‘deontic power role’ by which one may create or revoke permissions. For example, ICO: ‘description of risk’ is an IAO: ‘directive information entity’ which prescribes certain individuals and institutions to perform specific action types despite the attending risks. Likewise, a data field that directs the user to check ‘Yes’ or ‘No’ for a certain statement becomes a new directive which prescribes some action must (or must not) be taken. The class ‘stasis of regulation’ (a subclass of BFO:occurent) enables tracking whether, where, and when certain policies and directives are in force. This overcomes a limitation in OWL, since a ‘stasis’ can be used to indicate time, place, etc. The use of ICO’s class IRIs for tagging a variety of informed consent forms (research and clinical forms) showed ICO’s coverage for the core parts of the forms, including descriptions, and directives, according to expected needs of users, as elicited by domain experts.

Discussion

With the new release, we have enabled ICO to be more useful as a mid-level reference ontology, importable into an application ontology tailored to a specific research or practice area, using a BFO-based ontology-driven information system (ODIS). Permissions can be represented as an ‘information directive entity’ prescribing a ‘deontic role’. One common complaint of OWL, the most commonly used ontology language, is the lack of time indexing for when agents participate in processes. By introducing the ‘stasis of regulation’ class, we provide an important and new contribution to the BFO-aligned ecosystem. The new release provides further granularity to differentiate informed consent processes which produce a legally effective consent from those who do not. Finally, the revised ontology avoids design issues in asserting negative claims where information is simply unknown (a violation of open-world assumption).

Evaluating a Visual Annotation Tool on Pediatric Weight Charts

P.J. Van Camp, MD1,2, Lei Liu1,3, C. Monifa Mahdi2, Andrew Spooner, MD2,3, Yizhao Ni, PhD2,3, Danny T.Y. Wu, PhD, MSi1,2

1Department of Biomedical Informatics, 2Department of Pediatrics, University of Cincinnati; 3Cincinnati Children’s Hospital Medical Center, Cincinnati, Ohio

Introduction

Weight is an important, vital sign in pediatric patients and often used for correctly dosing medications. Unfortunately, around 0.5% of the weights are entered incorrectly into electronic health record (EHR). These errors can lead to potential patient harm when under- or over-dosing medications based on these weights and thus capturing them as they enter the EHR would improve patient safety.

Statistical and mathematical methods already have been developed to evaluate pediatric weight charts and find outliers but we showed in previous work their performance is limited, especially in predicting new errors. Most weight-entry errors can be detected by medical experts by simply evaluating the weight charts, but time and workflow constraints make this impractical in clinic. By gathering a large collection of annotated charts, we could use supervised machine learning techniques to capture the expert’s intuition and build models with improved weight-entry error prediction. Building a large dataset of expertly annotated weight charts would be time-consuming without specific tools. Therefore, we developed a visual annotation tool (VAT) to aid in this process and present here the preliminary results of the first formal evaluation of this application.

Methods

The VAT utilizes visual analytics principles to improve annotation efficiency and accuracy. Specifically, it presents the participant with a grid of many charts at once, after which individual charts can be selected for detailed review and annotation. The annotation process has two styles: 1) one-step: annotate immediately after selecting a chart, or 2) two-step: first select all charts of interest and in a second pass annotate the selected charts one by one. Annotation is done by simply clicking weight points that are considered entry-errors. Coloring them red or orange will flag a weight as a definite or potential entry-error, respectively.

The user-centered evaluation was conducted in a lab setting. The participants, medical students who finished at least one pediatric rotation and pediatric residents, were assigned two datasets, each to be annotated with a different combination of settings for the size of the grid (3-by-3 or 5-by-5 weight charts), and annotation style (one-step vs. two-step). The two datasets contained 225 patient charts each and were randomly selected from a previously annotated dataset of 4,000 charts containing patients between 2 and 18 years old with at least 4 data points. This dataset had been annotated by three domain experts as reported in our previous work and would serve as a reference for error detection.

After testing, participants filled out the System Usability Scale (SUS), and 6 additional, tool-specific structured questions (scoring between 1 – 5 with 5 being highest) to provide feedback. Additional verbal feedback could be provided if clarification was needed. The experiment was reviewed and approved by the Institutional Review Board at the University of Cincinnati (IRB# 2017-2075) and supported by the Mary K. Logan research award received by Dr. Wu in 2018. A test version of the VAT can be accessed at http://3.16.217.8:3838/weed_dummy/

Results

This work reports the results of the first 10 participants (5 medical students and 5 pediatric residents). Seven of the participants were male. The average time to complete the first dataset (225 charts) was 9.1 minutes (SD 2.6) and 5.1 minutes (SD 1.6) for the second (significant time-difference, p = 0.001). The median number of points annotated over both datasets (550 charts) was 21 (range 16 - 39). Based on these results, it is estimated that an expert can annotate 1,000 weight charts in 30 minutes.

Table 1 summarizes the usability evaluation. The average SUS was 83.4 (SD 9.23). Scores above 68 are generally considered above average usability. For the structured questions (SQ), 5 out of 6 had an average score above 4. Based on SQ3 (score 3.1) our VAT could be improved in speed, though it is fast enough to complete the task without major impact on the usability according to the additional user’s feedback. Additional oral feedback also confirmed that the VAT supports rapid collection of expert annotation and was easy to use.

Figure 1 shows the relationship between participants and the study experts regarding annotation of the 21 (possible) entry-errors defined by the latter. A ‘conservative agreement’ distinguishes between the two error labels (e.g. experts said ‘possible’ not the same as participant said ‘definite’), whereas ‘liberal agreement’ just looks if either error-label has been assigned. ‘Reference agreement’ compares how many participants agreed with the team’s experts, while ‘equal agreement’ looks at the most assigned label among all (participants and experts together, no comparing).

Figure 1. Agreement on annotated points (errors)

Discussion

An unexpected observation looking at figure 1 is that the wisdom of the crowd seems to be more powerful than an annotation by a select group of experts. For example, a 30kg increase in 3 days would be an obvious outlier and would likely be annotated as ‘definite error’ by anyone, expert or not. In contrast, a weight difference of 2.1kg in a five-day period could simply be missed by some annotators (both experts and participants) while others would judge that this could be medically explained and yet others would say it’s likely an error looking at the rest of the chart. In this case, the level of expertise in annotating is less important, given even experts could differ in opinion (as they did). By considering instead the number of participants out of the total that flagged this point, we can get some sort of confidence score (i.e. the more agree, the higher the confidence in the error) which can be very useful in later machine learning to assign a weight to each data-point instead of just the a label (e.g. A = error weight 100% (13/13), B = error weight 38% (5/13)).

In summary, we conducted a formal evaluation of a visual annotation tool (VAT) for weight chart annotation and showed it is easy to use and can support rapid collection of expert-annotated data. Analysis of the agreement between the participants and what was considered the reference highlighted the complexity of annotating weight errors and the necessity to utilize the wisdom of the crowd to identify potential weight errors considering their clinical importance. Once validated, our VAT can be used to annotate time-series data in other domains. Future work involves completing the analysis of evaluation data and revising the VAT to improve its efficiency and generalizability on other time series datasets.

Patients’ Perceptions of Heart Failure Through the Lens of Standardized Nursing Terminologies

Haleh Vatani, MS, Sabita Acharya, PhD, Andrew D. Boyd, MD, Barbara Di Eugenio, PhD, Richard Cameron, PhD, Pamela Martyn-Nemeth, PhD, Debaleena Chattopadhyay, PhD, Pantea Habibi, BS, Carolyn Dickens, PhD, Amer Ardati, MD, & Karen Dunn Lopez, PhD
University of Illinois at Chicago, Chicago IL USA

Introduction

Effective communication between physicians, nurses, and patients is vital for patients to understand and engage in their self-care following hospitalizations. However, the use of different terminologies between physicians, nurses, and patients during hospitalizations can present a barrier to patients’ comprehension of health information. Our previous studies have shown only 21% of nursing concepts is used by physicians indicating lack of a common vocabulary between the two professions. Beyond the terminologies used by physicians and nurses when speaking to patients during hospitalizations, post hospitalization discharge summaries that inform patients of their self-care instructions often contain these terms that many patients find confusing. Although patients may be familiar with some of the physicians’ terms, research has demonstrated that patients make multiple types of errors when interpreting medical documents. Information on patients’ use and understanding of nursing terminology is limited. Although it is possible that patients are more familiar with terms used in nursing care documentation, there is a gap in knowledge of how often patients use terms that are synonymous with nursing care terms. These issues are particularly important for patients with heart failure (HF) because over 50% of HF patients do not have the required knowledge to understand their discharge instructions in order to take care of themselves at home. This lack of understanding is a contributing factor that makes HF one of the most common causes of hospital readmission within 30 days after discharge. The purpose of this study was to identify how often hospitalized patients with heart failure (HF) use terms that can be mapped to nursing terminologies, or their synonyms, when they describe their experiences with HF and health concerns.

Methods

As part of our larger research study (R01 CA225446-01), we conducted semi structured interviews with 21 patients (15 to 60 minutes, average 35 minutes) diagnosed with HF prior to their discharge from hospital. The research was approved by the IRB, participation was voluntary, and informed consent was obtained. The interviews, conducted by an expert in sociolinguistics, followed a narrative approach focusing on patient’s perceptions, feelings, and experiences of their disease. Interviews were audio-recorded and transcribed. Transcripts were preprocessed to remove sections where patients introduced themselves and answered general questions as well as the interviewers’ questions and responses. Then, the Clinical Text Analysis and Knowledge Extraction System (cTAKES) was used to process the remaining parts of the transcripts. cTAKES is a natural language processing system that turns health-related data extracted from unstructured text into structured data by mapping written words (e.g., “RA”) to medical concepts (e.g., “rheumatoid arthritis”) based on standardized medical ontologies. cTAKES mapped the health-related terms patients used with the Unified Medical Language System (UMLS) ontology to extract the Concept Unique Identifiers (CUIs). UMLS is a comprehensive list of clinical concepts and terms from various controlled vocabularies that provides a mapping structure among vocabularies and enables linking the terms from various terminology systems.

Second, we counted how many times a CUI from the UMLS 2018 files occurred in our patient interviews. From the UMLS 2018 mappings of Nursing Diagnosis: Definitions and Classification (NANDA-I), Nursing Interventions Classification (NIC), and Nursing Outcomes Classification (NOC) structured terminologies, nurse related CUIs were identified. If the same CUI belonged to more than one terminology (e.g., C0043144 is both NANDA-I and NOC), we credited both terminologies due to the overlap. To be most inclusive of patients’ use of terms, we included health-related terms (CUIs) that were negated (e.g. “no chest pain” or “no weight gain”).

Results

Our sample included 62% females (13) and 38% males (8) with an age range of 28 to 83 years old (AVG: 56; SD: 12.45) from three different ethnicity including 1) African American (86%, 18), Hispanic/Latino (10%, 2), and Pilipino (5%, 1). From the 21 interview transcripts, we identified a total of 2516 health-related terms (CUIs), 749 of
which mapped to the standardized 3 nursing terminologies. Theses 749 nursing terms were classified as 45% NANDA-I, 2% NIC, and 53% NOC. On average patients used 120 (SD: 61.82) health-related terms (CUIs) per interview with an average of 36 terms that mapped to nursing terminologies or their synonyms (SD: 19.31). Their use ranged from 19% to 67% per patient (AVG: 31.56%; SD: 0.11).

Figure 1. Percentage of health-related terms used by patients.  
Figure 2. Percentage of nursing terms used by patients.

Discussion
We found that nearly one-third of the health-related terms used by patients mapped to nursing terms or their synonyms for diagnosis, interventions, and outcomes. The vast majority of the terms were either diagnosis or outcomes with very little use of nursing interventions terms. This is not surprising given that patients may not be focused or aware of the many interventions that nurses perform during their hospitalization. However, patients’ understanding of the interventions performed by nurses (e.g. fluid management) in the hospital that will be shifted to the patient post hospitalization is vital to effective self-care. The high frequency of nursing terms or their synonyms in patient narratives and lack of nursing care documentation in Electronic Health Records (EHR) suggest an urgent need for incorporating interoperable nursing care information in patients’ longitudinal record to avoid any potential for gaps in care or communication. Our future work will examine patient use of physician terms or their synonyms in patient narratives. However, if nursing terms are commonly used, using these terms to frame patient discharge instructions may be an effective way to improve the effectiveness of discharge instructions.

Conclusion
Patients are using nursing terms or their synonyms to describe their health. As national efforts to engage patients in their EHR, these terms must be in the patients’ longitudinal record to increase patients’ comprehension about their health and empower their involvement in self-care.

Introduction
An essential prelude to precision medicine is the stratification of patients into subpopulations for increased diagnostic and treatment efficacy. By efficiently matching patients to the right care management programs, improved outcomes can be obtained at lesser costs and in shorter time. However, electronic health records (EHR) functionality to assist clinical decision-making is restricted due to bias in health records and the difficulty in synthesizing meaningful concepts from the records. To address these challenges, we have developed and implemented a process at Partners healthcare to stratify patients for initiating clinical workflows, as described in this presentation.

Methods
We implemented a data-driven computer-based process to facilitate initiation of clinical interventions in the domain of cardiovascular medicine. 1 The process was iteratively implemented in eight cycles over a one-year period. In each run of the process, a list of patients that are eligible for the intervention, was generated by querying EHR data. This list was manually screened for validated by ancillary clinical staff by performing an in-depth-chart review to categorize patients as truly eligible and ineligible. They initiated therapy for the validated eligible patients and provided feedback regarding ineligible patients. The objective of the overall process was to identify the entire segment/strata of patients in the hospital population that are eligible for the clinical intervention, while minimizing the manual effort of the clinical staff to perform chart review. The process was iteratively developed by addressing issues identified in each run, and the final version of the process is described below.

Results
The patient stratification process consists roughly of the following steps: i) create a data store limited to variables required for computing the clinical concepts, ii) query the datastore to identify segments of the patient population that most eligible for the intervention, iii) manual validation to identify errors in the query results and improve the algorithm to derive variables, and iv) update the datastore to execute the improved algorithms. Figure 1 shows the detailed steps, as described below.

Create concept ontology: The concepts needed for clinical decision making are listed in an ontology as shown in Table 1, along with the data-points in the EHR needed to compute the
variables. For instance, the criteria ‘low ejection fraction’, is a concept required for initiating therapy, which depends on extraction of ejection fraction from cardiology notes.

**Single Data store:** The EHR data for computing the ontology is imported into a single datastore. For instance the patients who have been previously screened are stored external to the EHR, similar to notes and there is often a dedicated death index database. Assimilating all the data into a single store is essential for querying the dataset.

**Derived variables:** All the clinical concepts needed for decision making at the point-of-care are not readily available in the EHR data, and they are derived from the raw data. For instance, body mass index (BMI) is computed from weight and height using the BMI formula. Similarly, we found that echocardiograms can be segregated from cardiology notes by searching for 37 of possible 629 metadata codes. The concept of ‘is the Ejection fraction low’ is derived by checking if the ejection fraction is less than 40%. The ejection fraction is itself determined by running a complex regular expression parser on an echocardiogram note, which depends on accurately detecting echocardiograms from the cardiology notes. Consequently, a large number of derived variables are created from the raw EHR data, by executing logic of varying complexity.

**Query data store to generate sub-cohorts and a consort diagram:** After assimilating all the necessary information in a single store, the queries for the eligibility criteria are now executed to generate i) sub-cohorts for manual screening/validation and ii) a consort diagram that provides a quantitative view of how the criteria segment the patient population. The latter enables the team to estimate the number of patients for enrollment. Figure 2 depicts a consort diagram that provide a high-level view of the population segments. Next, the cohort generated for screening is sorted by sorting patients in order of decreasing confidence. For instance, patients visiting the hospital in recent months are more likely to continue care at the hospital and will consent for the health intervention. Hence the last visit date can be used for sorting the patient list. Similarly, a probability score output by ML can also be used for sorting.

**Learning from manual screening results:** The clinical staff now perform an in-depth chart review for the patient strata (segment) identified to be eligible for the intervention, tagging the reasons for ineligibility, along with the particular variable that was ‘derived’ inaccurately. Analysis of the screen-out reasons tagged by the clinical staff, helps identify inaccuracies in the data and the derivation. Moreover, additional data elements are identified that can improve the detection of eligible patients. Accordingly, the concept ontology is modified, and new EHR data is pulled into data-store, and the derived variables are recomputed.

**Discussion and Future work**

Bias and noise in health records poses a challenge to derive meaningful concepts from electronic health records, often making manual screening necessary to accurately identify the patient strata that is eligible for intervention. From an intensive validation approach, we decomposed the stratification process into data processing constructs, which can be individually fine-tuned to accurately identify eligible patients. Using an iterative approach that couples data-driven patient stratification with manual validation, helped scale the clinical intervention to a wider population, while minimizing the effort for the manual chart review. We continue to refine the stratification process and are currently implementing tooling to aid the process. Use of advance phenotyping techniques including unsupervised learning and active learning can further augment the efficiency of stratification.

Dynamic Reaction Picklists for Improving Allergy Reaction Documentation

Li Qin Wang, PhD1,2, Suzanne V. Blackley, MA3, Carlos Ortega, BS1, Diane L. Seger1,3, Zfania Tom Korach, MD1,2, Kenneth H. Lai, MS4, Foster Goss, DO, MMSc5,6, Paige G Wickner, MD, MPH1,2, Kimberly G. Blumenthal, MD, MSc2,7, Li Zhou, MD, PhD1,2 1Brigham and Women’s Hospital, Boston, MA, USA; 2Harvard Medical School, Boston, MA, USA; 3Partners HealthCare, Boston, MA, USA; 4Brandeis University, Waltham, MA, USA; 5University of Colorado School of Medicine, CO, USA; 6University of Colorado Hospital, CO, USA; 7Massachusetts General Hospital, Boston, MA, USA

Introduction

Many allergies and adverse reactions need to be recorded into the electronic health record (EHR) allergy section to inform future prescribing. It is critical to obtain a complete and reliable allergy history for each patient and provide clinicians with efficient medication clinical decision support, e.g., drug-allergy alerts. However, the allergy modules in most existing EHRs have limitations in allergy and adverse reactions documentation and subsequent alerting. Although EHRs allow structured/coded entries, most current EHR allergy modules rely on commercial or local dictionaries whose adverse reaction lists often contain a limited number of reactions using a single, static pick list ordered alphabetically. Lack of a reaction terminology expressive enough to encode diverse reactions encountered in practice may lead to incomplete or free-text documentation. Recently, half of the reaction fields in the EHR were determined to be blank, and one sixth of reactions were entered as free-text. Incomplete allergy lists inhibit the triggering of necessary alerts, while inaccurate allergy entries will trigger unnecessary or inconsequential alerts. For example, any free-text entry will trigger allergy alerts with high-severity reaction regardless of its content, contributing to alert fatigue. In the present study, we investigated a dynamic reaction pick list using an enhanced reaction lexicon. With a dynamic pick list, once an allergen is entered, the reaction pick list will be populated with the most likely reactions based on that allergen. We hypothesize that the dynamic reaction pick list will allow providers to more efficiently select the correct reaction, thereby reducing the number of free-text entries.

Methods

Reaction List Development. In a previous study, we developed a comprehensive reaction value set of 787 reaction concepts using both coded and free-text entries over three decades from Partners Healthcare’s (PHS) Enterprise-wide Allergy Repository (PEAR), enhanced with adverse drug reactions data from two other institutions. The customized reaction picklist in our current EHR (Epic®) contains 49 reactions, including commonly reported reactions (e.g., rash, hives, itching) and serious reactions (e.g., anaphylaxis, Stevens-Johnsons syndrome). We merged and refined the reaction value set and the EHR picklist, resulting in 697 reactions to incorporate into the dynamic pick lists.

Allergy Entry Retrieval. We extracted all allergy entries from the inception of the PEAR database to October 8, 2018. Inactive entries and entries consist of “NO KNOWN ALLERGIES” were excluded.

Reaction Reconciliation. With our NLP tool, MTERMS, we extracted reactions from the free-text comment field in PEAR. For each allergy entry, we excluded any reactions found in free-text that were also among the coded reactions for that entry. This resulted in an updated table where each allergy entry contained all unique coded and free-text reactions associated with that allergen.

Allergen Consolidation. Our EHR contains 42,027 allergens, among which are many synonyms, brand names, or other variations. We used PHS’s mappings between allergens and medications and between medications and RxNorm ingredients to identify allergens with same substance(s) but different names, which we then merged into one allergen. All allergens at the drug class level (e.g., penicillins) were excluded from consolidation. We then generated an allergen and reaction co-occurrence table using the reconciled reactions and consolidated allergen list for developing dynamic reaction pick list.

Developing Dynamic Reaction Pick Lists. Based on the allergen-reaction entries, we developed dynamic reaction pick lists. We explored three approaches to rank reaction concepts with respect to a given allergen substance: support, lift (interest), and derived term frequency inverse document frequency (i.e., tfidf'). Figure 1 shows the formulations of the three measures we used to develop the dynamic reaction pick list.

\[
\begin{align*}
(1) \quad \text{support}(x, y) &= P(x,y) \\
(2) \quad \text{lift}(x,y) &= \frac{P(x,y)}{P(x)P(y)} \\
(3) \quad \text{tfidf}'(x, y) &= \frac{f_{x,y}}{1 + \sum_{i \neq x} f_{i,y}} \cdot \log \left( \frac{N}{1 + n_y} \right)
\end{align*}
\]

Figure 1. Formulations of three measures of strength of associations between allergens and reactions

1485
dynamic pick lists, where \( x \) is a reaction, \( y \) is an allergen, \( P(x) \), \( P(y) \), \( P(x,y) \) are the proportions of allergy entries with \( x \) reaction, \( y \) allergen and co-occurring \( x \) and \( y \), respectively, \( f_{x,y} \) is the frequency with which \( x \) and \( y \) co-occurred in the database, \( \sum_{x \in X} f_{x,y} \) is the total number of allergy entries with \( y \) allergen, \( N \) is the total number of allergens, and \( n_x \) is the number of allergens that co-occurred with reaction \( x \).

**Results**

We obtained 3,310,432 active allergy entries. After reaction reconciliation and allergen consolidation, those allergy entries included 2,500,055 allergy-reaction pairs. We generated dynamic pick lists for 9,992 allergens included in at least one allergy entry. Table 1 provides two example drug allergens, amoxicillin and ibuprofen, with their top 10 reactions ranked by support, lift, and tf-idf'.

N/V: Nausea and/or Vomiting; TR: Transfusion reaction due to serum protein reaction; SOB: Shortness of Breath; Rash W/ Joint Pain: Rash with Joint Pains (Serum Sickness); GI: Gastrointestinal; BSUS: Bleeding stress ulcer of stomach; DRF: Decreased renal function; VWD: von Willebrand disorder.

**Discussion**

The three approaches ranked reactions differently. Support tended to rank frequently occurring reactions more highly, while lift gave a higher rank to reactions specific to the allergen in question. The reactions picked by tf-idf' and support were overall similar, but tf-idf' tended to put a lower weight on common reactions. For example, in the dynamic pick list ranked by tf-idf', the reaction itching more frequently co-occurred with allergen amoxicillin compared to the reaction diarrhea but was ranked lower as it was associated with more of other allergens. Further investigation is required to evaluate the impact of dynamic reaction pick lists on allergy module free-text allergy entries, clinical workflow, and user satisfaction, which can further inform which ranking mechanism is optimal for clinical documentation of patient allergies.

Introduction

Medication information encoded in clinical notes within EHR can be critical for research on drug exposure response relationship to develop strategies to improve patient treatment. Existing medication extraction algorithms have been more general purpose, intended for extracting all medications within a piece of clinical text. A more targeted system that has the flexibility to adapt to idiosyncrasies in prescribing and writing patterns could ultimately lead to higher quality research datasets for studies including pharmacokinetic or pharmacogenomic analyses. We describe a natural language processing (NLP) algorithm developed using R called “medExtractR” to extract medication information such as strength, dose amount, and frequency from clinical notes. R is commonly used by many researchers, particularly statisticians, and at the time of submission there was no medication extraction package available. The medExtractR software is available for download as an R package from the Comprehensive R Archive Network (CRAN). We also compared medExtractR to three existing NLP systems for medication extraction: MedXN version 1.0.1, MedEx version 1.3.7, and CLAMP (Clinical Language Annotation, Modeling, and Processing) version 1.4.0.

Methods

MedExtractR was implemented using the R programming language. It relies on a combination of lexicons, rules, and regular expression patterns to identify relevant medication information. Lexicons for drug entities such as frequency were manually curated from expressions observed in training notes. The regular expressions were initially created by analyzing the contextual format of drug regimen information in manually annotated clinical notes in the training set. These were then iteratively refined to produce maximum performance on the training set. The system is designed to extract particular medications of interest, rather than all possible medications mentioned in a clinical note. Once medExtractR identifies a drug mention of interest within a note, it searches within a surrounding window for drug entities including drug name, strength, dose amount, and frequency. MedExtractR has function arguments which allow it to be customized for the drug of interest, including the size of the search window around a drug name and edit distance allowance for fuzzy matching of drug names.

We developed medExtractR on two medications, tacrolimus and lamotrigine, whose prescribing patterns ranged from simple to highly complex. We identified clinical notes for patients being treated with each drug from Vanderbilt University’s Synthetic Derivative, a de-identified database of clinical records derived from Vanderbilt’s EHR system. From these, we randomly selected sets of 60 training and 50 test notes for each drug. To create a gold standard dataset, we used manually annotated drug entities based on annotation guidelines developed using a double-annotation process. Inter-annotator agreement was assessed separately for tacrolimus and lamotrigine on a set of 20 clinical notes, each, using Cohen’s kappa. Performance was assessed using precision, recall, and F1-measure (F1). Additionally, we tested all four NLP systems on 110 clinical notes for an additional drug, allopurinol, to see how they worked on a novel drug not used in medExtractR development. In order to fairly compare medExtractR with the existing NLP systems MedXN, MedEx, and CLAMP, we manually reviewed raw output from both the existing NLP systems and medExtractR to ensure compatibility during evaluation, for example by converting semantically equivalent partial extractions to a standardized format. To evaluate uncertainty in our estimates, we computed 95% bootstrapped confidence intervals with 5,000 bootstrap replications at the note level.

Results

On 20 notes used for double annotation, the Cohen’s kappa for inter-annotator agreement for tacrolimus and lamotrigine was 0.970 and 0.837, respectively. Annotation guidelines were updated and clarified to resolve any instances of annotator disagreement prior to annotating the training and test sets. The training sets for tacrolimus and lamotrigine contained 60 notes each, with 105 and 102 drug mentions, respectively. MedExtractR achieved high precision/recall/F1 overall (macro-averaged over all drug entities combined) on the training set for both tacrolimus (.99/1.00/.99) and lamotrigine (1.00/.97/.98). The test sets for tacrolimus, lamotrigine, and allopurinol contained 50,
50, and 110 notes with 88, 76, and 191 drug mentions, respectively. Comparisons between medExtractR and MedXN, MedEx, and CLAMP were macro-averaged across each drug-entity (i.e., drug name, strength, dose amount, and frequency) pairing. MedExtractR often performed as well as or better than MedXN, MedEx, and CLAMP (Figure 1). For some entities (e.g., drug name for tacrolimus and allopurinol), medExtractR achieved lower precision than MedXN.

**Figure 1.** Entity-level comparison of medExtractR with existing medication extraction algorithms on test sets. Here, “n” refers to the number of annotations for that drug-entity combination in the gold standard dataset. Symbols and lines represent estimates and 95% bootstrapped confidence intervals, respectively. Arrows along the bottom x-axis indicate that either part or all of the confidence interval is below .80.

**Discussion**

Accurate and informative studies require high quality data, and thus the precise extraction of medication information from EHRs is a pivotal step in advancing research in the medical field. We developed medExtractR, a natural language processing system in R that performed better than three existing NLP systems (MedXN, MedEx, and CLAMP) for three different drugs, including one for which no training was performed. MedExtractR’s higher performance may be partially due to its ability to capture variations in writing patterns through customizable function arguments.

MedExtractR can be used to obtain more precise medication information that can provide quality data in diverse medication-based population studies, such as pharmacoepidemiology or pharmacogenomic studies. In order to improve medExtractR for use with other medications, we plan to implement expansions that will allow the system to extract drugs of different administration types, such as intravenous or oral solution medications. Future work will validate the system’s ability to correctly determine important clinical quantities including dose given intake and daily dose.

Using GPS to Locate the Missing and Track Wandering in People with Alzheimer’s Disease

Janusz Wojtusiak, PhD¹; Reyhaneh Mogharabnia, MS¹; U. Nalla B. Durai, MD¹;
Beverly Middle, DNP¹; Robert J. Koester³, PhD; Catherine Tompkins, PhD¹
¹George Mason University; ²Department of Veterans Affairs; ³dbS Productions LLC

Introduction

Alzheimer’s Disease (AD) and other forms of dementia constitute a large-scale public health concern with significant number of people with dementia being at risk of wandering and getting lost. These individuals may get hurt, cause distress to families and caregivers, and require costly search parties. Ubiquitous presence of IoT health technologies including health trackers, GPS devices, smartwatches and other wearables open new possibilities for improving safety and care for individuals with AD. In the presented work, we utilize GPS SmartSole by GTX Corp., one of several types of trackers available on the market, to assess feasibility of finding and predicting movement patterns¹ to aid in searching for missing people with AD and to better understand wandering. The GPS trackers work as long as they are charged and within cellular network range to send location data. This study addresses the issue of modeling movements so that a lost person can be found even if the device is not worn, not charged, or out of range.

The presented work is an extension of earlier study¹, in which we presented the possibility of predicting frequent locations for people with dementia. There are a number of other research projects related to the approach presented here, however, is unique because of its aims, scope and methodology. Some of the related works include research by Shoval et al.² to identify differences in movement patterns in people with dementia, Saltzman et al.³ that uses video-based observations to categorize wandering, further extended by Vuong et al.⁴ to implement a classification algorithm.

Our main objective is to study the application of machine learning methods to data from GPS trackers to create individualized models that describe patterns of movement, including frequent locations and local trajectories in the context of socioeconomic and AD specific information. Part of the process is construction of a decision support tool that helps to locate missing people with AD. The tool first predicts general possible area of search based on frequently visited locations. Then applies local trajectory modeling for specific patterns of movement in a given area.

Methods

Data Collection: Participants enrolled in the study are provided with GPS trackers. GPS data are extracted from the manufacturer’s information system. Caregivers are surveyed to establish baseline and resurveyed every 3 months, as well as asked to keep journals of wandering incidents. The survey questions include basic demographics, detailed information about incidents of being lost, information about caregivers, description of patient routines, detailed information about AD diagnosis, 13 questions specific to wandering, comorbidities in Charlson-Deyo categories, and medications used. Surveys are collected in Qualtrics and on paper, whichever form is preferred by caregivers.

Preprocessing: In the initial set of experiments sample data of 337 devices obtained from the GPS tracker manufacturer was analyzed. These pilot data were not linked to surveys. To date, additional data for 6 devices linked to surveys were analyzed. To protect the privacy of the individuals, we first de-identified data by randomly shifting and rotating all coordinates (such transformation still allows for spatiotemporal mining). We then converted timestamped geolocation data to weighted frequency domain as reported by Wojtusiak et al.¹. The data were then ordered by timestamp separately for each device. The first portion of the data was used for training and the 7 last days or 25% (whichever greater), was used for testing. This approach allows for simulating training and application of individualized models in realistic setting, as opposed to random data selection including cross-validation.

Spatiotemporal Clustering: We identified frequent locations using multipass version of DBSCAN (Density-Based Spatial Clustering of Applications with Noise) method, a clustering algorithm that is particularly applicable to geospatial data. In the first round, we identified top clusters with very high frequency in the data. We identified less frequent clusters in the following rounds. The multiple rounds of DBSCAN are needed because of large disproportion of weights between the most common locations and other locations, which also varies between devices. Our experiments indicate that the simple approach of 2-stage clustering procedure is typically sufficient.

Classification of Frequent Locations: Following the clustering analysis, we fitted classification models capable of predicting frequent location (given as a cluster assignment). In the first set of experiments we fitted models based on only two inputs: day of the week and time of the day. In the second set of experiments we included previous known locations coded as n-grams with n increasing from 1 to 5 and encoded duration of time spent in each cluster. Finally,
we simulated a delay between last known location and the time of prediction ranging from 1/2 to 5 hours, to model late search for a missing person.

We have tested a number of standard classification learning methods, including regularized logistic regression, random forest, naïve Bayes, deep neural networks and decision trees, as well as a baseline with Markov model. Hyperparameter tuning indicated that random forest with 100 trees achieved the best results. The model parameters were optimized in order to find tradeoff (Pareto solutions) between number of considered locations and model accuracy (AUC). Initial data preprocessing has been done in SQL and the all experimental work using Python 3 with Pandas and scikit-learn libraries.

Results

The applied spatiotemporal clustering led to stable results indicating frequent locations. The number of clusters varied from 1 to 9 between devices. Figure 1 illustrates identified frequent locations (marked in colors) for an example device. Points not belonging to any clusters (noise) are marked in black.

The obtained prediction results vary between devices. The performance of the method depends on specific individual being followed. In the first approach, for some individuals, based just on day of week and time the method is able to correctly predict 100% of outside home locations, indicating a very regular lifestyle. For others, the accuracy can be as low as 0%, indicating irregular lifestyle (frequent locations do not repeat over time).

The highest average prediction accuracy is achieved when using 2-grams previous known locations as inputs to the model. The average AUC is 0.774 +/- 0.214, accuracy 0.634 +/- 0.285, precision 0.669 +/-0.258, and recall 0.608 +/- 0.248 indicating moderate overall ability to predict locations. When considering delay in the search efforts, the AUC slowly drops to the value 0.724 when predicting with delay up to 5 hours. Slightly higher accuracies are obtained in devices with fewer frequent locations, but the number of clusters only partially explains variation in accuracy. Instead, low accuracies for certain devices are explained by very short time periods in which data were recorded.

Discussion

The presented results indicate the possibility of predicting locations of people with dementia using individualized models can contribute to search & rescue efforts when a person is missing. The presented research represents one step in larger project that aims at detecting and predicting wandering patterns. The models are being learned and applied in an adaptive decision support tool that learns movement patterns until certain accuracy is achieved. Our current efforts include using map data to probabilistically approximate likely trajectories from unequally spaced in time and distance GPS data reported by tracker devices.

Predicting Length of ICU Stay via Random Forest

Jingyi Wu, MS1,2,3, Ke Lin, MS1,2,3, Yu Lin, MS1,2,3, Yonghua Hu, PhD1,4, Guilan Kong, PhD2,3*
1Department of Epidemiology and Biostatistics, School of Public Health, Peking University, Beijing, China; 2National Institute of Health Data Science, Peking University, Beijing, China; 3Center for Data Science in Health and Medicine, Peking University, Beijing, China; 4Medical Informatics Center, Peking University, Beijing, China. *Corresponding email address: Guilan.kong@hsc.pku.edu.cn

BACKGROUND: The intensive care unit (ICU) provides advanced and resource-intensive treatment for the sickest hospitalized patients. The medical resources in ICU are usually in shortage compared to demands of ICU patients. Length of stay in ICU (LOS-ICU) is a key indicator for assessing efficiency of inpatient management. Prediction of LOS-ICU helps clinicians risk-stratify patients and allocate medical resources optimally. Although some studies have developed models to predict LOS-ICU, most of them are based on traditional methods such as logistic regression, and sample sizes are also limited in most studies.

METHODS: We used medical information mart for intensive care (MIMIC) III database1 for model development and validation. MIMIC-III contains medical records of 38,597 distinct adult patients admitted to critical care units between 2001 and 2012. In this study, we constructed three models: customized simplified acute physiology score (SAPS-II) model, classification and regression trees (CART) model, and random forest (RF) model for LOS-ICU prediction. The primary outcome was prolonged LOS-ICU (pLOS-ICU), defined as longer than the third quartile of patients’ LOS-ICU in the studied dataset2. Originally, the SAPS-II model is a tool used in ICU to assess the severity of illness for critically ill patients. There are a total of 17 variables used in the SAPS-II scoring system, consisting of age, type of admission, three types of chronic diseases, and 12 routine physiological measurements during the first 24 hours in ICU. Recently, some studies3,4 have customized the SAPS-II model for LOS-ICU prediction. The idea of building a SAPS-II based LOS-ICU prediction model is inspired by those studies. To compare performance of the three models objectively, all variables used in the customized SAPS-II model were used to construct the CART and RF models. Patients with variable missing rate larger than 30% were excluded. For those patients with more than one ICU admission during one hospitalization, we randomly selected one ICU admission record for each patient. Patients died within ICU were also excluded, as the LOS-ICU pattern of those patients who died within ICU may not be consistent with those patients who survived in ICU. The technique of Synthetic Minority Over-Sampling Technique (SMOTE) is a resampling approach to deal with imbalanced data. We used SMOTE to solve the problem of data imbalance in this study. We adopted 5-fold cross validation to evaluate prediction performance of the three models. The area under the receiver operation characteristic curve (AUROC), accuracy, sensitivity, specificity, Kappa value, positive predictive value (PPV), and geometric mean (Gm) were used as performance measures. Performance of the three models developed using raw dataset and the SMOTE processed dataset was compared. Performance differences between different models were assessed using two-sided t test.

RESULTS: After excluding 353 patients with variable missing rate >= 30% and 5160 patients died within ICU, a total of 39,162 ICU patients were included in the final cohort in this study. The observed average LOS-ICU was 3.8 +/- 5.7 days, with 23.6% proportion of pLOS-ICU. The proportion of male patients is 57.4%, and the average age of all patients is 61.8 +/- 16.6 years old. The prediction performance results, including the AUROC, accuracy, sensitivity, specificity, Kappa value, PPV, and Gm of the three models are compared in Table 1. Among the three models, the RF model achieved the most discriminative power with the highest AUROC (0.911), the highest accuracy (83.5%) and the highest Kappa value (0.670). The RF model also achieved the highest sensitivity (83.5%) and it outperformed the other two models in terms of the balanced accuracy Gm (83.3%), but the customized SAPS-II model achieved the highest specificity (98.1%). On the whole, the RF model had the best prediction performance taking into consideration of all performance measures. And we considered the CART model as the second best as CART yielded the second highest AUROC (0.808), the second highest accuracy (77.6%), and the second highest Kappa value (0.551). Table 2 shows the prediction performance of both the RF and CART models developed using the raw dataset and the SMOTE-processed dataset respectively. Models developed from SMOTE-processed dataset all performed better than those without SMOTE processing with statistical significance (P<0.001), especially in terms of balanced accuracy (Gm).

DISSCUSSION: Three models for LOS-ICU prediction were developed in this study. LOS-ICU prediction models based on the RF and CART outperformed the customized SAPS-II model, which is based on logistic regression algorithm. Using SMOTE method to deal with data imbalance made a substantial improvement of overall performance for the RF and CART models. SMOTE creates synthetic minority class examples based on the similarity on feature space, and can thus improve prediction performance of the derived models significantly. RF model showed the best...
discriminative power among the three models. Compared with the customized SAPS-II model, the RF and CART models were better at dealing with collinear data and therefore could achieve better predictive performance. Unlike CART model, RF model is an ensemble learning method. RF trains a multitude of decision trees independently and each tree is built using a bootstrap sample of the dataset. The output of the RF model depends on the voting result of all trees. Among the multiple trees, each one tries to model the relationship between the output and the covariates, and the RF model aggregates predictions of all trees to achieve a superior and more stable performance. The study results showed that RF based LOS-ICU prediction model had the best prediction performance among the three models based on the MIMIC-III dataset. Moreover, we confirmed the validity of using SMOTE to deal with data imbalance in prediction model development. However, this study has its limitations. First, the MIMIC-III database contains only patient data between 2001 and 2012, and has no data after. Second, selection bias may exist as we excluded those patients who died in ICU. Thus, the LOS-ICU prediction model developed in our study may not apply to those patients who will die in ICU. This study lays a foundation for future application of RF-based LOS-ICU prediction model in ICU clinical practice. It may help physicians make appropriate clinical interventions and do optimal medical resources allocation in ICU. However, further validation of its clinical effect is needed.

Combining Publicly-Available and Electronic Health Record Data to Reposition Drugs

Patrick Wu, BS¹; QiPing Feng, PhD²; Joshua C. Denny, MD, MS¹,³; Wei-Qi Wei, MD, PhD¹
¹Department of Biomedical Informatics, ²Division of Clinical Pharmacology, ³Department of Medicine, Vanderbilt University Medical Center, Nashville, TN 37232

Introduction
Repositioning of 'old' drugs to treat diseases is an attractive biomedical research topic, since it may substantially accelerate drug development by reusing compounds whose safety has been thoroughly examined in clinical trials.¹ We proposed to combine publicly-available results from genome-wide association studies (GWAS) and gene expression databases to find drugs that could potentially be repositioned to treat a new disease, followed by a validation analysis in the electronic health record (EHR). In this study, we demonstrated the feasibility of this approach to reposition drugs for hyperlipidemia. We found that lisinopril had an unexpectedly significant clinical effect on decreasing low-density lipoprotein (LDL) plasma levels. To our knowledge, this is one of the first studies to combine these unique publicly-available resources, contemporary computational tools, and EHR data for discovering drug repositioning candidates.

Methods
To impute hyperlipidemia gene expression signatures, we applied S-PrediXcan² on regression coefficients generated from a GWAS on LDL levels.³ We uploaded the top fifty (ranked by z-scores) up- and down-regulated genes to the integrated Library of Integrated Network-Based Cellular Signatures (iLINCS) platform.⁴ Pearson correlation coefficients were used to measure the similarity between the imputed transcriptome with the drug-induced expression patterns in the DrugMatrix library.⁵ We downloaded a list of drugs that generated only a reverse expression pattern from ≤ 1 incubation day.

This study’s objectives were to replicate known lipid-modifying drugs and validate a drug repositioning candidate in the EHR. To accomplish these aims, we removed the drugs not contained in the MEDication INDication high-precision subset (MEDI-HPS) database.⁶ Including only MEDI-HPS drugs allowed us to identify medications indicated for lipid disorders. From among the candidates, we manually curated drugs prescribed for treating hypertension, a common disease that provided us with a large starting patient cohort and adequate statistical power to detect differences in a drug’s effect on decreasing plasma LDL cholesterol levels.

To measure the target drug’s clinical effect on LDL levels, we used the Synthetic Derivative (SD), the de-identified EHR at Vanderbilt University Medical Center (VUMC). We identified adult patients who had ≥1 LDL measurement before and after they started the target drug (t₀), and had the drug listed on their EHR on ≥ 2 separate occasions. To prevent confounding by drugs known to alter significantly lipid levels, we removed patients under lipid-modifying therapy (e.g. statins, fibrates, and PCSK9 inhibitors). Since two drugs that we chose for validation were indicated for hypertension, we also removed patients taking other blood-pressure lowering drugs (e.g. calcium channel blockers, angiotensin II receptor blockers, ACE inhibitors, thiazide diuretics, and beta-blockers). For example, for the simvastatin group, we removed patients who had blood-pressure lowering drugs in their EHR and lipid-modifying medications (besides simvastatin) listed in their EHR. We then extracted the most recent LDL measurement before t₀ and all the LDL measurements when the patients were exposed to the drug, defined as being the period between t₀ and the last time that the drug was listed in their medical record.

We removed patients who had baseline LDL measurements <100 mg/dL. We then matched patients on age (± 3 years), LDL measurement before t₀ (± 5 mg/dL), sex, and race. For these patients we calculated change in LDL as the difference between their baseline LDL and the median LDL measurements after t₀. We employed permutation testing⁷ to compare the median LDL changes between the lisinopril cohort and two control groups. For the negative control comparison, our null hypothesis was that lisinopril cohort would have an LDL change that was equal to or less than the hydrochlorothiazide (HCTZ) group. For the positive control comparison, our null hypothesis was that the lisinopril cohort would have an LDL change that was more than the simvastatin cohort.

Results
Of the 308 drug repositioning hits, 71 (23.05%) had only reverse expression profiles with ≤ 1 day of incubation and
were contained in the MEDI-HPS database. From the 71, we identified four drugs that were FDA-approved for treating hyperlipidemia: fenofibrate, atorvastatin, lovastatin, and simvastatin. For the study’s second objective, we identified blood-pressure lowering compounds (captopril and quinapril) as potential candidates to validate in the EHR, as hypertension is a common disease and would thus provide a large patient cohort that would allow us to conduct a validation study using EHR data.

We chose lisinopril to validate this study’s approach in the EHR. Since lisinopril was not tested in the DrugMatrix database, we did not expect to see it appear as a repositioning candidate; however, it was the most commonly prescribed ‘ACE inhibitor’, to which captopril and quinapril also belong, in the SD. We chose HCTZ and simvastatin as negative and positive controls, respectively. Like lisinopril, HCTZ is a first-line blood-pressure lowering medication and was chosen as a comparator because its expression signature did not have a significant association with the imputed transcriptome. On the contrary, we selected simvastatin as the positive control comparator, as it lowers LDL and had a reverse expression pattern in DrugMatrix. In our comparison of the clinical effects of the three drugs on lowering plasma LDL cholesterol, we observed a statistically significant difference in LDL changes between the lisinopril with HCTZ (median LDL change = -5.5 mg/dL vs. 0 mg/dL; p < 0.05) and simvastatin cohorts (median LDL change = -5.5 mg/dL vs. -30.0 mg/dL; p<0.001) (Figure 1).

**Figure 1.** LDL changes for HCTZ, Lisinopril, and Simvastatin cohorts.

**Discussion**

In this study, we combined publicly-available databases, contemporary statistical tools, and EHR data to find and validate drug repositioning candidates for hyperlipidemia. A previous study used a similar approach to identify drug repositioning candidates for a number of brain-related disorders. We show that their pipeline can be replicated for non-psychiatric and neurological diseases and present a framework for validating these hits in the EHR.

Prevalence and Predictability of Low Yield Inpatient Laboratory Diagnostic Tests

Song Xu, PhD,1 Jason Hom, MD,2 Santhosh Balasubramanian,1 Lee Schroeder, MD, PhD,3 Nader Najafi, MD,4 Shivaal Roy,5 Jonathan H. Chen, MD, PhD1,2

1Center for Biomedical Informatics Research, Department of Medicine, Stanford University, Stanford, CA; 2Division of Hospital Medicine, Department of Medicine, Stanford University, Stanford, CA; 3Department of Pathology, University of Michigan, School of Medicine, Ann Arbor, MI; 4Department of Medicine, University of California at San Francisco, San Francisco, CA; 5Department of Computer Science, Stanford University, Stanford, CA

Introduction

Lab testing is an important target for high value care initiatives, constituting the highest volume medical activity. It was estimated that up to half of all inpatient labs may be medically unnecessary1, but there is no systematic method to identify these in individual cases. Prior studies used machine learning to infer results of specific laboratory tests, such as ferritin2 and gamma-glutamyl transferase3, given results from other tests simultaneously available. Our initial investigation illustrated the predictability of machine learning methods on four laboratory tests at Stanford hospital4. In this work, we aim to identify low yield inpatient diagnostic lab testing based on more advanced machine learning methods that can make individualized estimates of likelihood on more than 90 high volume laboratory tests in a systematic and scalable way, validated on more recent data across datasets from multiple hospitals.

Methods

![Figure 1. Data processing, machine learning, and statistical analysis pipeline. Label “0” denotes the laboratory test actually generates a normal/negative result while “1” means the result is abnormal/positive. NPV: negative predictive value, PPV: positive predictive value, ROC: receiver operating characteristic.](image)

Data sources include structured electronic medical records from 110,000 inpatients at Stanford University Hospital in 2008-2017, 40,000 inpatients at University of Michigan (UMich) in 2015-2018, and 17,000 inpatient encounters at University of California at San Francisco (UCSF) in 2018. For each lab test, we randomly sampled 10,000 orders and separated them into training (development) and held-out test (validation) sets with a 75:25 split by patients IDs. We extracted over 800 features from both sets that are available at the time of the order entry, including patient demographics, most recent tests, Charlson comorbidity categories, common laboratory results, specialty teams treating the patient, and recent vital signs. Specialty team and vital sign data were not accessible in the UMich dataset, but predictions were still possible with other available contextual data. Counts of orders and comorbidities were binned into different time windows (last day, last week, last month, etc.). Numeric results of laboratory tests from last two weeks and vitals from last three days were summarized into various statistics (mean, max, most recent, etc.). We developed multivariable prediction models using various machine learning algorithms (Figure 1) and...
evaluated their performances in predicting the likelihood of a lab test order to yield a normal/negative result (defined by internal laboratory reference ranges). This likelihood score was then translated into a normal/abnormal final prediction by comparing against a decision threshold that was obtained by targeting at 95% negative predictive value in the training data. Statistical metrics including area under the receiver operating characteristic curve (AUROC = C-statistic), negative predictive value (NPV), positive predictive value (PPV), sensitivity, and specificity were then calculated. We further evaluated the performance of models trained at one site but tested at another.

Results

The fraction of common inpatient laboratory tests that are repeated orders within 24 hours is plotted in Figure 2a. We evaluated the predictability of 76 high volume non-panel (standalone) labs and 15 common lab components (from “broad panels” such as Complete Blood Count and Metabolic Panel) at Stanford on whether they yielded a normal result. The best performing machine learning models generate >0.9 C-statistic for large volume standalone tests such as Troponin I, Lactate Dehydrogenase Total, and Sodium (Figure 2b) and common test components such as Hemoglobin, Platelet Count, Urea Nitrogen, Creatinine, Albumin, Total Protein, and Alkaline Phosphatase. For UCSF and UMich datasets, locally trained models outperformed models remotely trained at Stanford, but can still retain significant discriminatory power (C-statistic >0.85 for common test components).

Discussion

Low yield diagnostic testing is common and can be systematically identified through data-driven methods and patient-context-aware predictions. Our work is the first to do so by connecting advanced machine learning techniques to massive patient data, validated on a wide range of laboratory tests and across multiple hospitals. The method can be applied when highly predictable normal result is considered uninformative, including optimizing guideline and protocol-based testing and implementing precise best practice alerts in clinical decision support.

Computerized Conjoint Analysis of the Preferences of Patients with Serious Mental Illness

Alexander S. Young, MD MSHS1, Amy N. Cohen, PhD1, Nichole Goodsmith, MD1, Alison B. Hamilton, PhD1, Gerhard Hellemann, PhD1, Nancy Nowlin-Finch, MD1,2

1UCLA Department of Psychiatry and Biobehavioral Sciences, Los Angeles, CA, USA; 2Los Angeles County Department of Mental Health, Los Angeles, CA, USA

Abstract

Healthcare often involves choices among alternative treatments, considering patient preferences. It is not known whether automated assessment of preferences can be valid in patients with serious mental illness. We assessed preferences using a novel kiosk system tailored for patients with serious mental illness and conducted computerized conjoint analysis. This was implemented with 35 patients with schizophrenia at a public clinic. Computerized conjoint analysis produced valid assessments. The relationship between preferences and subsequent service use was complex.

Introduction

It is important that patients with common, serious mental illnesses such as schizophrenia have access to treatments that meet their preferences, and make informed choices among alternative treatments. Often, preferences are not elicited from patients and used to guide which treatments are implemented. Obesity is very common in serious mental illness and a cause of premature mortality. This population often takes medications that can cause substantial weight gain. People with serious mental illness die many years prematurely, mostly due to cardiovascular illness and cancer. In treatment guidelines for serious mental illnesses, there are multiple, different psychosocial treatments that result in reduced weight. None is widely used. If patient preferences were routinely assessed, clinicians and managers could know when to make alternative treatments available and for which patients. This project implemented and studied an innovative method for routine, automated assessment of treatment preferences. Marketing research has shown that choice-based methods of eliciting preferences, such as conjoint analysis, better predict revealed preferences, compared to direct questioning. However, people with serious mental illness usually have substantial cognitive deficits, can have limited literacy, and have somewhat less computer experience than the general population. The feasibility and validity of conjoint analysis in patients with serious mental illness (SMI) is unclear.1, 2

Methods

We developed computerized conjoint analysis for people with schizophrenia and implemented it at a public mental health clinic. Synthesizing the literature, interviews, and focus groups with 35 individuals with SMI, four key dimensions of weight services were identified: location (community or clinic); delivery mode (internet or in person); leader (clinician or layperson); and training mode (individual or group). A visual interface detailing choice options for these attributes was developed and presented to a focus group of 4 individuals with SMI. Enhancements were made and the design finalized. An additional 34 overweight, SMI-diagnosed patients at a community mental health clinic completed a computerized conjoint analysis session with the developed interface, and were administered the Computer System Usability Questionnaire (CSUQ) to assess user satisfaction and usability of computer systems (1-7 scale, lower indicates greater usability); the CSQ to assess satisfaction with services (1-4 scale, higher is more satisfied); and a qualitative interview about the conjoint session. They then were referred to a weekly weight management group at the clinic that was led by a clinician. After 3 months, patients were again administered the CSQ and completed a qualitative interview that explored their preferences for services as they related to the weight management groups.

CSUQ data were compared to established norms. Content analysis was performed on the qualitative data. We studied the validity of computerized conjoint preference assessment and whether the elicited treatment preferences predicted use of weight services. A multilevel logit model estimated both aggregate and individual level preference parameters from the partial preference data. The aggregate preference parameters show the overall weights that each specific feature of the intervention has in the logistic model predicting the choice between two interventions. The multilevel analysis framework also allows the estimation of the parameters of each individual participant’s logistic regression predicting their choice between any two interventions with known features. Using the individual participant’s preference models, we estimated their likelihood of choosing an intervention with the features of the provided in-
person weight management group compared to a neutral reference intervention with no features. Using this likelihood, we studied how closely the intervention that was provided matched their ideal intervention, and we report this as a treatment preference score.

Results
The average body mass index of participants was 35 (SD=5.1). Usability of the computer system was rated as excellent, with a mean overall usability rating of 2.01 (SD=0.99, scale mean: 2.82), system quality 2.04 (SD=1.04, scale mean: 2.8), information quality 2.12, (SD=1.17, scale mean: 3.02), and interface quality 1.9 (SD=1.11, scale mean: 2.49). Most participants praised the system for its ease of use, highlighting its visual aids, audio guidance, and touchscreen interface. However, many found its repetition of response options confusing or monotonous. Early feedback regarding the conjoint analysis system was used to simplify the system by reducing the number of characteristics per page, and to clarify administration by increasing indicators of the separation between pages. Seventeen participants utilized the weight management group, attending an average of 8.6 group sessions during the study period (SD = 8). Satisfaction with services on the CSQ averaged 3.5 (SD=0.6) at baseline, and 3.5 (SD=0.4) at follow-up. This is mid-way between good and excellent, and was unchanged over time.

Group-wide preferences had significant contributions from location (p<.001, favoring clinic), leader (p=.018, favoring clinician) and training (p<.001, favoring group), but not delivery mode (p=.68). Preferences did not correlate with age, gender, illness severity or body mass index. There were non-linear relationships among preferences and utilization of weight services (Figure 1).

Conclusion
Tailored computerized conjoint analysis can produce valid assessments of treatment preferences in patients with serious mental illness. Conjoint analysis could be a component of measurement-based care and inform decision-making. It can guide implementation of treatments consistent with patient preferences, and has the potential to increase use of effective treatments. The findings here may have applicability to other populations with cognitive deficits.

Classifying Non-Small Cell Lung Cancer Histopathology Types and Transcriptomic Subtypes using Convolutional Neural Networks

Kun-Hsing Yu, MD, PhD¹, Feiran Wang, MS², Gerald J. Berry, MD³, Christopher Ré, PhD⁴, Russ B. Altman, MD, PhD⁵, Michael Snyder, PhD⁶, Isaac S. Kohane, MD, PhD⁴
¹Department of Biomedical Informatics, Harvard Medical School, Boston, MA; ²Department of Electrical Engineering; ³Department of Pathology; ⁴Department of Computer Science; ⁵Department of Bioengineering; ⁶Department of Genetics, Stanford University, Stanford, CA

Introduction

Non-small cell lung cancer is a leading cause of cancer death worldwide, and histopathological evaluation plays the primary role in its diagnosis. However, the inter-observer disagreement on this histopathological diagnosis is recognized, and the morphological patterns associated with the molecular subtypes have not been systematically studied. To bridge this gap, we developed a quantitative histopathology analytic system using convolutional neural networks to identify non-small cell lung cancer types and gene expression subtypes objectively.

Methods

We obtained the whole-slide histopathology images from 427 lung adenocarcinoma and 430 lung squamous cell carcinoma patients in The Cancer Genome Atlas (TCGA) database¹². Additional 87 patients with lung adenocarcinoma and 37 with lung squamous cell carcinoma were identified in the International Cancer Genome Consortium (ICGC) cohort. We retrained four convolutional neural network (CNN) models, including AlexNet¹³, GoogLeNet¹⁴, VGGNet-16¹⁵, and ResNet¹⁶, to identify tumorous regions from adjacent dense benign tissue and to classify tumor types. The models were fine-tuned by cross-validation on the training set. We divided the training set into two parts, trained the models with one part and examined the changes in performance in the other. Once we finalized the selection of hyperparameters, we trained a final model using the entire training set. We evaluated their performance by the areas under the receiver operating characteristic curves (AUCs) in the 20% held-out TCGA test set, validated the results in the independent ICGC cohort (n=124), and visualize the regions of importance in the classification process using the gradient-weighted class activation maps (Grad-CAMs)⁷.

To associate transcription-based subtypes of NSCLC with their histopathology patterns, level 3 publicly-available gene expression data of the tumor samples were acquired from the National Cancer Institute's Genomic Data Commons and the methods described by the TCGA Consortium¹² were used to determine the transcriptomics subtypes of each tumor. The associations between histopathology patterns and the transcriptomic subtypes were investigated by building a multi-class VGGNet-16 classification model. The output of the last layer of the VGGNet in the held-out test set was obtained and transformed using principal component analysis, with the first two principal components visualized. In order to evaluate the correlations between the variations in the transcriptomic signature that defined tumor subtypes and the histopathology-predicted subtype score, the Spearman’s correlation coefficient between the transcriptomic subtype score and the subtype probability predicted by histopathology images in the test set was calculated for each transcriptomic subtype. All statistical analyses were performed in R version 3.3.

Results

The CNN models successfully distinguished lung adenocarcinoma from the adjacent dense benign tissue (total patient number = 427), with the areas under receiver operating characteristic curves (AUC) approximately 0.941-0.965 in the TCGA test set. The results were validated in the independent ICGC cohort, with AUCs 0.890-0.935 (Figure 1A). For lung squamous cell carcinoma cohort (total patient number = 430), convolutional neural network classifiers achieved AUCs of 0.935-0.987 in distinguishing the tumor parts from the adjacent dense benign tissue in the TCGA test set. Similar performance was observed in the independent test cohort from ICGC (87 adenocarcinoma patients and 37 squamous cell carcinoma patients), with AUCs more than 0.979 (Figure 1B). Comparing with a previously-reported quantitative method for pathology analysis using the TCGA datasets⁸, our neural networks attained 6-12% performance improvement in the TCGA test set.

In addition, convolutional neural networks successfully distinguished adenocarcinoma from squamous cell carcinoma with AUCs in the TCGA test set 0.883-0.932, which were 12-27% better than the previously-described feature-based machine learning methods⁸. The AUCs of the finalized models applied to the independent test cohort (ICGC; total patient number = 124) were 0.752-0.857 (Figure 1C). The Grad-CAMs highlighted tumorous regions important for the tumor type classification (Figure 1D).
Discussion

We successfully classified the types and transcriptional subtypes of non-small cell lung cancer using convolutional neural networks. Compared with the previous methods\cite{6-8}, our approaches require no human segmentation or feature definition, making them easily fit into the clinical workflow of pathology diagnosis. In addition, we connected histopathology image patterns with gene expression profiles, which extended beyond previous works on single gene mutation\cite{3,4,5}. Furthermore, our models performed 6-27% better than the previously-proposed feature-based methods\cite{3}, and the results were validated in an independent cohort. The developed procedure is generalizable to other tumor types and can provide decision support to clinicians.

INTRODUCTION

The prevalence of antidepressant use among Americans increased from 7.7% in 1999–2002 to 12.7% in 2011-2014 (1), with the global market estimated at $11.6 billion in 2017 (2). The therapeutic benefits of antidepressants depend on adherence to the prescribed regimen, yet between 30 to 68% of patients discontinue their medications without completing an adequate course of treatment (3). This continuation can lead to poor health outcomes such as depression relapse, emergency department visits, low quality of life, and significant burdens on the individual, caregivers, family members and the health care system (4).

Although self-report scales (such as Adherence Barriers Questionnaire (ABQ)) for measuring patients’ discontinuation behavior towards antidepressants are well validated, they are associated with some methodological difficulties, such as not detecting potential factors and sampling bias. The premise of this study is that patient self-reports of their experiences with antidepressant therapy on drug review forums may constitute a reliable source to uncover various dimensions of antidepressants discontinuation that may not be identified by the self-report scales. To date, there are no reports in the literature that focus on identifying factors affecting antidepressants discontinuation in patients with depression as reported by patients in online healthcare forums. In sum, the objective of our study was to utilize patient self-report experiences, in online healthcare forums, to identify factors affecting patient discontinuation behavior of antidepressant medications in patients with depression.

METHODS

We used a novel mixed method approach to generate structured data from unstructured patients reports to test the hypotheses and model the relationship between antidepressants discontinuation and personal and healthcare variables. The detail of the methodology is as follows:

- **Identifying data source and drug source**: The data of this study collected from a healthcare forum called “askapatiens.com” that collects information on patients’ experiences with medications, age, gender, and duration of usage, and satisfaction with the drugs rated in a Likert scale from 1 (strongly dissatisfied) to 5 (strongly satisfied). For the purpose of this study, we considered patients’ satisfaction with antidepressants equivalent to patients’ attitudes towards antidepressants. A total of 892 patient reviews were randomly collected from the forum for the four most commonly prescribed antidepressants, including Sertraline (Zoloft) and Escitalopram (Lexapro) from the SSRI class, and Venlafaxine (Effexor) and duloxetine (Cymbalta) from the SNRI class.

- **Developing the Analytical Framework**: We used the Framework Method (7) with deductive-inductive approach to identify themes affecting patients’ discontinuation. In the deductive approach, we identified factors affecting patients’ antidepressants discontinuation toward antidepressants using thorough literature review. The factors were used as the initial themes for constructing the initial analytical framework for data analysis. In the inductive approach (open coding), 310 drug reviews were randomly selected for initial analysis using the initial analytical framework. Passages of drug reviews that could not be covered by the initial analytical framework were discussed in our regular team meeting for generating new themes. In the final step, themes were refined based on some rules, such as themes that covered less than 5% of the drug reviews were eliminated or merged with other themes. The identified themes were used for summarizing patients’ experiences with antidepressants and developing highly structured data from qualitative patient reports.

- **Analysis of dataset using the analytical framework**: In the first step of this phase, we addressed the grammatical and punctuation errors in the patient comments, and then split the comments into sentences using NLTK (a module from Python). All drug reviews in the sample were annotated using the analytical framework at sentence level. Four annotators with health backgrounds participated in the process of data annotation. All sentences were double-coded. **Calculating the Inter-annotator agreement (IAA)**: The Inter-annotator agreement (IAA) was calculated using Cohen Kappa. The overall IAA for the entire dataset was 0.75.

- **Strategy for handling missing values**: To handle the missing values, we eliminated all the drug reviews with no text. We also removed variables with low IAA and high number of missing values. To handle the rest of missing values, we adopted different imputation methods regarding the nature of the missing values for each variable. The details of the methodology for
developing this dataset were explained in our previous study with focus on identifying factors affecting patients’ attitudes towards medications (8).

RESULTS

Drug reviews were posted between February 2001 to February 2016. The majority of the patients (76%) were female. Approximately 30% of patients were less than 40 years of age. The majority of the reviews (63%) were posted by patients who had experience of using antidepressants for more than 3 months.

Testing the association between variables and drug discontinuation showed the following variables: “experience of adverse drug reactions” (ADRs), “perceived distress from ADRs”, “drug effectiveness”, “complaint about the lack of knowledge”, “patients’ attitude toward antidepressants”, and “duration of usage”, were all significantly associated with antidepressants discontinuation (P <0.05 for all listed variables). The variables of “age” and “gender” were not associated with drug discontinuation (P >0.05 for all listed variables). Moreover, modeling the relationship between variables and antidepressants discontinuation showed that variables “drug effectiveness” and “patients’ satisfaction with antidepressants” are the two most significant factors associated with drug discontinuation in patients with depression.

We also used a generated dataset to train a range of supervised machine learning classifiers to identifying text (annotated sentences) segments with comments related to adverse drug reaction, withdrawal symptoms, effectiveness, and ineffectiveness. Classifiers include: Support Vector Machine (SVMs), Random Forest (RF), Naïve Bayes (NB), and Logistic Regression (LR). The average F-score for SVM, RF, NB, and LR classifiers were 0.9, 0.87, 0.88, and 0.86 respectively, indicating that SVM classifiers outperform the RF, NB, and LR for this task.

DISCUSSION

The findings of this study have significant implications for developing clinical interventions aiming to improve patient adherence towards medications. One major implication of this study is that patients’ attitude is the most significant predictor of antidepressant discontinuation. This finding is in line with the literature showing that patient’s adherence behavior is strongly associated with patient’s attitude and belief towards medications. Clinicians are recommended to pay close attention to patients’ attitudes towards antidepressants and ensure that patients consider antidepressant usage as an essential part of their treatment. In addition, perceived drug effectiveness is a significant factor affecting drug discontinuation in patients with depression, and the full effect of antidepressant medications are not seen for typically four to six weeks. Therefore, clinicians are encouraged to track patients’ response towards antidepressants and encourage them to complete the adequate trials. Moreover, physicians should provide patients with adequate knowledge about antidepressants adverse effects and withdrawal symptoms. Providing patients with sufficient information on adverse effects can help them to have an informed decision about starting and continuing the medications and consequently reduce risk of abrupt discontinuation. In summary, the finding of this study may also help clinicians tailor interventions to improve their patients’ perceptions of their medications and consequently improve adherence to the antidepressant treatment.

Early Prediction for Multiple Adverse Outcomes in Acute and Chronic Back Pain Transitions

Samir E. Abdelrahman¹, Michael G. Newman², Christina A. Porucznik²
Department of Biomedical Informatics¹ and Department of Family and Preventive Medicine ², School of Medicine, University of Utah

Introduction: Back pain is the most frequent cause of disability and inability to do activities of daily living. It usually results in dramatic social/economic/family costs, with an estimated U.S. prevalence of 27%¹. Prescribed medication may cause adverse outcomes including events (i.e., overdose, dependence, addiction) and side effects (e.g., sedation and respiratory depression). A back-pain patient may have multiple adverse outcomes (i.e., two or more outcomes that occur at the same time). Such outcomes are due to the interactions among the taken drugs that may introduce more pain complications or lead to a transition from acute to chronic pain. Clinicians still need to early predict the onsets of these multiple adverse outcomes to initiate a treatment or modify their treatment plan. Despite the various predictive analytics solutions in non-cancer or back pain domains, no study has been designed to satisfy this unmet need. Here, we propose to predict multiple adverse outcomes using the patient-specific data of the first day from encounter admission time for each back-pain transition.

Methods: We randomly selected 150,632 encounter (i.e., visit) data points from the University of Utah Healthcare (UUHC) electronic medical records (EMR) to train and test the predictive models. In this pilot study, we only used and analyzed a subset of patient features. For example, for back pain comorbidities, we only selected osteoarthritis, fibromyalgia, migraine, and headache as the most commonly-reported non-cancer chronic pains. For medications, we selected classes of opioids, nonnarcotic, and nonsteroidal anti-inflammatory agents as the most frequently used medications in the back pain literature. Furthermore, we only used repeated measures of the vital signs.

For each patient encounter, we included the following feature set. For the encounter outcome, we encoded the patient pain status into acute (A) or chronic (C) pain if the pain lasted shorter or longer than 3 months from the first patient encounter, respectively. Also, we encoded all occurrences events into E and all side effects into S such that each encounter had E/NE and S/NS to present event/no-event and side-effect/no-side-effect, respectively. Hence, our encounter outcome included 8 labels to present the 8 combinations of A/C, E/NE and S/NS, namely: A-E-S, A-NE-S, A-E-NS, A-NE-NS, C-E-S, C-NE-S, C-E-NS, and C-NE-NS. For the encounter predictor, we first used demographic information of age at admission time, patient class of inpatient/outpatient/emergency department, gender, ethnicity, visit types, and insurance classes. Second, we added 1-year prior information of the frequencies of back pain with 4 comorbidities, the frequencies of adverse outcomes, the counts of medication class orders, and the average of each vital sign repeated measures. Third, we collected the first 30-day repeated measures for each vital sign and discretized them into 30 features such that each feature had the average value of the repeated measures in the corresponding day. Finally, we imputed each day vital signs using the “last value carried forward” for the next patient days. If there is no patient value in that encounter, we used the literature clinical normal value of that vital sign to impute its missing value. To develop and test the trained models, we used 10-fold cross-validation and AutoWeka. AutoWeka is a widely used machine learning software package that validates different state-of-the-art classifiers with different hyper-parameter tuning to select the highest-performing classifier and the corresponding optimal classifier parameters. While running different AutoWeka classifiers, we also ran SubsetEval feature selection method and AntSearch algorithm to select the model with the highest area under curve (AUC) and the optimal number of features. We standardized all numeric predictors and used the one-hot encoding to encode each categorical predictor.

Results: Initially, we identified 86 predictors per day using our predictor encoding process. Among them, the selected predictors of the best predictive model performance were 32 including age at admission time, female, commercial insurance category, five visit types, all year prior information, and each day information of (prescribed medications, respiratory rate, temperature, and systolic blood pressure). The highest AUC resulted from random forest classifier of the first day with values 72.9% for A-NE-S, 79.1% for A-E-NS, 75.4% for A-NE-NS, 76.3% for C-NE-NS, 73.9% for C-E-NS, 70.5% for C-A-S, 62.3% for C-NE-S, and 75.5% for A-E-S with 1.5± 74.2 over the AUCs of all models’ at 30 days. We also conducted a comprehensive set of empirical experiments to assess the effect of predictors group combination by removing a combination of one or more group of predictors, i.e., demographics, prior, and current information. We found that removing priors decreased the models’ AUC by around 10% on average, and the worst results were obtained from the models that included only demographic information.

Discussion: Prior information has high predictive power. The data is imbalanced with respect to the 8 outcome values that led to moderate AUC results. Many patients were outpatients with length of stay ≤ 1 day; hence, the highest model performance was achieved using the first day data with priors. More advanced predictive analytics will be conducted.

mHealth Tool for Patient-Centered Informed Consent

Fuad Abujarad, MS, PhD¹, Sandra Alfano, Pharm.D.¹, Peter Peduzzi PhD², Geoffrey Chupp MD¹

¹Yale School of Medicine, New Haven, CT, USA; ²Yale School of Public Health, New Haven, CT, USA

The objective of the informed consent (IC) process is to inform the patient or research subject about the purpose, procedures, risks, and benefits associated with clinical research and medical procedures.¹ However, the current IC process does not always guarantee full patient comprehension due to a number of barriers, including high-level medical vocabulary and lack of patient engagement.²-⁴ Therefore, we created an innovative IC communication process that overcomes barriers in IC communications and improves comprehension.

Our tool, Virtual Multimedia Interactive Informed Consent (VIC), was developed using a patient-centered design approach. We used front-end subject matter expert interviews and stakeholders focus groups with patients, researchers, and IRB members to develop a set of requirements. We completed a series of patient experience evaluations that mapped on to the standard development cycle, (i.e., user requirements analysis, design, implementation, testing, launch, and maintenance). To demonstrate VIC feasibility, we ran a two-arm randomized clinical trial to test VIC in an asthma study at the Yale Center for Asthma and Airway Disease Mechanisms.

We were able to surmount IC communications barriers with our innovative mHealth tool that runs on an iPad to communicate and deliver the IC process to patients in the asthma clinical trial. Information and messages were displayed on the iPad screen and spoken through headphones for patient privacy. An innovative feature of the tool is its ability to assess patient comprehension and offer a customized level of information. VIC educates and reinforces topics through the use of multimedia. The patient can view demos and presentations, listen to comments and explanations, get customized information, click on links to drill down for more information, ask questions and get answers, and rewind and replay as needed. We tested our tool using randomized control trial with 50 subjects in real world genetic clinical trial. Initial analyses of the study data suggest that comprehension was higher in the tablet informed consent group.

Efficient and Robust CT Image Segmentation with a Level Set Network

Jonas A. Actor, MA¹, Beatrice M. Riviere, PhD¹, David T. Fuentes, PhD²

¹Rice University, Houston, TX; ²MD Anderson Cancer Center, Houston, TX

Introduction

Medical image segmentation remains a difficult task: liver segmentation from abdominal CT scans is often done by hand, requiring too much time to use to treat hepatocellular carcinoma. Previously, image segmentation was done by solving the level set equation, a partial differential equation (PDE) describing how a boundary curve evolves given an image¹. Level set methods successfully capture clear edges and are robust to perturbation, due to the underlying structure of the PDE. In contrast, deep convolutional neural networks (DCNN) are susceptible to large changes in output given small perturbations of input². Despite this drawback, DCNNs are increasingly popular for liver segmentation.

Approach and Methods

We unrolled an iterative method for solving the level set equation, creating a level set network. In this framework, each iteration becomes a layer in a DCNN. The correct curve evolution is then ‘learned’ by the neural network. By definition, the output of this network solves the level set equation, and is therefore robust to perturbation. To test this method, we employed three segmentation methods on the MICCAI 2017 LiTS Challenge dataset³, consisting of 131 abdominal contrast-enhanced CT image stacks. These methods were: UNet⁴, a type of DCNN; ITK-SNAP⁵, a segmentation application using the level set equation; and our level set network (LSN). For UNet and LSN, we performed a 5-fold cross validation. In each fold, the selected LiTS data were split into training (90% of 4 remaining folds) and testing (10%). These networks trained via the Adadelta optimizer until saturation (40 epochs for UNet, 20 for LSN), with the Dice Similarity Coefficient (DSC) as the loss function. For ITK-SNAP, which allows users to hand-tune a few parameters, we allotted 10 min for a user to alter these parameters to achieve the best segmentation, after which ITK-SNAP solved the level set equation until DSC no longer improved.

Results

After performing the described methods, we obtained the following DSC scores.

<table>
<thead>
<tr>
<th>Method</th>
<th>UNet</th>
<th>ITK-SNAP</th>
<th>LSN</th>
</tr>
</thead>
<tbody>
<tr>
<td># Parameters</td>
<td>32M</td>
<td>3</td>
<td>69K</td>
</tr>
<tr>
<td>Avg DSC</td>
<td>0.955</td>
<td>0.745</td>
<td>0.804</td>
</tr>
</tbody>
</table>

Table 1: Parameters and DSC scores from three segmentation methods.

Conclusions

We observed that LSN achieved an average DSC score superior to ITK-SNAP, but below UNet. However, LSN guaranteed robustness to perturbation due to its analytical structure.

Unraveling Asthma Racial Disparities in Emergency Department Visit Using Electronic Healthcare Records and Machine Learning Algorithms

Adeboye A. Adejare Jr, M.S.,1,2 Yadu Gautam Ph. D.,2, Mekibib Altaye Ph. D.1,2, Tesfaye Mersha Ph. D.1,2
1University of Cincinnati, Cincinnati, OH, USA 2Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

Asthma affects 12 million Americans, but the contributions towards asthma exacerbations do not equally affect all populations. African Americans (AA) are four times more likely to be hospitalized and five times more likely to die from asthma than European Americans. In addition, after being diagnosed with asthma, AAs have poor control leading towards more exacerbations. We developed a series of Machine Learning (ML) models including Logistic Regression (LR), Decision Tree (DT), eXtreme Gradient boosting (XGB) and Random Forest (RF), to determine asthma disparities between AA and EA patients in the Cincinnati Metropolitan area (Figure 1).

We leveraged data from University of Cincinnati (UC) electronic healthcare records (EHR) from the Emergency Department, pollution data from the Environmental Protection Agency (EPA) and environmental data from the Ohio Air Quality Agency (OAQA) between November 2012 and December 2017. We linked EHR clinical data together via unique deidentified identification numbers for a cohort of 42,374 patients (Table 1). We used the recorded entry date to merge the pollution, mold, and EHR data sets. This dataset was cleaned and fed to multiple machine models to predict both asthma severity and emergency visit disparities. FEV1% Values classified asthma severity, FEV1% ≥ 80, moderate (M), FEV1% 60-80, and severe (S) FEV1% < 60. Emergency Department (ED) visit frequency was counted for each person’s encounter in the ED in the time period. ED visitations below and at the third quartile for total visits by the cohort were classified as intermittent (I) visitors and visit frequencies above the third quartile as frequent (F) visitors. 

AAs samples were characterized by severe asthma and higher ED visits than their EA counterparts. AAs had a higher risk for environmental exposure with more elevated spores from mold and pollen than EAs. XGB produced the best predictive model for both AA and EA ED visit and severity (Figure 2). While pollution affected both groups, a higher predictive model was obtained for AAs than EAs. Environmental factors may contribute towards the disparities between races in asthma-related ED visits, and attention should be given to address these disparities.

\textsuperscript{1}Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA, USA; \textsuperscript{2}Harvard Medical School, Boston, MA, USA; \textsuperscript{3}UC Davis, Davis, CA, USA; \textsuperscript{4}VA Boston Healthcare System, Boston, MA, USA; \textsuperscript{5}Partners Healthcare System, Charlestown, MA, USA

Introduction

Rich, multifaceted data from electronic health records (EHR) are increasingly available for clinical research. However, a major bottleneck in realizing the full translational potential of this data is its lack of reliable labels for many diseases. Though "silver-standard" proxies such as ICD billing codes are often used in place of true labels, these often suffer from dismal specificity - especially for rare diseases. On the other hand, traditional supervised phenotyping approaches require expert chart review to manually annotate labels, limiting scalability. Previous studies have introduced unsupervised machine learning algorithms using silver-standard labels. However, these methods only consider a single disease at a time and hence may not perform well when the goal is to phenotype multiple diseases simultaneously. We propose a fully unsupervised algorithm to efficiently predict multiple phenotypes for potential use in large-scale deep phenotyping.

Methods

Surrogate-guided ensemble LDA (sureLDA) method is an unsupervised multi-class prediction algorithm that first uses unsupervised clustering to obtain initial disease probabilities and then employs these probabilities to guide Latent Dirichlet Allocation (LDA) – a commonly employed topic model. Specifically, sureLDA sets the Dirichlet prior of the document-topic (i.e. patient-disease) distributions to the initial probability estimates, ensuring that learned topics align closely with the true disease labels. In this way, sureLDA successfully learns topics with important features specific to the disease phenotypes of interest. After training LDA and thereby obtaining disease-feature counts (i.e. disease scores) for each patient, sureLDA then combines these scores with surrogates via clustering ensemble to obtain robust final disease probabilities.

Results

In both simulations and EHR data from the Partners Healthcare Biobank, sureLDA consistently outperforms existing unsupervised phenotyping algorithms, particularly for rare diseases. Averaged over 10 diverse diseases in the Partners EHR dataset, sureLDA improves upon existing phenotyping algorithms MAP, PheNorm, classic LDA, and XPress with AUC increases of 0.023 (p=0.007), 0.029 (p=0.006), 0.071 (p<0.001), and 0.113 (p<0.001) respectively. It also outperforms supervised methods trained on 200-300 gold-standard labels.

Discussion

Robust to a variety of disease characteristics, sureLDA offers improved accuracy and precision over existing unsupervised phenotyping methods. It also exhibits powerful feature selection properties that make it relatively immune to high feature dimensions.

Conclusion

With high accuracy and multidimensional phenotyping capacity, sureLDA holds promise for large-scale phenotyping of the EHR, enabling more powerful utilization of the EHR for downstream study.
A Social Network Analysis Perspective of Comorbid Conditions with Chronic Kidney Disease

Ashwag. Alasmari13, MSc, Lina. Zhou2, PhD

1University of Maryland, Baltimore County, MD, United States; 2University of North Carolina at Charlotte, NC, United States; 3 King Khalid University, Abha, Saudi Arabia

Introduction

Comorbidity presents health management challenges to patients, healthcare professionals and organizations at large. Comorbid patients impose a high treatment burden in terms of understanding and self-managing their conditions, attending multiple appointments, and managing complex drug regimens1. Kidney disease is a common condition that occurs in patients with other chronic medical problems or complications2. Therefore, providing support for self-management of chronic kidney disease is crucial to patient care. Social media is increasingly influencing people’s daily life and their health behavior3. In particular, community Q&A sites provide a venue for generally asking questions and posting answers. However, researchers have yet to fully utilized Q&A sites to understand comorbid diseases and online patient community beyond what is already known in the healthcare setting. This study approaches the comorbid conditions that involve chronic kidney disease (CKD) through analyzing online Q&A data from a social network perspective.

Methods

We collected data from Quora, a popular community Q&A site. In addition to the questions, we also collected data based on the topics and subjects of the questions. We first compiled a list of topics related to the kidney disease using the snowball sampling strategy and then selected questions related to kidney disease, chronic kidney disease, kidney failure, dialysis, kidney-stones, polycystic kidney disease, CKD, dialysis patients, kidney infection, and pyelonephritis, etc. The dataset consisted of 1,312 questions in which were collected based on the selected topics. We grouped the topics into disease categories by mapping them to the general categories of ICD-10. The mapping results were further validated by a researcher with the medical background. Each node in the graph network represented a disease category and the size of the node indicates a higher weighted degree of the disease. The thickness of the edge indicates the strength of connection between two diseases that were mentioned along with CKD. We then used Gephi for analyzing and visualizing the disease network.

Findings

The network consisted of 42 comorbid diseases. The common comorbidities included in these findings were diabetes, hypertension, anemia, heart disease, depression, and thyroid disorder. The weighted degree were as following: diabetes=80, hypertension=73, anemia=31, heart disease=21, depression=11, and thyroid disorder=2. Hence, the two significant comorbid diseases were diabetes and hypertension. The findings complement previous research that involved medical records for kidney patients discharged from hospital with comorbid conditions3. Thus, our preliminary results demonstrate that social media serves as a useful source of information for patients. The social network analysis revealed a promising perspective for uncovering and understanding the underlying common diseases associated altogether. Additionally, the results complement the existing body of knowledge based on clinical findings. At the end, our research helps to give more realistic view on the complex nature of comorbidity associated with CKD.

Ocelot: A Modularized and Interactive Tool for Visual Understanding of Patient State

Gabriel A. Aldana, BBA1, Rohit Chaudry, MS1, Rimma Perotte, PhD1,2, Zachary M. Grinspan, MD3,4, Natalie Yip, MD5, David Vawdrey, PhD1,2

1Value Institute, NewYork-Presbyterian Hospital, New York, NY; 2Department of Biomedical Informatics, Columbia University Irving Medical Center, New York, NY; 3Department of Healthcare Policy & Research, Weill Cornell Medicine, New York, NY; 4Department of Pediatrics, Weill Cornell Medicine, New York, NY; 5Department of Medicine, Columbia University Irving Medical Center, New York, NY

Introduction

Following principles outlined by an international working group for bedside multimodal monitoring1, and working directly with the group’s chair, we designed a tool to display physiological and clinical data that we named Ocelot: Overview of Clinical Elements and Observations Timeline. Ocelot presents temporally-dependent heterogeneous physiologic variables together on one screen to help clinicians visually identify patterns, detect anomalies, and quickly draw inferences. The tool’s timeline view shows physiologic data in context with fluids status and medication administration data, including individual doses and continuous infusions.

Methods

The program is data source-agnostic and created entirely with open source tools such as the D3 JavaScript library, in order to promote portability. Ocelot was developed by a panel of physicians, informaticians, and engineers to meet the user demands for data in an intensive care unit. The tool development began in October 2017 and was placed into production in May 2018. There was no significant marketing campaign; users learned about the software through word-of-mouth. Ocelot is a real-time live tool (Figure 1) that constructs a visual display of vital signs, drips, medications, and ins & outs. The current version presents vital signs from nurse-validated flowsheet entries.

Results

In January 2019, Ocelot had 251 unique users, 60% of whom were physicians. Users viewed 425 patients and interacted with the application 1,019 times. Among the physicians, the most common user specialties were internal medicine (25%), pediatrics (20%), and surgery (10%).

Figure 1. A screenshot of the application. The user is able to hover over the line graphs to see individual recordings, filter out particular data elements, and collapse individual data types. A 24-hour summary of all vital signs is also displayed in a separate panel (not shown).

Conclusion

In future work, we will supplement the current set of displayed flowsheet metrics with real-time vital sign data drawn directly from bedside monitors. We will also iterate on the design of the application through qualitative and quantitative user feedback. Because we are logging application clicks and not just page views, we can identify which modules provide the most utility for different specialties, thus enabling the application to be personalized for the user. Given the modular design of the application, which can display data in a temporal and interactive format, we believe that Ocelot paves the way to being able to display many types of medical record data, and potentially even external data, to clinicians in a uniquely useful manner.

# SUPPORT-AF: Supporting Provider Prescribing of Oral Anticoagulant Therapy for AF with Anticoagulation Decision Support Using the Electronic Health Record

Azraa Amroze, BS\(^a\); Gordon Manning, MD\(^b\); Doug Buell, BA\(^b\); Alok Kapoor, MD, MSc\(^{a,b}\); David McManus, MD, MSc\(^{a,b}\); Jomol Mathew, PhD\(^b\)

\(^a\) Meyers Primary Care Institute, Worcester, MA, USA

\(^b\) University of Massachusetts Medical School, Worcester, MA, USA

## Introduction
Atrial fibrillation (AF) currently affects 5.2 million Americans, with 12 million projected by 2050. Anticoagulation (AC) therapy is the cornerstone for stroke prevention in patients with AF. However, only about half of eligible patients (i.e. CHA\(_2\)DS\(_2\)-VASc ≥ 2) receive AC in contemporary US-based, ambulatory registries. Researchers have assessed various interventions including decision aids, audit and feedback, and electronic messaging, but have achieved limited success in filling the AC treatment gap. A potential explanation for the lack of success is the absence of a tool integrated within the typical flow of practicing clinicians. We set out to leverage our EHR and design and evaluate a best practice advisory (BPA) tool positioned to trigger at the time of an ambulatory visit with a cardiology or primary care provider (PCP).

## Methods
We created a novel registry of AF patients using our enterprise research data repository – the UMMS Data Lake – linked with the Epic electronic health record (EHR) at our institution, the UMass Memorial health care system. To identify patients with AF eligible for AC, we used ICD-10 diagnostic codes, problem lists, medication lists, and labs available in the EHR. We further developed an algorithm that calculated each patient’s CHA\(_2\)DS\(_2\)-VASc stroke risk. In addition to being able to follow the patients, development of the registry enabled us to derive the exact logic to design a BPA using diagnostic and medication groupers that would fire whenever a patient with a CHA\(_2\)DS\(_2\)-VASc score ≥ 2 not currently on AC schedules an ambulatory visit with a cardiology provider or PCP. Once fired, we requested the provider to inform us of the reason for the patient not being on AC. If the provider did not declare a reason for withholding AC, he or she could select from a Smart Set order designed to guide prescription of an appropriate AC and is offered a link to a referral to our institution’s AC clinic. Included in the Smart Set was logic to offer options consistent with best practices; for example, direct oral AC would not be offered to a patient with renal failure. To validate the accuracy of the BPA, we also conducted chart-reviews on 100 randomly selected patients from our registry to ensure precision of AF status and stroke risk calculation. To evaluate the effectiveness of the BPA, we plan to assess the change in AC prescription percentage from the time of inception (baseline) to six months later for the group of patients for whom the BPA was triggered (treatment group) compared with those also seen at the medical center (by non-BPA providers such as surgeons or other medical subspecialists) for whom it did not fire. In order to control for secular bias, we will compare the difference in change across both groups and control for potential confounders such as CHA\(_2\)DS\(_2\)-VASc score and bleeding history/bleeding score.

## Results
We identified 6469 patients in our healthcare system with AF with a CHA\(_2\)DS\(_2\)-VASc stroke risk score ≥ 2, 1770 of whom were not on AC (27%) at the time of launch of our BPA in February 2019. We anticipate collecting change in AC prescription in August 2019. During chart validation, we found that our BPA was highly accurate in identifying AF (100%) and CHA\(_2\)DS\(_2\)-VASc score ≥ 2 (100%).

## Discussion
The EHR contains valuable information that can help address the practice gap in patients with AF eligible for AC. The BPA we designed was highly accurate in identifying AF patients with high stroke risk. In the near future we will be able to assess its effectiveness in increasing the rate of AC in eligible patients and also documenting the range of reasons why patients may not be on anticoagulation. Together these results will form the basis of a toolkit that can be adapted by other centers across the country.

Using resilience engineering to understand an EHR transition

Shilo Anders, PhD, Patricia Sengstack, DNP, Carrie Reale, MSN, RN-BC, Laurie Novak, PhD, Joyce Harris, MA, Nancy Lorenzi, PhD, Elma Jashim, & Kim M. Unertl, PhD
Vanderbilt University Medical Center, Nashville, TN

Background. Large scale health systems that transition from one electronic health record (EHR) to another create a disruption to the organization, during which people must adapt and the environment must be redefined to accommodate the new EHR. This can also lead to numerous changes and even disruptions in clinical workflow, for which personnel can use resilient strategies in order to cope and adapt. Resilient performance is best understood as how people anticipate problems, monitor, adapt, and learn. From an engineering perspective, resilience is viewed as a way to offset when a system becomes brittle under production pressure or as a way to manage increasing complexity to minimize system failure or potentially catastrophic error. Organizations need optimal resilient performance from frontline personnel during an EHR transition. Thus, the goal of this research is to qualitatively examine the resilient performance strategies exhibited by a healthcare organization during and after a new EHR implementation.

Methods. Data were collected at 12 clinical sites (e.g. Adult Pulmonary Outpatient Clinic, Cardiac Inpatient Unit, Emergency Department) in 8 phases, beginning the day before implementation through 13 months post-implementation. Observation periods typically lasted 2 hours, although during Phase 1 of data collection (implementation day), observers were in place for up to 4 hours due to delays in the transition to the new EHR. Numerous observations were conducted at each location during each phase. During observation, the research team recorded free-text notes or had the option to record data on a workflow-focused data collection template. While observing, researchers conducted informal interviews with healthcare team members as time and circumstances allowed, typically asking questions related to the rationale behind observed behavior and on the impact of the new technology on work. Finally, observers collected artifacts related to the technology transition or to new processes related to the technology. All data were transcribed and uploaded into a web-based qualitative data analysis tool. Researchers coded documents for the use of resilient performance under the four “essentials” from the literature: 1) Learning – Knowing what has happened and training around system use; 2) Responding – Knowing what to do; 3) Monitoring – Knowing what to look for; and 4) Anticipating – Knowing what to expect.

Results. Researchers observed instances of all four categories of essential resilience strategies across all data collection sites. Along with consistencies between clinical sites, there were also variations in resilience strategies used immediately post-implementation versus after continued use of the new EHR that spanned all four themes. First, under the Learning category, new in-services were developed to help practitioners learn tips and tricks after rollout, even though the majority of the training had formally occurred prior to implementation of the new EHR. Informal knowledge learning occurred by asking peers with prior experience with the new EHR or with “super user” training. Secondly, in the Responding category, people throughout the organization experienced numerous issues and deviations across all observation phases and responded accordingly. Responses included: recruiting resources, resorting to and persistent use of paper, regressing to known prior EHR, and changing roles. For example, staff continually resorted to the previous EHR when they were short on time or had difficulty locating the information they desired in the new EHR. This was observed throughout the organization and persisted across all phases of observation. Thirdly, in the Monitoring category, researchers observed numerous people and processes designated specifically for monitoring emerging problems, as well as technologies that enabled individuals to report these problems. Lastly, in the Anticipating category, observations found varying responses at individual, unit, and organizational levels. For example, one nurse manager actually scheduled the most technology savvy nurses to work the day of the implementation on their unit.

Conclusion. Applying concepts of resilience engineering to the analysis of a large-scale health implementation affords a new framework to examine and understand the ways in which the organization and individuals adapt to handle disruptions to create a new routine. EHR system implementations continue across the nation. Understanding how resilience may impact success can provide organizations with important knowledge to prepare them for the challenge.

Managing Data Flows for Pediatric Complex-Care Patients and Their Families to Manage Care Plans

Steven B. Andrews PhD1, Mari-Ann Alexander PhD2, Justin Rousseau MD1, Anjum Khurshid MD PhD1, Jaimie Hancock1, Rahel X. Berhane MD2

1Dell Medical School at UT-Austin, Austin, TX 78712, USA
2Dell Children’s Medical Center, Austin, TX 78712, USA

Children with medical complexity (CMC) compose a sub-group of children with special health care needs (CSHCN) who face more hardships and have higher medical utilization. To support a mobile application providing shared care plans to enhance care coordination, our data team has been working to integrate data from a wide variety of sources. This poster describes the challenges and opportunities of bringing together these data to support care coordination and shared care plans for CMC.

Children with medical complexity (CMC) face hardships accessing medical care, often relying on tertiary hospitals for their care, and tend to be high utilisers of medical care in general.1-4 Care coordination has been suggested as a means of reducing medical utilization and helping CMC, but the results have been mixed. For example, while some studies have found significant results between care coordination and reduced ED visits, day-only admissions, reduced family travel time, and reduced school absences,5,6 others have found no improvement in health-related quality of life.6 Areas of research that have been emphasized are family-level interventions,1 integration of local health services with tertiary hospitals,7 and improving communication flows.7 Care planning interventions may help improve shared decision making for CMC, which has been shown to be important for improving quality care.2

Part of improving communications flows, increasing data and service coordination, and integrating the family more closely into the decision-making process is the use of a documented and easily accessed plan of care. Partnering with a commercial software development group, we have created a mobile app with the intention of providing care-related information to CMC and families, while also providing a mechanism for them to enter patient-reported outcomes (PRO) and manage a shared plan of care. This application is in production use, and we review some initial results.

This poster describes issues the team confronted bringing together data from multiple sources, including clinical settings with different EHRs (Cerner, Athena), payers, and PRO from the mobile app. Significant challenges were patient identification, patient matching, creating governance agreements to allow multi-directional data flows between partners, meeting and ensuring varying security requirements and processes, and working with the institutions on behalf of a population that comprises a small portion of the medical institution’s population. The poster summarizes lessons learned in unifying disparate data and providing a production environment to support families and clinicians.

Differing patterns in frequency of electronic health records documentation among clinicians following the replacement of a legacy EHR system

Nate C. Apathy, BS1,2; Joshua R. Vest, MPH PhD1,2; Nir Menachemi, MPH PhD1,2; Justin G. Morea, DO3; Christopher A. Harle, PhD1,2

1Richard M. Fairbanks School of Public Health, Indiana University, Indianapolis, IN; 2Regenstrief Institute, Indianapolis, IN; 3Eskenazi Health, Indianapolis, IN

Introduction
Documentation is a substantial part of electronic health record (EHR) usage. Documentation includes clinical needs to record relevant patient information and provider activities, but regulations such as the Merit Based Incentive Payment System can increase the amount and frequency of documentation. Additionally, implementations may exacerbate this documentation burden, as users must learn how to use increasingly sophisticated EHR systems and adjust workflows while maintaining quality. Therefore, this study examined changes in users’ self-reported frequency of documentation in 4 settings before and after implementation of a new EHR system.

Study Design & Methods
We analyzed 4 items from a 2-year longitudinal survey of EHR users in a large public hospital system that switched from a homegrown legacy EHR to a vendor system in Oct. 2016. In each of 6 survey time points, users reported the frequency with which they entered data into the EHR across 4 scenarios: 1) clinical workdays – in patient rooms with the patient, 2) clinical workdays – between patients, 3) clinical workdays – evenings or nights, and 4) on days off. Each item had a 5-item Likert scale response set: Never, Rarely, Sometimes, Often, or All the time. We limited our study sample to clinical EHR users, divided into 3 groups based on their self-reported role: 1) Physicians, Physician Assistants, & Nurse Practitioners; 2) Nurses & Medical Assistants; and 3) other patient care roles. We calculated the percentage of users in each group reporting frequent use (Often or All of the time) for each item.

Results & Discussion
Our study sample consisted of 868 respondents at baseline, 821 at 1-month post-implementation, 1022 at 3 months, 787 at 6 months, 657 at 12 months, and 739 at 24 months. At baseline, 30% of Nurses and MAs reported frequently documenting in patient rooms with patients. After 1 month with the new EHR, this percentage increased to 72% and remained high. Similarly, at baseline, 22% of other patient care providers reported frequent use in patient rooms; this increased to 47% after 1 month and also held over 2 years. We found relatively little change in the percentage of physicians, PAs, and NPs reporting frequent use. Our findings suggest that EHR implementations may be related to increased documentation in patient rooms for non-physicians, although our analysis precludes causal interpretations. Our findings illustrate a varying burden of documentation between physicians and non-physicians, which can inform health system efforts to reduce the burden of frequent EHR use for specific user groups in different scenarios.

Figure 1. Percent of respondents answering “Often” or “All of the time” to time use survey questions, by clinical role
Generic vs. Specialized Models for Assessing Disabilities among People with Dementia
Negin Asadzadehzanjani, MS¹; Janusz Wojtusiak, PhD¹, Allison Williams, PhD², Cari Levy, MD³
¹George Mason University, Fairfax, VA; ²Department of Veterans Affairs, Bay Pines, FL; ³Department of Veterans Affairs, Denver, CO

Introduction
About 46.8 million of people are suffering from dementia and this number is expected to rise to about 130 million by 2050¹. Dementia impairs memory, thinking ability, comprehension and judgment and it can decrease functional abilities such as activity of daily living (ADLs)², thus accurate assessment of the functional ability helps decision making in patient’s care. Current assessment of ADLs is manual, costly and time-consuming; therefore, there is a need to develop an automated decision support tool to assess and predict ADLs. This work is an extension of our previous research on using EHR and administrative data to predict ADLs² and consists of two related components: comparison of dementia and non-dementia patients in terms of their disabilities and comparison of performance of machine learning-based models for automatically assess disabilities based on medical histories for people with dementia.

Methods
Demographic information, diagnoses and functional evaluations of patients over a ten-year period were extracted from their EHR and administrative data. Data was limited to patients with more than two evaluations. The diagnoses were mapped to CCS codes resulting in 281 distinct codes and coded as the number of days between the first (CCS_Max) and last day (CCS_Min) of the diagnosis and the time of evaluation (562 codes in total). The predicted outputs were nine out of ten categories of functional status (Bathing, grooming, toileting etc.) measured through Barthel Index³ and coded to indicate any level of disability. In the first stage, dementia and non-dementia people were compared for ADLs using propensity score matching. In the second stage, two types of models were developed to predict current ADLs according to patients’ diagnoses. The first (generic) model was developed using training data that included both dementia and non-dementia patients. The second (specialized) model was specifically trained on people with dementia. From a number of tested supervised learning methods Random Forrest was selected as the best algorithm. Hyperparameters were tuned through 10-fold cross validation. The two models were finally tested on people with dementia and compared using area under receiver-operator curve (AUC), accuracy, recall, and precision. Two-tailed t-test was used to determine if the performance of the models vary significantly (p<0.05).

Results
The cohort included 181,213 patients and 855,731 evaluations from which 79,466 (44%) were identified by 653 CCS code (Delirium, dementia, and amnestic and other cognitive disorders). The propensity score matching results indicated that people with dementia were significantly more disabled (0.66 vs. 0.55, p<0.01) than people without dementia on all ADL categories except walking (0.75 vs 0.78, p<0.01). High accuracy was achieved in automatically assessing ADLs using Random Forests with the average accuracy of about 90%. The average performance of the generic versus specialized model is as follows: accuracy 90.5% vs. 90.3%, AUC 94.7 vs. 94.6%, recall 92.3% vs. 92.4% and precision 92.8% vs. 92.4%. However, t-test revealed that the two models are not significantly different (p>0.05).

Conclusion
Our initial hypothesis was that specialized model would perform better than genetic model as the propensity score matching results indicated higher level of disability for dementia group. However, results revealed that the generic model performed slightly better than the specialized model even though the difference was not significant. The analysis of the learning curves indicated that the lack of difference was not caused by the size of the training data, but most likely by larger variance of data in the non-dementia group.

Which Patient Engagement Functionalities Are Salient for Quality of Patient Care?
O. Elijah Asagbra, PhD, MHA, CPHQ
East Carolina University, Greenville, NC, USA

Introduction
Hospitals are increasingly adopting health information technology (HIT) to facilitate patient engagement to meet governmental pressures,1, 2 as well as consumer demand for using technology in their health.4, 5 Several studies have highlighted the functionalities and benefits of HIT for patient engagement, and others have examined the association of HIT and care quality. However, few have determined if any one HIT functionality may be salient for improved quality of care. This study therefore aims to examine the relationship between the specific patient engagement functionalities offered through health information technology (HIT) and quality of care.

Methods
Data on hospital adoption of patient engagement functionalities obtained from the American Hospital Association (AHA) IT supplement were combined with quality data obtained from the Centers for Medicare and Medicaid Services (CMS) Hospital Compare. Hospital fixed effects regression models with time dummies were used to analyze a panel data consisting of 1,463 hospitals from 2012 to 2014. Quality of care was measured as patient satisfaction and 30-day readmission rate for acute myocardial infarction, heart failure, and pneumonia.

Results
This study revealed that certain patient engagement functions were significantly associated with improved quality of care measures in hospitals. For instance, it was determined that hospitals offering patients’ electronic access to patient–specific education materials (β= 0.806, p < 0.05), the ability to download their health information (β= 0.640, p < 0.05), the ability to request changes in their medical records (β= 0.778, p < 0.05), and the ability to generate their own health data (β= 0.832, p < 0.05) were associated with improved patient satisfaction. Additionally, hospitals allowing patients to view their health records and to download their health information were also significantly associated with improved readmission rates for acute myocardial infarction, heart failure, and pneumonia respectively. Permitting patients to access their discharge instructions electronically (β= -0.658, p < 0.05) was significantly associated with improved acute myocardial infarction readmission rates and allowing patients to generate their health data (β= -0.280, p < 0.05) was significantly associated with improved readmission rates for heart failure.

Conclusions
Hospitals can improve their overall quality by offering health information technology with certain engagement functionalities to their patients. While it is important to adopt a broad range of functionalities to meet internal and external demands, the findings of this particular study suggest that hospitals that offer patient engagement HIT functionalities related to patient education, viewing and downloading health information, requesting changes in medical record, and patient generated data entry are likely to have higher patient satisfaction and lower readmission rates for acute myocardial infarction, heart failure, and pneumonia. It may be because these functionalities enable patients to become more engaged and activated in their care. This study will potentially assist hospital administrators in justifying their strategic deployment of HIT resources to improve both perceived and actual care quality.

A checklist to support effective and scalable design of ePRO tools in electronic health records

Elizabeth Austin, MPH1, Courtney Segal, BA1, Joseph Heim, PhD1, Savitha Sangameswaran, MS1, Danielle Lavallee, PharmD, PhD1

1University of Washington, Seattle, WA

Introduction: Patient-reported outcomes (PROs) provide important information about how patients experience health conditions and treatments, as well as quality of life. When integrated into care delivery, PROs can provide clinically-meaningful data and ensure treatment decisions are guided by patient perspectives. Yet current use of PROs in clinical care is often limited to paper-based workflows that prohibit efficient, integrated reporting and data use. Therefore, many health systems are starting to utilize electronic PROs tools, often through electronic medical record systems (EMR). The electronic capture of PROs parallels many other types of patient-reported data currently in use, yet PROs also introduce nuanced challenges (i.e. adaptive logic, complex scoring and interpretation) that add complexity to the inputs, activities, and outputs designed in ePRO tools. While there is a growing evidence base on how PROs can inform care, evidence based practices for ePRO design and implementation are limited.1 As clinical and quality drivers continue to increase the demand for PROs, health systems need guidance on how to best govern the ePRO build and implementation process to support diverse clinical and user needs.1

Methods: Working with a multidisciplinary group (clinical, administrative, IT, research, systems engineering), we supported the design of four distinct PRO tools within our EMR (Table 1). The team identified that existing tools used to request IT resources did not adequately prepare project teams for ePRO builds. We used structured analysis and design technique (SADT, or IDEF0) methodology to identify core functions (i.e. activities) related to ePRO use. We then leveraged the four PRO tools as use cases to model related mechanisms and constraints for each core function. Learnings from the build and pilot experiences of each of the use cases were applied to ensure validity across clinical contexts and workflows. Lastly, we developed an ePRO implementation checklist to support the intake and design of future ePRO builds, based on workflow gaps identified via SADT modeling and pilot results.

Table 1: Clinical context of PRO tool pilots

<table>
<thead>
<tr>
<th>Use case</th>
<th>Clinical context and goal</th>
</tr>
</thead>
<tbody>
<tr>
<td>Total Joint Replacement</td>
<td>Pre and post-surgical assessment of functional status</td>
</tr>
<tr>
<td>Depression Screening</td>
<td>Population health screening for depression risk</td>
</tr>
<tr>
<td>Depression Management</td>
<td>Ongoing assessment of depression symptoms and response to treatment</td>
</tr>
<tr>
<td>Medicare Annual Wellness Visit</td>
<td>Multiple PRO and health status measures to identify preventive care needs</td>
</tr>
</tbody>
</table>

Results: SADT modeling helped identify five principal functions related to the use of ePROs in clinical care: deploying ePRO measures, collecting ePRO data, tracking ePRO completion, reviewing ePRO results, and storing ePRO data for future use. Evaluation of the four pilots emphasized the need to consider enhanced design choices beyond the patient-facing survey itself as part of the preliminary build intake assessment. In particular, activities related to the functional area of tracking were missed in all four build examples, and several critical activities related to all five functions were not addressed in existing IT build assessment tools. The ePRO implementation checklist translated modeling results into questions that would help teams better identify ePRO-specific dependencies (e.g., existing ordersets, optimization of local clinic roles) and constraints that might negatively impact the build and implementation process (e.g., EMR data lags). The checklist reviews elements of the ePRO project scope, data collection and submission workflow, and electronic tools needed to support ePRO data review and documentation.

Conclusion: As health systems seek to leverage their EMRs to engage with patients through the use of PROs, there is a need to understand best practices that can support effective and repeatable ePRO design and builds. SADT modeling across four ePRO use cases highlighted multiple considerations that impacted the success of ePRO tools. The resulting ePRO implementation checklist provides a standardized tool to guide teams in the assessment, prioritization, and governance of ePRO builds. Future work should identify useful metrics to monitor the effectiveness of ePRO tools, including understanding reach, workflow efficiency, and variation in clinical practice.

Solutions in Health Analytics for Rural Equity Across the Northwest

Uba Backonja, PhD MS RN1,2, Seung Eun Park, RN MSN2,
Anne M. Turner, MD MLIS MPH2, India Ornelas PhD MPH2, Greg Whitman, BA2,
Melinda Schultz, MS2, Betty Bekemeier, PhD MPH FAAN2

1University of Washington Tacoma, Tacoma, WA, USA;
2University of Washington, Seattle, WA USA

Introduction

Public health decision making requires access to data to identify health disparities, implement prevention efforts, and ensure health care access. Clinical care is being transformed by advancing analytic methods applying a large volume and variety of data. However, these benefits have yet to be realized in rural public health, which faces a lack of access to quality data to understand communities’ needs and is impacted by a lack of access to data that includes marginalized and underserved populations. These data gaps reduce rural public health’s capacity to identify and address inequities. Therefore, there is a need to support rural public health’s access to and use of data.

SHARE-NW: Solutions in Health Analytics for Rural Equity across the Northwest

The project: SHARE-NW is a 5-year, user-centered project funded by the U.S. Health and Human Services Office of Minority Health (tinyurl.com/sharenw). Our goal is to identify, gather, and visualize data to support rural public health agencies and leaders to more effectively understand and address inequities in rural Washington, Oregon, Idaho, and Alaska. The final product will be a website that supports access to data on health outcomes and social determinants of health (SDOH), provides visualizations of data to facilitate understanding of local health equity, and engages users in training opportunities regarding data use and equity. We are engaging end-users – rural public health agency leaders and data users – throughout the project lifecycle to support the development of a solution that meets their needs.

Completed work for SHARE-NW: In Year 1 (2017-18), we interviewed end-users and learned they lack capacity to access and use data, encounter data quality issues, and desire training on using data. We also compiled, and are continuing to compile, publicly available data on SDOH and health outcomes related to six priority areas for rural health: obesity, diabetes, tobacco, mental health (including substance abuse and suicide), violence/injury, and oral health. In Year 2 (2018-19), we developed paper mockups of visualizations using data related to opioids. Designs were informed by Year 1 findings, a review of online health data dashboards (e.g., countyhealthrankings.org), and the literature (e.g., Munzner’s visualization model). We evaluated mockups in-person, via phone, or videoconference with end-users. Initial analyses indicate participants found value in the dashboard to make data easier to access, use, and share. We also identified (a) indicators included in publicly available datasets matching our six priority areas and (b) publicly available trainings related to needs identified in Year 1. All project endpoints to date have been met.

Future work for SHARE-NW: In Year 3 (2019-20), we will build a visualization prototype in Tableau based on the work completed Years 1-2. This prototype will be tested among end-users and updated based on resulting feedback. We will also develop trainings in partnership with the Northwest Center for Public Health Practice (nwcpp.org). Trainings will include how to use the website and data for decision-making regarding health equity, as well as other topics identified through the project. In Years 4-5 (2020-22), we will continue usability testing, and update of the dashboard, provide trainings, identify more datasets to integrate, and develop strategies to sustain SHARE-NW.

Conclusion

There is a great need to develop informatics solutions to support rural health equity. SHARE-NW aims to address this need by engaging rural health practitioners to develop a solution to support data access and training. There is potential for this work to inform practices and policies regarding user-centered development of public health data dashboards.

Growing Up Stronger: Improving Pediatric Population Health with HealtheRegistries
Ranjodh Badh, Children’s National Medical Center, Washington, DC;

Abstract
Children’s National Health System set out a lofty goal aimed at improving the health of children in the region with five health conditions: Asthma, Cardiomyopathy, Diabetes, Inflammatory Bowel Disease and Sickle Cell Disease. Our workflow-integrated decision support tools guide our providers by alerting them to evidence-based improvement opportunities for children with these conditions. We describe how EHR-derived data aggregation, data quality improvement, and workflow integration can effectively improve population health outcomes. Our learning objectives are identifying data integrity challenges and best practices to overcome these with successful outcomes; understanding the relationship for improving data quality, workflow integration and improvement in regional pediatric health for chronic conditions.

Introduction
In 2017, CDC estimated 17,429 children in Washington D.C. have Asthma. Children’s National Health System provided services to 15,192 children, reflecting 87.5% data capture. In 2018, Children’s National Health System started with the goal to improve health of children in the region. As an example, we identified at-risk children with severe persistent asthma, with more than 20 ED Visits in past 3 years and multiple hospitalizations over the same period. Meaningful data from our population health analytic tools enabled coordinated interventions and communications for patients with certain (chronic) conditions, to empower patients and families to manage their disease and prevent complications. Success in population health is multifaceted and includes engagement of subspecialists caring for these children. Our analytics platform helps to identify opportunities for improvement, care coordination and management across the continuum, and clinical integration with the primary care team.

Two-arm Approach—Data Quality and Care Outcomes
Advancing quality outcomes in select population health diagnoses across the continuum of care through our patient registries drives our organization to focus attention on the measures of health on data quality and care coordination—our action arm. Data quality is challenging in a multifaceted manner:
- Health quality measure performed, but not in accessible or documented
- Care ordered but not carried out
- Measure documented in an unstructured (narrative) manner
- Mapping from EHR to enterprise data warehouse (EDW) is inaccurate and requires correction

The chart below displays progression of two measures over time.
1. The sudden increase/decrease in % of patients met is due to changes in data correction
2. Gradual improvement seen in both measures is weekly improvement made by clinical teams.

In our approach to each of the above issues we have seen some steady improvement in data quality over the course of the year. It is clear data quality is only part of the story. Our second arm, the clinical integration with Ambulatory Case Management, is a crucial role to improve outcomes of care align with support case managers in mobilizing care resources to mitigate risk of adverse events.

Conclusion
Transforming population health is central to our mission which requires reaching to region, inclusive of kids who may not seek out our care. Granting our clinicians provider facing analytic tool aims at helping our care teams take better care of our kids through data understanding.

Completeness and Concordance in Electronic Health Record Documentation of Chemotherapy-Induced Nausea and Vomiting in Pediatric Cancer

Melissa Beauchemin, MSN, RN,1 Rebecca Schnall, PhD, RN, MPH,1 Chunhua Weng, PhD, MS2

1School of Nursing, Columbia University, New York, NY
2Department of Biomedical Informatics, Columbia University, New York, NY

Introduction

Electronic health records (EHRs) are ubiquitous in healthcare settings. EHR-derived clinical data can be used to improve identification and management of patients at-risk for or diagnosed with diseases; however, the quality of the data must first be assessed.1 Chemotherapy-induced nausea and vomiting (CINV) is a common cancer treatment-related symptom. The quality of the EHR documentation, specifically related to completeness, concordance, and heterogeneity,2 related to CINV assessment is not known. This study aims to evaluate the documentation practices of providers and the quality of the data regarding assessment and identification of CINV, and to develop a post-coordinated approach to better identify patients.

Methods

We evaluated the EHR of patients ≤ 18 years old with cancer who had received emetogenic chemotherapy in the outpatient setting between 1/1/2016 and 12/31/2017. The patients’ EHR data, including structured and unstructured data, was explored and annotated to identify domains where CINV was assessed and diagnosed. We extracted the variables of interest (Table 1) and compared the concordance of CINV-related documentation by prescriber (physician or nurse practitioner), RN, and ICD-10 billing codes. We then manually mapped the related terms and concepts for CINV, identified through our data extraction, through UMLS Metathesaurus to SNOMED-CT. We identified all terms, or atoms, listed in UMLS that were classified under nausea, vomiting, or chemotherapy-induced nausea and/or vomiting. Qualifiers and modifiers that provide a deeper level of granularity about temporality, severity, and negation were also searched and included. In an iterative process, we developed a concept mapping of CINV to inform a post-coordinated approach that would improve identification of patients with CINV.

Results

Thirty unique patients were included in the analysis. RNs were more likely to document an assessment of CINV compared with prescribers, and there was frequent discordance between RN and clinician reporting of CINV. ICD-10 codes designated by prescribers were concordant with primary oncologic diagnosis, but not chemotherapy encounters (47% agreement) or diagnosis of CINV (33% agreement with prescriber documentation). Mapping the identified terms through UMLs informed a post-coordinated expression that will increase identification of the relevant components to completely and accurately document CINV (Fig 1).

Conclusion

Inconsistencies by provider type and lack of completeness were noted in this pilot study assessing data quality of CINV documentation. Post-coordinated expression can improve the characterization of CINV specifically relating to temporality, severity, and negation.

Diagnosis Combinations Associated with Longer Length of Stay

Patrick E. Beeler, MD¹, Karol Tarcak, MSc¹, Ulrike Held, PhD², Edouard Battegay, MD¹
¹Department of Internal Medicine, University Hospital Zurich & University of Zurich, Switzerland; ²Department of Biostatistics, Epidemiology, Biostatistics and Prevention Institute, University of Zurich, Switzerland

Introduction: Various factors such as specific diagnoses have been found to be associated with worse clinical outcomes among inpatients. However, little is known on interactions between diagnoses, i.e. combinations of conditions with an excessive impact not explained by additive effects. The aim of this study was to identify interactions between diagnoses that are independently associated with increased length of stay (LOS).

Methods: In this exploratory study at a large tertiary care academic medical center, all 287,255 inpatient stays over an eight-year period were included. Professional coders added ICD-10 codes to all diagnoses as defined by the physicians in charge of the patients, independent of whether the patient received care for a specific diagnosis or whether it contributed to the billing. We grouped the diagnoses assigned to the stays into 1,595 distinct categories based on the first 3 digits of the ICD-10 codes. A Lasso regression was applied to identify the 483 most important columns using cross-validation over alphas as well as lamdas, afterwards α=1 was selected. We then ran 19,608 regression models, each combining two distinct diagnoses, with a support >10, to evaluate whether there was evidence for a potential interaction. In each of these models, the main effects of all considered diagnoses were included. The outcome variable was LOS (days), which was log-transformed due to its skewed distribution. Raw computation time, with cross-validation and all subsequent regression models, took two days on a SMP machine with parallelization at 18 threads. We controlled for multiple testing by applying the Bonferroni correction (p value cut-off at α/19,608=2.5E-6). A final regression model was run including all 483 diagnoses, age, and 2,519 statistically significant interactions. Analyses were conducted with the software R.

Results: Due to the Lasso regression, age was kept, however, sex was not. The final model included 483 diagnoses, age, and 2,519 interactions. Eating disorders were separately investigated (not presented) due to a known standard LOS of 3 months for these patients. Ultimately, a total of 774 interactions were statistically significant. Of those, the top five beta weights and most frequent (N) interactions were:

Discussion: The prevalence of multimorbidity is increasing with a growing elderly population. Although many single risk factors worsening clinical outcomes have been identified as being critical, only very little is known about interactions of diagnoses that prolong LOS beyond additive effects due to the burden of the diseases. The negative impact of diagnosis interactions on the LOS of multimorbid inpatients has not been established yet and might have been underestimated so far. Finally, another crucial clinical outcome, 30-day readmissions, will be investigated in a next step by applying the same approach with multivariable logistic regression models.
FURTHER DATA VISUALIZATION DESIGNS TO SUPPORT SHARED DECISION MAKING ABOUT BLOOD PRESSURE

Abstract

We present a simplified data visualization of home and clinic blood pressures (BP) to support shared decision-making by the patient-physician dyad, visually emphasizing elements that have long term clinical significance (cardiovascular outcomes). We manage large volumes of patient-generated BP data by summarizing and smoothing to simplify interpretation of control and to remove distracting variability of no clinical consequence.

Background

Only about half of the 78 million US adults diagnosed with hypertension have their blood pressure controlled. The majority of BP measurements are currently gathered in physicians’ offices. Recent research has identified the important role of home BP measurements, considered equal—or even superior—to clinic BP measurements in their predictive value. Home BP monitoring is becoming more common, with seamless uploading of home BP measurements directly into a patient’s EHR on the horizon. As with recent innovations in continuous personal heart rate monitoring (e.g., Apple Watch), a future of continuous BP monitoring is rapidly approaching. While past literature has shown that data visualization of physiological data is highly effective at improving clinical understanding, we must design for the transition from the current landscape of BP data scarcity to a future of data abundance and, if we are not prepared, data overload.

Objective

Current EMR systems have only limited abilities to visualize BP data. Our goal was to develop a display—simple enough for patients but powerful enough for physicians—to allow for the visualization of a patient’s home BP measurements to support shared decision making.

Methods

We used a rapid prototyping process in which candidate visualizations were iteratively refined based on regular feedback from both patients and physicians. Several focus groups with hypertensive patients, and family and internal medicine physicians, were held to gather feedback on candidate visualizations.

Results

Data density

With an abundance of home BP values, we can manage the volume of displayed data to enhance readability by smoothing, averaging, and/or hiding (binning multiple measurements into one displayed measurement; Figure, note 1). We find that we suppress display of single outliers when variability is high (when it’s likely unimportant clinically), but still display clusters of outliers (of likely or potential clinical consequence—e.g., a cluster of outliers might show symptomatic temporary low BP that requires clinical attention (Figure, note 2).

Smoothing

In experimental studies, we have previously found that patients perceive increased BP variability (Figure, note 3) as decreased control—despite the literature showing mean BP to be most predictive of health outcomes, with variability accounting for only a tiny fraction of the variance. To improve perception of BP control, we smooth raw data using the LOWESS algorithm (Figure, note 4).

Conclusions

The purpose of the visualization drives the design requirements. We designed for simplicity to support shared decision-making by the patient-physician dyad, visually emphasizing elements that have long term clinical significance (cardiovascular outcomes). Managing data density by binning in our display makes it more readable without hiding important outliers. Smoothing makes it easier to identify the recent average trend, reducing the recent distraction of any variability.

Description
Cancer genomics studies produce massive, heterogeneous datasets with variable characteristics, creating challenges during data integration, analysis, interpretation of results, and extrapolation of meaningful observations across different datasets. Consequently, attempting to utilize, analyze, or combine datasets from multiple sources proves inefficient and convoluted. The OncoMX knowledgebase and corresponding web portal is actively being developed to mitigate such challenges by leveraging biomedical ontologies to unify disparate data while emphasizing the availability of multi-faceted evidence for cancer biomarkers. The OncoMX knowledgebase is accessible via a searchable web portal and enables integrative exploration of cancer genomics data from mutation, disease and normal expression, literature mining, and biomarker and pathway databases. OncoMX was designed, with key user input, to better facilitate cancer biomarker research and discovery through four major use cases: 1) exploration of cancer biomarkers, 2) evaluation of mutation and expression in an evolutionary context, 3) side-by-side exploration of published literature for mutation and expression in cancer, 4) and exploration of a specific gene or biomarker within a pathway context. OncoMX is expected to benefit basic cancer research, promote efficient consumption of information by end users, and ultimately improve biomarker and cancer detection capabilities. OncoMX is available at https://www.oncomx.org/.

Figure 1. DNA/RNA-seq-based mutation and expression data are integrated and unified by DO and Uberon terms into BioMuta and BioXpress at the HIVe Lab. Data is supplemented by Bgee normal expression, literature mining for mutation (DiMeX) and expression (DEXTER) in cancer, functional annotations, EDRN biomarkers and a pilot dataset of FDA Approved Breast Cancer biomarkers, and Reactome pathways. All data are subject to unification processes and provenance capture before being consumed by the OncoMX processing pipeline.
Providing Data Security Guidance for Researchers

Drew University of Medicine and Science, Los Angeles, CA.

Introduction

When investigators undertake research, they assume the responsibility to protect subjects’ privacy in collecting, transmitting, analyzing and storing health-related information. However, researchers are often uncertain how these responsibilities play out across the different types of data that they deal with and across steps in the data lifecycle. This uncertainty may inhibit their research activities, or conversely, may put them and their institutions at risk. We set out to create a guidance document for researchers to serve as a reference for their data security responsibilities.

Methods

The UCLA CTSI convened a Data Security Work Group (DSWG), consisting of the Informatics Program leads and the information security officers from each CTSI partner site, among others. The DSWG first evaluated several information security frameworks and chose the NIST 800-171 standard\textsuperscript{1} as the best framework for organizing an analysis of security practices. In addition, the working group determined that the sites’ highest priority was to provide data security guidance for researchers to use in preparing their protocols and data security plans. In response, the CTSI staff worked with security experts from each campus to create a grid that guides researchers about their minimum responsibilities for each type of data they may collect and across each stage in the data life cycle.

Results

We produced a Research Data Security Grid that provides investigators with guidance for protecting 4 different types of data across 10 steps in the data life cycle. The four data types are: identified data derived from patient care (PHI), de-identified patient data, identified data collected from research subjects (which is termed research health information, or RHI), and Intellectual property (IP). The steps in the data life cycle are: data collection or generation, data transmission inside the institution, data storage by the researcher, data analysis, user training, audit and accountability, data transmission outside the institution, data storage and analysis at collaborating institutions, data destruction, archiving final data and sharing with outside researchers or the public. Note that simple use cases, such as a researcher collecting and analyzing data on her or his own, may involve only selected data types and may not involve all of the steps. Multi-institutional studies typically involve all of the steps. The grid also contains a glossary of terms and contains footnotes to indicate site-specific considerations. As an example, the guidance cell for data transmission of PHI reads “Encrypt data in transit. Use approved file sharing or file transfer platform.[2] Encrypted, password-protected email attachments are also permitted for internal data transfers.” The poster presentation will include the full grid and qualitative feedback on its acceptance among the UCLA CTSI institutions.

Conclusion

Data security guidance for researchers can by summarized in a grid format, organized along the axes of type of data being dealt with and stages in the data life cycle. We anticipate retaining this format as technology, and data security requirements, continue to evolve in the future.

Posda: An Open Source Curation Tool for Validation, Editing, and Inspection of DICOM Objects for Large Scale Imaging Archives

Bill Bennett, B.A.¹, Kirk E. Smith, B.S.¹, Quasar Jarosz, B.S.¹, Sonya Utecht, B.S.¹, Fred W. Prior, Ph.D.¹

¹Biomedical Informatics, University of Arkansas for Medical Sciences, Little Rock, AR

Introduction

Disclosure of protected health information (PHI), data quality and provenance tracking are primary concerns of large scale publicly accessible image archives such as the National Cancer Institute’s Cancer Imaging archive (TCIA)¹². Posda³ is a set of open-source scalable curation tools that we developed to address these concerns.

Methods and Materials

Posda is a custom set of open-source curation workflow tools dockerized for easy deployment in a Linux environment. De-identification software such as RSNA’s Clinical Trials Processor (CTP) redact PHI assuming the DICOM conforms to a standard which is rarely the case, do not test for DICOM consistency or validity and are ill suited to find and redact PHI or correct errors on a large scale. Posda is a role-based application that parses DICOM tags and stores values into a database (even if they are not DICOM compliant), which allows DICOM encoding errors to be captured, analyzed, and corrected prior to publication. Posda maintains a DICOM validation rule set and maintains an up-to-date DICOM private tag dictionary. These underpin DICOM validation and guide de-identification processes. The original files are stored in a file system and subsequent modifications are stored in the Posda database.

<table>
<thead>
<tr>
<th>The current Posda release supports:</th>
<th>6. Visual inspection of RT object alignment</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. DICOM send and receive</td>
<td>7. Checks for duplicate SOP Instance UIDs</td>
</tr>
<tr>
<td>2. Summary spreadsheets for data verification</td>
<td>8. Semi-automated detection/correction of PHI</td>
</tr>
<tr>
<td>5. Visual inspection of DICOM images</td>
<td>11. Prioritization of multiple data streams</td>
</tr>
</tbody>
</table>

Results

Posda has been successfully used as the primary curation tool for TCIA for the past three years. A scalable TCIA workflow supports the curation of DICOM objects prior to release. Submissions Managers use Posda generated reports to ensure all DICOM objects are received from submitting sites, to schedule PHI reviews, check adherence to the DICOM standard, check linkages to referenced objects and review issues related to PHI. Data Support Specialists review PHI reports and images for potential PHI and report potential issues. DICOM curators edit the data to ensure DICOM objects are valid. TCIA’s Posda instance has processed over 100 submissions containing more than 57 thousand series and over 5 million images during that time. There have been 310 distinct edit operations affecting 23,406,766 files.

Conclusion

Posda is the primary curation tool used by TCIA to ensure submitted DICOM objects are free from PHI, are valid DICOM objects, and are scientifically useful. Open source Posda tools allow review and correction of DICOM objects for improved DICOM conformance and consistency within healthcare environments and image archives.

Potential Benefits of Dental Visits in Managing HbA1C And Identifying Diabetes and Prediabetes in the U.S.
Munder Ben-Omran, BDS, MS1, Paul Fontelo, MD, MPH2, Gabriela Lopez Mitnik, MPhil1, Darien Weatherspoon, DDS, MPH1, Bruce A. Dye, DDS, MPH1.
1 National Institute of Dental and Craniofacial Research, Bethesda, Maryland; 2 National Library of Medicine, Bethesda, Maryland

Introduction:
A Patient-Centered Healthcare delivery model can enhance disease identification and is appropriate for disease prevention and treatment delivery. Periodontitis is a chronic oral disease and given the bidirectional relationship between diabetes/prediabetes and periodontitis, timely referral of patients with diabetes and prediabetes during dental and medical encounters would benefit both patient and health care systems. The large number of people with diabetes or prediabetes in U.S. necessitates attentive monitoring and referral to decrease morbidity and associated financial burden of these conditions, and to improve health outcomes. The objective of this study was to determine how many adults with elevated (unmanaged) blood glycemic levels and periodontitis could potentially benefit from proper referrals in a fully integrated health-system.

Methodology:
Data from 6,691 adults aged 30 and older who participated in NHANES from 2011-2014 were analyzed to assess the relationship between managed and unmanaged HbA1C levels according to recent medical (MV) and dental visit (DV) utilization, after controlling for sociodemographic, health, and medical insurance factors. Unmanaged HbA1C population (HbA1C>= 5.7%) were determined using the American Diabetes Association guidelines. All statistical analyses were weighted and population-adjusted using SAS statistical software 9.4.

Results:
Information from study participants representing 143 million (M) non-institutionalized US adults aged 30 and over was analyzed. More than half of this population had unmanaged HbA1C levels (62.1 M). There were (2.4 M) undiagnosed diabetics, (39.3 M) undiagnosed prediabetics, and (53.5 M) adults with periodontitis. Among the population with a MV in the past year but no DV, there were (9.4 M) diagnosed diabetics, (6.1 M) diagnosed prediabetics, (1 M) undiagnosed diabetics and (22.7 M) undiagnosed prediabetics. The number of adults estimated to have periodontitis and a medical visit but no dental visit in the past year was (17.7 M). Among the population with a DV in the past year but no MV, there were (0.25 M) diagnosed diabetics, (0.34 M) diagnosed prediabetics, (0.36 M) undiagnosed diabetics and (2.1 M) undiagnosed prediabetics. Adults with periodontitis were more than twice as likely to have unmanaged HbA1C compared to individuals without periodontitis (OR=2.30, p>0.0001). Unmanaged HbA1C levels and periodontitis were more pronounced among older adults (age > 65 y), (affecting 17.2 M and 13.7 M respectively), and non-Hispanic blacks (5.7 M and 7.7 M respectively). Adults with a recent MV but no DV were 35% more likely to have unmanaged HbA1C compared to adults with recent MV and DV, controlling for sociodemographic factors and medical insurance.

Conclusion:
In a fully integrated health care system, upwards of (2.8 M) people with unmanaged HbA1C levels could be referred by dental providers to medical providers for further evaluation and (17.7 M) adults with periodontitis could be referred by medical providers to dental providers for further evaluation of periodontitis. Improving processes that facilitate referrals that lead to improvements in glycemic control and management of periodontitis could potentially reduce disease and economic burden in large health care delivery systems. Our findings suggest that tools to assist healthcare providers, such as machine learning algorithms and Clinical Decision Support Systems (CDSSs), operating with integrated electronic dental and medical records, could help primary health care providers (medical and dental) to: identify undiagnosed diabetic, prediabetic and periodontitis patients; facilitate referrals; and improve disease management.
Analysis of Representative Cases of Diagnostic Error in the Inpatient Setting
Kerrin Bersani^1, Kevin Carr BSIE^1, Nicholas Piniella^1, Kumiko Schnock, PhD, RN^1, Marc Pimentel, MD^1, Jacqueline Griffin, PhD^2, David W Bates MD, MS^1, Anuj K Dalal, MD^1

^1Brigham and Women’s Hospital, Boston, MA; ^2Northeastern University, Boston, MA

Introduction: Diagnostic errors is an ongoing threat to patient safety: an incorrect or delayed diagnosis can lead to patient harm, affecting up to 1 in 20 U.S. adults each year. Patients who encounter a diagnostic error may undergo additional testing, a delay in treatment, and potential harm due to inappropriate interventions or treatment. In the hospital setting, the root causes of failures in the diagnostic process have not been well characterized. In this study we describe our approach to identifying root causes of failures in the diagnostic process through analysis of representative cases of diagnostic error.

Methods: We conducted this study at Brigham and Women’s Hospital (BWH) in Boston, MA. We have identified the types of symptoms (e.g., chest pain) and conditions (e.g., pneumonia) in which diagnostic error may lead to harm for patients admitted to the general medicine service at BWH. We retrospectively identified cases of potential diagnostic error from various institutional forums and reporting structures (Table 1). To classify and prioritize root causes of error, we have modified the Safer Dx framework and the DEER Taxonomy tool to correlate failure points to diagnostic process dimensions (Figure 1), which we are using to confirm diagnostic error.

Results: To date, we have identified 1611 reports from various reporting structures (Table 1) that might be associated diagnostic error. We have currently confirmed errors in 8 cases using our chart review tool.

Conclusion: Identifying cases of diagnostic error is a labor-intensive process that requires retrieving potential cases and then confirming the presence of errors using a validated instrument. Our team is conducting fault tree analyses of confirmed cases of diagnostic error to prioritize failure points in the diagnostic process during acute care. We will then aggregate fault trees across all representative cases to identify common root causes of diagnostic error. Failure points will be prioritized to serve as potential targets of technological interventions to prevent diagnostic error.

The Role of Bipartite Networks in Stratified Predictive Modeling
Suresh K. Bhavnani PhD1, Clark Andersen MS2, Yu-Li Lin MS2, Emmanuel Santillana MS1, Tianlong Chen PhD1, Yong-Fang Kuo PhD3

1Instit. for Translational Sciences, 2Preventive Medicine and Community Health, Univ. of Texas Medical Branch

Abstract
Although several studies have identified strong heterogeneity in comorbidity profiles of patients readmitted to the hospital, current CMS models do not use such information. Here we used bipartite networks to automatically identify biclusters of patients and comorbidities, and used them to develop stratified predictive models, with implications for precision medicine.

Introduction
A wide range of studies on topics ranging from molecular to environmental determinants of health have shown that most humans tend to share key characteristics (e.g., comorbidities or genes) forming distinct patient subgroups. A primary goal of precision medicine is to identify such patient subgroups and to infer their underlying disease processes in order to design interventions that are targeted to those processes. To address this goal, here we use bipartite networks to identify clinically meaningful subgroups of readmitted patients with congestive heart failure (CHF) from the Medicare dataset, and explore the use of those subgroups to develop stratified regression models for predicting hospital readmission.

Method and Results

Data: We extracted cases (CHF patients readmitted within 30 days of hospital discharge) and controls (not readmitted within 90 days of discharge, matched by age, gender, race, and Medicaid eligibility as a proxy for economic status) from the Medicare Provider and Analysis Review (MedPAR) Files for 2013 and 2014 combined. This resulted in a training dataset (25,775 matched pairs), and a replication dataset (25,775 matched pairs). Variables consisted of 42 unique comorbidities highly prevalent in the elderly extracted from the Elixhauser, Charlson, and CMS-CC indices, in addition to history of coronary artery bypass graft surgery, critical in the analysis of CHF readmission. Using odds ratio with Bonferroni correction, we identified 37 comorbidities that were both significant in the training dataset, and replicated in the replication dataset.

Method: The analysis consisted of three modeling stages: 1. Visual Analytics Modeling was done by (a) representing the data as a bipartite network where nodes represented either patients or comorbidities, and the edges represented the presence or absence of a comorbidity, (b) identifying patient subgroups and their most frequently co-occurring comorbidities using bicluster modularity (Q) and testing its significance through comparisons to 1000 random permutations of the data, and (c) using the Rand Index (RI) to measure the similarity of comorbidity co-occurrence between the training and replication datasets, and testing the RI significance. The network was presented to a geriatrician specializing in CHF hospital readmission, who examined the clinical meaningfulness of the co-clusters in the network. 2. Classification Modeling was done by (a) building and validating a multinomial regression model to predict the probability of a patient belonging to each of the subgroups identified by the visual analytics based on their profile of 37 comorbidities described above, and (b) classifying each patient to a subgroup based on the highest probability of cluster membership. 3. Predictive Modeling was done by (a) building and validating a logistic regression model using all the patients lumped together to predict the probability of a patient being readmitted based on their profile of 37 comorbidities, age, sex, and race, and (b) using the C-Statistic (a validation measure of predictive accuracy) to compare the above lumped model to the validated stratified logistic regression models representing each of the patient subgroups (identified from the visual analytics), using the same above variables.

Results: The visual analytics identified 4 biclusters with significant modularity (Q=0.17, z=8.69, p<0.001), and significant co-occurrence replication (RI=0.94, z=17.66, p<0.001). The pulmonologist verified that the patient subgroups were clinically meaningful (e.g., a patient subgroup had a combination of psychological comorbidities with COPD, known to be high risk for CHF readmission). Fig. 1 shows how the C-Statistic of the lumped model (which ignores patient subgroups) compares to the 4 stratified regression models. As shown, Subgroup Model-1 (SM-1) has a significantly lower C-Statistic compared to the lumped model, suggesting that the current approach (used by the Centers for Medicare and Medicaid Services) of using a single model for predicting CHF readmission, significantly underperforms for a patient subgroup. Our current work explores whether a similar heterogeneity in predictive accuracies exists in other conditions tracked by CMS such as stroke, with the goal of developing targeted predictive models that have equivalent and high predictive accuracy across all patient subgroups. Such models could help hospitals predict and design interventions targeted to specific patient subgroups.

Developing Synthetic VA Healthcare Data in OMOP CDM Model

Jiantao Bian, PhD¹, Hamid Saoudian, MS¹, Brett R. South, PhD¹, Kristine E. Lynch, PhD¹, Benjamin Viernes, MPH¹, Michael E. Matheny MD, MS, MPH², Scott L. DuVall, PhD¹
¹VA Salt Lake City Health Care System and University of Utah, Salt Lake City, UT, USA
²VA Tennessee Valley Healthcare System and Vanderbilt University, TN

Introduction

The field of Biomedical Informatics could greatly benefit from new sources of open, sharable data. However, legislative mandates under the Health Insurance Portability and Accountability Act (HIPAA) and the Common Rule that protect patient privacy, confidentiality, and consent strictly limit the availability of shareable patient healthcare data. An open area of research and application of informatics methods has focused on generating realistic synthetic healthcare datasets that are representative of target patient populations. Under most situations patient identifiable clinical data are “locked down” and subject to institutional and federal regulations regarding data sharing that include de-identification approaches that focus on removing the 18 types of PHI specified under the HIPAA safe harbor standard and anonymization which goes further to remove all linking information to minimize risk of patient re-identification. However, these methods are labor intensive and may still put the patient at risk for re-identification when data are publicly released. Our goal is to provide a realistic synthetic data resource, SynVA (Synthetic VA), that could be used for research, software development, and training by healthcare community.

Methods

We limited our work to only structured data obtained from the VA Corporate Data Warehouse (CDW) that had been previously transformed into OMOP Common Data Model Version 5.1. We focused on simulating patient records from outpatient clinical visits by modeling the relational dependencies and conditional probabilities of actual VA medical record data. The methodology consisted of two parts. First, we calculated the aggregated distribution of clinical data from real patients. We then populated the synthetic data according to these distributions. This distribution-based method enables us to generate any arbitrary size of synthetic patient population. We iteratively populated synthetic data into the OMOP Person and Condition Occurrence tables. For the Person table, we categorized our entire VA Patient population (11.3 million) into 200 demographic groups according to the joint distribution of patient gender (M/F), age (ten groups), race (five groups) and ethnicity (Hispanic or Latino/Not Hispanic or Latino). We selected 60 groups based on the inclusion criterion of at least 10,000 patients/group. This allowed us to include the majority of patients and also ensure each group had enough patients to generate its distributions for the clinical elements (i.e., clinical condition, medication, and lab). For the Condition Occurrence table, we selected the top 1,000 clinical conditions in each of the 60 patient groups to ensure adequate coverage of clinical conditions. We evaluated the resultant synthetic data by comparing the distributions of condition records between the synthetic patient data and the original patient data (1). All steps were implemented in SQL Server Management Studio.

Results

We successfully generated 1,000,000 synthetic patients in the Person table to match the distribution of source population with respect to demographics. The most common demographic group was patients male, 65-74 years old, white, and not Hispanic or Latino. We generated 145,507,660 records in the Condition Occurrence table. The proportion of condition records from each of the 60 groups ranged from 0.004% to 24.16%, which closely mirrored that of our source data. The differences in distribution between synthetic and real data ranged from 0.0003% to 0.28%.

Conclusion

A distribution-based method is promising for developing synthetic health care data that protects patient privacy and confidentiality. Future versions of SynVA will populate additional OMOP tables (e.g., Visit Occurrence, Drug Exposure), consider the temporal and clinical plausibility between data elements, and incorporate more source-to-SynVA validations (e.g., Charlson Comorbidity Index comparison).

Tracking Breast Cancer Survivorship over time using the Claim Framework

Catherine L. Blake, PhD
University of Illinois, Champaign, IL, USA

Introduction

Concerted efforts such as STEEP\(^1\), DATECAN\(^2\), and REMARK\(^3\) are underway to harmonize breast cancer outcomes. At the same time automated methods to detect outcomes from peer-reviewed literature have advanced from identifying sentences to identify a specific noun phrase\(^4,5\). We show how integrating outcome entities into the Claim Framework\(^6\) enables physicians to visualize how survivorship has changed over time for different treatment strategies.

Method

Searches were conducted for brand and generic names of five drugs that are employed in systemic treatments of breast cancer from the 2016 baseline MEDLINE files. The treatments were chemotherapy (Doxorubicin and Docetaxel), hormone therapies (Tamoxifen, Raloxifene, and Bazedoxifene), and a targeted therapy (Trastuzumab). Explicit claims that involved a survivorship outcome were extracted and quantified from the 88,727 abstracts. Explicit claims were further grouped into those that show an improvement (e.g. improve, extend), a change where directionality was not provided (e.g. change, effect), and where survivorship did not improve (e.g. reduce, decline).

Results and Conclusion

Survivorship outcomes were reported 65,614 times in 21,906 abstracts. There were 12,445 explicit claims reported in 8,850 abstracts. Figure 1 provides a visual summary of how survivorship outcomes have change over time. Even though these treatment strategies were introduced at different times (see the x-axis) the proportion of abstracts with improved survivorship generally peaks just after a strategy is first introduced. These results suggest that automated methods could be used to track changes in outcomes over time and potentially to identify promising new strategies as they emerge. Further work is needed to differentiate between clinically relevant and surrogate endpoints.

![Figure 1. Percentage of abstracts that report an increase (purple), change (grey), or decrease (orange) in breast cancer survivorship for chemotherapy, hormone therapy, and targeted therapies over time.](image)

Sequential Analysis of Handoffs in a Mixed Methods Study

Katherine Blondon, MD, PhD¹, Pejmon Noghrehchi², Brian Hilligoss, PhD², Mustafa Ozkaynak, PhD³

¹University Hospitals of Geneva, Geneva, Switzerland; ²University of Arizona, Tucson, AZ, USA; ³University of Colorado, Denver, CO, USA

Introduction

Handoffs are the transfer of accountability and patient information from one healthcare provider to another. Handoff-related errors are common and can threaten patient safety and quality of care. One approach to improve handoffs includes the use of mnemonics such as the SBAR (Situation, Background, Assessment and Recommendation)¹ to help organize the content of handoffs. Sequences matter for effective cognitive processing when communicating large amounts of information. We hypothesized that some handoff content may already be structured with components of the SBAR, thus we aimed to study to what extent the sequential organization of handoff communication content is congruent with SBAR to inform future training interventions.

Sequence analysis is a challenging analytic task. Current software tools to support qualitative analyses do not sufficiently support sequence analyses. They can facilitate coding, linking, mapping of the data and querying in large datasets, but lack visual or statistical tools for sequence analyses. We propose an approach combining two software applications to conduct the sequence analysis, and discuss the implications of our results for future handoff training.

Methods

This is a secondary analysis of simulation-based verbal sign-outs. Twenty-one internal and family medicine physicians from a teaching hospital were enrolled to study handoffs in a simulated nightshift setting. Each participant received the handoff of four fictitious patients, and were given access to the EHR. Participants then received a page about each patient from ward nurses, which they needed to manage. They signed out their four patients to an investigator. This study focuses on one of the eight patient cases from this sign-out dataset, which was transcribed verbatim, and coded in Atlas.ti using an in-depth thematic analysis. Codes were grouped into the SBAR themes. Each code group then was assigned a time stamp to preserve the temporal order of the codes that were identified in thematic analysis. The list of time-stamped code groups were analyzed using Eventflow² which provides aggregated summaries of sequential data patterns in an interactive visual way.

Results

EventFlow visualizations highlighted the sequence patterns of SBAR elements stated by the eleven participants for this patient case. Durations of sign-outs varied between 2:06 and 6:46 minutes. All participants communicated patient identification features in the beginning of the sign-out. Overall, the majority of the participants communicated Background information early in the sign-out, and the Assessment was followed by Recommendations. The Situation information, however, was spread out during the sign-out in multiple segments; one participant even ended with a Situation segment. Recommendations were also often in multiple segments, following either a Situation or Assessment segment. There was no association between sign-out duration and organization of information.

Conclusion

Our mixed methods approach provides insight into the information sequences used in sign-outs. Based on this analysis, training could focus on the Situation segment, which should be given earlier in the sign-out. On-going research is exploring the generalizability of these results with the other patient cases. Future research should focus on how technology and training interventions can help clinicians organize their sign-outs better, supporting the use of validated mnemonics that can reduce medical errors.

Providing a User-oriented Interface to Enable Semantic Queries in PRISM
Jonathan P. Bona PhD, Joseph Utecht BS, Mathias Brochhausen PhD
University of Arkansas for Medical Sciences, Little Rock, AR, USA

Introduction
The Platform for Imaging in Precision Medicine (PRISM) expands core capabilities of The Cancer Imaging Archive (TCIA) to support the evolving requirements of cancer Precision Medicine research. This poster highlights our work extending PRISM’s ability to integrate and manage clinical, patient demographic, and other non-image data that typically accompany many of the collections comprising millions of de-identified DICOM-format cancer research images currently stored and managed by TCIA. Non-image data provide valuable information about the subjects of these images useful for search, exploration, and use of these data. However, clinical and other non-image data have historically been submitted and stored as spreadsheets lacking a common representation scheme, and that are not easily combined or queried. We integrate these into a semantic knowledge graph in a triple store database, and are developing user-facing tools for exploration of these data, allowing users to search across image collections by patient demographics, tumor location and disease types, diagnoses in clinical data, and more.

Methods
This poster presents our representation, transformation, and use, of de-identified non-image data accompanying two different public TCIA collections of head and neck cancer images. Though these collections originate from different sources, some types of non-image data are found in both, including basic demographic information, tumor sites, cancer types, and HPV diagnoses. These elements have been the focus of our work to integrate data from these collections, translating them to a shared semantic representation that is used for similar data appearing in other collections. Our representations for these data use OBO Foundry ontologies, including the Human Disease Ontology (DO), and the Uber Anatomy Ontology (Uberon). Instances are generated for each occurrence of the data elements we use and linked to ontology classes that explicitly represent the entities that the data are about (anatomical locations, disease types, diagnoses, demographic characteristics, etc). We have written Python programs that apply the matching semantic representation patterns to the input data, generating OWL/RDF files as output. These are loaded into a triple store, resulting in a queryable knowledge graph with built-in logical inference. This is immediately useful, for instance to find non-exact but matching results based on partonomic knowledge in an anatomy ontology. A simple web interface leverages semantic web technology without requiring the user to understand the technical details, hiding the complexity of OWL/RDF representation, the details of the ontology classes, and the SPARQL queries used. This interface presents simple, familiar user interface elements, such as an auto-completing typeable select box for tumor sites that is populated using the human-friendly labels attached to Uberon classes used in the instance data; or input boxes allowing the user to specify a search range for the age of subjects in the collections. These search elements generate a combination of SPARQL queries in the triple store and SQL queries in the relational database that manages TCIA image collection metadata.

Results
The knowledge graph resulting from this transformation links patient identifiers to representations of patients and patient characteristics and disease and diagnosis information, and the relations among those. Ontology terms classify these instances, defining the classes and relations used. This graph can be queried using the interface we have developed to identify records matching criteria based on fields that were previously not queryable, for instance to find records across head-and-neck cancer collections for Male patients over the age of 55 with a positive HPV diagnosis and a primary tumor in the oropharynx. The search results produced by this interface link directly to downloadable images, allowing users to quickly identify and view images that match their selection criteria.

Discussion and Future Work
This work demonstrates the usefulness of ontologies and semantic web tools to transform non-image data accompanying cancer image collections into shared semantic representations that enable integration, query, discovery, and exploration of both image and non-image data in these collections. Work is ongoing to roll out semantic representations of additional data and data types, and to develop further user-facing tools to support exploration and use of these data.

SMOREs: Synergistic Medication Organizer for RxNorm and Expansions, a Tool For Improving Semantic Relationships of Institutional Medications to Standardized Ontologies
Robert L Bradford, BS, CCIS, Marshall Clark, BS, Emily Pfaff, MS
University of North Carolina at Chapel Hill, Chapel Hill, NC

Introduction
Analyzing medication data longitudinally presents a significant challenge due to new medications routinely coming to market and others being removed. These changes in available medications lead to constant fluctuations in the available discrete codes used to describe those medications. While there are different coding sets, such as RxNorm, NDC, CPT or SNOMED-CT that provide semantic concepts for these medications, they must be kept in sync with the prescribe-able medications to maintain accuracy. Multiple endeavors at the University of North Carolina at Chapel Hill (UNC) require the semantic interoperability of these different medications codes across data sets. One such endeavor, the clinical research networks (CRN) including PCORnet and Accrual to Clinical Trials (ACT) have chosen to harmonize medication coding around RxNorm, a code set curated by the National Library of Medicine (NLM). In the development of a prototype clinical triplestore utilizing the FHIR® R3 RDF specification, we identified the need to develop a comprehensive and harmonized approach to mapping medication codes. Additionally, a key component of our clinical triplestore includes the integration of insurance claims and EMR data. Therefore, we developed the Synergistic Medication Organizer for RxNorm and Expansions (SMOREs) to input local medication codes and produce mappings to standardized ontologies such as RxNorm. SMOREs also aims to address gaps present in both EMR and claims medication data. For example, the Carolina Data Warehouse for Health (CDWH), contains EMR data from 2004, including medication prescriptions for which at least 21% were discovered to have no internal mappings to RxNorm, in contrast to the absence of mappings within the available insurance claims. By using SMOREs we were able to acquire semantic interoperability of EMR and claims medication data.

Development
The NLM and the Food and Drug Administration (FDA) have provided multiple API endpoints that provide access to different ontologies. To develop SMOREs, multiple endpoints were identified that could be used to lookup information on medication ontologies (Table 1). SMOREs was structured to allow for easy addition of new API endpoints as additional data needs were identified. Development started with utilizing the RxNAV API to focus on RxNorm base information, followed by support for openFDA and UMLS. These APIs populate the outputs of the SMOREs pipeline: a valid FHIR® JSON file or CSV with “synonyms” for all requested medications. SMOREs was written in Python 3.6 and designed to be system agnostic.

Conclusions
SMOREs provides a multitude of functions that allow for significant expansion of information on local medications (Figure 1). Using SMOREs we were able to create a comprehensive medication dictionary that provided RxNorm code mappings at the Semantic Clinical/Branded Drug (most specific) and the ingredient/multi-ingredient (most generic) levels in FHIR® R3 RDF format for prescriptions from the EMR and medication claims data. Accomplishing this allowed us to group medications together in a semantically consistent manner utilizing relationships of RxNorm to other ontologies (ATC, NDFRT, etc.) and integrate them into our clinical triplestore.

Nursing Informatics Pioneers Identify Influencers

Juliana J. Brixey, Susan K. Newbold, Dianna Dodd

School of Biomedical Informatics and Cizik School of Nursing, University of Texas Health Science Center at Houston, Houston, Texas, USA; Nursing Informatics Boot Camp, Franklin, Tennessee, USA; Cerner Corporation, Kansas City, Missouri, USA

Introduction
The American Medical Informatics Association (AMIA) Nursing Informatics History Project was established to record and maintain the history of nursing informatics primarily in the United States to 2000 [1]. At the project start, 143 individuals were designated as pioneers of which 33 were interviewed and videotaped by convenience. Pioneers were defined as innovators, trailblazers, or groundbreakers in some aspect of nursing informatics, first to open a new area and prepare a way for other nurses to follow [2, 3]. The designated pioneers advanced nursing informatics through innovation in clinical practice, education, administration, and research. This study is an extension of a systematic review used to identify manuscripts published by the pioneers in PubMed for the years 2010-2015 as evidence of continued contributions to nursing informatics [4]. Contributions to the field of nursing informatics as evidenced by participation in social media – specifically Twitter and LinkedIn was studied. These applications were deemed mostly likely to be utilized for a public professional presence [5].

Methods
A retrospective review of publicly available transcripts available from the AMIA website was conducted for 33 American Pioneers in Nursing Informatics. Each transcript was read line by line to identify themes and specific individuals as identified by pioneers as impacting nursing informatics. A concept map was created for each pioneer to visualize the themes and identified individuals.

Results
The following themes were identified
- Impacts nursing informatics
- Contributes to nursing informatics
- Brings the practice along
- Guiding lights
- Pioneers
- Leading edge
- Pioneers as friends

Examples of concept maps illustrating the connections among pioneers.

Conclusions
This project is a continued systematic study of pioneers in nursing informatics. The text transcripts are a rich historic repository of information provided by the pioneers regarding their lived experience in nursing informatics.

Results from this study led to the identification of seven themes. These themes reveal how the pioneers described relationships as well as those influencing the nursing informatics. Relationships among the pioneers extended to nursing informaticians in other countries. This provides insight that nursing informatics was a global phenomena.

Further study is suggested to refine the themes identified in this study. It is recommended that future research explores connections formed from attendance at professional conferences and meetings.

Estimating Uncertainty in Deep Image Classification

Katherine E. Brown, BS, Douglas A. Talbert, PhD
Tennessee Tech University, Cookeville, TN

Introduction

Recently, the application of deep learning to medical diagnosis has been an active area of research. Convolutional neural networks (CNNs) have made the computational processing of medical images more achievable. CNNs automatically extract important features from images that are then processed by an Artificial Neural Network to produce a prediction. Deploying CNNs in a clinical setting motivates a measure of the certainty of its prediction. In this study, we evaluate the effectiveness of various uncertainty measures on binary classification by CNNs.

Background

Gal et al.\textsuperscript{1} show uncertainty can be measured by calculating the standard deviation of the probability distribution resulting from repeatedly sampling a CNN with dropout active during training and testing. Leibig et al.\textsuperscript{2} demonstrate that this approach performed well in the classification of retinal images on the presence or absence of diabetic retinopathy. Tumor-Infiltrating Lymphocytes (TILs)\textsuperscript{3} are the infiltration of the immune system into a cancerous tumor and can be computationally detected in pathology slide patches using CNNs. In most patients, the presence of TILs is correlated with more positive response to treatment and increased survival.

Methods

We train two CNNs on a dataset of 85,000 images to determine the presence or absence of Tumor-Infiltrating Lymphocytes. The first network (VGG-16 predictor) is fine-tuning a VGG-16 CNN with ImageNet weights. VGG-16 is an effective CNN for image classification and performed well with this dataset\textsuperscript{2}. Our second model (Bayesian predictor) is a VGG-16 model augmented with dropout layers placed in the fully-connected layers, to create a network suitable for utilizing the Bayesian uncertainty measure\textsuperscript{1}. Our experiments compare two measures of uncertainty in deep image classification. The first is the Bayesian technique outlined by Gal et al\textsuperscript{1}. The second, naïve measure (softmax) is the absolute value of the difference of the predicted probabilities of binary classes from a standard CNN.

Experimental Analysis and Results

To evaluate these uncertainty measures, we first remove the most uncertain images from the classifier and measure the resulting performance of the classifier. Second, we simulate the use of an experienced pathologist by replacing the most uncertain labels with the known correct labels. For the first experiment, the accuracy of the Bayesian predictor improved more when using the Bayesian uncertainty quantification (UQ) (+17.0%) than when using the softmax UQ (+1.5%). The accuracy of VGG-16 predictor had a larger net increase in accuracy using the softmax UQ (+8.0%) compared to Bayesian UQ (+3.5%). For the second experiment, the accuracy of the Bayesian predictor had larger net increase from the Bayesian UQ (+16.5%) compared to the softmax UQ (+10.0%). The VGG-16 predictor had a larger net increase from the softmax UQ (+11.1%) compared to the Bayesian UQ (+9.0%) 

Conclusion

From our analysis, the best increase in accuracy occurs when uncertainty is measured directly from the predicting model. This is in contrast to using the more theoretically grounded Bayesian technique for measuring uncertainty and performing predictions with another model. In the future, we intend to further analyze this phenomenon to better understand UQ in deep learning.

The Role of Perceived Legitimacy in Clinical Decision Support

Julian Brunner, PhD, MPH, Elizabeth M. Yano, PhD, MSPH, Emmeline Chuang, PhD, Jeremy Shelton, MD, MSHS

VA HSR&D Center for Healthcare Innovation Implementation & Improvement, Los Angeles, CA; University of California Los Angeles, Los Angeles, CA

Introduction

There is growing recognition that clinical decision support (CDS) does more than inform or remind: it affects provider behavior through complex psychosocial channels, most notably by signaling the legitimacy of a given clinical practice to providers and patients. However, the specific role that legitimacy plays in CDS remains unclear. The goal of this analysis is to develop a conceptual model of the role of perceived legitimacy in CDS. Our objective is to describe how perceived legitimacy works as a mechanism for CDS to shape provider behavior, and identify moderating factors that determine the role of perceived legitimacy.

Methods

We conducted semi-structured qualitative interviews about CDS with 25 primary care providers from VA medical centers and community-based outpatient clinics within the VA Greater Los Angeles healthcare system. We derived our model after conducting thematic analysis of interviews with deductive and inductive techniques.

Results

Our analyses, summarized in Figure 1, identified moderating factors that shape the role of perceived legitimacy: provider uncertainty is typically a prerequisite for CDS to change behavior, provider attitudes about their organization determine the persuasiveness of organizational endorsement, and the extent to which CDS confers legitimacy depends in part on its content and framing, e.g. citing reputable sources, or showing the patient-specific information that informs the recommendation. We also identified multiple forms of provider-perceived legitimacy: hierarchical authority (e.g. my bosses want me to follow this recommendation), expert endorsement (e.g. locally-respected experts endorse this recommendation), institutional support (e.g. my organization or government endorses this recommendation), and peer support (e.g. members of my in-group endorse this recommendation). Finally, we found that CDS can also shape patient-perceived legitimacy, e.g. when providers point to computerized recommendations to demonstrate their institutional/societal endorsement.

Discussion

Failure to understand the psychosocial mechanisms of CDS can lead to ineffective or counterproductive interventions. Clearly specifying the role of legitimacy in CDS may enable CDS design to better target this mechanism whose role is widely acknowledged but imprecisely understood.

Electronic Informed Consent (eIC) Platform for Clinical Trials: An Operational Model and Suite of Tools for Consent Authoring, Obtaining Informed Consent, and Managing Consent Documents

Michael Buckley, MS, MBA, Joseph Lengfellner, Matthew Koch, Hector Pacheco, Carol Hoidra, MDiv, Dorothy Damron, MS, Collette Houston, Roy Cambria, Ann Rodavitch, MA, Paul Sabbatini, MD
Memorial Sloan Kettering Cancer Center, New York, NY

Introduction
The informed consent process is the foundation of human research subject protection, and studies have shown that enhancing the consent experience with introductory videos and visual aids, can improve participant engagement and comprehension.1,2 The eIC platform was developed to augment educational alternatives for research participants, reduce administrative time and effort associated with paper consenting, improve the IC audit trail, and streamline consent document authoring for clinical research studies. This web-based platform is device-agnostic and browser-independent; it is now used by 35 Services for 36 institutional and sponsored therapeutic and non-therapeutic clinical trials. Three protocols in the platform have an educational video embedded in the eIC, and 5 have an embedded image flow that gives an overview of the protocol timeline for tests and clinic visits.

Methods
To evaluate the pros and cons of the eIC platform versus the paper, we assessed: 1) the availability of the finalized document in the electronic health record (EHR), 2) processing time, and 3) the accurate completion of required data fields. A five-question survey was used to assess participant’s feedback on the eIC process, and free text responses were reviewed for common topics. Participants drive the decision to use electronic or paper consenting, and the discussion process is the same for both methods.

Results
As of July 2019, 201 active consenting professionals use the module, and 5,320 research participants were consented. Average eIC monthly accrual from January-June 2019 was 485 (+/- 45). Compared with paper consent forms, which take ~ 72h to post to the EHR, the signed eIC is sent and stored in both the EHR and the Patient Portal in < 2 minutes. The eIC platform decreases administrative effort associated with paper-based consenting by 5-15 minutes/form. The eIC module has a robust audit trail that tracks the consent session and participant interactions via timestamps. We compared results of 170 patients consenting to one protocol during the same timeframe; 85 used eIC, and 85 used paper. eIC use increased the completion of required data fields in the consent form by 4%, versus paper. Surveys were sent to 2,120 eConsent users, with 456 responses received (22%). Most respondents (370, 81%) noted electronic consenting was very easy (168), or easy (202) to use. Only 14 respondents (3%) noted that electronic consenting was somewhat difficult or difficult to use, and 72 were neutral. The majority of respondents (444, 97%) noted they would recommend electronic consenting to another patient at MSK. Free text responses were submitted by 229 respondents (50%), and surfaced the consistent themes noting the electronic process was simple, convenient, and user friendly.

Conclusion
The eIC platform provides an innovative operational model for electronic consenting in the academic medical setting, enhances the engagement and education of study participants, and improves quality and compliance in the consent process. We plan to expand our preliminary analysis by creating an assessment tool that will gauge participant understanding/engagement in the consent process.

Combining Neural Nets

Nithin Buduma¹, Aviv Segev, PhD², Dorothy W. Curtis, M.Sc.¹
¹Computer Science and Artificial Intelligence Laboratory, MIT, Cambridge, MA, USA; ²Department of Computer Science, University of South Alabama, AL, USA

Abstract

To date many papers have been published describing neural networks’ successes at classifying medical images. Our work seeks to combine these neural nets into a web service so that a client can submit a file (or files) and receive one or more analyses of their images. Our poster will show results from experiments testing the effectiveness of our combined neural nets on a variety of images. We see this as a step towards developing decision support software for medical image analysis.

Introduction

Patients as well as clinicians would usually like to consult multiple specialists when there is a tricky issue to resolve. Many papers have been published showing useful results from applying neural networks to medical images¹². We propose to bring these results to life by creating a web of neural nets which embody this knowledge. These neural nets will provide analyses to our clients of images they upload to our web service. To explore this architecture, we are first implementing our system to analyze images outside the medical domain. We are using the MNIST³ and CIFAR⁴ datasets. Our work will then progress to analyzing medical images.

System Description

Our Neural Net Web system consists of three main parts: (1) the user interface; (2) middleware; (3) and the individually trained neural nets. The user interface collects a file to be analyzed from the user. The middleware, or master neural net, uses a pre-trained convolutional net framework from torchvision⁵ to select individual neural nets should analyze the image. The middleware also converts the image if necessary to a common image format that all the individual neural nets have been modified to accept. The individual neural nets are built on top of a generic neural network which has been trained on a dataset collected from the web. When the selected neural nets have analyzed the image, their results are passed back through the middleware to the user.

Conclusion

We developed a model for decision support software for medical image analysis that integrates neural nets into an online system for image classification. Our software achieves 78% accuracy on the CIFAR-10 dataset and 99% accuracy on the MNIST dataset.

Feasibility of Using Computerized Adaptive Testing To Capture Patient Reported Outcomes in an Outpatient Setting: A Pilot Evaluation of PROMIS-CAT in Neurosurgery

Mohamad Bydon, MD; Kelsey Wolff, M.Ed.; Anshit Goyal, MBBS; Mohammed Ali Alvi, MBBS; Sandy Goncalves, M.S.; Travis Paul; Aaron Biedermann, MBA; Carolyn M. Macken, M.S.; Janine Kamath, MBA; Andrea Cheville, MD; Mark Nyman, MD; Mayo Clinic, Rochester, MN, United States

Introduction
Current challenges around Patient Reported Outcomes (PRO) administration include redundant and uncoordinated PRO collection leading to excessive patient burden and diminished response rates. In this pilot, we aimed to improve the completion rate of baseline Patient-Reported Outcomes Measurement Information System (PROMIS) questionnaires among patients presenting for outpatient evaluation in Neurologic Surgery, while reducing patient burden, using a computerized adaptive testing (CAT) format.

Methods
PROMIS-CAT was selected as the tool for capturing PROs using our institutional patient online services (POS) portal, linked directly to the electronic health record (EHR). Prior to the pilot, PROMIS-29 was administered online via an iPad at the point-of-care immediately prior to provider encounters, but was not immediately available within the EHR. The switch to PROMIS-CAT was driven by the benefits of enhanced efficiency and precision with CAT, as well as the immediate availability of PRO data in the EHR for provider reference. With PROMIS-CAT, participant responses inform a computer algorithm to select the subsequent items from an item bank that are most likely to inform trait estimation.

Results
Prior to the pilot, PROMIS-29 completion rate was 30%. During the two month pilot, 1863 patients were assigned PROMIS-CAT, of which 1285 or 69% of patients completed the questionnaire. The average number of questions answered by each patient was 45.2. Upper Extremity Function (which is not included as a domain within PROMIS-29) represented the domain with the highest number of questions administered while the least number of questions were administered in Fatigue and Physical Function domains.

Conclusion
EHR linked CAT may represent a valid tool to increase PRO collection rates. Selective domain administration may alleviate patient burden. Use of a cross-cutting PRO like PROMIS-CAT over multiple redundant legacy PRO measures, may also alleviate patient burden.
Developing a Performance Matrix for Multidisciplinary Teams

J. Callister, T. Kwan, S.K. Poon, The University of Sydney, Sydney NSW, AU
Y. Liu, L. Evans, P. Harnett, Western Sydney Local Health District, Sydney NSW, AU

Introduction
Multidisciplinary teams (MDTs) are considered the “gold standard” of care for patients with cancer. However, the performance of MDTs varies widely. While validated observational tools for assessing MDT performance have been developed, it is essential to develop a self-assessment tool for MDTs to review their performance and monitor improvement over time.

Aim
The aim of this study is to develop a reliable and valid performance matrix as an instrument for MDTs to evaluate their level of performance and monitor their improvement over time.

Methods
The methodology is shown diagrammatically below. Green = completed, Orange = current, Blue = future.

Phase 1: Criteria from an MDT member survey and key themes in the literature were incorporated into a 2-dimensional matrix. The matrix comprised five levels of performance (columns), from most basic to most advanced, and five components (rows) - governance and leadership, clinical discussion and decision making, meeting organisation, data analysis and research, infrastructure and workforce. Each component contained several sub-components.
Phase 2: The Delphi methodology was adopted to assess the reliability of subcomponents. 27 selected MDT members and Cancer Innovation Managers, with diverse medical, allied health and nursing expertise, were asked to categorise each criterion into a sub-component using a card sorting software. A formula was developed based on the concepts outlined in Bhattachery to evaluate the reliability and variance of members’ responses.
Phase 3: The card sorting test was repeated for the Performance levels and this was followed up by an online survey of a further 11 members using a 1 to 5 Likert scale.

Results
For the subcomponents, results showed 86% agreement between the opinions of MDT members and the original categorisation of criteria. 67% of these results were of high normal distribution. The results for performance levels showed general correlation but were not as consistent as those for the sub-components.

Discussion and Conclusions
This study aims to develop a valid and reliable performance matrix for MDTs to measure their performance against standardised criteria and monitor their improvement over time. Whilst preliminary results demonstrated good correlation for sub-components, levels of performance are currently being further reviewed by a small group as part of the Delphi process. Future research will focus on finalising performance levels and statistical validation of the matrix.

Investigating Pregnancy-Related Health Outcomes Among Patients with Sickle Cell Disease and Linking with Health Disparities
Silvia P. Canelón, PhD1, Mary Regina Boland, MA, MPhil, PhD1,2
1University of Pennsylvania, Philadelphia, PA, USA
2Children’s Hospital of Philadelphia, Philadelphia, PA, USA

Abstract
Sickle cell disease (SCD) is a severe inherited hemoglobinopathy, challenging to study due to its low prevalence. Our study investigates the relationship between SCD and adverse pregnancy outcomes: preterm birth and Cesarean delivery (C-section). Of 50,616 women who gave birth at the Hospital of the University of Pennsylvania, 2,069 had SCD. SCD women were at decreased risk of preterm birth (8.7% vs. 9.27%) and increased risk of C-sections (36.78% vs. 34.5%) versus African Americans.

Introduction
Sickle cell disease (SCD) is a complex inherited genetic disorder and the most common hemoglobinopathy in the United States, affecting roughly 100,000 Americans1. SCD primarily affects individuals of African ancestry and is associated with high lifetime morbidity and premature mortality2. In addition, those pregnant with sickle cell disease have been shown to be at an increased risk of adverse outcomes3. Because SCD occurs in those of African ancestry it can be difficult to determine if the adverse pregnancy outcomes are due to SCD or because of health disparities common among the African American (AA) community4.

This study assesses the rate of pregnancy-related conditions and complications – specifically preterm birth and Cesarean delivery (C-section) – in AA patients, and specifically those with SCD.

Methods
We obtained data from the Hospital of the University of Pennsylvania (HUP) for 1,060,100 women treated at either in-patient or outpatient clinics between the years 2010 and 2017. We identified 50,616 women with delivery diagnoses and procedures. We then investigated two common pregnancy-related complications: preterm birth and C-sections.

To identify preterm birth diagnoses, and cesarean delivery procedures, we used relevant ICD-9 and ICD-10 codes. We identified our SCD population using diagnosis codes for SCD and found 2,069 females with SCD who gave birth at HUP. To investigate potential health disparities, we compared maternal outcomes between those with SCD, the AA population and also the general population of women giving birth at HUP. This study was approved by the Institutional Review Board of the University of Pennsylvania.

Results
At HUP, 50,616 unique women delivered and 2,069 of these also received a SCD diagnosis (4.09% of all deliveries at HUP). Overall, we found that 7.35% were preterm (3,709 patients), and 35.41% were Cesarean deliveries (17,925 C-sections). We found lower rates of preterm birth (8.7% vs. 9.27%) and higher C-section rates (36.78% vs. 34.5%) among patients diagnosed with SCD vs. the AA population. In addition, the AA population had higher preterm birth rates (9.27% vs. 7.35%), but lower C-section rates (34.5% vs. 35.41%) compared to HUP’s general population (Table 1).

Conclusions
In conclusion, studying pregnancy outcomes in those with SCD is complex due to a mixture of health disparities among African Americans and the disease state itself. Future work includes further distilling of the health disparities among the AA community and its role on SCD progression and adverse pregnancy outcomes.

Normalizing Medication Data in the UK Biobank
Michael N. Cantor, MD MA
Regeneron Genetics Center, Tarrytown, NY

Abstract
The UK Biobank, a significant resource for both clinical and genetic data, displays information about medications that participants were taking at the time of enrollment (field 20003). This list is not currently mapped to a standard, so contains entries that may be analyzed as individual traits. We used a set of reference terminologies to map medication entries to RxNorm CUIs. Of 6750 unique entries, we were able to map 91% using automated methods.

Introduction: The UK Biobank (UKB) (1) is a significant resource for both clinical and genetic data. Upon enrollment, participants respond to a number of questions, including self-reported medications (field 20003 in the UKB data showcase). This is the only data field that collects data on specific medications (rather than classes of medication), and data in this field is not standardized, so medications may be interpreted as individual, distinct traits, rather than being grouped together for analysis. For example, the list has separate entries for “Zantac” and “ranitidine”, and “Pulmicort” and “budesonide.” Mapping these medications to a reference ontology- in this case RxNorm- would provide more confidence in medication-related associations (2) and improve patient care through more extensive understanding of pharmacogenetic and gene-medication-disease interactions.

Methods: We obtained the medication list from the UKB data showcase, field 20003. We used the REST APIs and some form of string matching for all of the resources listed. Initially we used RxNAV to obtain RXCUIs (RxNorm Concept Unique Identifiers) from the raw, unedited entries (e.g. “timolol 0.25% eye drops) and then from edited entries with dosages and formulations removed. For the unmapped entries, we used the UK SNOMED CT drug extension as well as the UK’s dictionary of medicines and devices (DM+D), using those references to map to ingredients to obtain RXCUIs where the UK brand names were not available in RxNorm. For the remaining unmapped medications, we used the European Bioinformatics Institute’s (EBI) ontology lookup service; EBI’s chemical database, ChEMBL; and the Unified Medical Language System (UMLS).

Results: Though there are 6750 entries in field 20003, only 3674 are associated with at least one participant in the UK Biobank. However, for completeness we attempted to map the entire list. Using automated methods and these reference terminologies, we were able to map 91% of UKB medication entries to RXCUIs, and 93% of entries that were associated with at least one participant. The entries mapped to 1849 unique RXCUIs, and each unique RXCUI was represented between 1-65 times. Matching raw text and eliminating dosages and formulations produced 58% of the mappings; DM+D and SNOMED CT added 15%; and the remaining ontology tools produced the remaining 18% of mappings.

Discussion: The challenges in this project are typical of attempts to map self-reported data to a standard. Apart from the usual issues of mapping international brand names to a U.S.- based vocabulary (RxNorm), several of the brand-named medications that were represented in the DM+D dataset were not linked to their ingredients (e.g. product identifier that was not mapped to any active ingredients), possibly because the medication was no longer marketed, or if they were linked, they were only linked to their inactive ingredients. Additionally, though several medications without RXCUIs were initially mapped to the UMLS, these CUIs often did not map to specific ingredients or therapeutic categories, thus making these mappings unhelpful for categorizing specific drugs. Other issues included ordering of terms (e.g. “chlorothalidone / atenolol” vs. “atenolol / chlorothalidone”), ambiguous brand names, and unique misspellings that were not caught by approximate matching functions. Future work will address these issues programmatically and potentially use other vocabulary resources (e.g. OMOP’s ATHENA) to complete the mappings. Because of the idiosyncrasies of certain entries, we expect that at least some manual work will be required to achieve 100% mapping. The mappings will be available on request upon their completion and validation.

Conclusions: Standardizing medication names in the UK biobank is emblematic of the typical challenges of mapping self-reported data. Limiting input to only generic names would make standardization easier but would put an undue burden on participants; however, limiting input to a set of standard brand and generic names would most likely strike the correct balance.

Patient Timelines for Research-Oriented Exploration of Longitudinal Cancer Patient Data: PT Explorer

Rodrigo Carvajal, BS, Guillermo Gonzalez-Calderon, PhD, Miguel Betin-Montes, MS, Rhoda Gai-Cherry, MS, Jordan H. Creed, MPH, Travis Gerke, PhD, Joseph Markowitz, MD, PhD, Steven Eschrich, PhD, Anders Berglund, PhD

Moffitt Cancer Center, Tampa, FL

Clinical data integration has significantly advanced the ability to perform translational cancer research. Challenges still remain in the navigation of complex, high-dimensional and longitudinal patient data. Many systems provide a cross-sectional patient snapshot at a time point (e.g., current state) to enable efficient navigation. We apply clinical practice-centered navigation of complex patient timelines to create a framework for research-oriented data exploration. The goal is to provide a “movie” of the patient’s medical history as a dynamic timeline. Using the Moffitt Cancer Center (MCC) research data warehouse (111,667 research patients; 5,490 patient-oriented data elements), we developed the Patient Timeline Explorer (PT Explorer). We provide a multi-resolution, continuous view of the patient where patient encounters are classified and presented in a dynamic timeline. PT Explorer integrates data from clinic scheduling, billing, imaging, medication, biobanking, cancer treatments, and patient reported outcomes. The framework can be adapted to any encounter-based dataset with longitudinally captured events.

Currently available cohort exploration tools focus on drilling down to specific data elements, either for a single patient or for a cohort, then exporting these selected elements. PT Explorer allows multi-resolution access to a longitudinal series of data elements available from MCC’s data warehouse. Our case study involves a recent MCC data request for all data elements in a patient cohort. The current cohort explorer does not support this query and resulted in multiple linked spreadsheets. PT Explorer, in contrast, presents visual summaries of the data allowing for access to all variables for all patients within a cohort (see Figure 1), setting the stage for efficient downstream analysis planning, and making visualization more intuitive. Once a patient is selected, categories of data elements (low resolution) are represented as an integrated timeline (Figure 2). Specific longitudinal data types are represented compactly when drilling further into the data, for instance as heatmaps for symptoms assessment surveys (Figure 3). The views can be exported to different data formats (JSON, CSV, Excel), visualized as images, or accessible directly from analysis tools such as R.

With the availability and integration of clinical data elements in research data warehouses, the display and navigation of this information becomes crucial to the research enterprise. PT Explorer presents a “movie” of the patient clinical history from first physician visit in a web-based interactive timeline. This allows event-related data exploration and visual integration of timelines and, ultimately, better understanding of the cancer patient experience.
Addressing physical activity barriers among prostate cancer survivors through a peer-based digital walking program

Regina A. Casanova Perez MS,† Harsh Patel BS,† Savitha Sangameswaran MS†, David J. Cronkite MS,‡ Courtney Segal BA†, Dori Rosenberg PhD MPH,§ John L. Gore MD MS,¶ Jonathan L. Wright MD MS,¶ Andrea L. Hartzler PhD†

Introduction
Prostate cancer (PC) survivors face significant barriers to survivorship-enhancing physical activity (PA). Although regular PA improves vitality, delays PC progression, and reduces the risk of PC mortality, only 30% of PC survivors meet national PA recommendations. Barriers to traditional structured exercise programs include lack of motivation, support, and exercise partners, which limit engagement and program impact. Although technology-based programs may improve access and reach, most lack social features many cancer survivors desire. Social media-based programs improve PA in young adult cancer survivors. Adding Fitbit tracking to such programs shows further promise. Yet, this approach has not been explored with older PC survivors. We know little about their design preferences or the efficacy of digital features to tailor such an approach. We engaged PC survivors in 3 human-centered design phases to develop and evaluate a digital program that combines technology and peer support to promote walking.

Phase 1. Assessing needs for improving PA: Using a series of 3 focus groups with PC support group attendees (N=61), we gathered needs and design preferences for our digital program to promote PA through personalized walking goals, supportive content, and peer support while facilitating step count tracking. Although most participants reported high interest in improving their PA level, there was agreement that “connections are what matters most to a group like us, not technology in isolation.” Preferred design features included: (1) high-quality content, (2) personal feedback on individual goals, and (3) support from small walking teams and peer mentors.

Phase 2. Designing a peer-based digital walking program: Informed by Phase 1, we built a program that includes: a self-selected ‘walking buddy’, a private Facebook group to access PA content and interact in group discussions, and a Fitbit Zip to track progress toward personalized walking goals. We developed a Python script to retrieve Fitbit steps.

Phase 3. Evaluating program efficacy for promoting PA over 6 weeks: We collected baseline step count for 1 week then held a kick-off meeting for participants (N=18) to meet, practice using the technology, and receive personalized walking goals to increase their average daily step count from baseline by 250 steps each week. Program evaluation followed a quasi-experimental pre-post design. After 6 weeks of program use, we found a significant improvement in average daily step count (mean increase of 2,463 steps/day, p<0.001). Exit surveys demonstrated moderate program acceptability with a mean(sd) System Usability Scale of 74(21). Exit interviews added qualitative insights into perceived program benefits, limitations, and future improvements. We are further investigating program engagement by analyzing week-by-week interactions with the Fitbit and Facebook group.

Conclusion
Findings establish a tested innovation, built in partnership with PC survivors, that demonstrates the potential to address PC survivors’ PA barriers in their everyday lives with a peer-based digital walking program. In future work, we plan to make improvements based on participants’ feedback and evaluate the program in a larger trial.

Usability Evaluation of a Clinical Decision Support Tool for Management of Peripheral Artery Disease Patients

Mayo Clinic Rochester, Minnesota.

Introduction: Practice guidelines for peripheral artery disease (PAD) patients recommend use of secondary prevention therapy with antiplatelet agents, statins, angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers, and smoking abstention. However, these strategies are underused by patients with PAD, with one study finding that only 16% of patients received all four recommended strategies in the community.1,6 Our study aimed to conduct a usability test on a clinical decision support (CDS) tool for populations of patients with PAD, entitled PAD cohort knowledge delivery solution (CKS), developed with the goal of assessment of guideline-based care received by PAD patients for quality improvement projects. The CKS tool links patient data with electronic knowledge bases to provide information/recommendations to providers at the point of care.5

Methods: We assessed both time savings and cognitive burden from the CKS compared to the electronic health record (EHR). The EHR was used to compare to the CKS because in the clinical workflow providers use information obtained by manual review of EHR for management of PAD patients. A set of 21 tasks were developed by study investigators to evaluate usability of the PAD CKS tool and the EHR system. Morae software was used to run the usability tests and to analyze data collected from these tests.2 Each scenario was also followed by an evaluation question regarding ease of completion of tasks within usability scenarios. The median for number of clicks, time taken, and number of keystrokes was calculated due to the skewed distribution of the data. Questions from the Quantitative System Usability Scoring System were included at the end of only the CKS usability test scenarios to generate a system usability score (SUS).1 Usability tests were conducted on 5 providers.4

Results: Mean system usability score (SUS) for the CKS was 90.5, with score > 80.3 considered excellent with a grade A rating. The median total amount of time taken to complete all 21 tasks in the EHR was 15.5 minutes compared to 4.5 minutes for all 21 tasks completed in the CKS (Table 1). EHR tasks had a median of 118 clicks in comparison to 31 clicks for the CKS, resulting in a difference of 98 clicks between the EHR and CKS. The EHR had a median of 26 keystrokes to complete the tasks, while the CKS had a median of 1 keystroke to complete tasks.

Table 1: Time and cognitive load for tasks with EHR and CKS

<table>

Introduction
An artificial intelligence clinical decision-support system (CDSS), Watson for Oncology (WFO), processes structured and unstructured patient data using natural language processing and machine learning. WFO identifies therapeutic options for cancer patients based on patient-specific information, called attributes. Examples of attributes abstracted by WFO include age, gender, stage, metastatic disease, imaging measurements, labs, prior treatments and co-morbidities. WFO provides a set of evidence-informed treatment options based on training cases provided by MSK cancer experts. Attributes can be entered in WFO manually or automatically by integration with an EHR system. An EHR synced tool like WFO provides value for having to incur the burden of data entry into an EHR. This is a retrospective study comparing EHR-WFO integration versus manual WFO data entry in colorectal cancer patients.

Methods
WFO was implemented in 3 Taipei Medical University (TMU)-affiliated hospitals; only one hospital integrated WFO with their EHR system. The EHR-WFO integrated hospital automatically processed cases after the first report of cancer by a pathologist, while in the other two hospitals, attributes were entered in WFO manually. Patient age, gender, imaging and pathology reports identified on or after the index date (14 days prior to diagnosis) were integrated as part of the relevant EHR for each case. Colorectal cancer patient attributes entered manually versus those abstracted by the integrated EHR-WFO system from 1/2018 to 2/2019 were compared. Shapiro-Wilk’s test for normality of variables summarized the data as median. Significance of differences was determined by Wilcoxon sign-ranked test.

Results
Of the 140 cases analyzed by WFO, 63 (45%) used the integrated EHR-WFO system to abstract attributes; 77 cases (55%) required manual data entry into WFO. EHR integration significantly decreased manual attribute entry (Figure 1, median values 14 vs. 16, respectively, \(P = .00014\)). EHR-WFO integration abstracted significantly more attributes into WFO, including optional ones, than manual input alone (median 23 vs. 16, respectively, \(P < .0001\), Figure 2).

Conclusions: EHR-WFO integration significantly increased the number of attributes entered into the system for treatment decision making and decreased manual attribute input, potentially saving time and enhancing the comprehensiveness of data. These findings suggest that EHR-WFO integration increased the richness of data available for treatment decision making beyond what WFO minimally requires, as optional attributes may be omitted during manual entry. The types of attributes extracted by each method and the effects of additional attributes extracted on decision making are under further study.
Ensemble Imputation for Healthcare Data

David Chen, PhD1, Christopher G. Scott, MS2, Christina L. Luong, MD3, Itzhak Zachi Attia, MS3, Che G. Ngufor, PhD1, Adelaide M. Arruda-Olson, MD, PhD3, Patricia A. Pellikka MD3

1Division of Digital Health Sciences, 2Division of Biomedical Statistics and Informatics, 3Department of Cardiovascular Medicine, Mayo Clinic, Rochester, MN

Introduction
Missing data is a common problem afflicting the vast majority of healthcare data[1]. Imputation methods can bias the final model and reduce the predictive accuracy. In this work, we combine bootstrap aggregation and imputation to capture the uncertainty in the imputed missing values and reduce the variability in the final learned model[2]. We demonstrate bootstrap imputation (BI) in an analytic task of predicting 5-year mortality in patients who have undergone a stress echocardiography test.

Methods
Figure 1 compares the schematic of conventional single imputation (SI) with the proposed algorithm. No imputation, null, mean, hot deck, and multiple imputation methods were compared. A decision tree (C5.0) and gradient boosting machine (GBM) methods were used to model. Area under receiver operating curve (AUC) metric with 5-fold cross-validation was used to evaluate predictive accuracy. All models were trained and evaluated in R.

A retrospective dataset of 68,706 patients was created from all adult patients who underwent stress echocardiography exam at Mayo Clinical Rochester. A total of 150 variables were abstracted from echocardiographic data, with missingness ranging from 0% to 48% and median missingness of 4.1%.

Results and Discussion
Table 1 shows comparison of results of the various imputation methods. The mean improvement in AUC using BI over all imputation methods for was 0.029 for decision trees and 0.006 for GBM. More representative imputation methods (hot deck or multiple imputation) show improved performance compared to simple ones. We hypothesize that single imputation cannot capture the uncertainty of the imputed missing value. Therefore a poor imputation model can severely bias the final classifier. Second, the imputation itself maybe unstable. Using bootstrapped sampled data for imputation reduces overfitting due to the imputation.

Table 1: AUCs of various imputation methods. Single and bootstrap refers to single imputation vs aggregation imputed bootstrap sampled data.

Conclusion
The results presented in this work demonstrate how ensemble based imputation can lead to more robust classification for a complex healthcare analytics task. The presented method allows for flexibility depending on the characteristics of the dataset and the limitations of the computing environment.

Bipartite Network Analysis with Multiple Datatypes: Implications for Precision Medicine in the Age of Multi-omics Data

Tianlong Chen PhD¹, Yu-Li Lin MS², I-Chia Liao MPH³, Yong-Fang Kuo PhD², Emmanuel Santillana MS⁴, Clark Andersen MS², Laurel A. Copeland PhD³, Suresh K. Bhavnani PhD¹

¹Inst. for Translational Sciences, ²Preventive Medicine and Community Health, Univ. of Texas Medical Branch, Galveston, TX; ³Center for Applied Health Research, Baylor Scott & White Health, Temple, TX

Abstract

Bipartite networks, which simultaneously model both patients and their characteristics, have been useful for identifying significant and comprehensible patient subgroups, a critical step in designing targeted interventions. However, because clustering algorithms require uniform data ranges to identify subgroups, bipartite networks have been used mainly to model uniform data types such as only the binary status on comorbidities, or only the continuous range-normalized values of gene expressions. Here we demonstrate the use of predictive probabilities to transform variables of multiple datatypes into a uniform range, which enabled the use of bipartite networks to identify and comprehend significant subgroups of readmitted patients.

Introduction

Because bipartite networks model both patients and their characteristics, they have been useful in not only identifying significant and replicated patient subgroups, but have also enabled clinicians to interpret why patients in each subgroup have negative outcomes, critical for designing interventions. However, because biclustering algorithms such as modularity require uniform ranges to enable the partitioning of patients and characteristics into subgroups, they are limited to modeling variables that have uniform ranges such as only the binary status of comorbidities, or only range-normalized gene expressions. Here we use predictive probabilities to transform multiple datatypes into a uniform range, enabling us to simultaneously model all relevant clinical variables like number of opioids (continuous), marital status (categorical), and presence of anemia (binary).

Method and Results

Data: We extracted 100% cases (total hip arthroplasty [THA] patients readmitted within 30 days of hospital discharge) and controls (not readmitted within 90 days, matched by gender, age and race) from the 2006-2015 data in the Veteran’s Administration Clinical Data Warehouse (VA-CDW). This resulted in 460 matched pairs each in the training dataset and in the replication dataset. Variables consisted of those identified by a physician and occupational therapist that were high risk for readmission, and all comorbidities from the Charlson, and CMS-CC indices that were also in the VA-CDW, resulting in 47 variables (41 binary, 1 categorical, 5 continuous). As domain experts prefer up to 10 variables when interpreting patient subgroups, we used logistic regression to estimate the significance of each variable for predicting readmission in each dataset, and selected the top-10 in the training dataset that were also highly ranked (in the top-20) in the replication dataset. Next, we transformed the value of each variable for each patient into the respective univariable probability (range 0-1) for predicting readmission. As we used a 1:1 case-control study design, the readmission probability in the study cohort is 0.5. We therefore dichotomized all the probabilities (<=.5=0; >.5=1) to conduct the bipartite network analysis.

Method: The analysis consisted of two steps. (1) Identification of patient subgroups by representing the data as a bipartite network where nodes represented either patients or variables, and the edges represented the dichotomized predictive probability of a variable. The training network was analyzed using bicluster modularity to calculate the number and boundaries of the biclusters (containing patients and variables), and the degree of biclustering (Q). The significance of Q was calculated by comparing it to a distribution of Q generated from 1000 random permutations of the network. The resulting patient subgroups were visualized using the ExploreLayout¹ algorithm. (2) Replication testing by repeating the above analysis on the replication dataset, and using the Rand Index (RI) to measure the proportion of pairs of comorbidities that co-occurred and did not co-occur within the same cluster in both networks. RI significance was calculated by comparing it to a distribution of RI generated from 1000 random permutations of both networks.

Results: As shown in Fig. 1, the analysis identified 7 biclusters with significant modularity (Q=0.35, p<0.05), and significant replication (RI=0.87, p<0.05). The visual separation of the biclusters in the network layout enabled the clinicians to infer the reason for readmission in each bicluster. For example, the patient subgroup in the upper right hand corner had a combination of gait disorder and peripheral vascular disease requiring different interventions compared to the patients with COPD. The results suggest that the method could be useful in analyzing multi-omics data to identify patient subgroups for precision medicine applications.

Review and Analysis of Current Mobile Apps for Depression
Lewis Chesebrough, M.S.¹, Annie Myers, M.A.¹ Lingchen Lou¹, Ruixuan Hu¹, Meghan Reading Turchioe, PhD, MPH, RN¹, Ruth Masterson Creber, PhD, MSc, RN¹

¹Weill Cornell Medicine, Department of Healthcare Policy and Research, New York, NY

Introduction
Clinical depression, defined as having one major depressive episode in a given year, affects 8.1% of American adults age 20 and over, and 37% of adults in all ages received no treatment. (1) Although psychological and pharmacological treatments for depression exist, many patients do not receive formal care and remain undiagnosed. (1) Consumer mobile apps have potential to improve patient outcomes and increase access to care but a systematic review of the quality and functionality of apps for depression has not been completed.

Objective
Using a standardized methodology, examine the quality of mobile apps targeting individuals with depression.

Methods
We completed a systematic review of mobile apps for depression self-management by entering six relevant search terms in the Apple, Android, and Amazon app marketplaces: "depression", "mood improvement", "mental health self-management", "depression monitoring", "depression screening", and "depression self-management" We selected apps using four rounds of ad hoc inclusion and exclusion criteria. We downloaded and independently reviewed the final apps and rated them according to the Mobile Application Rating Scale (MARS)(2), IMS Institute for Healthcare Informatics functionality scores (3), and general guidelines for depression management in the absence of patient-specific self-management guidelines. (5) We also conducted a literature review to assess whether the selected apps had been tested in clinical trials.

Results
Of 1198 potentially relevant apps searched, 31 apps met inclusion criteria. Most apps were excluded because they were unrelated to depression, were designed for educational purpose and diagnoses only, or were games. Inter-rater reliability between reviewers was high (0.75 – 0.83). Pacifica had the highest average MARS total score (4.6 out of 5). More than half of the apps (23/31, 74%) had acceptable MARS scores (≥3.0) and among those, 10 apps had MARS scores ≥ 4.0. Pacifica also had highest score for engagement (4.8), satisfaction (4.6) and behavior change (4.8). Elevat (4.4) had the highest score for behavior change. For functional score, the top three apps were Snapclarity, Pacifica, and Joyable. For Depression Management Features, the top performing apps were AkiliHealth, Booster Buddy, and InnerHour. Only one app, Woebot, was tested in an RCT, which showed that compared to a control group provided information on depression self-management, the app intervention group had significantly reduced depression symptoms. (5)

Conclusion
Mobile apps for depression exhibit a wide range of quality, but more than half of the apps included in this review had acceptable quality. The MARS scores correlated with IMS Functionality Scores, but not with the number of features for depression self-management. The high scoring apps in this review show that mobile health interventions can increase access to support, help manage symptoms of depression, and improve quality of life.

Reading Emotional Support Messages on a mHealth App Predicts the Initial Lapse after Alcohol Detox

Ming-Yuan Chih, PhD1, Woohyun Yoo, PhD2, Dhavan V. Shah, PhD3, Andrew Quanbeck, PhD3, David H. Gustafson, PhD3

1University of Kentucky, Lexington, KY; 2Incheon National University, Incheon, South Korea; 3University of Wisconsin-Madison, Madison, WI

Introduction
A key feature of Addiction-Comprehensive Health Enhancement Support System (A-CHESS),1 a smartphone app for relapse prevention after alcohol detox, is to provide preemptive services (e.g., sending alerts to addiction counselors) when patients are likely to lapse based on a built-in risk assessment/prediction model2. However, the predictability of this model can be improved.3 Based on the theories of emotional support, a computer-aided content analysis was conducted to analyze messages in an online forum provided in A-CHESS.4 These online peer-to-peer messages filled with emotional support contents may influence the lapse risk of patients who read them. We reported here the results of an effort to integrate these emotional support message coding data into the prediction model. The hypothesis is that reading messages with emotional support contents may affect patient’s imminent risk to lapse.

Methods
Data were from the intervention arm of a randomized control trial testing A-CHESS.1 The dataset—142 patients (51 initial lapses and 91 matched non-lapses)—in a prior study was used.3 2745 messages from the online forum in A-CHESS were retrieved. A hybrid human-computer coding method, reported elsewhere4, included the following steps: (1) developing theory-based coding constructs; (2) creating dictionaries of keywords in each construct; (3) establishing relationships between multiple terms/concepts in two software programs, WordStat 6.1 and QDA Miner 4.1; and (4) running the computer programs to generate coding scores in each coding construct. These message coding data were merged with the log file-derived messages reading activities 7 days prior to the prediction timepoint.3 A reading event was defined as the action when a user clicked on the link to open a particular message. Blocked logistic regression model was used. Three blocks included gender (1st block), 10 items in the weekly self-reported recovery status (e.g., urge) (2nd block), and the total scores of each of the 9 emotional support message coding constructs of the messages read 7 days prior (3rd block). Between-block model comparison was done by comparing changes of the chi-square and the degree of freedom values. Area Under receiver operating characteristic Curve (AUC) analysis was reported.

Results
Every new block accounted for significant model variance (see Table 1). Therefore, adding message coding improved the prediction model. On average, the most read coding construct in a week is Encouragement (mean=4.27) and then Care (mean=1.97). Based on the full model, confidence staying sober (p=0.02) and reading more messages containing Prayer words (such as “God with you”, p=0.044) were significantly associated with a reduced risk to lapse. Interestingly, reading more messages with Empathy words (e.g., “sorry” or “worry”) and Encouragement words (e.g., “cheer” or “hope”) was associated with an increasing risk to lapse in trending p-values (0.098 and 0.079 respectively). AUC is 0.862 with 95% CI [0.8, 0.92].

Perceptions of the Use of a Real-time Medication Monitoring Pill Bottle linked to a HIV Self-management App

Hwayoung Cho, PhD, RN1, Gabriella Flynn, MED2, Maureen Saylor, MPHc2, Melissa Gradilla, MPH2, Rebecca Schnall, PhD, MPH, RN, FAAN2

1College of Nursing, University of Florida, Gainesville, FL, USA; 2School of Nursing, Columbia University, New York, NY, USA

Introduction
Non-adherence to antiretroviral therapy (ART) among persons living with HIV (PLWH) remains a critical problem. Mobile health (mHealth) technology has the potential to be a useful tool in self-management of HIV to improve health outcomes such as medication adherence, engagement in healthy behaviors, and health-related quality of life.1-5 To improve long-term medication adherence using effective interventions that enhance the HIV care continuum, the ‘Wise App’, an HIV self-management app with real-time medication monitoring, was developed (Figure 1). The purpose of this work was to conduct an in-depth analysis of factors influencing use of the electronic pill bottle linked to the Wise App among PLWH.

Methods
This study was conducted as part of a larger randomized controlled trial with 200 PLWH who were assigned to the intervention or control group (1:1) through block randomization. In-depth interviews were conducted using a semi-structured interview guide at the 3-month follow-up visit with intervention group participants. All interviews were audio-recorded and transcribed. We explored emerging themes with similar patterns across interviews through thematic analysis and organized the themes according to the constructs of the Fit between Individuals, Task and Technology (FITT) framework.6

Results
Thirty-eight PLWH participated in the interviews. Nine themes organized by the FITT framework were identified. Three themes related to the fit between individuals and task were: motivation for strict medication adherence, self-efficacy for overall health management and engagement with medication reminders. Four themes related to the fit between individual and technology were: ease of use, HIV-related stigma and disclosure of HIV status, customized alert of medication time windows based on individual routine set-up and preference for device design. Two themes related to the fit between task and technology were: system functionality of data transfer from the electronic pill bottle to the app and self-awareness of system syncing signals.

Conclusions
This work demonstrated that tracking medication adherence and receiving push-notification medication reminders through the electronic pill bottle connected to the app supports PLWH in adhering to their medication regimens. Findings from this study highlight the importance of adequate consideration of the needs of intended users in designing customizable mobile health technology, including HIV-related stigma, disclosure of HIV status and ART regimens.

Changes in Nursing Activity After Implementing a CDS Service Predicting the Risk of Falling Based on Electronic Medical Records Data

Insook Cho, PhD1, Insun Jin, PhD2
1Inha University, Incheon, Republic of Korea; 2Public Health Insurance Ilsan Hospital, Goyangsi, Republic of Korea

Abstract

One-third of inpatient falls are preventable, but preventing them is hindered by the inability to accurately estimate their risk. A well-designed clinical decision support (CDS) service can help nurses decide how to allocate their services and resources. Here we report preliminary prospective observations obtained from the implementation of a CDS service designed to predict the risk of falling for individual patients based on electronic medical records data captured during nursing care.

Introduction

The quality of hospital care would be greatly improved if nurses are able to predict patient events that are likely to occur within 24 hours based on data available in electronic medical records (EMR). We developed a conceptual predictive model for estimating the risk of falling at the individual level using data captured routinely by an EMR system. The model was a Bayesian belief network with 48 nodes, 80 links, and 11 million conditional probabilities, and it was cross validated at 2 hospitals with different EMR systems and different nursing vocabularies. We used the model to implement a clinical decision support (CDS) service that predicts the daily probabilities from EMR data at a metropolitan hospital in Seoul, Republic of Korea.

Methods and Results

This prospective cluster randomized trial involved 12 nursing units of medical-surgical, neurology, and geriatrics departments. It was implemented in May 2017 and designed to finish in April 2019. The 12 units were randomly allocated to the experimental and control groups. The experimental units provided the CDS service and the control units provided their usual care. According to the data analysis frame defined in our previous work, we monitored the daily frequencies of nursing assessment and intervention activities provided to patients during two time periods: the first evaluation (6–12 months after implementation), and the second evaluation (12–18 months after implementation). We used the existing information as baseline (January 2015 to March 2017) for the experimental group. The assessment activities increased about 54-fold in the experimental group compared to the baseline, but the interventions had not increased after 12 months and only slightly after 18 months (Table 1). The assessment activities in the control group remained at similar levels throughout, but there were more interventions than in the experimental group after 12 months.

Data are mean (95% confidence interval) values.

Conclusion

These preliminary results give a clue that the CDS service predicting the daily risk of falling based on EMR data may affect positive changes of relevant nursing activities in terms of efficiency and resource allocation. To confirm it, further data collection and detailed analyses of nursing processes depending on patient risks are needed.

Effective Use of Secure Text Paging for Subspecialty Consult Requests

Chi D. Chu, MD1, Delphine S. Tuot, MDCM MAS1, Jonathan Duong, MD2, James D. Harrison, PhD2, Raman R. Khanna MD MAS2

1Division of Nephrology, University of California San Francisco, San Francisco, CA; 2Division of Hospital Medicine, University of California San Francisco, San Francisco, CA

Introduction
Despite the widespread prevalence of electronic health records, subspecialists receiving consult requests often benefit from an informational context provided via phone or in-person conversation with requesting clinicians. Based on previously developed frameworks for teaching effective consultation, the “best practices” for providing such context include a description of patient identifiers, the reason for consult, the level of urgency, and caller contact information. Alphanumeric text paging to request subspecialty consultation allows some context to be provided in the content of the page itself; however, the most effective use of this limited medium for providing such context is not known.

Methods
We extracted 12,290 secure text pages sent at the University of California, San Francisco Medical Center between 4/5/2017 and 11/17/2018 containing the case-insensitive string “consult” or “c/s”. From this, we randomly sampled 30 pages requesting consults sent to each of the 7 most consulted medical subspecialties, for a total of 210 text pages. Messages were coded independently by three raters (C.C., D.T., R.K.) for inclusion of elements based on literature review on consultation “best practices”: caller details (name, service, phone number, pager number), reason for consult, and indication of urgency. Additionally, we assigned a global quality rating (5 categories from “Very Poor” to “Very Good”). We used multivariable ordinal logistic regression to determine predictors of higher quality pages.

Results
The proportion of pages that included each best practice element is summarized in Figure 1. Of these elements, most pages included basic contact information and reason for consult; fewer than 20% explicitly indicated urgency. Of these 6 elements, the majority of pages included at least 4 or more elements (Figure 2).

Figure 1: Elements Included in Consult Pages

Figure 2: Consult Page Completeness

In multivariable ordinal logistic regression, the most important element associated with higher page quality was reason for consult (OR 22.35; 95% CI 8.10 – 61.66, p < 0.01), followed by callback number (OR 6.19; 95% CI 0.77 – 49.50, p = 0.09), caller name (OR 5.04; 95% CI 1.93 – 13.12, p < 0.01), and urgency indication (OR 3.28; 95% CI 1.59 – 6.72, p < 0.01).

Conclusion
Despite limitations of the medium, the majority of text paged consult requests contained 4 or more informational elements; however, urgency was infrequently included despite being traditionally included in “best practices” for consultation. This suggests there may be differences in elements influencing effectiveness of consults requested by text page as opposed a telephone conversation; thus, established best practices for telephone consultation may not apply directly to text paged consult requests: this is a potential area for future research. Our results suggest that clinicians requesting consults via text page should be aware that reason for consult was by far the most important element.
Hospital Performance on Unsafe Medication Orders in the 2017-2018 CPOE Evaluation Tool

Zoe Co1, Diane Seger1, RPh2, Lisa Newmark, BA3, Melissa Danforth, BA3, David C. Classen, MD, MSc4, David W. Bates, MD, MSc1,2,5

1Department of General Internal Medicine, Brigham and Women’s Hospital, Boston, MA, 2Clinical and Quality Analysis, Partners Healthcare, Somerville, MA, 3The Leapfrog Group, Washington D.C., 4The University of Utah, Salt Lake City, UT, 5Harvard Medical School, Boston, MA

Introduction: Although electronic health record (EHR) and computerized physician order entry (CPOE) implementation is now widespread, evidence suggests that these systems do not always result in reduced harm.1 Every year, hospitals in the U.S. take the CPOE Evaluation Tool via The Leapfrog Group’s annual Hospital Survey, to assess their EHR system’s ability to alert prescribers to common and serious prescribing errors, as implemented.2,3 The results of the tool provide hospitals with an overall percentage score of potentially unsafe orders detected, as well as a fatal orders analysis, which lists the potentially fatal orders that a hospital failed to stop or alert on. We evaluated how hospitals’ EHR systems performed overall and on potentially fatal orders in 2017 and 2018.

Methods: Detailed datasets containing the 2017 and 2018 CPOE Evaluation Tool results were extracted for analysis. The datasets only included the highest test score for each hospital, and any incomplete tests were removed. We also only included electronically orderable test orders by hospitals, meaning if a certain medication was not electronically orderable by a hospital, that test order was removed from their denominator during scoring.

To analyze how hospitals performed against potentially unsafe orders, we calculated the mean overall percentage score, and the mean overall fatal order score. For the 2017 and 2018 versions of the test, the fatal orders were distributed throughout the following order categories: drug dosing (both single and daily dosing), drug laboratory, drug route, and drug-drug interaction.

A secondary analysis was performed, in which we compared hospitals’ responses to the same fatal orders between the 2017 and 2018 test.

Results: From the 2017 data, we evaluated results from 1,750 hospitals. There was a total of 6,591 orderable fatal orders distributed throughout the test. Of these, 1,603 (24%) did not cause an alert to fire. Within these orders, drug dose daily was the fatal order category that hospitals performed the worse in, with 933 (58.2%) orders not alerted on. In contrast, drug-drug interaction was the category that hospitals performed the best in, with only 21 orders (2.25%) not alerted on.

The mean overall score in 2017 was 58.0%, while the mean fatal orders score was 76.1%. More than half (55.4%) of the hospitals received a fatal order score of 100%, while 44.6% of hospitals got at least one fatal order incorrect. Of these hospitals, 113 hospitals did not alert on any fatal orders.

Comparing these results to 2018, hospitals showed improvement. The mean overall score in 2018 was 65.8%, while the mean fatal order score was 83.5%. There was a total of 5,486 fatal orders, and 933 fatal orders (17.0%) were not alerted on. The percentage of hospitals that got at least one fatal order incorrect decreased to 35%. Drug dose daily was still an area that hospitals struggled with. However, the percentage of daily dose orders not alerted on decreased to 43.4% (405 orders).

From the secondary analysis, we identified 422 hospitals that received the same fatal order in 2017 and 2018. Of these hospitals, 81.3% (343 hospitals) got the same orders correct in both years, and 11.1% (47 hospitals) alerted on the fatal order they did not alert on in 2017. However, 7.6% (32 hospitals) got the same order wrong in both years.

Conclusion: Although the mean overall score suggests that most hospitals’ CPOE systems alert on most common prescriber errors, there is still important room for improvement in how systems respond to potentially fatal orders. These results reveal critical areas of improvement that hospitals can use to improve their EHR system. The tool is being expanded to include other domains, which will hopefully help hospitals improve their safety further.

Impact of EHR Usability on Provider Efficiency and Patient Safety in Non-Hospital Settings

Jamie Cole, P.S.M. ¹, Wanda Sankey B.S.¹, Guenter Tusch, Ph.D¹, Raymond Higbea, Ph.D., FACHE¹, Marie Vanderkooi, DNP, MSN, RN-BC¹, Larry Warkoczeski, M.H.S.A. J.D.¹

¹Grand Valley State University, Allendale, MI, USA

Abstract

Electronic health records (EHRs) have been implemented in many healthcare settings under the premise of increased productivity and improved patient interactions. However, severe unintended consequences from implementation and design of these systems have emerged. Poorly implemented EHR systems may endanger the integrity of clinical or administrative data. That, in turn, can lead to errors that may jeopardize patient safety or decrease quality of care. Therefore, analysis of the benefits anddownfalls of the implementation of EHRs is paramount step to improving provider-patient interactions and overall public health. Prior review of the implementation of these record keeping systems has been primarily focused on the hospital setting. Given the variability and importance of non-hospital medical centers, assessing the impact of EHRs to local offices is of exceptional importance. This study aims to better assess the implementation of EHRs by electronic survey and group interviews of local medical centers in an effort to improve patient safety and EHR usability.

Introduction

EHR usability refers to the efficiency and effectiveness of the system’s use and the satisfaction of the users when accomplishing specific tasks within their environment; this includes user–friendly workflow design supporting efficient, effective quality care. The lack of standard user interfaces remains a challenge for clinicians who work in multiple care settings potentially influencing provider productivity and patient safety. EHR-related errors have been documented in the past, however this documentation has been primarily focused on the hospital setting. Identifying the errors and benefits of implementing EHR in non-hospital settings is still needed to improve these patient-provider interactions. The purpose of this project is to identify the impact of EHRs on local medical offices as a means to improve local implementation of EHRs as well as identify common hindrances to the efficacy of EHR implementation in a non-hospital setting.

Methods

An initial literature review of current EHR studies was performed by reviewing over 300 articles from various databases including PubMed, ProQuest, Google Scholar. These articles included inpatient and ambulatory settings and were used as a basis to construct a series of interview questions. These questions focused on the categories and subcategories of provider centric (sub-categories: design, workload, implementation), patient centric (sub-categories: care coordination, patient safety, quality) and outcomes (sub-categories: patient-provider relationship, health outcomes). Through a partnership with the Michigan Medical Group Management Association, local medical offices were interviewed as well as surveyed on these topics. Finally, their responses were recorded and analyzed in an effort to identify shortcomings and benefits EHRs have in local medical offices.

Results and Conclusion

In this study, a series of questions were developed based on a current literature search of EHR implementation. The focus of these questions were established during a previous phase of this study, where a literature review of EHR impact demonstrated three major categories (provider centric, patient centric, and outcomes) and eight sub-categories (design, implementation, workload, safety, quality, care coordination, patient-provider relationship, and health outcomes) were heavily impacted by EHRs. Based on this literature review, a model was established and the effectiveness of the implementation of EHRs was analyzed through the lens of this model. This study is ongoing and the data collection and analysis continue to grow. It is anticipated that this study will be completed over the next 1-1.5 years. After assessing the advantages and disadvantages of EHRs, this information will be shared with these medical offices as well as possibly establishing coordination between the medical offices and Grand Valley State University to assist in the improved implementation of EHRs to office usability and patient safety.

Automated Prediction of Patient Stability and Discharge within 36 Hours

Kevin Coppa,1 Marsha Meytlis, PhD,1 Jamie S. Hirsch, MD,1,2 Jan Horsky, PhD3
1Department of Information Services, Northwell Health, Lake Success, NY
2Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Hempstead, NY
3Center for Research Informatics and Innovation, Northwell Health, Manhasset, NY

Introduction

Extensions of hospital stays that do not add clinical value over necessary treatment and stabilization are associated with increased risk of iatrogenic infection, poor nutrition and unwarranted higher care utilization.1 Planning of care in the community and completion of documentation usually starts after a patient discharge decision has been made, often adding hours and days to stay. Advance identification of stable patients who will be soon ready for discharge would allow starting the administrative process early, reducing exstraneous hospitalization days. Data routinely collected and stored in the EHR can be automatically analyzed by machine learning algorithms to calculate how likely a specific patient is to be stable enough for discharge within 24 to 36 hours. This pilot study compared four classification algorithms and a regression model for best performance in predicting patient stability within 36 hours: a two-class support vector machine, a random forest model, decision tree, a neural network and a logistic regression.

Methods

Algorithms were trained on 90% of available data and their predictive ability tested on the remaining 10%. A set of suitable clinical markers and salient patient characteristics that a hospitalist would likely consider when making a discharge decision was derived from discussions with clinical experts. It included age, data flows, order-related data and recent laboratory test results that were entered as features into the models to approximate a decision-making process. Binary values represented the presence and absence of orders for oxygen, pain management, telemetry and imaging studies, antineoplastic, steroid, and diuretic medications, the need for blood transfusions and the presence of an active diet order. Parameters related to the stay were the number of orders and notes in the preceding 24 hours, weekday and inpatient unit. Laboratory results included oxygen saturation, temperature, hemoglobin, white blood cell count and sodium level and were converted to binary markers as normal or abnormal. The most recent LACE score, Charlson Comorbidity Index and MEWS score were also included. We queried a clinical data repository that contained 76,587 visit days from 14,804 unique patient stays. Eliminating rows with incomplete data reduced the set to 74,129 visit-days from 13,864 unique admissions. Performance of the algorithms was then evaluated on this dataset.

Results

Non-customized random forest model using optimized hyper parameters showed better performance than its competitors (Table 1), with positive predictive value of 48% and a balanced accuracy of 70.6% (95% CI: 0.690.71). (Figure 1). The four algorithms and logistic regression model had similar performance characteristics, and all performed better than the decision tree.

Table 1 Algorithms predicting 36-hour patient stability

Figure 1 ROC, random forest

Conclusion

The random forest model using data routinely available in medical records provided guidance for the optimization of the discharge process, possibly avoiding unnecessary extensions of stay. This model likely performs better as it has intuitive decision rules, allows non-linear variables and accounts for their interaction. The usual length of stay during the study period was shorter than 2 days which likely increased the negative predictive values of all tested algorithms. The algorithm is currently used to prioritize the scheduling of imaging tests needed before discharge.

Mount Sinai Spanish-Language OpenNotes Navigator Program

Catherine K. Craven, PhD, MA, MLS1,2, Lina Jandorf, MA2, Cristina Villagra, MPH2, Zeida Quintero-Canetti2, Joseph Kannry, MD1, Bruce Darrow, MD, PhD1
1 Clinical Informatics Group, IT Dept., Mount Sinai Health System, 2 Dept. of Pop. Health Science and Policy, Icahn School of Medicine at Mount Sinai, NY, NY

Introduction
The New York State Health Foundation offered OpenNotes (ON) implementation program grants in spring 2017. The Clinical Informatics Group, Mount Sinai Health System (MSHS), was one of seven grant awardees for our proposal to offer a one-year navigator program surrounding our enterprise ON rollout, spring 2018. Our program’s focus was a patient-facing bilingual Spanish-English navigator to help our Spanish-language preferred patient population sign-up for and navigate MyChart accounts, find their ON office visit notes, understand the importance of engaging with their health information, and if desired, provide a verbal translation of clinical notes. Spanish-language preferred patients were the focus because they comprise ~30% of patients at the main Mount Sinai Hospital (MSH) and affiliated practices, which borders East Harlem, in which 50% of the population is Hispanic. This group is the largest with the lowest uptake of MyChart although system-generated numbers on this do not exist.

Methods
From the Jandorf research group, we hired two highly experienced minority-population navigators.1 The second navigator educated staff and clinicians about ON and encouraged them to discuss ON and the navigator program with patients. In spring 2018, we created scripts, FAQs, flyers, signs in Spanish and English; a training PPT; and ordered easel signs. We created question protocols for three rounds of IRB-approved program evaluation; each round comprised two focus groups with navigated patients, two with staff, and interviews with clinicians. Patient navigation launched in May 2018, at our two largest primary care and internal medicine practices. Staff/clinician navigation launched that June, with invitations to all MSH-affiliated outpatient practices. We heavily promoted the program including features in MSHS publications “Your Voice Counts,” the Patient Experience newsletter, the English-Spanish “Our Community” newsletter - distribution of 10,000 including patients; presentations to groups such as the East Harlem Community Health Committee and the Harvard ON group with guests from West Coast systems with large Spanish-preferred populations; hospital lobby tabling sessions; and a Black History Month event.

</tbody>
</table>

We navigated 517 patients. We trained 222 staff/clinicians, ~ three times the goal. Results from the evaluation rounds will be presented. A key finding: Patients loved this program, and because of it, even those with truly limited English felt empowered to use MyChart and ON. Staff/clinicians did not spread the word to patients as hoped, but their ON awareness increased, and they strongly supported the dedicated Spanish-language ON navigator.

Discussion
ON founders at Beth Israel Deaconess Medical Center-Harvard have called our program “ground breaking,” yet from the lessons learned, we know that this program could be recreated readily elsewhere. Where “build it and they will come” fails, the human navigator touch reduces hurdles and empowers patients to succeed.

Leveraging a Participatory Informatics Platform for Patient-Reported Outcomes in a Clinical Trial.

Cummings AL, MD; Goldman JW, MD; Arevian A, MD PhD.
David Geffen School of Medicine, University of California - Los Angeles, Los Angeles, CA.

Introduction
The integration of web-based applications for patient-reported outcomes (PRO) has been proven to have significant benefit in cancer care and survival (1, 2). The UCLA Lung Correlative Team (LCT) developed a web-based application, L07-PRO, with the participatory informatics platform Chorus (https://chorus.semel.ucla.edu) (3) to capture PRO for a phase 1b/2 clinical trial, “Talazoparib and low-dose temozolomide in treating participants with relapsed or refractory extensive-stage small cell lung cancer (TRIO-US L07)” (NCT03672773). The trial opened in October 2018 at several sites in California, Nevada, Indiana, New Jersey, and Florida and will enroll 28 participants.

Methods
The design of the application (L07-PRO) was informed by unstructured interviews with and testing by primary investigators, clinical trial coordinators, Chorus staff, and patients. Chorus enables individuals without technical backgrounds to visually create mobile apps through a web interface. A clinical fellow (non-programmer) constructed L07-PRO overseen by Chorus staff. L07-PRO was included as an optional measure and exploratory outcome in the TRIO-US L07 protocol, which received regulatory approval through the UCLA data safety monitoring board (DSMB) and Food & Drug Administration (FDA). The protocol specified L07-PRO assessments be completed at minimum on day 1 of each 28-day cycle, as well as day 14 of cycle 1 and 2. If participants did not wish to complete these assessments through L07-PRO, they could complete them on paper. All entries are user/time/date stamped and trigger email messages if certain criteria are met. Training on the application was scheduled with clinical trial coordinators prior to first enrollment; if participants opted in, they received training during their first study visit. Text messages or emails based on participant preference were sent as reminders the day of the first 4 assessments.

Results
Based on stakeholder feedback, L07-PRO consists of a participant, administrator, and data portal. Once participants opt in, they receive a login and 4-digit pin set through the administrator portal, which is used to review all application submissions. The patient portal includes options to start an assessment, which leads to select multi-choice items from the patient-reported outcomes version of common terminology criteria for adverse events (PRO-CTCAE) (4), report an emergency room or hospital visit, contact their trial coordinator, or provide feedback on L07-PRO or the trial. To date, 3 out of 4 participants have elected to use L07-PRO (age range 40-80s). The patient that declined did not own a smartphone or other mobile device with internet capability. All 3 using L07-PRO requested text message reminders. Of 11 protocol-required submissions, only one was done on paper, related to a forgotten pin. The assessments associated with trial response.

Conclusion
Utilizing participatory informatics in developing PRO applications is feasible in clinical trials. L07-PRO serves as a proof-of-concept for further application development. An adapted version will be used in future lung cancer clinical trials.

Missing and Discordant Race Data Documented in Electronic Health Record Systems at an Academic Medical Center

Marika M. Cusick, BA1, Evan T. Sholle, MS1, Marcos A. Davila, MS1, Joseph Kabariti, BS1, Thomas R. Campion, Jr. PhD1,2,3

1Information Technologies & Services Department, Weill Cornell Medicine, New York, NY; 1Department of Healthcare Policy & Research, Weill Cornell Medicine, New York, NY; 3Clinical and Translational Science Center, Weill Cornell Medicine, New York, NY

Introduction

Racial minorities are underrepresented in clinical research, which hinders the ability of investigators and practitioners to address health disparities in vulnerable populations. To identify patients from minority racial groups for participation in studies, researchers can query structured race data documented in electronic health record (EHR) systems. Although meaningful use requirements in the United States require documentation of race in EHR systems for all patients, some patients may have missing data or their race values are discordant across electronic systems. Understanding the degree to which missing or discordant structured race values exist in electronic patient data can inform efforts addressing underrepresented minority participation in research. The objective of this study was to measure patients’ missing and discordant structured race data as documented in multiple EHR systems at one academic medical center.

Methods

We obtained demographics for all patients from the outpatient EHR, inpatient EHR, and inpatient billing system used at Weill Cornell Medicine in New York City. The three systems captured race data according to Federal Office of Management and Budget categories: White, Black or African American, American Indian or Alaska Nation, Asian, Native Hawaiian or Other Pacific Islander, and Other Combinations not described. Because the outpatient EHR contained the most patients, we used it to establish the baseline number of patients, including how many had missing race as defined by NULL or “Declined” values recorded. For patients missing race data in the outpatient EHR, we determined the extent to which race data existed in the inpatient EHR and billing systems. For each patient, we also determined the degree to which race values were concordant across the three systems.

Results

Of 2,887,195 total patients, 1,598,919 patients (53.72%) had missing structured race values in the outpatient EHR. Of these patients, 101,494 (6.34%) had a race value in the inpatient EHR system. Of the 864,742 patients with a structured race value in all three systems, the number of patients with a concordant value across all systems was 547,317 (63.29%) and across two systems 399,743 (35.17%). 22,337 (1.54%) had a differing race value across three systems.

Of the 1,158,702 patients with a structured race value in both the outpatient and inpatient EHR systems, patients identified as Asian (89.62%), African American (88.83%), White (85.72%), and Native Hawaiian or other Pacific Islander (80.06%) patients had concordant races values. In contrast, patients identified as Other Combinations not Described and American Indian or Alaska Nation had higher discordance, as 68.66% and 59.9% had concordant race values, respectively. A Chi-squared test for independence between race and concordant race values proved statistically significant with a value of 85360.62 and an associated p-value of 0.00.

Discussion

We observed missing and discordant data in patient race values from multiple electronic systems within a single academic medical center. Missing and discordant data existed across all races. When researchers and clinicians make use of patient race data, it is important that they are aware of “missingness” and discordance. Informaticians may seek to describe concordance of patient race across electronic systems as an indicator of data quality for investigators seeking to use the values for clinical trial screening and other research purposes. In further analysis, we plan to expand the analysis of concordance with race data obtained from laboratory results and unstructured physician notes using natural language processing.

Patient Perceptions of Missing Health Information in Outpatient Settings

Elizabeth C. Danielson, MA1, Christopher A. Harle, PhD1,2
1Richard M. Fairbanks School of Public Health, Indiana University, Indianapolis, Indiana, USA; 2Regenstrief Institute, Indianapolis, IN, USA

Introduction Missing clinical information at the point of care can burden patients, frustrate clinicians, increase costs through repeated testing, and pose safety risks. Although most patients are willing to share their health information across providers, missing information remains a common problem. An estimated 14-49% of patient visits have missing information1,2, while 20-55% have repeat testing3,4. To date, most research and policy has focused on addressing missing information through provider-directed approach. Meanwhile, new policies, like the Centers for Medicare and Medicaid Services’ Merit-based Incentive Payment System (MIPS), incentivize providers to better exchange health information and engage patients. Despite these efforts to engage patients in their personal health record, few studies have evaluated patient perceptions of missing health information or examined whether certain patient populations are more likely to perceive experiences of missing information. To address this gap, we examined two waves of a nationally representative survey to examine the frequency of and factors related to patient experiences of missing information and repeat testing during ambulatory health care encounters.

Methods We conducted a pooled cross-sectional analysis of the 2017 and 2018 Health Information National Trends Survey 5 (HINTS) cycle 1 and 2. Our outcomes were yes/no responses to three questions about patients’ experiences during health care visits: “Had to provide your medical history again because your chart could not be found?”, “Had to redo a test or procedure because the earlier test results were not available?”, and “Had to bring a test an x-ray, MRI, or other type of test with you to the appointment?” We conducted three multivariable logistic regression models to estimate the relationship between each outcome and respondent characteristics: health status, have a usual source of care, survey year, insurance, gender, age, race, disability, household income, education, body mass index (BMI), past cancer diagnosis, smoking status, and Patient Health Questionnaire (PHQ-4) anxiety and depression scores. In order to obtain nationally representative estimates, we applied HINTS survey weights in the models.

Results Approximately 22% of respondents brought a test to an appointment, 6% repeated their medical history, and 6% repeated a test. Patients were more likely to perceive bringing a test if they scored as severe on the PHQ-4 (OR=2.5; p=.002) relative to normal and were in ‘fair’ health (OR=1.9; p=.0017) relative to ‘excellent’. Patients without health insurance (OR=0.45; p=.025) were less likely to perceive bringing a test than patients with private/employee insurance. Patients were more likely to perceive repeating their medical history if they scored as severe on the PHQ-4 (OR=2.0; p=.044) relative to normal and were in ‘fair’ (OR=3.6; P=.023) or ‘poor’ health (OR=6.0; p=.012) relative to ‘excellent’. Patients were more likely to perceive repeating a test with ‘very good’ (OR=2.5; p=.021), ‘fair’ (OR=3.8; p=.003), or ‘poor’ (OR=5.3; p=.008) health status relative to ‘excellent’. Meanwhile, patients with incomes in categories greater than or equal to $20,000 were less likely to perceive repeating a test than patients with incomes less than $20,000 ($20k-49k OR=0.41, p=.005; $50k-74k OR=0.44, p=.048; >$75k OR=0.43, p=.039).

Conclusion Patients perceive missing health information and repeat testing much less often than estimates from studies of health records. Moreover, patients in some vulnerable groups, such as those without health insurance, low income, or poorer health status may be more likely to perceive they have experienced missing health information or repeated tests. These findings suggest an opportunity to increase patient awareness of the frequency of missing health information, including targeting awareness toward patient groups that are more likely to experience missing information.

Acceleration Gait Measures as Proxies for Motor Skill of Walking: A Narrative Review
Pritika Dasgupta, MPH MHI MS; Jessie VanSwearingen, PhD; Alan Godfrey, PhD; Ervin Sejdić, PhD
University of Pittsburgh, Pittsburgh, PA

Introduction

Acceleration gait measures (AGMs) are a promising component to motor skill research, which can help older adults’ (65 years or older) quality of life and reduce the burden of fall-related healthcare. A decline in motor skill or control\(^1\), often associated with both cognitive and gait changes during aging, is a public health matter because it is one of the significant causes of falls, morbidity, and low quality of life\(^2\). However, motor skill is multifaceted and complex. For example, older adults may walk slowly with adapted optimal motor skill some may walk slowly with poor motor skill, and some older adults with or without diagnosed disease may walk at clinically normal speeds with altered control. The first line of gait assessments is known as collecting simple gait measures, which researchers collect through observation, magnetic systems, optical systems, and video recording; these measurements consist of visual observations of spatiotemporal gait measurements, which include gait speed as well as stride and step characteristics\(^3\). Unfortunately, research suggests that simple gait measurements are not able to contradistinguish between age and disease-related gait dysfunction\(^4\), and simple gait measurements do not provide adequate information about the quality of the translation of the body motion during walking. AGMs can enrich simple gait measurements of walking and motor performance by allowing researchers to see if the motor skills were compensated (such as energy expenditure or smoothness).

Methodology

Research literature was drawn from published journal articles and conference abstracts in the following scholarly databases: PubMed, IEEE Xplore, and SpringerLink. This narrative review does a critical analysis of categorizing motor skill aspects of walking and organizing AGMs. To date, there has not been a wide-scale mapping of specific motor skills aspects of walking to AGMs – we seek to survey the literature to understand how AGMs are being used as proxies for motor skills.

Motor Skill

The motor skill of walking results in smooth and efficient translation of the body over the surface. A decline in motor skills refers to a loss of the coordination and timing of stepping with postures and phases of gait in the performance of walking. Based on the literature search, we defined seven characteristics of the performance outcome of motor skill of walking: 1) smoothness, 2) efficiency, 3) automaticity, 4) adaptability, 5) variability/regularity, 6) stability, and 7) symmetry.

AGMs

AGMs are one of the multiple ways to measure human movement, but other measures are costlier, demand challenging environment setups, and are bulky. Based on how researchers perform signal pre-processing and the nature of their research questions, there are many different forms of AGMs\(^4\). We organized these AGMs via various signal pre-processing methodologies/groupings: 1) gait cycle timings, 2) statistical features, 3) signal-frequency features, 4) time-frequency features, and 5) information-theoretic features.

Mapping Motor Skill and AGMs

Clinically, mapping motor skill characteristics to categories of AGMs may be capable of providing relevant and accurate measurements. In the review, we summarized a selection of references for each of the motor skill-AGM mappings. By doing so, we will address the existing gap by seeing how researchers have combined multiple features extracted from gait accelerometry signals into a derived AGM that will potentially be a marker for walking related changes in physical function.

Conclusion

We have an urgent need for more holistic motor skill research since people are living longer and may be more prone to neuromotor illness; for example, fall-related injuries result in millions of US patients per year in emergency rooms; for example, over 800,000 patients/year are hospitalized\(^5\). In application, AGMs have been used and can be used more effectively to detect differences and changes in motor performance due to learning/expertise, or task and environment manipulations\(^6\).

Teledermatology service in HealthNet Platform: an Experience Report

Keilla T. Martins de Melo, M.Sc.¹, Nelson G. de Sá Leitão Júnior, M.Sc.¹, Danilo F. S. da Silva, M.Sc.¹, Webber S. Fantini, M.Sc.¹, Alexandra M. M. Grisolia, Ph.D.² Magdala de A. Novaes, Ph.D.¹

¹Telehealth Center (NUTES), Federal University of Pernambuco, Recife, PE, Brazil.
²Biomedical Center, State University of Rio de Janeiro, Rio de Janeiro, RJ, Brazil.

Introduction

A teledermatology service is a dermatological practice performed without the need for face-to-face intervention of a specialized healthcare practitioner. This practice, which is a form of telediagnostic, has a relevant visual component that favors the development of iconographic representation techniques in telehealth. Teledermatology aggregates the documentation of clinical information and images of dermatological lesions for healthcare, offering additional benefits to the traditional methods of dermatological evaluation. The Telehealth Center (NUTES) of the Clinics Hospital of the Federal University of Pernambuco (UFPE) implemented a set of specific features on the HealthNet software platform to support the Teledermatology service, which is the object of this case report.

Specific purposes of the system

The HealthNet¹ is a telehealth platform that offers integrated teleconsulting and telediagnostic services, facilitating the clinical cooperation and the exchange of experiences among healthcare practitioners from the Brazilian government Unified Health System (SUS). In this context, the NUTES team implemented a set of specific features for practice, based on the requirements of contextualization of clinical practice, the incorporation of medical images and the easy access to information as a tool to support a medical decision. Those requirements were constructed according to archetypes that were applied in the subdivisions Action, Instruction, Observation, and Evaluation; grouped into archetypes of the Section type². Each subdivision corresponding to an activity related to teledermatology, such as Action for the execution, Instruction for the request, Observation for the description of aspects observed during the execution, and Evaluation for the exam results.

Results of the usage

In telediagnostic, a health care practitioner, as a solicitant, submit a clinical exam in the HealthNet for obtaining this exam results from a remote health care specialist. In our teledermatology service, a solicitant submits a particular telediagnostic with the patient information, additional exam data, and specific dermatological data by using a specific HealthNet feature for the dermatoscopy procedure. The solicitant includes a structured medical record, according to the mentioned archetypes, and he may also include detailed lesion information with the help of a graphical human body model delimited by dermatologic regions and images of the patient, both for further analysis. When the solicitant concludes the exam submission, another healthcare practitioner, identified as a teleguider, redirects this telediagnostic request to an available health care specialist, who in turn, may request more details on this matter to the solicitant or directly perform an analysis on the exam data to submit the results in the platform.

Conclusion

Based on our experience with the HealthNet platform and the results from remote specialists concerning dermatoscopy exams, we conclude that adopting teledermatology is a viable approach for healthcare practitioners. Additionally, we may highlight that in the last six months of pilot operation, practitioners performed more than 140 dermatoscopy exams by the HealthNet, thereby, fully supporting the proposal of the teledermatology service.

Federal Research Data Infrastructure: Tools and Services for Health Care Needs

Rina Dhopeshwarkar, a MPH, Lauren Hovey, a MA, Krysta Heaney-Huls, a MPH, Prashila Dullabh, a MD, Scott Smith, b PhD

a NORC at the University of Chicago, Bethesda, MD; b The Office of the Assistant Secretary for Planning and Evaluation, Washington, DC

Research Objective

The proliferation of electronic health data is a rich resource for the health system, with the potential to fuel research and evidence generation that expands knowledge about the effectiveness of health interventions. Challenges have emerged, given the volume and technical complexity associated with data collection, aggregation, and analysis. A variety of tools, standards, and services are needed to make diverse electronic health data available and usable for patient-centered outcomes research (PCOR). NORC at the University of Chicago analyzed a sample of projects funded by the PCOR Trust Fund (PCORTF) to identify solutions and the types of challenges they ameliorate.

Study Design

The Patient Protection and Affordable Care Act (ACA) created the PCORTF to build national data capacity and infrastructure and to help researchers leverage existing data for PCOR. It is administered, in part, by ASPE. We conducted a retrospective analysis of 11 projects funded by the Office of the Assistant Secretary for Planning and Evaluation (ASPE) whose activities concluded in 2018. We then categorized the projects’ contributions to broader health system issues and research goals. Our review included project statements of work, quarterly reports, meeting summaries with project leads, final reports and deliverables. This retrospective approach allowed us to assess project goals and trajectories, outputs (e.g., services and standards), and their broader significance to the health system.

Principal Findings

The 11 projects, conducted at six federal agencies, addressed PCOR data infrastructure needs and innovations in the following categories: 1) use of application programming interfaces (APIs) to improve capture and use of health data; 2) enhancements to data governance structures; 3) patient matching solutions; 4) facilitators for research across distributed networks; 5) data standardization; and 6) improved mechanisms for linking patient records. These projects also addressed federal strategic priorities, including: 1) collection of participant-provided information; 2) standardized collection of standardized clinical data; 3) linking of clinical and other data for research; 4) use of clinical data for research; and 5) use of enhanced publicly-funded data systems for research.

Conclusions

The PCORTF projects contribute substantially to PCOR data infrastructure, addressing multiple priority area. They do so via an array of services, standards, analytic and patient matching tools, and governance structures that facilitate the exchange and use of electronic data from diverse sources. As such, their products are of practical use to PCOR stakeholders and many are publicly available for immediate use.

Implications for Policy or Practice

The health system goals to support patient and provider decision-making with evidence-based medicine, to improve patient outcomes, and address pressing health issues like opioid use require robust health data infrastructure. The PCORTF projects offer a variety of research-focused tools for aggregating, linking, and analyzing data; as well as tools designed to increase patient autonomy in managing their health records and contributing data to research, all of which have broad potential for use and utility in PCOR.

Patient Perspectives of Utilizing Multiple Mobile Health Technologies to Self-manage Type II Diabetes

Anna Diane BSN RN1; Allison Lewinski PhD2; Jacqueline Vaughn BSN RN1; Janee Stevenson BSN, RN3; Ryan J. Shaw PhD RN1

1Duke University School of Nursing, Durham, NC; 2 Durham Center of Innovation to Accelerate Discovery and Practice Transformation, Durham VA Health Care System, Durham, NC 3 Winston-Salem State University, Winston-Salem, NC

Introduction: Type II Diabetes (T2D) is a complex, chronic illness that requires daily self-management of blood glucose levels, weight, medication adherence and attention to lifestyle behaviors. Mobile health (mHealth) technologies (e.g., wearables, wireless glucometer, wireless scale, text message surveys) facilitate the collection of real-time, in situ patient-generated health data (e.g., physical activity, blood glucose, weight, and medication adherence)1. These data can help patients monitor their daily behaviors thus improving the patient’s ability to engage in diabetes self-management. These real time data can be leveraged to deliver real-time targeted self-management interventions.

Methods: We conducted a mixed-methods exploratory study to examine the feasibility and utility of patients using multiple mHealth devices in diabetes self-management. We provided participants (N=60) with a wearable accelerometer, wireless glucometer and wireless scale during the 6-month study period to respectively track physical activity, blood glucose and weight. We purposively selected 20 patients based on study engagement (e.g., high, low, medium) to participate in semi-structured interviews. The interviews queried patients to discuss their experiences in self-managing diabetes with the three mobile devices.

Results: Directed content analysis was performed and analyzed to describe participants’ perceptions on utilizing mobile health technologies to collect and monitor their diabetes related health data. We identified two main themes related to the patients’ perceptions of utilizing mHealth devices in diabetes self-management. The first theme, feasibility, described how easy or difficult the patients found each device to use. We noted two sub-themes: (1) usability—which described the extent to which the devices were used to manage diabetes-related tracking behaviors; and (2) satisfaction—which discussed the level of acceptability of the devices. The second theme, utility, described how they used each of the three devices over the six-month study period. We noted four sub-themes (1) accountability—which discussed prompts and reminders for self-management behaviors; (2) facilitation of conversation—which detailed conversations that participants had with others about device and data utility; (3) accuracy—which described the patient’s perceptions regarding the validity of devices and; (4) accessibility—which discussed the participant’s ability to have their own data within reach.

Conclusions: Our findings indicate the importance of obtaining patient feedback in utilizing multiple mHealth devices to self-manage diabetes. Understanding the range of participant-centered perspectives can inform design of future mobile health interventions aimed at promoting patient self-management of chronic illnesses.

Ascertaining Medication Adherence Utilizing Open Claims Data

John E. Doole, Pharm.D., MFA1, Pamela B. Landsman-Blumberg, MPH, DrPH1, Matvey B. Palchuk, MD, MS, FAMIA1,2

1TriNetX, Inc., Cambridge, MA; 2Harvard Medical School, Boston, MA

Introduction

Comparative effectiveness studies, predictors in medical outcomes models, and targeting patients to medication therapy management programs are typical applications of medication adherence metrics. Adherence is usually calculated using “closed” claims data. These are fully adjudicated and contain data for all prescription fills available within a fixed period. A different source of claims data – “open” claims – is used much less frequently to measure adherence. These claims cover a much broader swath of payers, may not be fully adjudicated and may be missing claims for fills from pharmacies utilizing a clearinghouse not included in the pool of data providers. We set out to show that medication adherence can be determined using open pharmacy claims data.

Methods

Using a commercially available open pharmacy claims dataset covering 99% of US payers, we calculated common measures of medication adherence. Data elements such as supply duration, quantity dispensed, fill number and corresponding date ranges are needed to determine Medication Possession Ratio (MPR), which measures the percentage of time a patient has access to a particular medication. Given the potential for an incomplete view of the claims lifecycle, we applied a number of heuristic rules to de-duplicate records for a given prescription fill where correction and denied claims may be submitted before the clearinghouse sends a final claim to the payer and a final remittance is sent back to the clearinghouse and ultimately the dispensing pharmacy.

Results

We calculated MPR for all drugs in the dataset. Adherence with MPR of 0.9 and above was considered high, 0.8-0.89 – fair, and under 0.8 – poor. We evaluated our calculations by visualizing the relationship between prescription complexity (>2 takes per day=complex) and route of administration to adherence. The results are in line with our expectations. A Sankey diagram (see Figure 1) demonstrates, for example, that lower prescription complexity leads to better adherence and that patients are more compliant with oral medications.

Conclusion

Open claims datasets pose unique challenges for calculating medication adherence. We demonstrated that it is possible to generate such metrics and confirmed our results by seeing expected trends in relationships between prescription complexity and the route of administration to medication adherence.

Improving Accuracy of Patient Speech Transcription Using Dialect-Specific Automatic Speech Recognition Models

Rachel Dorn, B.A.¹, Scott Vrana, Ph.D. ², Bridget T. McInnes, Ph.D.¹
¹Computer Science Department, Virginia Commonwealth University, Richmond, VA, USA
²Psychology Department, Virginia Commonwealth University, Richmond, VA, USA

Introduction. Much progress has been made in automatic speech recognition (ASR), but it has not been evenly distributed across all dialects of English¹. African American Vernacular English (AAVE) is a widely-spoken English dialect in the United States, yet it is grossly underrepresented in common speech corpora². As a result, patients who speak this dialect are at risk of being misunderstood by clinical speech applications more often than Standard American English (SAE) speakers, negatively affecting their user experiences and hindering downstream clinical applications that rely on ASR data. This study explores the effect on transcription accuracy of using AAVE data.

Methodology. The dataset consists of 36 AAVE-speaking interviewees and 6 SAE-speaking interviewers from the Corpus of Regional African American Language (CORAAL)³, which were split into 31,471 utterances by speaker. Transcription models for AAVE-only utterances, SAE-only utterances, and the combined set of the two (Combined) were trained using Mozilla’s DeepSpeech ASR engine⁴. We evaluated the models using word error rate (WER) and Levenshtein distance. Levenshtein distance was included as a way to reward partial credit, as many of the outputs included correct syllables but incomplete words. Lower numbers indicate higher accuracy for both measures.

Results. Table 1 shows that both the average WER and Levenshtein distance decreased for both AAVE and SAE models as compared to the Combined model. The WER rates are nearly all above 1 due to the outputs putting in extra word breaks. There was an 18% improvement across both metrics for the AAVE utterances and a 13% improvement for SAE utterances. The larger increase for AAVE is likely due to the combination of: 1) AAVE contains a larger number of utterances in the dataset; and 2) the average length of an AAVE utterance is longer than an SAE utterance.

Conclusions. Different dialects within the same language can have conflicting patterns of phonemes; the ambiguities arising from having to learn opposing patterns can cause errors and lower overall accuracy. Applications which handle diverse patient speech can benefit from using dialect-specific models for speech recognition. This is particularly useful in contexts where the speech data is gathered in advance, rather than in real-time. Future research will train a classifier to automatically detect the dialect being spoken as well as to expand the datasets to improve overall accuracy.

Customization of an Antimicrobial Stewardship Clinical Decision Support Module: Reducing the Noise and Improving Reporting

Evan Draper, PharmD¹, Brian K. Fung, PharmD¹, James Steckelberg, MD¹, Abinash Virk, MD¹, Sara Ausman, PharmD², Sara Lessard, PharmD³, Aaron Tande, MD¹, Lynn L. Estes, PharmD¹

¹Mayo Clinic, Rochester, MN, ²Mayo Clinic Health System, Eau Claire, WI, ³Mayo Clinic Health System, La Crosse, WI

Introduction
Mayo Clinic recently implemented Epic® as a single Electronic Health Record across all of Mayo Clinic’s campuses. Implementation of Epic® replaced two Antimicrobial Stewardship Clinical Decision Support (CDS) systems. Antimicrobial Stewardship CDS systems use rules to flag patients for clinical review. Logic within a CDS system cannot replace clinical judgement and some alerts will be non-actionable.¹ One of the replaced systems was a mature, home-grown system² that allowed users to defer or dismiss rules after review and provided reports on the frequency of alert firing. Current limitations in the out-of-the-box Epic® Antimicrobial Stewardship module include an inability to turn off rules after review and limited reporting on alert firing.

Methods
We developed a novel approach to surveillance within Epic® that allows users to defer or dismiss flags and provides the ability to report on when rules fire. During a pilot of the novel approach from 1/1/18 to 2/28/18 we captured the number of days any patient is flagged for review at 7 pm for the usual approach and the novel approach. The rules contained the same clinical criteria but the novel approach allowed users to dismiss or defer the rules.

Results
Over 2 months a comparison of the approaches shows a reduced frequency of alerting with the novel approach.

<table>
<thead>
<tr>
<th>Rule Description</th>
<th>Usual Approach (#{days alert is active})</th>
<th>Novel Dismiss/Defer approach (#{days alert is active})</th>
</tr>
</thead>
<tbody>
<tr>

Clinical Decision Support Flow Diagram for Management of Chronic Kidney Disease by Primary Care Physicians

Vishal Duggal, MD1,2, Mary K. Goldstein, MD, MS1,2

1 VA Palo Alto Health Care System, Palo Alto, CA
2 Stanford University School of Medicine, Stanford, CA

Chronic kidney disease (CKD) affects more than 15% of adults in the United States1, and the Veterans Affairs health system is the single largest provider of health services in the U.S. for patients with CKD2. The MEDSAFE-CDS is a knowledge-based system developed jointly by the Department of Veterans Affairs (VA) and Stanford University that is designed to aid primary care physicians within the VA Health Care System in the identification and management of multiple chronic health conditions. This clinical decision support (CDS) tool, currently in development for MEDSAFE, provides direction for physicians caring for patients with CKD Stage 3 and guideline-supported recommendations to manage the progression and complications of CKD.

CDS systems require specific disease definition criteria to identify eligible patients. While phenotypic determinations exist for CKD, they do not identify groups specifically amenable to care via CDS. Here we present a preliminary decision flow diagram that adheres to VA/Department of Defense (DoD) Clinical Practice Guidelines for the Management of CKD in Primary Care. This diagram details the entry point into the CDS tool, decision branch points, disqualifying criteria, and recommendations for physicians including laboratory tests, medication prescriptions, and conditions that should prompt referral to specialist care. Recommendations from this CDS are provided in an online report for primary care physicians alongside recommendations for chronic diseases such as hypertension and diabetes mellitus. Such reports can be used in pre-clinic huddles and during patient visits.

The CDS decision flow diagram, a portion of which is illustrated in Figure 1, specifically includes recommendations for frequency of kidney function laboratory testing, assessment of estimated glomerular filtration rate trends, management of metabolic acidosis, and investigation of anemia related to CKD. The VA/DoD guidelines were augmented with those of Kidney Disease International Improving Global Outcomes (KDIGO)3.

Figure 1. Subset of the ATHENA-CDS Clinical Decision Support Flow Diagram

Views expressed are those of the authors and not necessarily those of the Department of Veterans Affairs.

Leveraging Technology to Promote Healthy Cooking Literacy and Kitchen Confidence for Overweight and Obese Adolescents

Introduction

Obesity and overweight are a major public health issue affecting 12.7 million children and adolescents. One of the recommendations to combat obesity is to maintain healthy diet and eat home cooked meals. Providing user-centered technology-enabled solutions to overweight adolescents can equip them with necessary skills towards managing their health behaviors. Most of commercially available apps, however, do not address all components of Culinary Nutrition Education (CNE) (e.g. knowledge about intake of fruits and vegetables, sodium, and added sugar) and are not tailored to the adolescent audience. In this design science study, we therefore aim to inform functional requirements, design requirements, and insights regarding contextual use of tailored CNE technology that could enhance teens’ healthy cooking literacy and kitchen confidence - thereby promoting their healthy lifestyle management through personal choices, increased self-efficacy, and influencing family eating habits.

Methods

The study was completed in 2 distinct phases that engaged overweight and obese adolescents, parents, and providers. Phase 2, our primary source of data, consisted of multiple user-centered design methods (e.g., usability analysis and semi-structured interviews) involving mid-range prototypes informed by Phase 1 with 70 adolescents from a healthy behavior camp and 10 providers. Data were analyzed using the constant comparative method analysis to identify functionalities, design preferences, and context of use of our technology.

Results

Figure 1 summarizes findings regarding functional and design requirements as well as the context of use (environment, motivators, and barriers) of a CNE technology.

Discussion

The study reveals design and functional requirements of the CNE technology that reflect constructs from Social Cognitive Theory, one of the main behavior change theories focusing on the ongoing change in person’s behavior, and the Fog Behavior Model (FBM), which explores the effect of persuasive design on people’s behaviors. Our findings demonstrate support and provide contextual insight for these theoretical models.

Conclusion

Our technology-proposed solution reflects the goals and identified requirements of overweight adolescents; it also aligns existing behavior change theories to this technological context. We demonstrate the potentiality of creating a technology that could effectively lead to better self-care, induce sustainable behavioral change by way of education and activity, and promote self-efficacy by enhancing cooking literacy and kitchen self-confidence.
Understanding Nothing: Interpreting Models Using Sparse Longitudinal Data

Jacob M. Ekstrum B.S.¹, Noah J. Pocziwinski B.S.¹, Brett F. Cropp M.S.¹, John B. Coles Ph.D.¹
¹CUBRC Inc. Information Fusion Group, Buffalo, NY, USA

Abstract
Recent improvements in machine learning have led to the ability to generate both complex and sophisticated time-series models for healthcare situations. Though powerful, these models traditionally lack insight into the importance of each of the model’s input features. Here, we introduce a novel element of the Heartwood Analytics™ system that ranks both sparse and dense time-series features according to their importance in the model for clear communication of driving factors for complex medical decision making.

Introduction
Models integrated into important aspects of an individual’s healthcare must be explainable, lest the growing trust between professionals and computer systems begin to wane. Current models that can explain their decision process, such as linear models and shallow decision trees, lack the accuracy that attention-oriented methods, such as LSTM-based recurrent neural networks, produce for sparse longitudinal data. Even for those models that can be interpreted, it is difficult to concisely convey important information to care providers and clinicians as the input variables to be ranked increase in both count and sparsity, as is often the case with complex healthcare scenarios. Other attempts to promote interpretable models, such as the boosted tree mimic model described by Che et al.¹, use methods that are interpretable at their higher layers but become much less interpretable as the mimic model is explored.

Determining Insights
The Heartwood Analytics™ system addresses these problems through its feature importance framework. The data used to train the model is acquired and pre-processed, pruning sparse information and concatenating sparsity meta-information for each instance that heavily impacted model training. With sparse data condensed to a dense format, feature importance uses non-linear transforms to acquire an alternative representation of the selected input data. In a new data space with synthetically generated model features, this modified dataset is used to train an interpretable model, such as a linear model. This provides insight into how important each synthetic feature is to the complex model being evaluated. By reverse mapping the importance values for the synthetic features into the original feature space through an approximate inverse function, the framework can generate an accurate and easily interpretable scalar ranking value for each input variable, input timestep, and sparsity meta-feature in the complex model. This mapping procedure is designed to improve accuracy over traditional meta-model approaches while maintaining the interpretability that linear meta models provide. The global approximations embedded in our meta-model are used to generate per-patient models of the impact of variables, which are gaining popularity among Heartwood adopters in the complex care and autism care spaces.

Explaining Variable Impact
Once these scalar values are obtained, Heartwood Analytics™ performs one additional step by explaining and communicating the results to less-technical audiences, such as clinicians and staff that require more information to reduce autism-related behavioral events. Through a custom web interface, features along with their scalar importance values and directionality (positive or negative impact on outcome) are displayed to the user. Adjustments made to feature values in the interface generate real-time predictions alongside previous predictions in order to communicate feature importance. Allowing healthcare providers to verify a model’s accuracy through medical intuition builds trust in the model’s ability to improve decision making overall, supporting better patient outcomes.

Conclusion
By leveraging high-dimensional global interpretability measures, the Heartwood Analytics™ feature importance framework provides an interpretable ranking scale that input variables can be measured against at different points in time. Through the use of a custom web framework, these generated rankings can be filtered in order to tactfully communicate high-impact insights from the model to care providers in myriad health-related situations.

Challenges to a Data Driven Approach to Population Level Analysis of Hypersensitivity Events in Cancer Clinical Trials

Christina Eldredge, MD¹, James E. Andrews, PhD¹. Maryam Zolnoori, PhD², Timothy Patrick PhD³, Joel Gallagher, MD⁴, Cesar Lam, MD⁵, and Jake Luo, PhD³

¹University of South Florida, Tampa, FL; ²Mayo Clinic, Rochester, MN; ³University of Wisconsin-Milwaukee, WI; ⁴Allergy and Asthma Center of North Carolina, Greensboro, NC; ⁵Moffitt Cancer Center, Tampa, FL

Objective: To present an analysis of the terms used to report hypersensitivity events (HEs) in cancer clinical trials in order to better understand how HEs vary across studies.

Introduction: National efforts to accelerate cancer research and improve outcomes have led to improved patient access to innovative therapies¹. Yet, new therapies also increase risks for adverse events, including HEs. HEs may present as a non-serious event (e.g. mild allergic reactions such as rhinorrhea) or a serious event (e.g. life-threatening severe allergic reactions, referred to as anaphylaxis). Coding of these events using standard terminologies is complicated and inconsistent, especially given the lack of universal agreement on a specific definition of “anaphylaxis”²; however, effective use of terminologies for representing HEs is needed for data sharing, reuse, and interoperability across cancer trials.

Methods: Investigators are required to submit clinical trial adverse events to ClinicalTrials.gov in the form of two tables, serious and other-than-serious events. ClinicalTrials.gov specifies how data elements related to adverse events (including HEs) are to be entered³. Investigators select a Collection Approach (either Systematic Assessment or Non-Systematic Assessment) and a standard terminology⁴. A publicly available dataset of cancer clinical research trial outcomes and adverse events reported to ClinicalTrials.gov for the period November 1999 to November 2017 was analyzed. HEs were extracted from semi-structured text, within adverse event tables, using an XML parser. We then determined whether investigators used systematic or non-systematic data collection methods, and which standard terminology they used to characterize HEs.

Preliminary Results: Preliminary analysis of 582/5,596 HEs from 1,331 clinical trials revealed the majority of events, 366/582 (63%), were not recorded using a systematic method, and in 64/582 (11%) of HEs no method was specified. Variations were found across clinical trials with several types of terminologies used to code HEs including: COH, CTC (v3 and v4), CTCAE (2.0, 3.0, and 4.0), and MedDRA (versions 5, 9, 10, 12, 13, 15, 17-20). Term inconsistencies were evident when coding severe allergic-type hypersensitivity reactions, especially with regard to coding the etiologic agent. For example, the following terms and their respective vocabularies were used: Anaphylaxis (CTCAE and MEDRA); Anaphylactic shock (MEDRA); and, Bactrim anaphylaxis (Not specified). Anaphylaxis can occur with or without shock symptomatology, so it is unclear whether these events are indeed equivalent. Additionally, term use inconsistencies were also seen within clinical trials; for example, as the result of using several versions MedDRA to code “anaphylaxis” within a single clinical trial.

Future Work: Our analyses suggest barriers exist to population level analysis of HEs in cancer trials, including an overall lack of granularity when coding the severity of these events, as well as a lack of consistent notation of the etiologic agent. We plan to normalize the identified HEs by mapping them to SNOMED CT, which has better coverage for allergy reporting. Normalized data can be used to evaluate the association between cancer intervention therapies and HEs.

Towards Optimizing Usability in e-Government Healthcare Administration Systems: Recommendations from a Comprehensive Evaluation Study

Forhan Bin Emdad, BSc, and Güneş Koru, PhD
University of Maryland, Baltimore County, Baltimore, MD

Introduction
Several research studies have reported that perceived system complexity and a lack of usability prevent e-government healthcare administration systems from achieving their full potentials.1 In spite of the presence of general usability guidelines and considerable investment of resources for design and development, usability problems are still persistent in e-government healthcare administration systems.2 It is still challenging to guide government healthcare and information technology(IT) professionals in a right direction in this domain. Therefore, this study had the following objectives: (a) applying a usability evaluation initiative to understand and document top usability challenges and improvement opportunities in a real-life e-government system, and (b) provide a set of recommendations that can be useful for the government officials and IT vendors which can further benefit similar e-government healthcare administration systems.

Methods
We have designed and conducted an iterative usability evaluation and improvement project for an eminent active e-government healthcare system adopted by one of the states in the US. In the first iteration, seven usability experts performed an evaluation of the system’s usability compliance with 10 heuristics.3 Secondly, person-to-person interviews using think-aloud protocol was conducted with 23 participants for usability testing. Thirdly, an online survey based on the questions in the System Usability Scale (SUS) was conducted with 1,800 system users for a quantitative assessment of usability. For analyzing user satisfaction in SUS, maximum SUS score was set to 100 with three categorizations: above average (80 or higher), average (68 to 79), poor (52 to 67), and unacceptable (51 or lower) based on usability condition. Finally, a semi-structured focus group interview was conducted with eight participants including government officials working in health care administration system to obtain further detailed qualitative information regarding usability challenges and improvement opportunities. Accumulated quantitative data were analyzed by statistical techniques and qualitative data were analyzed by transcribing interview records, and triangulation.

Results
The top usability challenges identified were categorized using weighted metrics considering priority and severity.4 The usability experts identified 41 unique usability challenges through heuristic evaluation of the system. Among them, top challenges were navigation problems, unfamiliar icons, and a complex index page structure. Nine additional usability problems were found from person-to-person think-aloud interviews where confusing name conventions, lack of tutorials, and lack of filtering options were identified as the top usability challenges. The survey resulted in a SUS score of 35, which is a very low score for any system, indicating that usability problems should receive attention. Furthermore, in online surveys, almost 20% participants "strongly disagreed" that learning this system is easy, instructions are understandable, system performs without error or system is comfortable to use whereas nearly 13% strongly agreed. Over 20% participants had neutral point of view. In focus groups, challenges such as inexperienced developers, lack of training for the users, and lack of co-ordination among users, developers, and stakeholders were most highlighted for improving usability of the e-government healthcare administration system. Initiatives can be taken to make proper investments to hire skilled IT professionals to resolve these challenges and to train the system users to perform their task appropriately.

Conclusion
This study has successfully documented top usability challenges and improvement opportunities focusing on a real life usability evaluation project for an e-government healthcare administration system. Furthermore, this study has drawn attention to the potential benefits of making recommendations based on the usability challenges identified in this study and other similar studies in the future. In the future, researchers should study the people and organizational challenges of usability improvement in e-government administration systems.

Preliminary chart review for Natural Language Processing development among electronic health records with documentation of marijuana use

Termeh M. Feinberg, PhD, MPH1,2, Joseph Goulet, PhD1,2, Amy Justice, MD, PhD2,3, Sameh Fodeh, PhD1,2, Lori Bastian, MD, MPH2,3, Qing Zeng-Treitler, PhD4, Cynthia Brandt, MD, MPH1,2

1Yale University School of Medicine Center for Medical Informatics, New Haven, CT; 2VA Healthcare Connecticut Pain Research, Informatics, Multimorbidities, and Education (PRIME) Center, West Haven, CT; 3Yale University School of Medicine Department of Medicine, New Haven, CT; 4George Washington University Biomedical Informatics Center, Washington, DC

Abstract
Marijuana use is increasing in the U.S., due to increased legalization for medical use and may be used by patients with pain. The development and refinement of search terms is a necessary step preceding use of informatics tools to identify marijuana documentation in the free text of patient charts. We used low-level text processing tasks to compare terminology used in a different sample. Documentation of any positive-use term was present in 56% of pulled charts.

Introduction
Marijuana is the most common illicit substance used worldwide with increasing use in the U.S. due to increased legalization for recreational (10 states) or medical use (33 states) and may be used by patients with a musculoskeletal disorder as a maladaptive coping strategy. Epidemiological examination of marijuana in relation to health outcomes remains sparse, and there is a lack of rigorous evidence for both benefits and risks. Unstructured text (i.e. ‘patient notes’) within Veterans Health Administration (VA) Electronic Health Records (EHRs) are largely untapped in relation to marijuana use among Veterans in VA care. The development and refinement of search terms is a necessary step preceding use of informatics tools to extract, retrieve, and automate data extraction on patients who report marijuana use. We sought to replicate and compare the lexicon used by colleagues in a separate published research study, while assessing presence of the term ‘medical’.

Methods
We conducted a manual chart review of 75 EHR notes chosen from 1000 randomly selected veterans diagnosed with musculoskeletal disorder who had any documented encounter with a VA provider in any clinical setting. We categorized EHRs into those containing information on marijuana use in the past or present, had either positive or negative medical marijuana classification, and documentation containing lexicon terms with no meaningful information regarding endorsement/use. Our lexicon contained the following: “marijuana”, “mjx”, and “cannabis”.

Results
Overall current documentation of any term was present in 56% of EHRs (42/75); current use of “marijuana” was present in 24 EHRs, in addition to adjacent term “medical” in 7; medical-related “cannabis” was not referenced. A positive current use of “cannabis” was documented in 21 EHRs, with few (3) duplicates between “cannabis” and “marijuana” and 1 EHR with conflicting documentation across both terms. Overall previous use was documented in 19% of EHRs (14/75); the term “marijuana” was used to indicate previous (i.e. past) use in 10 EHRs while previous use of “cannabis” was present in 6 (2 overlap). The term “mjx” was not contained in any EHRs, while 4 contained terms not resulting in meaningful information (i.e. unfilled templates(2), mention of cannabis cultivation(1), and provider instruction not to engage in use(1)). Negation statements regarding a lack of current use was minimally present for both “cannabis” and “marijuana” (5 and 3, respectively).

Conclusion
“Marijuana” was the preferred term when specifically documenting non-VA medical marijuana. There was minimal overlap between “cannabis” and “marijuana”, suggesting both terms may be uniquely important for lexicon inclusion. Providers should continually update EHR templates and outdated notes in relation to patient marijuana endorsement in order to create meaning from data and turn new knowledge into action. Future research should continue refinement of identification of marijuana use within EHRs by inclusion of additional terms.
Aiding in the Identification of Acute Respiratory Distress Syndrome (ARDS) from Radiograph Reports using Natural Language Processing

Jeffrey P. Ferraro PhD1,2, Jason Jacobs, PhD3, Ithan Peltan, MD3, Michael Lanspa, MD3, Raj Srivastava, MD4,5, Colin K. Grissom, MD3

1Intermountain Healthcare, Salt Lake City, Utah; 2Department of Biomedical Informatics, University of Utah, Salt Lake City, Utah; 3Intermountain Medical Center, Division of Pulmonary and Critical Care, Salt Lake City, Utah; 4Healthcare Delivery Institute, Intermountain Healthcare; 5Primary Children Medical Center, Division of Inpatient Medicine, Salt Lake City, Utah

Introduction
Acute Respiratory Distress Syndrome (ARDS) is a severe form of respiratory failure that impairs normal lung function resulting in deficient oxygenation leading to increased morbidity and mortality among critically-ill patients. Mortality rates range from 26% - 58% and increase based on severity of disease. Incidence among ICU patients is reported as high as 10.4% and increases to 23.4% in patients on mechanical ventilation. The current diagnostic standard for ARDS is the Berlin definition which has three components: 1) acute onset within 1 week of clinical insult or new/worsening respiratory symptoms; 2) PaO2/FiO2 ≤ 300; and 3) radiographic evidence of bilateral infiltrates. Early and accurate identification of ARDS may lead to more expeditious treatment with lung protective ventilation that can result in positive outcomes for critically-ill patients that are already battling with insufficient life-sustaining reserves. To address this need for early and accurate identification, we are in the process of developing a real-time ARDS case detection system that will automatically identify ICU patients at high risk for ARDS. The major challenge and critical component of this system is a natural language processing algorithm that can interpret radiograph reports for bilateral infiltrates consistent with the Berlin definition with a high level of accuracy. We describe our retrospective results demonstrating the efficacy of using natural language processing to identify radiograph reports consistent with the presence of bilateral infiltrates.

Methods
A reference set was constructed from previously confirmed ARDS cases (n = 1,171) included in several NIH sponsored ARDSNet studies where Intermountain Healthcare was a participating study site. This set was augmented with negative cases (n = 3,513) for whom ARDS was a possible diagnosis but was ruled-out as not meeting the Berlin definition for ARDS. Cases ranged over the period from August 11th, 2000 to March 12th, 2018 and were cared for at an Intermountain facility in Salt Lake City, Utah. One-view and two-view x-ray studies were pulled from Intermountain’s Enterprise Data Warehouse. A radiograph study range was defined as all films 3 hours prior to intubation and 72 hours post intubation date. Study inclusion criteria for NLP processing was set as 1) interpret all studies 24 hours post intubation; 2) if no studies were found 24 hours post intubation, include all films 3 hours prior to intubation; 3) if still no studies are found, interpret the first study found between 48 and 72 hours post intubation. For cases that did not have an intubation date index, studies were pulled within a 72 hours window post admit date index. Any positive interpretation for bilateral infiltrates or direct mentions indicative of ARDS among the set of interpreted reports was considered positive overall for ARDS. Several machine learning models including SVMs, Random Forest, and Gradient Boosted Trees were considered for document level classification using an n-gram feature space. Performance was assessed using 10-fold cross validation, training folds were down sampled to balance positive/negative cases while test folds maintained case prevalence.

Results
Controlling for over-fitting, the Random Forest (401 trees) was the best performing model. Sensitivity: 0.88, Specificity: 0.80, Positive Predictive Value: 0.81, Negative Predictive Value: 0.87, Accuracy: 0.84, AUC: 0.84.

Conclusion
Natural language processing can be an effective clinical decision support tool to assist in the real-time identification of ARDS cases. Early identification may lead to early effective treatment, positively impacting outcomes of this life-threatening disease. Further work is underway to optimize NLP operating characteristics by using a more sophisticated phrase level entity recognition strategy that further disambiguates complex diagnostic mentions and harnesses partial evidence towards ARDS by preserving clinical context more effectively.
Exploring Marijuana Use in Patients Suffering from Pain

Dezon Finch, PhD, Stephen Luther, PhD
1James A Haley Veterans Hospital, Tampa FL

Introduction

While marijuana is by federal law an illegal substance and is considered an illicit drug by the Veterans Health Administration there is a movement to evaluate its use for therapeutic purposes1. Our objective is to determine if information on the use of marijuana is recorded in medical documents such that it could be reliably extracted with the use of Natural Language Processing.

Methods

As a part of a jointly funded (HSR&D and the NIH) retrospective cohort observational study to develop pain care quality indicators, NLP was used to extract evidence of marijuana use from medical progress notes. A corpus of 4400 medical progress notes from patients who suffer from pain in the primary care setting was annotated by two clinicians and adjudicated by a third expert to develop NLP. One of the concepts targeted was the use of Complimentary and Integrative Health modalities which included the use of marijuana. A list of terms representing marijuana use was developed from the annotations and supplemented from other sources. A simple regular expression-based extraction method was developed on the annotated reference set (F-Measure = .89) and applied to a corpus of 152,620 medical progress notes.2.

Results

We found a total of 12,518 separate mentions of marijuana in the corpus. We found marijuana mentioned in a variety of ways. Marijuana use was mentioned in cases where the patient was found positive for THC, was a past user, current user, in rehab, and as a user for medical purposes requiring a state card. In many cases notations were made that the Veteran was using marijuana to reduce pain or for reducing anxiety. Claims were often documented that the use of marijuana was effective, in some cases “the only thing that works.”

Conclusion

While this effort is largely exploratory, our efforts show that evidence of marijuana use is documented in medical documents in a way that can be reliably extracted and is talked about in a variety of circumstances. In some cases it appears to be useful for the treatment of pain or anxiety. Studies on the prevalence of marijuana use among Veterans who suffer from pain could be determined as well as the reason for its use and its effectiveness as a replacement for opioids. For Veterans who suffer from chronic pain: Is there a lower rate of opioid use among Veterans who use marijuana than those who do not use it?

Generating Synthetic Control Subjects Using Machine Learning for Alzheimer's Disease Clinical Trials

Charles K. Fisher, PhD, Yannick Pouliot, PhD, Aaron M. Smith, Jonathan R. Walsh, PhD
Unlearn.AI, San Francisco, CA

Introduction

Alzheimer’s disease (AD) is a complex neurodegenerative disease with multiple cognitive and behavioral symptoms. Since recruitment of subjects for clinical trials in AD is challenging, we propose a machine learning approach to address this problem. Specifically, we use data from control subjects of past clinical trials to train an unsupervised machine learning algorithm to model the clinical data of control subjects of future trials. We term these machine learning-generated control subjects “synthetic control subjects.”

Method

We developed an unsupervised model of AD progression using a Conditional Restricted Boltzmann Machine (CRBM)\(^1\). We trained this model using data from 1,908 control subjects from 28 randomized clinical trials (RCTs) involving mild to moderate AD, provided by the Coalition Against Major Diseases Online Data Repository for AD\(^2\). Specifically, we trained the model on 44 variables measured across 18 months in 3-month intervals.

Results

We validated our model by comparing synthetic control subjects generated from the CRBM to actual control subjects not involved in training the model. The synthetic control subjects were statistically indistinguishable from actual control subjects across multiple measures, with only minor differences identified. The Alzheimer’s Disease Assessment Scale–Cognitive Subscale (ADAS-Cog\(^3\)) is a prominent multi-component cognitive assessment scale used frequently as an endpoint in AD RCTs. We further validated our model by predicting the ADAS-Cog progression of control subjects in a past RCT, finding good agreement with the observed progression of the actual control subjects. We then compared CRBM-generated ADAS-Cog scores to those generated by supervised neural network, random forest, and linear regression models trained on the same data. All algorithms exhibited a similar error profile, with CRBM generally exhibiting the best performance. These comparisons provide evidence that our unsupervised learning model can generate accurate synthetic control subjects.

Conclusion

This work demonstrates the potential for the model described here to generate synthetic control subjects that may be used to supplement or replace actual control subjects and reduce the reliance on actual control subjects in randomized clinical trials.

Prescription opioid tapering: Mining structured and unstructured data

Samah J. Fodeh\textsuperscript{a,b}, E. Jennifer Edelman\textsuperscript{a}, William Becker\textsuperscript{a,b}, Cynthia Brandt\textsuperscript{a,b}, Sally Haskell\textsuperscript{a,b}

\textsuperscript{a} Yale School of Medicine, New Haven, CT, USA
\textsuperscript{b} VA Connecticut Healthcare System, West Haven, CT, USA

Introduction: In response to significant evidence of harms associated with prescribed opioids (e.g., opioid misuse, opioid use disorder and overdose deaths), the Centers for Disease Control and Prevention (CDC) issued the “CDC Guideline for Prescribing Opioids for Chronic Pain” in 2016.\textsuperscript{[1]} In this guideline, it is recommended that when “benefits do not outweigh harms of continued opioid therapy, clinicians should optimize other therapies and work with patients to taper opioids to lower dosages or to taper and discontinue opioids.” In particular, opioid taper to a reduced dosage or tapering and discontinuing opioid therapy is encouraged in specific contexts, such as patient requested dose reduction; lack of meaningful improvement in pain and function; and prescribed dose of $>50$ morphine milligram equivalents per day without benefit or combined opioid/benzodiazepine therapy. Given lack of robust evidence to guide tapering strategies, a dose reduction occurring at 10\% of the original dose per week is generally recommended with slower taper if symptoms arise and quicker tapers in the context of serious adverse events. These recommendations are consistent with other United States-based and international guidelines. Currently, the field lacks accurate and reliable approaches to identifying patients undergoing tapering using structured pharmacy fill/refill data which further limits our ability to understand the impact of tapering. In addition to structured data, we explored the utility of using text narratives in clinical notes to detect patients being tapered.

Methods: We identified patients on Long Term Opioid Therapy (LTOT) using pharmacy data (based on CN101 class of medications). LTOT is defined as receipt of more than one opioid prescription with 90 days supply within a given year allowing 30 days gap in between fills. Using the Women Veterans Cohort Study (WVCS) at the Veterans Healthcare system, we used Voogo\textsuperscript{[2]}, a search engine that supports both free text and structured data searches, to retrieve clinical notes in FY (2015-2017) on LTOT patients. We explored tapering mentions in primary care notes and substance abuse notes in FY2015 and FY2016 only for lack of access to FY2017 clinical notes. We ran multiple queries using a list of search terms including: taper, discontinue, lower dose and their combinations with medication names (e.g. taper methadone, discontinue oxycodone) and allowing for a word or two in the context.

Results: Using pharmacy data, we identified 36,365 patients receiving LTOT with 83,457 opioid prescriptions between FY2015 and FY2017. We collected 441,106 and 712,215 clinical notes in the FYs 2015 and 2016, respectively. A slight decrease in the number of patients and prescriptions between FY2015 and FY2016 is noticed compared to a more dramatic decrease from FY2016 to FY2017. Table 1 shows that 854 (5\% of LTOT patients in FY2015) have evidence of opioid taper discussions in their clinical notes compared to 456 LTOT patients (3\%) in FY2016. Only 25\% of these discussions occurred during their visits to specialty clinics as reflected by the clinical note type (substance use disorder) and the remaining 75\% occurred during their primary care visits. In FY2016, 3\% of LTOT patients had opioid taper discussions in their notes, 63\% of which happen at primary care.

Discussion: Pharmacy data reflected adherence to prescription guidelines as published by the CDC late 2016 (Figure 1). Using unstructured clinical notes, we had the capacity to identify LTOT patients who are being tapered. Searching FY2015 clinical notes for combinations of the terms taper and each opioid medication, we retrieved 323 notes as a result of the query. By adding the terms discontinue and lower dose, and substance disorder we identified 221, 519 and 391 more, respectively. In a similar manner, we identified 108, 97, 220 and 343 notes in FY2016, in the same respective order. This finding highlights the importance of mining clinical notes to help characterize the different tapering strategies not captured using pharmacy data. Using pharmacy data, we identified a high proportion of patients with prescription opioid receipt with patterns likely reflecting changes in opioid regulations (i.e., changes in hydrocodone scheduling) and guidelines recommending more judicious opioid prescribing. Using unstructured data, we captured patients being tapered with evidence of tapering discussions in clinical notes. We plan to enhance our approach by refining our definitions of long-term opioid receipt and applying more advanced computational approaches to not only detect tapered patients but also characterize the tapering strategies by different clinicians and how they affect clinical outcomes.

Immune-Related Adverse Events of Checkpoint Inhibitors

Paul Fontelo, MD, MPH; Fang Liu, MS
National Library of Medicine, Bethesda, Maryland

Background

The immunotherapy of cancers, particularly checkpoint point inhibitors (CIs), have revolutionized the treatment of malignancies leading to increasing survival. They have been mostly beneficial in patients with melanoma and certain types of lung tumors. Cancer cells evade detection and destruction by the body’s immune system by acquiring a coat of normal proteins on their surface. CIs block these protective “normal” proteins and allows them to be recognized as “foreign” cells and destroyed by the immune system. They also inhibit the proteins on T-cells that recognize normal cells and allows functioning T-cells to destroy malignant cells. However, because they are immune inhibitors, they may also trigger T-cells to attack normal cells which result in Immune-related Adverse Events (IrAEs). These side effects may cause serious harm, and death, even after the drug is discontinued. CIs are increasingly used in treating cancers unresponsive or resistant to chemotherapeutic agents or even as a primary line of treatment of malignancies. Reports of IrAEs, especially when used in combination, have increased with their growing usage.

Design

We reviewed publications in PubMed of IrAEs for seven CIs and 21 two-drug combinations from 2005 to 2017. The search strategy used was as follows: drug name(s) + organ or system or condition + human + hasabstract. A search tool was developed for finding reports of IrAEs (https://go.usa.gov/xRmHK).

Results

Immune-related adverse events report started appearing in the literature in 2005 (Ipilimumab) but the majority of reports were published between 2014 to 2016 when more CIs were approved by the FDA. Most adverse events reported were dermatologic, followed by endocrine, gastrointestinal, respiratory and neurologic. Single drug IrAEs are shown in Figure 1. For combined regimens, pembrolizumab and Nivolumab combination accounted for 25% of all reported adverse events (2888) in the literature, followed by nivolumab AND ipilimumab (22%), then pembrolizumab AND ipilimumab (16%). Other drug combinations were each less than 10% of the total. Among organ systems, dermatologic (24%), endocrine (23%) and gastrointestinal (16%), respiratory (15%) and neurologic (13%) side effects were the most common adverse reactions to checkpoint inhibitors. For two-drug combinations, Pembrolizumab and Nivolumab (25%), Nivolumab and Ipilimumab (22%) and Pembrolizumab and Ipilimumab (16%) account for majority all immune-related adverse events (2888) reported.

![# of Publications in PubMed by Year](chart.png)

Fig. 1. Number of Immune-related adverse events publications for one-drug regimens by year

Conclusion

The incidence of IrAEs to CIs has grown significantly with their increasing use. Dermatologic, endocrine and gastrointestinal are the commonly affected. For single drug regimens, ipilimumab, nivolumab and pembrolizumab account for the majority of immune side effects. Among the two-drug combinations, Pembrolizumab and Nivolumab, Nivolumab and Ipilimumab and Pembrolizumab and Ipilimumab account for 58% of all adverse events.
mHealth for Weight Management Among Breast Cancer Survivors from Vulnerable Populations

Quintiliani, PhD, Boston University, Department of Medicine, Section of General Internal Medicine, Boston, MA

Introduction

Advances in detection and treatment of breast cancer has led to a large cohort of cancer survivors who may have an increased awareness of health promotion; mHealth technologies have the potential to deliver effective behavioral interventions in a format suited to everyday life. While researchers have identified Behavior Change Techniques (BCTs; Taxonomy version 1) present in efficacious interventions for weight loss among cancer survivors, the features that should be included in mHealth interventions for cancer survivors have not been well specified, particularly among those from low income or racial/ethnic minority groups.(2,3) Purpose: The objective of this study is to examine perceptions of evidenced-based features that breast cancer survivors from underserved populations would find important to include in a mHealth weight management app. Method: Female breast cancer survivors were recruited from a large safety net hospital to participate in an individual interview or small group discussion. This study was approved by the Boston University Medical Campus/Boston Medical Center IRB. In phase 1, participants were shown a presentation depicting a BCT, one at a time, along with accompanying pictures depicting how each BCT could be incorporated into a mHealth app. Participants rated how important each feature would be from 1 (not at all important) to 9 (very important). Using a modified Delphi method, each participant was then asked to re-rate the features after seeing their own rating compared to the group rating. Participants also answered open-ended questions about their perceptions of mHealth apps. Evaluation results: In phase 1, thirteen women participated; the majority were from a racial/ethnic minority group (85%), and received medicaid (65%). All were overweight or obese. Upon re-rating after seeing the group average, scores ranged from 6.1 -8.6 for the BCTs. Lower rated BCTs included the need for specifying credible sources; higher rated features included feedback and self-monitoring of outcome of behavior (weight). Participants valued mHealth apps that were simple to use “It has to be simple enough…I’m not a technical person. So, it has to be simple and somebody like me can use [it]”; had new/engaging information, “…as long as it was interesting reading, if that makes any sense. ... If it’s more funny, or quick, or easy to read, interesting and incorporated some features specifically for breast cancer survivors. In phase 2, 9 women participated. The majority (n=8) rated the usability of the mock-ups in the good/excellent range (scores ≥68). Conclusions: Breast cancer survivors from underserved populations were able to identify important features to include in a mHealth app and to elaborate on preferred app design characteristics. Future research will involve further refinement of the mHealth app, ultimately resulting in a mHealth app ready for efficacy testing in a larger trial.

Planned modifications to the study and app

1. Perform field testing of the app, make further refinements based on user feedback.
2. Test app in a larger efficacy trial.

SNOMED CT: Interoperable but silos remain between medicine and nursing

Dan Fraczkowski¹, RN, Andrew D Boyd ², MD, Karen Dunn Lopez³, PhD
¹ College of Nursing, University of Illinois at Chicago- Chicago, IL, USA ² College of Applied Health Sciences, University of Illinois at Chicago- Chicago, IL, USA

Introduction

Transitions of care can impair communication and lead to adverse events. Our prior work examined the lack common terms between the professions caring for the same patient. [1] SNOMED CT is an interoperable healthcare terminology with potential to facilitate interprofessional communication. [2] NANDA-I[3], more commonly known as nursing diagnoses, contained in SNOMED CT, represents the nursing diagnostic judgements. The objective of this study was to identify patterns of terms used by physicians in their discharge summaries that map to NANDA-I terms/concepts.

Methods

We performed a secondary data analysis merging 3 data sets: 1. Physician discharge summary Concept Unique Identifiers (CUIs) from a large urban tertiary care hospital for a six year period. 2006-2012 (12,968 terms). CUIs were assigned using MEDlee across all disciplines and over 100,000 notes. [1] CUI’s were used at least 15 times/year. 2. SNOMED CT US nursing terms(673 terms)[4]. 3. NANDA-I list of nursing diagnosis (244 terms)[5]. CUI terms were identified via manually searching in the UMLS and compared against the SNOMED CT database

Results

Of the physician CUI terms, we identified 159 (23%) terms in nursing subset within discharge summaries. The following NANDA-I categories were represented: 87 defining characteristics, 45 associated conditions, 38 related factors, 27 risk factors and 17 population at risk for (CUI could belong to several). Among the SNOMED CT Nursing terms, 21%(33) unique CUI’s mapped directly to NANDA-I. These encompass 6 of the 13 NANDA-I domains, absent are health promotion, life principles, growth and development, coping/stress tolerance and role relationship.

Discussion

Our results show that despite continued development of SNOMED CT with greater inclusion of nursing terms, from 368 to 673 in 2017 [3] physicians do use some nursing concerns in discharge summaries. However, the minimal presence of nursing documentation in physician summaries is a limitation of SNOMED CT as a universal terminology. Also concerning in terms of semantic interoperability, physician terms that map to the SNOMED CT nursing subset leave room for ambiguity, for example, “hyperthermia” has 7 associated conditions, 11 defining characteristics, 2 risk factors and 1 related factor. The associated conditions varied from, “Sepsis” to “Increase in metabolic rate.” Finally, the omissions of the six domains reflect care that may be a unique focus for nurses, reflecting gaps and opportunities to improve the patient care record.

Conclusion

Standardized terminologies are proposed as a means to “bridge the gap” however nursing and physician care are unique. Our results indicate little use of nursing terms in physician discharge summaries, thus we haven’t yet reached full integration with these terminologies in practice. The limited level of crossover indicates challenges remain as we seek for SNOMED CT to reach full potential.

Evaluating the performance of a general diagnostic decision support system on case data from urgent cardiology admissions

Fraser HSF, MBChB MSc
Brown University, Providence, RI, USA

Abstract

Many new diagnostic decision support systems have been introduced in recent years but lack rigorous clinical evaluation or even use of real patient data. We used data on urgent cardiology admissions to test an established general diagnosis program Isabel. Results were similar to a specialised Heart disease diagnosis program (HDP).

Introduction:

Misdiagnosis is a common problem affecting 5% of ambulatory care patients in the US. It can lead to poor investigation and management of patients, and put lives at risk. Diagnostic decision support systems go back to the beginning of medical informatics, and underwent a resurgence over the last 5 years. This likely stems from better access to medical data, better algorithms, and better delivery methods through EHRs or mobile devices. However there is a lack of rigorous evaluation using real patient presentations and validated clinical diagnoses rather than the use of case scenarios created by physicians. This study used case data on urgent admissions to a cardiology ward entered in real time by medical residents with “gold standard” diagnoses from detailed chart review and follow up, to test “Isabel” a well-established general medical diagnosis program.

Methods:

Data on urgent admissions to the cardiology service at the New England Medical Center in Boston, MA was entered into a web based clinical interface by the admitting residents. The study tested the diagnostic performance of the Heart Disease Program (HDP) 1 which was built with a Bayesian belief network modified to handle temporal and severity characteristics of clinical data. After the data was entered the residents were required to enter their own differential diagnosis before they could view the HDP diagnosis. The patients were then followed up after their admission to determine the final clinical diagnoses. In the current study the diagnostic performance of the general diagnosis program Isabel 2 was tested using the clinical data entered into the HDP in the earlier study. The differential diagnosis from Isabel was then coded with the same vocabulary as the HDP. Diagnostic performance of Isabel against the gold standard diagnoses was compared with the performance of the resident physicians and the HDP also against the gold standard. Performance metrics were Comprehensiveness (similar to sensitivity), and Relevance (similar to Positive Predictive value), calculated per case and reported as mean values.

Results:

Isabel was tested with 16 sequential cases from the original study including demographics, clinical history, cardiac risk factors, physical exam findings and investigations. Diagnoses included hypertension, myocardial infarction, angina, valvular heart disease and congestive heart failure. The Comprehensiveness of Isabel was 56% compared to 46% for the residents and 61% for the HDP. The Relevance was 19% for Isabel versus 51% for the residents and 26% for the HDP, the lower scores for the diagnosis programs reflected larger numbers of diagnoses per case.

Discussion and conclusions:

Comprehensiveness of 50 – 60% is not surprising given that the gold standard was based on follow up and extensive further investigation. Data entry into Isabel was significantly less detailed than the HDP, particularly timing of symptoms, numeric data for vital signs, cardiac exam and investigations. This may have contributed to the 5% lower Comprehensiveness of Isabel, which also covers a much more complete set of adult and paediatric diagnoses. This is part of a larger study of diagnostic programs using real patient data entered in real time.

Incorporating Social Determinants of Health in Electronic Health Records (EHRs): A Qualitative Study of Perspectives among EHR Vendors

Maysoun Freij,1 Prashila Dullabh,1 Sarah Lewis,2 Scott Smith,3 Lauren Hovey,1 Rina Dhopeshwarkar1

1NORC at the University of Chicago, Bethesda, MD; 2 Centers for Medicare and Medicaid Innovation, Baltimore, MD; 3Assistant Secretary for Planning and Evaluation, Washington D.C.

Introduction

Health care reform initiatives over the past decade have simultaneously incentivized value-based care payment models and the adoption and development of electronic health records (EHRs).1 Further, the emphasis on value over volume has drawn attention to the importance of social determinants of health (SDH) (i.e., socioeconomic issues such as housing, food, transportation, income, education, social isolation) in potentially affecting health outcomes.

Methods

We conducted a literature review on current uses of EHRs for assessing and documenting SDH. To further investigate the development of SDH-related software products, we conducted interviews with EHRs vendor representatives purposefully selected based on vendor market shares in both ambulatory and inpatient settings. We recruited six vendors with large market shares in one or both settings. Interviews were conducted by phone, and notes were transcribed. We qualitatively analyzed interview notes using NVIVO software for (1) motivations to develop such software products (2) descriptions of their products and uses, and (3) facilitators and challenges to collection and use of SDH data. This study was approved by NORC’s Institutional Review Board; all participants gave informed consent, and agreed to the confidential presentation of their findings.

Findings

Our findings indicate that vendor systems and their functionalities are influenced by client demand and initiative, federal initiatives, and the vendors’ strategic vision about opportunities in the health care system. Among the sampled vendors, SDH is a new area for growth, and the vendors range in the number and sophistication of their SDH-related products. While all participating vendors have enabled some SDH data collection screening instruments or measures in their EHR platform, they varied in terms of capacity to track referrals and analyze data. Vendor representatives reported a range of activities within this field, ranging from helping clients meet regulatory obligations to developing SDH-related products for use in population health management. They identified a number of challenges with analyzing SDH data and sharing them among health systems, including multiple overlapping but distinct performance metrics and indicators across various federal and state programs, lack of agreement on mapping SDH measures to codes, and lack of codes for all measures. Vendor representatives recognized the need for more standardization of SDH performance measures across various federal and state programs, better mapping of SDH measures to multiple types of codes, and development of more codes for all SDH measures of interest.

Conclusion

Though EHR vendors have both indirect and direct roles in working with policymakers and health care systems on value-based care and health care quality initiatives, there are few systematic studies of the EHR vendors and their motivations. Their perspectives are important given that product-specific decisions may end up becoming de-facto policies given the market shares of particular vendors, particularly in areas where policy guidance is lacking, as it is for SDH data collection and use. Commercial vendors appear ready to collaboratively discuss policy solutions, such as standards or guidelines with each other, health care systems, and government agencies in order to further promote integration of SDH data into the standard of care for all health systems. Findings from this study have been published by the Office of the Assistant Secretary for Planning and Evaluation, and will appear in a forthcoming report to Congress.

Conversion of a Complex Legacy Antimicrobial Stewardship Clinical Decision Support System into Epic

Brian K. Fung, PharmD1, Evan Draper, PharmD1, James Steckelberg, MD1, Abinash Virk, MD, Sara Ausman, PharmD1, Sarah Lessard, PharmD1, Aaron Tande, MD1, Lynn L. Estes, PharmD1
1Mayo Clinic, Rochester, MN, 2Mayo Clinic Health System, Eau Claire, WI, 3Mayo Clinic Health System, La Crosse, WI

Background

The hospital rules-based system (HRBS) was the first rules-based informatics program developed at Mayo Clinic in the 1980s in an effort to improve patient care through the reduction of medication errors, enhanced education, and clinician communication. Computer-based antimicrobial monitoring (CBAM) was the first of the six HRBS subsystems to be developed and demonstrated positive patient outcomes and favorable cost reductions in medications. In January 2015, Mayo Clinic announced the selection of Epic as its partner for a single, integrated electronic health record (EHR). We describe the conversion of Mayo Clinic’s legacy decision support system CBAM into Epic’s antimicrobial stewardship program (ASP) module for eighty hospitals and clinics across four states.

Methods

The project kicked off in July 2015 and planning began between project analysts and subject matter experts. Epic’s antimicrobial stewardship strategy handbook was used to guide core implementation and build principles. Due to insufficient functionality using Epic’s foundation tools, in April 2016, the strategy shifted from using foundation Epic build to designing a customized ASP module that mirrored the complexity of Mayo’s CBAM system.

Results

The design, build, and implementation required substantial effort from key stakeholders from infectious disease physicians, infectious disease pharmacists, and project analysts. Bi-monthly meetings were set up in March 2016 to facilitate convergence and rapidly mitigate issues as it pertained to the Epic build. Over 200 legacy antimicrobial stewardship rules were reviewed, converged, and replicated into 75 customized rules for build in Epic. Estimated effort for rule build varied between 5 hours to 30 hours. Of the planned 75 rules, 17 were unable to be replicated by the first go-live in July 2017 due to complexity and constraints of the existing EHR tools. Project analysts innovated a solution that combined multiple tools in nontraditional methods to replicate minimum functionality that included rule interaction (i.e. dismiss and defer) and rule complexity (e.g. relative properties). A prototype of two rules using the new framework was introduced in the second go-live in November 2017. Given the successful implementation of the prototype, a full-scale conversion of existing rules and completion of the remaining 17 rules were implemented by the third go-live in May 2018. While this go-live marked the completion of converting the legacy systems into Epic, the initial weeks were characterized by false positives and usability issues. Significant optimization efforts of the ASP module persisted until the fourth go-live in October 2018 and the project officially closed on January 1, 2019. Despite the challenges, the ASP module is markedly improved from its earlier prototypes and its success and progression has served to inform Epic on multiple areas for future research and development.

Discussion

Implementation of Mayo Clinic’s legacy decision support systems for antimicrobial stewardship was achieved within project timelines. Innovative solutions with existing tools were required to fully replicate legacy functionality that allowed for interaction with individual rules.

Corpus Size Influences Clinical Concept Embeddings

Cheng Gao PhD\textsuperscript{1}, Chao Yan MS\textsuperscript{2}, Bradley A. Malin PhD\textsuperscript{1,2}, You Chen PhD\textsuperscript{1}
\textsuperscript{1}Vanderbilt University Medical Center; \textsuperscript{2}Vanderbilt University

Introduction

Word embedding has shown great promise for many natural language processing tasks. It is a general belief that a larger corpus results in better word embedding. However, a recent work\textsuperscript{1} showed that the combination of PubMed and PMC on clinical text generated worse embeddings than PubMed alone, indicating that a larger corpus cannot guarantee better word representation. In this study, we investigated in learning of International Classification of Disease, 9th Revision (ICD-9) codes how the corpus size influences word embedding. Specifically, we used word2vec\textsuperscript{2} to train word vectors of ICD-9 codes from de-identified data and fed these word vectors to deep learning model to predict neonatal encephalopathy (NE). We found that the word embeddings learnt from a smaller corpus had a better performance in predicting NE comparing to a larger one.

Materials and Methods

This study relies on two corpora of timestamped ICD-9 codes to learn word vectors: i) Global dataset: all Vanderbilt University Medical Center (VUMC) patients – approximately two million; ii) Local dataset: 31,158 maternal patients at VUMC. Word2vec is applied to learn word embeddings from these two datasets. To investigate which dataset generates better embeddings for ICD-9 codes, we evaluate these embeddings intrinsically and extrinsically.

Intrinsic Evaluation: CCS, including 285 clinically meaningful categories, is used as a gold standard for ICD-9 codes. For each code, we perform nearest neighbor (NN) search based on the word vectors (word2vec\textsuperscript{2}). If the code and its NN belong to the same CCS category, we consider the word vector for this code is correct. The correct rate will be reported along with 95% confidence interval.

Extrinsic Evaluation: We feed learned word vectors from Global and Local datasets as inputs into long short-term memory (LSTM) network to predict NE. This is a particularly challenging task due to the heavily unbalanced nature of its classes: 104 NE cases and 31,055 patients. We use 10-fold cross-validation and report the area under the receiver operating characteristic curve (AUC) with a 95% confidence interval on test data.

Results and Discussion

Table 1 summarizes the word embedding performance for both datasets, with the best results in bold font. It can be seen that the embeddings learnt from Global dataset are better when they are intrinsically evaluated, implying that a larger corpus generates better embeddings in identifying similar ICD-9 codes. However, the local dataset yielded the best extrinsic results in predicting NE and the statistical test (Delong method) show that AUCs are significantly different with p value of 0.005. This implies that locally-learned word embeddings are more appropriate for the NE prediction task. Since NE prediction is the only task tested in this study, the result may be different in other clinical datasets. It is suggested comparing AUC results from global dataset and local dataset.

Application of IBM Watson to clinical decision support: a preliminary experience on the interpretation of DSM-5

Enrico Garbelotto, MS¹, Marco Prenassi¹, PhD, Sara Marceglia, PhD¹
¹Dipartimento di Ingegneria e Architettura, Università degli Studi di Trieste, Trieste, Italy

Introduction
The Diagnostic and Statistical Manual of Mental Disorders launched its 5th edition (DSM-5) in 2013¹. The manual is a reference for psychiatric and neuropsychiatric practice and introduced novel advances in disorders diagnosis and treatment thanks to the recent research in the field. Despite the attempts to decrease the total number of categories, the manual remains very complex, and includes a large co-occurrence of diagnoses (sometimes known as comorbidities), with sometimes a lack of distinctiveness between diagnoses². This work aimed to test whether a system based on IBM Watson services could be implemented and used to support the clinician in an immediate and easy consultation of the DSM-5, also simplifying the identification of the most probable diagnoses.

Methods
Three IBM Watson services, namely Knowledge Studio, Discovery, and Natural Language Understanding (NLU) were used to build up the system for DSM-5 interpretation. A concept model was developed and trained in Watson Knowledge Studio using 60 extracts from 6 DSM-5 chapters previously annotated according to the entities and relationships defined in the concept model. The precision of the system (percentage of true positives on the overall positives recognized by the model) and the recall (percentage of true positives on the overall true from the ground truth) were used as performance measures of the model. A Java-based application was then implemented as user interface for the two other IBM Watson services (Discovery and NLU)³. The system was validated retrospectively using 5 case studies available in the literature, in order to test its ability to understand the clinical observations and to suggest the possible diagnosis/es according to the DSM-5.

Results
The semantic model included 9 main entities (among them, “disorder”, “subtype”, “specifier”, “diagnostic criterion”, “risk factor”) and 9 main relationships and achieved an overall precision of 85% and recall of 76%.

The application implements three main functions: (1) to retrieve the parts of the DSM-5 relevant for explaining specific clinical observations; (2) to obtain a list of probable diagnoses (with associated likelihood) starting from a set of clinical observations (diagnostic criteria, risk factors, or specifiers) listed in natural language; and (3) to extract the relevant concepts, according to the semantic model, provided an extract of the DSM-5. Whereas the first two functions can be used directly by clinicians, the third one is more useful for implementing other applications.

Examining 5 retrospective cases, we found that in all cases the correct diagnosis was reported in the list of probable diagnoses, being the first one in 4 cases (Panic Disorder, Post-traumatic Stress Disorder, Illness Anxiety Disorder, and Generalized Anxiety Disorder), and the second one in one case (Borderline Personality Disorder).

Conclusion
Our results show that IBM Watson services can be used to support the reading and interpretation of the DSM-5, and the diagnostic process. Even in a first implementation and testing, the system correctly recognized all the clinical observations and possible associated diagnoses. However, the validation should include a real-world testing and an improvement of the semantic model.

Factorial Design Survey Methodology on REDCap and Qualtrics: A Comparative Analysis

Jose P. Garcia, Jr., BA1, Sarah Collins Rossetti, RN, PhD3,4, Kenrick D. Cato, RN, PhD4, Suzanne Bakken, RN, PhD, FAAN, FACMI3, Haomiao Jia, PhD4, Min J. Kang, RN, PhD1,2, Christopher Knaplund, MPhil4, Patricia C. Dykes, RN, PhD, FAAN, FACMI1,2

1Brigham & Women’s Hospital, Boston, MA; 2Harvard Medical School, Boston, MA; 3Columbia University, Department of Biomedical Informatics, New York, NY; 4Columbia University, School of Nursing, New York, NY

Problem

A factorial design survey (FDS) is an experimental design that includes multiple iterations of a survey, where the factor content and order change from iteration to iteration to determine which combination of statistically significant factors are perceived as clinically significant, yielding more generalizable conclusions. The beauty of FDS is that it combines the strengths of a factorial experimental research design with a sample survey, but it can employ ten or more variables to study within one survey.1 An appropriate FDS software is needed to reduce the complexity associated with measuring the effect of each variable over numerous trials in both survey development and end-user experience to ensure design worktime is feasible and an acceptable response rate is achieved. This case study compares the ability of two popular survey platforms (REDCap and Qualtrics) to efficiently run an FDS trial.

Methods

A pilot survey trial was conducted on both REDCap and Qualtrics. REDCap lacks on-platform survey field randomization, so a workaround was developed. An off-platform block randomizer was used to generate and randomly assign surveys containing four vignettes to participants, and a template survey containing fields with every possible vignette (n=16) hidden from survey view was created on REDCap. To create test surveys, copies of the template were made, and the fields containing the vignettes assigned by the block randomizer were unhidden, leaving only the vignettes (n=4) randomly assigned to each participant in their survey view. The pilot survey on Qualtrics was conducted completely on platform. A master survey was created using Qualtrics’ Randomizer element in Survey Flow that would randomly populate embedded fields with one of two levels for each factor (n=5) in every test vignette (n=6) for each survey recipient. The surveys for each trial were disseminated through their respective web-based tools. Time required to develop the surveys and end-user perceived ease of use were measured for both platforms. A student T-test was used to test perceived differences in ease of use.

Results

For REDCap, 42 surveys were created and disseminated in approximately three hours (~4.5 minutes/survey). One survey was created and sent to 34 participants in approximately one hour (~1.75 minutes/survey) on Qualtrics. The ease of use survey results for both software were not statistically different (p=0.19).

Conclusion

REDCap’s lack of randomization and automation functions are limitations for factorial design. The reliance on a workaround requiring manual input for executing FDS in REDCap introduces potential for human error when scaled up. Qualtrics, however, possesses the tools necessary to efficiently and automatically run a factorial design survey while showing no significant difference in participant-reported ease of use.

Querying Clinical Datasets with GraphQL and Concept IDs

Julie P. Garcia¹, Rimma Belenkaya, MS¹, Peter Stetson, MD, MA¹, and John Philip, MS¹
¹Memorial Sloan Kettering Cancer Center, New York, NY, USA

Introduction

At Memorial Sloan-Kettering, we are working on ways to automate the retrieval of patient data from clinical systems for research purposes. One approach is to combine a system for storing ontologies, such as TopBraid EDG, with a GraphQL Server to query data from many sources. GraphQL is a fast, flexible query language and server framework that allows you to combine multiple data sources in a single request.¹² This allows the aggregation of datasets across the organization with metadata (e.g. alternative labels, data provenance).

Using GraphQL to Query Data by Concept ID

We demonstrate a query schema that combines data with ontologies stored in TopBraid EDG. The GraphQL server allows for full-text searching to retrieve an associated concept ID and location of the data. For example, when searching for all concepts containing the term “specimen”, you would receive a list of concepts that contain this search term. A selected concept ID can then be used in combination with a patient identifier, such as a medical record number, to retrieve the actual data value or value set from the source. In this example, pathology specimen data from a Cerner CoPath Sybase Database is mapped with a concept ID stored in TopBraid (Figure 1a). The query asks for a concept value, given a concept ID and patient MRN (Figure 1b) and the data value or value set is returned.

![Figure 1](image.png)

Figure 1. a) GraphQL Server combines pathology data with concepts stored in TopBraid EDG to allow for single request from frontend platforms b) Query by Concept ID and patient MRN returns requested related data from associated source

This GraphQL API server can be used as the backend for various data analysis tools that include custom web applications, dashboard platforms and mobile apps. Multiple data sources can be queried at once, and only the data that is needed will be returned. This allows for rapid frontend development, with very little backend refactoring that is generally required with traditional RESTful APIs.²

Conclusion

Utilizing a GraphQL API server to aggregate data and metadata across an organization can simplify the process of retrieving data from multiple sources, while forcing use of standardized terminologies. This can rapidly accelerate research and reduce tedious manual data abstraction processes.

Description of Problem Addressed by Project:
Over the past six years many vaccine manufacturers have affixed two-dimensional (2D) barcodes onto vaccine vials and syringes; the majority of which are now 2D barcoded. Some electronic medical record (EMR) systems have incorporated 2D barcode functionality, applications to not only capture and process the barcoded data but to incorporate patient safety alerts. The Centers for Disease Control and Prevention (CDC) conducted several pilots to explore the impact of 2D vaccine barcode scanning on the data quality captured during vaccine administration. Healthcare practices considering the implementation of vaccine barcode scanning face not only technical challenges but also human considerations as staff adjust to and adopt new work flows and protocols.

Description of Project and Lessons Learned:
CDC has developed an implementation guide based on the experience with the pilots on how to scale the adoption of the 2D barcode scanning technology in the clinical setting. Specifically, this guide was developed as part of a pilot to implement 2D barcode scanning in a large healthcare system. Approximately half of the large healthcare system’s practice sites participated in the pilot. For a period of six months, participant sites used a 2D barcode scanner to capture vaccination data for patients receiving a vaccination. The pilot investigated when, why, and how barcode scanning should be implemented to achieve the highest return on investment, and how behavioral strategies can be used to improve consistent adoption over the long-term. This resulted in an implementation guide that is the basis for the poster.

Poster Content:
This poster will provide an overview of 2D vaccine barcoding in 2019 and summary of project lessons learned including how behavioral strategies (“nudges”) to promote scanning impacted scanning rates and longer-term adoption. The poster will also describe baseline scanning rates across groups, changes to rates based on implementation of behavioral strategies, resolution of key challenges, and insights about scalability within a single healthcare system. A detailed description of the steps to implement vaccine barcode scanning in clinical settings will feature prominently on the poster. This information is based on lessons learned in the actual implementation described above and involves six key steps: decide, plan, train, assess, adjust, and sustain. The poster will describe these steps and essential lessons that can be used when introducing a new technology, including how to design strategies to encourage staff to implement new protocols.
Usage Patterns of a SMART on FHIR Application to Improve Platelet Transfusion Workflow

William J Gordon MD MBI1,2,3, Maria Aguad BS1, Heather Appello BS1, Samuel J Aronson ALM2, Jane Baronas BA1, Indira Guleria PhD1,3, Richard M Kaufman MD1,3, Edgar Milford MD1,3, Michael Oates2, Rory dela Paz BS2, Melissa Yeung MD1,3, William J Lane MD PhD1,3

1Brigham and Women’s Hospital, Boston, MA, 2Partners Healthcare, Boston, MA 3Harvard Medical School, Boston, MA

Introduction

Worldwide, more than 50,000 patients undergo Hematopoietic Stem Cell Transplantation (HSCT) each year1, and many of these patients will develop transfusion-dependent thrombocytopenia. We have previously described2 a FHIR-based application designed to improve platelet utilization and transfusion workflow at a single center. We now report initial provider usage of this application along with patients loaded in the application.

Methods and Applications

We developed a visualization application to improve the workflow around platelet transfusion for patients undergoing HSCT. The application provides a unified view into several essential data elements relevant for patients requiring platelet transfusion, including platelet count trend, prior transfusions, patient HLA data, and current blood bank platelet inventory. This product was launched October 1st, 2018, at a single institution, after extensive validation and updates to the blood bank Standard Operating Procedures (SOPs). Initial usage of the application was high and has remained consistently high for the first 5 months of production use (Figure 1). Users include blood bank technicians, supervisors, physician trainees, and attendings. Usage has been limited to patients already identified as requiring Human Leukocyte Antigen (HLA) matching for platelets (for example, due to high calculated panel reactive antibody scores), though we are in the process of updating our SOPs to include additional patient groups (for example, all stem-cell recipients requiring platelet transfusions at our institution).

Conclusion

Initial usage of a SMART-on-FHIR application to optimize platelet transfusion workflow has been consistent with dozens of patients impacted. Work is ongoing to study the clinical impact, for example, transfusions prevented, or prevention of dangerous thrombocytopenia.

Figure 1. Initial usage characteristics of the application. Shown are plots for unique users (clinicians, blood bank staff, etc.) and number of patients loaded into the application (aggregated per month).

Assimilating Pollen into Exposomes for Pediatric Asthma Research

Ramkiran Gouripeddi, MBBS, MS¹, Le-Thuy Tran, PhD¹, Tanvi Gangadhar, BTech¹, Randy Madsen, BS¹, Katherine Sward, PhD, RN, FAAN¹, Julio Facelli, PhD, FACMI¹
¹University of Utah, Salt Lake City, UT, USA

Introduction

Pollen is a common trigger for pediatric asthma (PA) exacerbations and other allergic reactions¹. However, there are limited studies that seek to understand the cumulative effects of pollen with chemical species in air quality, and the role of different types of pollen species. In addition, recent reviews of PA have called for incorporation of detailed spatiotemporal dimensions of environmental factors in future studies¹.

Methods

As a part of the Exposure Health Informatics Ecosystem (EHIE)², we have extended the OpenFurther (OF) platform as a comprehensive, standards-based, open-source informatics platform for providing semantically consistent, metadata-driven, event-based integration of exposomic data generated from environmental and physiological sensors, human observations and computational models, with other biomedical data. OF uses an event-driven architecture allowing modeling and storage of all activities related to a study’s operations along with associated metadata in their primitive form on a timeline as events that can be transformed to higher/analytical models based on use-cases.

In order to add pollen data with already existing capabilities of assimilating air quality data with clinical data, we followed these steps. We first surveyed literature for pollen data used in PA research and listed key variables utilized in these studies. We then sampled data available with existing pollen data sources and developed an initial draft of a conceptual model. We reviewed this model with PA researchers and deployed this in a graphical metadata repository.

Results and Discussion

We extended our sensor common metadata specification (SCMS)² to include sensors that measure biological species such as pollen. The extended SCMS captures metadata about (1) instruments used to measure pollen, (2) how these instruments were deployed, and (3) pollen output from these instruments (Figure 1). The output includes concentrations for pollen categories, details about each pollen species, pollen indices, and spatio-temporal coordinates of these measurements. Using this metadata within OF, we generated pollen events representing pollen measurements with spatial and temporal coordinates from two sources: (1) Pollen.com and (2) National Allergy Bureau starting 10/01/2018 for participant locations enrolled in a EHIE pilot study, and are assimilating them with meteorological (supports modeling pollen dispersion), air pollutant and clinical data for PA exposomic studies.

Conversational Agents for Chronic Disease Self-Management: A Systematic Review

Ashley C. Griffin, MSPH1-2, Zhaopeng Xing, MPS1-2, Saif Khairat, PhD, MPH1-2, Yue Wang, PhD1-2, Stacy Bailey, PhD, MPH3, Jaime Arguello, PhD, MS1, Arlene E. Chung, MD, MHA, MMCi1-2

1University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 2Carolina Health Informatics Program, Chapel Hill, NC, USA; 3Northwestern University, Chicago, IL, USA

Introduction

Conversational agents, which are systems that communicate with users in their natural language and are often referred to as chatbots, have the potential to deliver patient-centered interventions that focus on goal setting, feedback, and education. However, little is known how these agents may be utilized to assist patients with chronic disease self-management. Thus, the objective of this study was to review the literature to assess how conversational agents have been used for chronic disease self-management and to identify gaps in the evidence base.

Methods

We conducted a systematic review using Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines using five databases (PubMed, Scopus, Embase, Cumulative Index of Nursing and Allied Health, and Association for Computing Machinery Digital Library). A priori search terms included variations of the following: chatbot, virtual coach, dialogue system, and conversational agent. We included full text journal articles or conference proceedings that contained primary research findings for text-based conversational agents focused on self-management for chronic diseases in adults. Studies that did not contain one or more self-management skills1 or chronic diseases as defined by the Centers for Medicare and Medicaid Services were excluded. Two reviewers extracted information from the included studies, analyzed the data, and then grouped studies into themes using an inductive thematic approach. The risk of study bias was rated using the Agency Healthcare Research and Quality internal validity quality evaluation criteria.

Results

We identified 1,606 studies across the databases, and 12 studies met the inclusion criteria. The studies were published between 2012 and 2018, which included five randomized controlled trials, five quasi-experimental, and two non-experimental studies. The duration of studies, excluding laboratory-based studies, ranged from two weeks to four months. The total number of participants across the studies ranged from 10-401, and participants were between 18-92 years old. We rated the risk of bias of one study as good, five studies as fair, and six studies as poor, largely due to the lack of methodological rigor and inconsistent measures. The majority of agents (7) were primarily targeted towards individuals with depression or substance use. Across studies, participants mostly reported a positive attitudes towards agents, and there were improvements on the Patient Health Questionnaire, Generalized Anxiety Disorder Scale, Perceived Stress Scale, Flourishing Scale, and Overall Anxiety Severity and Impairment Scale between the conversational agent intervention and control groups in three randomized controlled trials (p<.05). Major themes that arose from the analysis of user perspectives were related to personalization, engagement, and social support. These themes revealed that 1) participants were interested in tailoring the agents based on their health condition and preferences, 2) graphs, videos, and games facilitated their engagement, and 3) agents have the ability to promote collaboration with support structures.

Conclusion

This systematic review suggests that conversational agents are acceptable to patients and have the potential to support self-management for some chronic diseases. However, this is still an emerging area of research as there is limited evidence for the long-term use of agents at scale. Additional research is needed to assess the influence of more sophisticated dialogue and user models and should use consistent measures for reporting outcomes.

Comprehension of Visualizations for Longitudinal Patient-Reported Outcomes

Lisa V. Grossman¹, Meghan Reading Turchioe, PhD, RN², Annie C. Myers², Dawon Baik³, Ruth M. Masterson Creber, PhD, RN²

¹Department of Biomedical Informatics, College of Physicians and Surgeons, Columbia University, New York, NY; ²Department of Healthcare Policy and Research, Division of Health Informatics, Weill Cornell Medicine, New York, NY; ³School of Nursing, Columbia University, New York, NY

Introduction

An increasing number of healthcare organizations capture patient-reported outcomes (PROs) to better monitor patients' health status, as federally mandated by the U.S. financial incentive policy Meaningful Use. Several promising initiatives to design electronic PRO (e-PRO) systems exist, but most do not help patients comprehend their PRO survey results. Helping patients comprehend their results can facilitate self-management, because periodically-repeated PRO surveys can capture changes over time. Typically, researchers use line graphs to help patients comprehend numeric changes over time, including changes in PROs. Unfortunately, previous research indicates that inadequate graph literacy is prevalent, around 40% of the U.S. population. The purpose of this study was to assess patients' comprehension of non-graph visualizations that display longitudinal changes in PROs.

Methods

A purposive sample of 40 hospitalized, English-speaking heart failure patients diverse on age, gender, and race was recruited. We excluded patients with severe cognitive impairment or active psychosis. We assessed demographics, graph literacy, health literacy, and cognitive status. Comprehension (ISO 9186-1) was tested in four conditions, including: (1) text only, (2) text plus visual analogy, (3) text plus number line, and (4) text plus line graph. Each participant viewed every condition, and we systematically randomized the order and information contained in each condition to control for potential learning effects.

Results

Participants had an average age of 61.3 years (SD: 12.5) and were 22% female, 23% Black, 52% White, and 38% Latino. On average, participants scored poorly on graph literacy (mean 1.1 out of 4; SD 1.1), and 37% did not answer any graph literacy items correctly. 55% screened positive for inadequate health literacy, comparable with the U.S. mean. 88% had inadequate cognition (MoCA score < 26). 63% correctly comprehended the text-only condition and 60% comprehended the line graph, compared to 83% for the visual analogy and 70% for the number line (p=0.05). The visual analogy performed significantly better than the text-only (p=0.02) and line graph (p=0.02). Low comprehension was associated with worse cognition (MoCA score 15.7 low vs. 22.3 high, p<0.001), lower education level (p=0.02), and fewer financial resources (p=0.03).

Conclusion

Non-graph visualizations (visual analogies) enhanced understanding of longitudinal PROs compared to text only, but line graphs did not. Our results support using visual analogies rather than text to display longitudinal PROs, but caution against relying on line graphs. Future work will explore comprehension in a larger sample.

Prioritization of Clinical Content Informatics Requests Using Multi-Criteria Decision Analysis (MCDA)

Randall W. Grout, MD, MS1,2,3, Dan Seitz, MD3, Justin Morea, DO, MS3
1Children’s Health Services Research, Indiana University, Indianapolis, Indiana; 2Regenstrief Institute, Inc., Indianapolis, Indiana; 3Eskenazi Health, Indianapolis, Indiana

Introduction
Clinical content informatics change requests can overwhelm information technology support and development teams, necessitating a prioritization to optimize their resource utilization. We developed a prioritization algorithm for order set and decision support requests using a consensus rank and multi-criteria decision analysis (MCDA) approach.

Methods
A governance committee (n=17) of informatics, information technology, and clinical stakeholders developed an initial set of prioritization criteria relevant to our organization through a brainstorming and group consensus meeting. They completed an anonymous online survey to rank the items on importance in determining the priority of a request (Figure 1). Consensus ranking was determined via a branch and bound algorithm for a rank correlation coefficient.1 Surrogate weights for criteria were set by the Simple Multi-attribute Rating Technique Extended to Ranking (SMARTER) process and rank order centroid (ROC) formula.2 Scores within each criterion were set as simply linear, equally distributed between 0 and 1. The final prioritization metric was the weighted sum of criterion scores and was implemented in an Excel-based tool for routine use over 1 year.

Results
There was moderate interrater concordance (Kendall’s W = 0.383) in the ordinal rank elicitation. Table 1 contains the final criteria, description, ranks, scores, and weights. Regulatory compliance was an overriding approval mechanism. The committee determined priority scores for 32 significant content and change requests since March 2018, ranging from 0.55 to 0.94 (mean 0.76, SD 0.11).

Table 1. Criteria, scores and weights of MCDA matrix.

<td>Rarely, Monthly, Weekly, Daily</td>
<td>.073</td>
</tr>
<tr>
<td>Quantity</td>
<td>How many patients a month would this be used for?</td>
<td>&lt;10, 10-100, &gt;100</td>
<td>.044</td>
</tr>
<tr>
<td>Finance</td>
<td>Does this request improve the organization’s financial interests</td>
<td>Yes, Maybe, No</td>
<td>.020</td>
</tr>
</tbody>
</table>

Conclusion
We developed and present a MCDA model for prioritization of informatics content and change requests. The weighted scores help allocate and align staff resources with organizational informatics priorities; evaluations are underway. Other institutions may use this decision model or follow the outlined steps to create a model based on local preferences.

Extracting the Effectiveness of Physical Activity Interventions from Abstracts

1William Gu, 1Yujing Ke, 1Arthur Zhao, 2Hyeoneui Kim
1Department of Computer Science, 2School of Nursing; Duke University, Durham, NC

Introduction
The health benefits of being physically active are now accepted as a fact. Numerous interventional studies have shown the direct impact of physical activities on disease onset and progress, as well as treatment outcomes.1 However, there has been limited efforts for systematically profiling various physical activity interventions in relation to their clinical benefits by population characteristics. Appropriate intensity and amount of physical activities can vary by patient’s characteristics.2 Linking precise physical activity measures obtained through a personal sensor device with the types, intensity, and amount of physical activities with proven clinical benefits for patients with different socio-demographic background is certainly a crucial milestone towards realizing the precision health initiatives. As an early step toward this goal, this pilot study tested the feasibility of extracting scientific evidence on the effectiveness of various physical activity interventions provided to the patients with Non-Alcoholic Fatty Liver Disease from published abstracts.

Methods
We retrieved 278 lifestyles (including physical activities) related interventional studies on NAFLD patients published in last 10 years from PubMed. Irrelevant studies (e.g., without lifestyle and/or physical activity interventions, study protocol without reported results) were filtered out by reviewing the abstracts. Remaining abstracts were analyzed using Clinical Language Annotation Modeling Processing toolkit (CLAMP).3 To explicitly define and guide the types of information to extract, we first developed a concept model (a.k.a. type system) by analyzing 40 abstracts. In this study, as shown in Figure 1, we focused on extracting relatively simple and straightforward information such as intervention details, effectiveness of the intervention, study sample, and clinical parameters measured to assess the intervention effectiveness. These categories of information and the links that connect these categories are called entities and relations respectively in CLAMP. We trained a text processing algorithm based on this concept model by manually annotating 108 abstracts using CLAMP. The algorithm performance was evaluated with 5-fold cross validation. We defined the type system in such a way that relations are uniquely identified once the two entity types that a relation connects are identified. The key task here was to identify the two entities to pair with a relation. We explored a distance-based approach to relation identification. We developed a rule-based algorithm outside CLAMP that first identified all entity pairs that can be linked with a relation then selected the ones with closest entities.

Results and Discussion
The F-scores of outcome measure, finding, and intervention; which are the core entities of the concept model; were below 0.5 (i.e., 0.44, 0.47, and 0.25 respectively), where precisions were slightly higher than recalls. This result clearly indicates the annotation algorithm needs further improvement. We noted that the inconsistencies in annotation, as small as annotating “ALT (alanine aminotransferase) value” as an outcome measure in one place but only “ALT” in other, hurt the performance significantly. We also encountered common challenges in text mining such as reference resolution (e.g., “it did not improve ALT”, “intervention group showed decrease in body weight”) and omission (e.g., “vitamin A and C”). After correcting the inconsistencies in annotation, the F-score was slightly improved to 0.54. The rule-based relation identification reached the F-score of 0.88. Our follow-up study will focus on improving the performance of the annotation algorithms by training with a larger corpus with better annotation quality. We will consider expanding the corpus to the full text papers especially the method sections to capture the key information with sufficient details. We will also continue refining the type system to incorporate more complex evidence such as comparative findings among interventions, samples, and/or clinical parameters.

Researchers’ Perspectives on Symptoms related to Cancer Pain: A Network Analysis of Literatures

Jia-Wen Guo, PhD1, Christina L. Radloff, BSN1, Susan L. Beck, PhD1, Gary W. Donaldson, PhD1, Wendy W. Chapman, PhD1, Katherine A. Sward, PhD1, Lewis J. Frey, PhD2

1University of Utah, Salt Lake City, Utah, USA; 2Medical University of South Carolina, Charleston, South Carolina, USA

Abstract
A network analysis was conducted to explore researchers’ perspectives on symptoms related to cancer pain. Eight symptoms clusters with 24 symptoms were identified. Network structure of symptoms related to cancer pain was similar to that reported by patients, indicating that the available research evidence is applicable to patients.

Introduction
Cancer pain is multifaceted; patients frequently report other symptoms at the same time as they report pain. In order to cope with cancer pain properly, researchers often include other symptoms besides pain in their research. Patients and researchers may have different perceptions of symptoms co-occurring with cancer pain. A network analysis study showed that patients reported cancer pain co-occurring with symptoms of abdominal, urinary, and neurological dysfunction. However, what symptoms researchers included in pain management studies is as yet unknown.

Purpose
To compare researchers’ perspectives on symptoms related to cancer pain with patients’ perspectives.

Methods
Using symptoms related to cancer pain from the literatures as the surrogate for researchers’ perspectives. PubMed, CINAHL, PsycINFO, and the Cochrane Reviews were searched for eligible articles. The search was limited to articles with full-text available in English published between 1990 and 2018. Content analysis was conducted by two nurses using NVivo11 to extract symptoms from the literature. Network analysis was performed in R environment using IsingFit, qgraph, and igraph packages. Data were coded as binary variables, with 0 for absence and 1 for presence of symptoms in the methods or results section of the literature.

Results
Twenty-four symptoms related to cancer pain were extracted and synthesized from content analysis of 144 literatures. To present a network of common symptoms related to cancer pain, 6 symptoms (i.e., body image, hair loss, edema, hot flashes, sexual dysfunction, and weight loss) were excluded in network analysis due to their were coded less than 10 times in the sample literature. The 18 symptoms included in network analysis were: (1) appetite issues, (2) breathing issues, (3) fatigue, (4) sleep issues, (5) anxiety, (6) depression, (7) nausea, (8) vomiting, (9) constipation, (10) diarrhea, (11) cognitive issues, (12) emotional/mental distress, (13) bleeding risk, (14) neurological issues, (15) orthopedic issues, (16) mucositis or dysphagia, (17) skin toxicity, and (18) urinary issues. Eight clusters were suggested (Figure).

Discussion
Clusters found in this study were similar to symptom clusters reported by patients. For example, cognitive and emotional/mental distress in this study were presented as a group of Psychological Symptom Cluster in the previous research. Hormonal Symptom Cluster reported by patients was not presented in this study due to those symptoms were not commonly included in available cancer pain research. Some symptoms were measured collectively in cancer pain research (e.g., emotional distress) while others were measured individually (e.g., anxiety, depression); researchers need to be aware of it when viewing the analysis outcomes.

Conclusion
The similar perspectives between researchers and patients regarding cancer pain symptom clusters indicated that the available research evidence is applicable to patients for cancer pain management.

Factors Influencing Telehealth Adoption in Critical Access Hospitals: Insights from a Demonstration

Saira N. Haque, PhD, MHSA, FAMIA, Alison Banger, MPH, Sydney DeStefano, BS, Regina Rutledge, PhD, Melissa Romaire, PhD
RTI International, Research Triangle Park, NC

Introduction

Telehealth can expand access to healthcare, particularly in rural areas. However, uptake is low due to several factors including reimbursement and credentialing, among others. The CMS Frontier Community Health Integration Project (FCHIP) Demonstration changes Medicare reimbursement for telehealth, ambulance, and swing bed services at 10 critical access hospitals (CAHs) in frontier communities in Montana, Nevada, and North Dakota over a 3-year period (2016-2019). Eight sites are participating in the telehealth component of the demonstration and receive higher reimbursements (101% of costs) for originating site telehealth visits to increase access to and integration of care. We present facilitators and barriers to telehealth implementation after the first year (2016-2017) of the FCHIP demonstration.

Methods

This work was conducted as part of a larger evaluation of the FCHIP demonstration program. Participating sites were eight CAHs in frontier communities in Montana, Nevada, and North Dakota. We reviewed sites’ applications and progress reports and conducted in-person interviews in May and June 2017 with clinical, administrative, and IT staff. Interview notes were NVivo coded and analyzed using a version of the Consolidated Framework for Implementation Research to identify themes.

Results

Factors influencing telehealth adoption and use include specialty availability, administrative requirements, and change management. The availability of telehealth in relevant specialties can give providers confidence to keep patients in the local community, keeping patients closer to their support networks and reducing travel burden and lost wages. Administrative requirements for credentialing of distant providers in relevant specialties (who provide telehealth services from a second location) also influenced specialty availability. Regional and state-wide shortages of certain specialists, especially in behavioral health, were also cited as challenges. Shortages coupled with low volumes can make it difficult for distant providers to prioritize telehealth visits with CAHs. Administrative challenges included credentialing, identifying workflow processes for telehealth visits and billing and reimbursement. The low volume of telehealth visits can make it difficult for CAH staff to gain familiarity with new systems and protocols. The impact of financial reimbursement was too nascent to assess quantitatively, but was not a primary facilitator because of the low volume of telehealth visits (average of 7 per year in the first year). Change management and implementation support were key factors for telehealth implementation and use. Implementation support for change management included additional funding, training resources, and educational and outreach programs.). CAHs reported that patients were generally receptive to the idea of telehealth visits, especially due to avoided travel time, but knowledge of telehealth services was often low.

Discussion

The findings point to main areas in which those to implement telehealth need support: specialty availability, administrative requirements, and change management. Prior to implementation, identifying specialties for which telehealth services are desired and ensuring that these specialists are available would influence telehealth use. Another area of support is for administrative requirements such as credentialing, reimbursement, and service delivery. The third area of focus relates to change management, including provider acceptance, staffing, workflow and roles and responsibilities.

A Scoping Review to Identify Biobank Classification and Permission to Share Metadata

Marcelline R. Harris PhD1, Frank J. Manion PhD1, Madhuri Sankaranarayananpillai PhD2, Hsingyi Song MS2, Cui Tao, PhD2
1University of Michigan, Ann Arbor MI, USA; 2University of Texas Health Science Center at Houston, Houston, TX, USA

Introduction. Biobank classification systems are motivated in part by expressed needs for standardization across biobanks, especially in an era of global collaboration and goals of web-based queries to identify shareable specimens and associated data. Sharing specimens and data requires knowledge about permissions to share that are documented within in consent forms, regulations, and policies. In this project, we explored a) whether the metadata suggested in biobank classification schemes included information about permissions to share, and b) whether the literature on consent to share addressed information about biobanks. This project is part of larger effort to refactor and extend an ontology of informed consent metadata (ICO).

Methods. We applied scoping review methods described by O'Brien (2016). Literature search strategy. A research informationist (MC) searched MEDLINE via PubMed using the Ovid platform, spanning Jan 1 2010 - Feb 23 2018, and using combinations of MeSH terms and keywords: (biobank OR biorepository OR biospecimen resource) AND informed consent; (biobank OR biorepository OR biospecimen resource) AND classification; (biobank OR biorepository OR biospecimen resource) AND informed consent AND classification. Using similar search terms, we later searched Google and Google scholar to identify biobank best practice guidelines, and any articles published after the informationist-aided search. Literature selection process. Abstracts and descriptions of documents were screened for inclusion criteria: English language, full text available, only human specimens and data, and for exclusion criteria: materials were not peer reviewed, did not represent consensus statements, or were not freely available. We then reviewed full text materials. Data collection process. A spreadsheet was used that allowed for online collaboration by the primary reviewers (MRH, FJM, HS) included column headings such as reference, purpose of document, classification categories, terms describing classes and their content, etc. Each document was reviewed by two reviewers, and resolved through discussions with the third reviewer. Synthesis process. A mind mapping tool (Mindjet MindManager 2018) was used to synthesize the data. The classification literature was synthesized first, then best practice guidelines, and finally the consent literature. In this way, biobank classification metadata framed the organizing structure of the mind map.

Results. Our final set of documents for review included 83 articles and 4 best practice guidelines. Not surprisingly, we identified considerable variation across biobank classification schemes. We did not identify meta-level information about permissions for sharing specimens and data in any of the literature on biobank classification schemes, however recommendations about consent information was frequently mentioned as a management and/or quality control process in the best practice documents. We identified two early efforts to ‘ontologize’ permissions for sharing specimens and data, however follow-up with a first author confirmed the dormant nature of that work. We identified several relevant standards-based initiatives, e.g., GA4GH and CDISC.

Discussion
This scoping review identified metadata relevant to both biobank classification and permissions for specimen and data sharing. Interestingly, just as the biobank classification literature did not identify permissions to share as an attribute of the classification scheme, the consent permissions literature did not point to biobank classification systems as context. We are currently in the process of integrating this information into our Informed Consent Ontology and in alignment with other BFO-based ontologies.

Detection of Opioid Overdose Cases from Text in Electronic Health Records using Machine Learning Methods

Rashed Hasan, PhD1, Mitra Ahadpour, MD1, Henry Francis, MD1, Alfred Sorbello, DO, MPH1
1US Food and Drug Administration, Silver Spring, MD, USA

Introduction:
With the increasing availability of electronic health records (EHR) resources, recent studies at the US Food and Drug Administration are focused on exploring artificial intelligence methods to extract information from text regarding the risk factors for opioid misuse and overdose. To augment opioid overdose case classification from free text clinical narratives, we investigated the application of various machine learning approaches to narratives in discharge summaries using data collected from the Medical Information Mart for Intensive Care III (MIMIC III) database1.

Methods:
We used SQL queries to extract 41,127 text discharge summaries from the MIMIC III database. We used k-nearest neighbors (kNN), decision tree, and artificial neural network (ANN) based machine learning methods to classify the clinical narratives as to their relevance to opioid overdose. For dataset preparation, we used the Natural Language Toolkit (NLTK) set of natural language processing programs to convert sentences to words, remove unnecessary punctuation, dates, and integers, and other related data cleaning tasks. For feature engineering, we used scikit-learn CountVectorizer to prepare the text by converting the patient’s narratives into a bag-of-words model. Each discharge summary was separated into tokens, and the number of times each token occurred in a discharge summary was counted. Then, we used ‘fit transform’ method that helps fit the model to the data then transform the data according to the fitted model. We compiled a set of 129 clinical narratives containing opioid-related terms that were manually assessed as probable or confirmed opioid poisoning cases based on the CDC case definition2 and divided it into a training set of 77 narratives and a test set of 52 narratives using a stratified k fold; a model was trained using k-1 of the folds as training data and the outcome model validated the test data set. Lastly, we applied the kNN minkowski Distance Metric to calculate the distance and find the neighbor overdose class from patient’s discharge summary. The classifier mapped the instances into one of two categories: ‘overdose’ and ‘non-overdose’. In order to measure the quality of the classification, we used a method called the “confusion matrix”.

Results:
As depicted in Table 1, kNN provided the best pattern recognition and classification results of the methods tested.

<table>
<thead>
<tr>
<th>Model</th>
<th>Precision</th>
<th>Recall</th>
<th>F1 score</th>
</tr>
</thead>
<tbody>
<tr>
<td>kNN</td>
<td>86.11</td>
<td>74.38</td>
<td>79.48</td>

<td>53.29</td>
<td>49.45</td>
<td>51.29</td>
</tr>
<tr>
<td>artificial neural network</td>
<td>49.21</td>
<td>45.33</td>
<td>47.19</td>
</tr>
</tbody>
</table>

Conclusions:
The kNN classifier provided the best performance in classifying the content of text narratives from EHRs into overdose and non-overdose categories. Challenges relate to the multidimensional nature of narrative content. We plan to explore the methodology on larger and more diversified EHR data sets to seek improved accuracy and generalizability.

Using Semantic Representations for Urine Drug Tests in the Veterans Health Administration

Corey J. Hayes, PharmD, PhD\textsuperscript{1,2}, Jonathan P. Bona, PhD\textsuperscript{3}, Mathias Brochhausen, PhD\textsuperscript{3}

\textsuperscript{1}Department of Psychiatry, University of Arkansas for Medical Sciences
\textsuperscript{2}VA HSR&D Center for Mental Healthcare and Outcomes Research, Central Arkansas Veterans Healthcare System
\textsuperscript{3}Department of Biomedical Informatics, University of Arkansas for Medical Sciences

Little Rock, Arkansas, United States

Introduction
In 2017 alone, opioid overdoses claimed over 47,600 lives.\textsuperscript{1} Early detection of patients misusing or abusing opioids is essential since receipt of rehabilitation and eventual recovery is unlikely.\textsuperscript{2} One component of early detection of opioid misuse and abuse is through the identification of aberrant urine drug tests (UDTs). Representations of UDTs and their results differ across each of the 170 VA medical centers limiting their usefulness outside of the clinical encounter. With over 125,000 UDTs conducted in one month for cannabis alone, the number of UDTs in VA data is extensive.\textsuperscript{3} This abstract discusses the creation of semantically rich ontological representations of the UDT domain which we are using to continue to provide the foundation for the Opioid Misuse Ontology,\textsuperscript{4} achieve data integration for research, and offer a potential means for early identification of opioid misusers and abusers.

Methods
We provide a basic semantic web framework for representing UDTs using Open Biomedical Ontologies (OBO) Foundry resources. In particular, the Ontology for Biomedical Investigations (OBI) contains classes for a number of similar measurement types, including ‘analyte assay’ (OBI\_0000443) and its subclass ‘measuring glucose concentration in blood serum assay’ (OBI\_0000418), defined as “An assay that determines the concentration of glucose molecules in a blood serum sample.” Its axiomatic definition uses web ontology language (OWL) classes and relations defined in OBI and in other OBO ontologies.

Results
One of the most common UDTs is a 7 panel test measuring the concentrations of marijuana, cocaine, opiates, phencyclidine, amphetamines, benzodiazepines, and barbiturates. To represent tests like the 7 panel UDT, we first define a new subclass of OBI: ‘analyte assay’ with the label ‘measuring drug concentration in urine assay’. To support discovery and use of this term, we also provide the alternative label ‘urine drug test’. We define this as “an analyte assay that determines the concentration of drug molecules in a urine sample.” The axiomatic definition specifies that this assay has as its input (evaluant) a urine specimen, produces measurement data about that specimen, and achieves some OBI ‘analyte measurement objective’. By using explicit machine-interpretable definitions with terms from existing ontologies to represent the involved entities (processes, tissues, molecules, etc), we support full semantic interoperability and automated reasoning about data that would be difficult to achieve with established terminological resources alone. To represent a specific type of drug test, for example the 7 panel UDT, we create a more detailed subclass that specifies the measurement objective in terms of the specific molecules, drugs, or drug classes of interest. When used to represent instance data (corresponding to individual urine drug tests that have occurred and their results), the measurement data item output by this assay is asserted to be about the molecules of interest in the urine specimen.

Conclusion
The variability in the number of ways UDTs and their results are displayed in VA points to the need for standardization of terminology across the VA nationwide. Semantically rich ontological representations of UDTs are a viable option to overcome this variability to improve research and help identify patients misusing and abusing controlled substances particularly by flagging those patients who have aberrant UDTs (e.g. patients positive for oxycodone on UDT but taking tramadol). Future work will include creation of an OWL artifact, publication for public comment, and trialing within a particular VA medical center to better identify patients with aberrant UDT results.

Predicting Mental Health Complexity Using EHR and Patient-reported Data

Shan He, PhD¹, Peter J. Haug, MD¹,², Kathryn G. Kuttler, PhD¹,
Brenda Reiss-Brennan, PhD, APRN¹

¹Intermountain Healthcare, Salt Lake City, UT; ²University of Utah, Salt Lake City, UT

Introduction
Integrating care for mental health illnesses into primary care has been proven to improve quality, decrease utilization and lower costs¹. Intermountain Healthcare has developed a team-based care process model for Mental Health Integration (MHI). A MHI packet (9-page questionnaire) is administered to patients who present with possible mental health concerns. The primary care provider (PCP) reviews the packet and assesses a patient’s mental health complexity as “mild,” “moderate,” or “high” based on an internally developed scoring guideline in PDF format. Appropriate mental health treatment plan and resources are subsequently allocated according to the level of complexity. The current process poses a significant challenge to PCPs. The packet generates a large amount of information (68 data items) to review. The scoring guideline is not currently integrated in the Electronic Health Record (EHR) workflow. Previous studies have attempted to computerize the scoring guideline using rule-based models. However, results show only a 53% agreement rate between the computer and physicians². The objective of our study is to apply machine learning (ML) algorithms to the patient-reported packet data combined with features extracted from the EHR to determine the mental health complexity. We have also applied ML techniques to identify patients who are likely to benefit from MHI evaluation with standard screening instruments such as the Patient Health Questionnaires (PHQ-2 & PHQ-9).

Methods
We extracted the MHI packet summary data between 2015 and 2018, crosslinked with 25 variables derived from EHR data (e.g. number of somatic complaints, number of mental health medications, Charlson Comorbidity Index, Area Deprivation Index, etc.) 6 months prior to the packet administration date (7,448 records). We first applied supervised classification modeling to the MHI dataset using physician’s assessment as the reference standard. We then developed a causal probabilistic model³ to identify key components that determine mental health complexity. We also extracted PHQ-9 results documented between 2015 and 2017, crosslinked with variables derived from EHR for the 6 months prior to the PHQ-9 screening date (37,169 records). A dichotomous outcome variable “PHQ9Indicated” was created based on the PHQ-9 total score to indicate whether a PHQ-9 screening is needed (“Negative” vs. “Positive”). Patients without any documented mental health screening (287,321 records) were assigned to “Negative” in addition to patients with a score less than 5. A combination of the WEKA machine learning platform, R, and the Netica Bayesian Network development tools were used to construct appropriate Bayesian Network classifiers and causal inference models.

Results
Predictive modeling using the patient-reported packet data combined with EHR data performed slightly better (66%, AUC=0.74) than results using either MHI data only (64%, AUC=0.72) or EHR data only (59%, AUC=0.64). Our analysis also showed that the individual scoring the patient complexity had the highest correlation with the complexity score, which indicates the limitation of using physician’s assessment as the reference standard for predictive modeling. The causal inference model identified 6 key components of mental health complexity: depression, anxiety/stress disorder, mood/affective disorder, attention-deficit/hyperactivity disorder, family style, and active physical diseases. The causal model was designed to correlate with the assigned complexity and succeeded 74% of the time. The model for predicting whether a patient needs the PHQ-9 screening demonstrated the highest accuracy (94%).

Conclusion
We have embarked on a process that will generate a complexity measure based on a variety of clinical, utilization and socioeconomic status data using both predictive and causal inference modeling. The results provide sufficient encouragement to conduct more extensive ML experiments. The goal is to identify an alternative complexity score that will better predict the therapeutic pathway matching a patient’s needs. We anticipate extending the MHI model and will provide it to all of Intermountain’s caregivers and patients through real-time clinical workflow integration.

Parallel Multiple Imputation for Large-Scale Association Studies in Complex Observational Data Settings

Zeling He, MS1,4, David Cheng, PhD2, Chuan Hong, PhD3, Paul Avillach MD, PhD1,3, Isaac Kohane, MD, PhD3, Tianxi Cai, ScD1,3

1Harvard T.H. Chan School of Public Health, Boston, MA; 2VA Boston Healthcare System, Boston, MA; 3Harvard Medical School, Boston, MA; 4Brigham and Women’s Hospital, Boston, MA

Introduction Real-world observational data such as electronic health records (EHRs) are increasingly capturing rich genetic and phenotypic data, making it a valuable resource for large-scale association studies and discovery research. One of the primary challenges in working with real-world data is addressing the extensive and complex missing data that commonly occur due to nonresponse and administrative or data entry error. Imputing the missing data via multiple imputation by chained equations (MICE) is a popular approach to addressing the issue. However, MICE can be highly unstable or computationally slow when applied to a large set of variables (e.g. 1000’s of variables), as required for example in phenome-wide association studies. We propose an alternative procedure that accommodates high-dimensional variables by first screening for predictive variables to use in the imputations and adopting an alternative parallel imputation scheme.

Methods For each variable $X_j$, $j = 1, \ldots, p$, we initially identify variables that are predictive of $X_j$ by testing for significant pairwise association with $X_j$ with correction for multiple testing. We subsequently obtain initial imputations by either a simple mean imputation or a more sophisticated procedure using one-bit matrix completion for binary variables and imputing variables of other types based on the imputed binary variables via regularized regression. Let $\hat{X}_j^{(k-1)}$ be the variables found to be predictive of $X_j$ with missing values imputed by imputations from the $k-1$-th iteration of imputations. The imputations in the $k$-th iteration is obtained by predicted values from a regularized regression of $X_j$ on $\hat{X}_j^{(k-1)}$, which does not depend on other imputations from the $k$-th iteration and can be done in parallel for variables $j = 1, \ldots, p$. This is repeated for $k = 1, \ldots, K$ total iterations until convergence. This entire procedure can be repeated to obtain multiple datasets as in multiple imputation.

Results We evaluated the algorithm in a dataset on autistic children from the Simon’s Simplex Collection (SSC) based on a survey of $n = 2,509$ children that includes $p = 5,459$ features describing demographics, clinical histories, and cognitive and behavioral profiles. The median rate of missingness among all variables was 48.5%. We applied the proposed procedure and calculated out-of-sample AUC and MSE (relative to mean imputation) by withholding 10% of observations for which data was observed, for each feature. The results in Figure 1 show that the proposed parallel procedure achieves comparable performance to that of traditional sequential imputation uniformly in iterations of imputation (cycle over all variables for sequential imputation, 0th round/cycle is initial imputation). Executing the algorithm on 10 parallel threads, the time required to complete 3 rounds of parallel imputations and 3 cycles of sequential imputations were 585 and 5,212 minutes, respectively.

Conclusion Imputations can be computationally difficult to compute in large datasets. We propose an alternative parallel imputation procedure that offers substantial improvements in computation speed without compromising on imputation quality, which can facilitate timely large-scale analyses. We plan to use the approach for large-scale association analyses in EHR data.

Application Programming Interfaces in Health Care:
Findings from a Current-State Assessment

Krysta Heaney-Huls, MPH¹, Prashila Dullabh, MD¹, Lauren Hovey, MA¹,
Nithya Rajendran, MHI¹, Adam Wright, PhD², and Dean F. Sittig, PhD³
¹NORC at the University of Chicago, Bethesda, MD; ²Departments of Medicine and
Biomedical Informatics, Brigham and Women's Hospital and Harvard Medical School,
Boston, MA; ³School of Biomedical Informatics, University of Texas Health Science Center
at Houston, TX

Background
Interest in application programming interfaces (APIs) as a means of increasing the ease of health data access for—and exchange among—patients, health care organizations (HCOs), and payers has been growing as federal and non-federal stakeholders look for technical solutions to interoperability challenges.

Research Objectives
We explored three thematic areas to elucidate the current state of API design, implementation, and use: 1) API use cases and standards; 2) challenges and facilitators for read and write capabilities; and 3) outlook for future development of write capabilities.

Methods
Our current-state assessment employed four methods: 1) a literature review of PubMed and the grey literature; 2) expert interviews with 13 API stakeholders (HCOs n=5; electronic health record (EHR) vendors n=2; app developers and third-party data sharing platform providers n=6); 3) a review of three EHR app galleries and the SMART® App Gallery; and 4) a 13 person multi-disciplinary technical expert panel (TEP) to discuss near-term challenges and opportunities to advance API development and use. We used an eight-dimension socio-technical model¹ to organize our findings. The model accounts for technical (e.g., standards) and non-technical (e.g., clinical workflows) aspects involved in the design, development, implementation, use, and evaluation of safe and effective health IT.

Findings
While the use of APIs in health care delivery and research is increasing at an astonishing pace, it is still in the pilot stages, with limited representation in the literature. The use of standards-based APIs to support exchange is an area in which there is much interest, discussion, and development. Experts indicated that where consensus technical standards are used, they are largely Fast Healthcare Interoperability Resources (FHIR®), which is a positive indication of the market’s support for interoperable solutions. A multitude of app marketplaces are becoming available. These marketplaces support a range of use cases, the majority (69% of apps) of which target providers, with far fewer (14%) supporting patient access to data. Results across methods indicate the current focus is on read APIs with very limited use of write APIs. Informants cited reluctance on the part of HCOs and EHR vendors to allow external data to be fully integrated (written) into an EHR. Finally, informants and TEP members agreed that there are inherent costs associated with API development and use that justify some level of fees. We identified five key issues with implications for the continued advancement of API use: 1) a robust normative FHIR® standard; 2) expansion of the Common Clinical Data Set to other clinical data including patient-generated health data and administrative data; 3) enhanced support for write implementation; 4) data provenance rules and guidelines; and 5) costs that are not prohibitive.

Conclusion
This assessment provides a significant window into the current API landscape—including the focus on provider-centric use cases; the rationale for the emphasis on read APIs; and the complexities related to standards. Thus, while APIs are being touted as a solution to the interoperability challenges, they remain an emerging technology that is likely only one piece of a multi-pronged approach to health information exchange, integration, and use.

Using Unsupervised Machine Learning Method to Define a New Normal for Body Temperature

Frederik Heath, Myroslava Protsiv, Sarah F. Poole, PhD Julie Parsonnet, MD
Stanford University School of Medicine

Background: Body temperature measurement is a low-cost and non-invasive diagnostic tool that is widely used in clinical practice to diagnose acute pathological states ranging from fever to hypothyroidism. The mean normal body temperature of 98.6 F was established in 1851. The mean body temperature in contemporary, high economy populations, however, is lower than this established standard. We used an unsupervised machine learning algorithm to define normal body temperature in a US population using age, sex, BMI and time of day as parameters.

Methods: The LIMIT Algorithm uses the Central Limit Theorem to mine patient data and establish reference intervals for laboratory tests. We applied LIMIT to outpatient visits (N=615,470) in the Stanford Translational Research Integrated Database Environment (STRIDE). Other variables included patients’ ages, diagnoses, medications, and time of visit. The Hampel method was used to determine if body temperatures (measured orally) were “extreme” (either high or low). Fisher’s exact test was then used to test associations between these extreme values and ICD10 codes or medications. All patients with ICD10 codes or medications that were overrepresented in the extreme temperature tails were excluded from further analysis. In total, 198,924 observations (32.3%) were removed. Diagnoses and medications excluded for high temperatures included acute respiratory infections, acute sinusitis, pharyngitis, bronchitis, pneumonia, viral infections and influenza, as well antibiotics (macrolides, penicillins, quinolones), antivirals and antitussives. Individuals with Type 2 Diabetes mellitus or taking over-the-counter decongestants and antihistimines were excluded for lower temperature values. The remaining population was used to define the normal range of temperature values.

Results: Normal temperature measured at noon assuming age of 30 and BMI of 25 was 97.96 F (95% CI: 97.95- 97.97) for men and 98.14 F (95% CI: 98.13- 98.15) for women. Temperature varied by time of day, age, and BMI (Figure 1).

Conclusion: LIMIT confirmed that normal body temperature is consistently and significantly lower than the canonical value of 98.6°F. Our results are alligned with past findings of the effect of age, sex, BMI and time on temperature, validating LIMIT’s unsupervised a posteriori approach. Accounting for such heterogeneities by using patient specific “precision measures” would allow for better clinical interpretation of body temperature in future.

Using the RE-AIM Framework to Assess the Potential to Use Mobile Diabetes Detective (MoDD) in Federally Qualified Health Canters

Elizabeth M. Heitkemper, PhD, RN1, Arlene Smaldone, PhD, CDE, RN2,3, Suzanne Bakken, PhD FACMI1,2, Andrea Cassells, MPH4, Jonathan N. Tobin, MD, PhD4, Lena Mamykina, PhD1

1Dept. of Biomedical Informatics; 2School of Nursing; 3College of Dental Medicine, Columbia University, New York, NY; 4Clinical Directors Network, Inc., New York, NY

Introduction: Underserved groups (low income, racial/ethnic minorities) with diabetes experience health disparities exemplified by an increased diabetes prevalence, poorer glycemic control, and greater severity of diabetes-related complications [1]. To address growing health disparities, translating innovations developed in research settings into clinical practice has become a national priority [2]. This study used the RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance) framework for clinical informatics interventions to identify the factors necessary for adoption of a novel web-based diabetes technology, Mobile Diabetes Detective (MoDD), in four NYC Federally Qualified Health Centers (FQHCs) that had participated in a randomized controlled trial (RCT) testing its efficacy.

Methods: This mixed methods study was comprised of homogeneous focus groups and individual interviews that included patients randomized to the MoDD clinical trial, health center staff at intervention sites, and study research coordinators. Qualitative data were analyzed using directed content analysis. Quantitative data from the FQHCs’ electronic medical records (EHR) and RCT intervention subject usage of MoDD were analyzed using descriptive statistics.

Results: From November 2015 to May 2017, 15 interviews and 8 focus groups were conducted with three stakeholder groups (patients [N=21], FQHC staff [N=28], research coordinators [N=3]). The majority of patients were female (58%) and African American (52%). Staff were predominately female (79%) and physician (57%). The MoDD usage data (Figure 1) showed that patients engaged with MoDD’s basic features, such as logging into the website and recording blood glucose values; goal setting, a more advanced feature was used less frequently with 41% of patients never setting one. Fifteen qualitative themes were identified corresponding to the dimensions of Efficacy (3 themes), Implementation (7 themes), and Maintenance (5 themes). The themes illustrated how much patients liked MoDD, but how hesitant they were to let providers see their data. FQHC staff stated clear interest in using MoDD, but did not believe that they had the space and staff required for patient training and continued use.

Conclusion: While all stakeholder groups were positive about MoDD, identified patient and health center barriers may limit broad implementation of technologies such as MoDD into practice, regardless of potential efficacy. This study illustrates the current complexity of implementing a web-based technology intervention in underserved groups. For technologies such as MoDD to augment diabetes self-management services in underserved adults, current barriers to implementation must be identified and overcome.

Development of an integrated system and central repository for clinical and education outcomes in Latin America

Juan Henao MD\textsuperscript{1,2}, Yuri Quintana PhD\textsuperscript{1,2}, Charles Safran MD\textsuperscript{1,2}

\textsuperscript{1}Division of Clinical Informatics, Beth Israel Deaconess Medical Center, Boston, MA
\textsuperscript{2}Harvard Medical School, Boston, MA

Introduction

Healthcare providers in resource limited settings have difficulties in improving care delivery, in part because of the challenges in systematically collecting outcomes and operational data to improve care interventions\textsuperscript{1,2}. Gains in coverage do not always result in safe and high-quality care due to limitations of training and process improvements.

Methods

Fundación Valle del Lili (FVL) is a 500-bed teaching hospital in Cali, Colombia, that provides training and consultation services to regional clinics with limited resources. To improve care delivery in the region, FVL is developing a community of practice site for regional healthcare providers in Latin America to deliver training, standardize the collection of outcomes, and monitor process improvements. Care delivery processes are being codeveloped and standardized with regional clinics. The goal is to applying learning systems analysis to plan the training, data collection and collect process-oriented data to identify areas for improvement at each center.

Results

A community of practice is being created to provide online access to evidence-based education and clinical best practices. The Alicanto™ is a social learning platform (http://www.alicantocloud.com) is being used that supports online learning communities, providing training, care communication, the collection of clinical, learning and process outcomes, and their review applying learning systems analysis. An online asynchronous discussion forum will be used for communities of practice to share their experiences and discuss challenges in care delivery and data collection with colleagues, and training on tools to collect and analyze that data for quality and process improvement. A group of physicians has been meeting online for the last year to define the educational needs and data collection strategies.

Discussion

Research has the opportunity to link medical education to practice outcomes; however, few educational programs get any substantive feedback on the quality of care delivered\textsuperscript{3}. Fundación Valle del Lili as a teaching hospital has the potential to develop an education data warehouse that combines data of medical school, residency program graduates and their subsequent practice; looking at the differences in value-based care and overall costs through what would constitute the first public database for such comparative analysis in Latin America. This project will also greatly inform new curriculum design efforts of clinical education and training in Latin America. With our comprehensive informatics monitoring framework, we illustrate an innovative continuously learning system that aligns medical education outcomes with clinical process outcomes and builds capacity at the institutional level to generate actionable and comparable knowledge that facilitates analysis, research, and evidence-based decision making in health care, while being scalable to country level in Latin America.

Conclusion

Education, process improvement and quality indicators are interrelated and need a coordinated approach to data collection, analytics, training, and follow-up on process improvements.

Data Subset Identification Using CUR Index Selection Schemes

Emily Hendryx, Ph.D.\textsuperscript{1}, Nabil Chaabane, Ph.D.\textsuperscript{2}, Béatrice Rivière, Ph.D.\textsuperscript{2}, Craig Rusin, Ph.D.\textsuperscript{3}

\textsuperscript{1}University of Central Oklahoma, Edmond, Oklahoma; \textsuperscript{2}Rice University, Houston, Texas; \textsuperscript{3}Baylor College of Medicine, Houston, Texas

Introduction

The ability to identify representative subsets of data can be valuable in a number of clinical applications. For example, identified subsets can be used in determining the number of classes present within a data set during a retrospective study, or they can provide a clinician with a summary of the types of physiological waveforms seen within a given time frame. The viability of subset selection using the DEIM-CUR matrix factorization for the primary purpose of class identification and subsequent classification has been demonstrated\textsuperscript{1}. While the DEIM (discrete empirical interpolation method) index selection scheme performs comparably to other methods in analyzing electrocardiogram (ECG) data, the CUR factorization can also be formed using a variety of other methods.

Comparison of Subset Selection Methods

This work compares four different CUR index selection schemes–DEIM, Q-DEIM, leverage scores, and volume maximization–against the more commonly used k-medoids, agglomerative, and Max-Min clustering algorithms. In doing so, we apply all of these unsupervised learning methods to three different freely available data sets: the MIT-BIH Arrhythmia Database of ECG waveforms\textsuperscript{2}, the Grammatical Facial Expressions (GFE) Data Set\textsuperscript{3}, and the MNIST Database of Handwritten Digits\textsuperscript{4}. These labeled data sets present data from a variety of settings, providing examples of physiological waveforms (MIT-BIH), coordinate data extracted from facial images (GFE), and images of handwriting (MNIST); while two of these sets are not directly from a clinical setting, they provide insight regarding expected algorithm performance on similar, yet more clinically-focused, data sets. Each data set is split into training and testing sets for parameter selection for each method of interest. In comparing schemes, we focus on the detection of at least one representative from each known class and the amount of data reduction achieved through subset selection.

Conclusion

While there is not one algorithm that consistently out-performs the others, Max-Min clustering with the dynamic time warping (DTW) similarity measure, Q-DEIM, and DEIM each obtain at least 90\% class detection in all experiments. Although Max-Min clustering achieves the highest class detection rates among these three methods, it does so with the lowest data reduction rate over all experiments at 86.86\% during the GFE analysis and was not allowed to finish the MNIST subset selection task due to excessive runtime. Where the computational complexity of Q-DEIM and DEIM is $O(mnk)$ to select $k$ representatives from $m$ observations of length $n$, the improved class detection results seen in Max-Min clustering with DTW are met with an $O(mn^2k)$ computational cost. With these and other results presented in our work, our experiments show that the CUR index selection schemes perform comparably, if not better than, the evaluated clustering schemes in terms of class detection and data reduction, and often at a reduced computational cost. As the presented methods are extendable to a vast array of biomedical data types, this work suggests that CUR index selection schemes should not be overlooked in data summarization and class identification tasks.

Automated Extraction of Computable Clinical Decision Support Rules from an Electronic Health Record (EHR) System

Branden C. Hickey, M.A.S.¹, Marc L. Sainvil M.S.¹, Adam M. Bartscher¹, Robert R. Freimuth, PhD¹, Jane L. Shellum, M.H.A, M.A.S.¹, Davide Sottara, PhD¹
¹Mayo Clinic, Rochester, MN, U.S.A.

Introduction

In 2018, Mayo Clinic replaced many of its clinical applications with a single electronic health record (EHR) system. In the process, several clinical decision support (CDS) rules were built in the new EHR. As manifestations of clinical knowledge, each rule must be validated and endorsed by knowledge oversight groups for patient safety and regulatory purposes. Transparency of rule logic is required to assess correctness, quality, impact and overall outcomes. Unfortunately, the new EHR system does not support standards-based representations suitable for verification and analytics, nor presentation forms accessible to the subject matter experts. We address this gap by means of an automated pipeline that reverse engineers the native implementation of the CDS rules and stores the rule logic and content as discrete data elements. This approach allows the rule to be loaded into a formal content management system and facilitates presentation in human-readable, rather than technical, renderings to subject matter experts (SMEs) and knowledge engineers.

Methods

We analyzed how CDS logic is exposed within the EHR as a large relational model of “configuration parameters”. Snapshots of this database are replicated and cached. We identified a clinically relevant, high impact set consisting of 1400 CDS rules. We implemented a processing pipeline using a C#.NET 4.7 framework: for each rule, information is extracted from the database, mapped to an object model, translated into a HL7 KNART-conformant XML document with CQL/ELM expressions and validated. Using XSLT, the KNARTs are rendered into HTML documents whose style has been informed by a user-centric design. In the process, an ANTLR-based formal grammar is used to analyze the complex logic expressions used in the rules. Coded concepts and value sets are also linked and mapped. The extraction process generates metadata, supporting identification and versioning, so that both the KNART and HTML renditions can be published into a Knowledge Management System (KMS). The stages of the pipeline are exposed through ReSTful APIs, and can be invoked on demand. Rendering of CDS rules will be illustrated in the poster as examples.

Figure 1. Transformation / Publication pipeline

Conclusions and Future Works

At any point in time, the pipeline is able to extract, standardize and publish all the CDS rules and their related value sets. The cache can be updated on demand, but the process takes, on average, less than one second per rule. The combination of the machine (KNART) and human (HTML) readable representations will enable several scenarios. Subject Matter Experts can verify that the actual implementation matches their requirements, and can easily propose updates. Providers impacted by the CDS rules have been able to understand why and how certain recommendations have been delivered. Conversely, reporting and analytics tools can be built to detect changes in the EHR implementation, and identify commonalities. This pipeline adds value to the enterprise by allowing subject matter experts (SMEs) to review CDS rule logic easily which can ultimately impact efficiency and safety.
Using the Lean Startup Method to Efficiently Create an Electronic Consent
Blair S. Hirst, MS, Felix Guerrero, Brendan Mooney, Yuri Turin, Gregory Jordan, Mary Mitchell, John McClean, Daniel Stein, MD, PhD
Memorial Sloan Kettering Cancer Center, New York, NY

Introduction
Procedural consents, one of the most frequently used type of consent forms at Memorial Sloan Kettering (MSK), are routinely conducted on paper. The paper consent process is a manual and time-consuming process and can lead to improperly filed documents, delayed workflows, and ultimately a suboptimal care experience for patients. Conversion from a paper-based to an electronic consenting process presents an opportunity to address issues with the current practice and ultimately to improve clinical care¹. However, converting workflow processes that are longstanding and central to medical center function can be challenging. We are using the Lean Startup method² as an approach to demonstrate how agile practices and data driven validation can produce innovative solutions within our complex, multidisciplinary cancer care setting.

Methods
Eric Ries is the architect behind the Lean Startup method, a Build – Measure – Learn cycle, which advocates for a cyclic and iterative practice in continuous innovation development and we used this method to foster an efficient process and an effective solution for our electronic consent project.

The first step is to generate a hypothesis to solve for a problem through the creation of a Minimal Viable Product (MVP). The hypothesis generated was that an electronic procedural consent will improve clinic and OR space and time utilization, increase patient access and engagement in the consenting process, decrease associated risks with paper consenting, and reduce paper consumption. Our baseline data points included mapping existing consent workflows, identifying usage of consent forms in the Electronic Health Record (EHR), number of consent visits scheduled, and identified usage of consent visits by services over a period of one year. The impact the consenting process has on clinic space and time, as well as a workflow map of the procedural consent clinic visit process was created and will be shown on the poster.

With this information, we began looking for electronic solutions that would address the project needs and be a viable candidate for the Build phase.

Results
Baseline information revealed 26 types of consents used at MSK between August 2017 and August 2018. Of the 26 consent types, only five types accounted for 93.8% of the consenting volume, with the procedural consent accounting for 34.1% of the total consent volume. Consent visits accounted for 2.1% of total clinic visits and a total of five services accounted for 62% of the total procedural consent visits. Over 17000 consent visits where scheduled across 20 services. The average in-room time for consent visits were 69.5 minutes.

The output of our Learn cycle explored and yielded several possibilities, including using existing enterprise systems such as our home-grown patient portal platform or buying off-the-shelf consenting products. In our current iteration, our approach involves integrating a vendor-supplied e-signature platform with our EHR system, using vendor APIs and in-house custom software development. The MVP is currently still being developed and will be used to test our original hypothesis in the clinical setting.

Conclusion
Using the Lean Startup approach, our team successfully generated a working MVP within six months of starting development. The cyclic nature of Lean Startup has allowed for quick technological pivots in the Build phase to ultimately find best solution based on project goals, legal and eSignature requirements. Ultimately, we aim to go beyond consenting in the clinical setting to a mobile and at-home setting based on clinician and patient preferences, possibly integrating with our patient portal.

Department of \textsuperscript{1}Information Sciences/\textsuperscript{4}Nursing, Toho University, Tokyo, Japan; \textsuperscript{2}Research and Development Center for Precision Medicine/\textsuperscript{3}Headquarters for International Industry-University Collaboration, University of Tsukuba, Tsukuba, Japan; \textsuperscript{5}Department of Health Care Services Management, Nihon University, Tokyo, Japan; \textsuperscript{6}Department of Nursing, Toyama Prefectural University, Toyama, Japan

Introduction

Concept analysis plays an important role in the development of knowledge in nursing science. Rodger’s evolutionary method is one of the well-known methods. Roughly, the method consists of data (i.e., literature) gathering, relevant data selection, and in-depth reading of the data to identify the major theme of the concept and the differences between related concepts. We experienced that these steps are not sequential but reciprocal, because we can refine the original keywords as we repeat searches; theses new keywords would lie in the sentences that are relevant to the working intention (definition) and extension (applicability) of the concept.

Therefore, finding out the relevant sentences to given description of a concept would be a major cognitive activity of concept analysis. However, this would be labor intensive without any computational support, and this computational support was the problem we addressed.

More specifically, the task to be supported was to find sentences relevant to the concept “diagnostic decision making error”. We defined the requirement for sentences to be relevant to “diagnostic decision making error” as follows: a) commentary on the possibility of misunderstanding in the diagnosis of the disease, b) attention to the fact that the disease may exhibit general symptoms or symptoms that seemingly irrelevant to the diseased organs (e.g., skin symptoms due to liver), and c) assessment of a case suggesting the possibility that a misdiagnosis was made, correct diagnosis was delayed, or the disease was not originally anticipated. We manually identified relevant sentences previously. We use recurrent neural network (RNN) to model the word contexts and the inside words of sentences as well as the sentence relevance, and use the model to predict relevant sentences.

Methods and Preliminary results

We made a dataset consisting of 305 abstracts that had been retrieved through PubMed with the keywords “decision making” and “diagnostic error”. We judged that 120 abstracts were relevant to “diagnostic decision making error”, from which we identified one or two consecutive relevant sentences that support this judge. To predict the relevance of a sentence, we modeled the documents following the method of Jagannatha et al (2016).\textsuperscript{1} Word embedding, or vector representation of the words, were done using general-purpose, pre-trained word2vec model.

We divide the dataset into 90% training set and 10% test set and repeat the training and test 100 times. We compare the prediction with our judgment. We also compare frequent words in the predicted sentences with “important words” that we arbitrarily chose from frequent words in the relevant abstracts.

Conclusion

We propose that concept analysis is a reciprocal process rather than sequential, through which keywords taken from relevant documents are enriched. This led us to test recurrent neural network classifier to predict relevance of a sentence to a given concept.

**SemMedDB-neo4j: A Graph Database of Biomedical Semantic Relations**

Dimitar Hristovski, PhD\(^1\), Andrej Kastrin, PhD\(^1\), Halil Kilicoglu, PhD\(^2\)

\(^1\)Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia;
\(^2\)National Library of Medicine, Bethesda, MD, USA

Semantic relations from the biomedical literature are increasingly used in knowledge management applications such as literature-based discovery (LBD) as well as in clinical decision-making support. SemMedDB\(^1\) is a repository of semantic predications (subject–predicate–object triples) extracted from the titles and abstracts of all PubMed citations by SemRep\(^2\), a rule-based semantic interpreter. SemMedDB has been so far distributed only as a MySQL relational database. However, for many biomedical applications, the domain knowledge is more naturally represented as a graph of concepts and semantic relationships between them. In this abstract, we describe our recent conversion of SemMedDB to a neo4j graph database (SemMedDB-neo4j).

We generated SemMedDB-neo4j by first exporting the SemMedDB data from the MySQL version (release 31) to several delimited text files. Then, using custom scripts, we calculated additional aggregated data and formatted the data. Finally, we loaded the data into a neo4j graph database.

Some of the data elements provided in the MySQL distribution of SemMedDB are the same as those provided in the neo4j distribution. However, we make some additional data elements available only in the neo4j distribution. These are mostly related to aggregated data and to publication history data. The additional data is especially suitable for discovery and evaluation in LBD.

In general, a Neo4j graph database contains nodes and relations between the nodes. Both the nodes and relations can have properties/attributes. The node types (labels) and relations used in the SemMedDB graph database are as follows: Citation (corresponds to a PubMed bibliographic record), Sentence (corresponds to a sentence), Instance (corresponds to a semantic predication extracted from a particular sentence), Concept (corresponds to UMLS concepts that represent the arguments of semantic predications). The nodes with label “Concept” also have at least one additional label for the corresponding abbreviated UMLS semantic type (e.g. “phsu”, or “dsyn”).

The nodes are linked with the following relation types: IS_IN (a relation between a sentence and a citation), Extracted_From (a relation between a predication instance and a sentence), Inst_Subject (a relation between an instance and the concept which is the subject of that Instance), Inst_Object (a relation between an instance and the concept which is the object of that Instance). Additionally, semantic predicates (e.g., INHIBITS, TREATS) linking arguments are represented as aggregated relations between Concept nodes. For example, there is only one INHIBITS relation between a particular Concept1 and Concept2, but there can be many instances of that relation (Instance nodes).

SemMedDB-neo4j contains ~67M instances of semantic predications aggregated into more than 18M semantic relations. The instances were extracted from ~18M sentences from more than 28M PubMed citations. The graph database is made available at [http://lbd.mf.uni-lj.si/semmeddb-neo4j](http://lbd.mf.uni-lj.si/semmeddb-neo4j). Neo4j provides a powerful query language, Cypher, specialized for graph data, and many well-known graph algorithms, such as shortest paths and community detection.

**Conclusion**

We believe SemMedDB-neo4j will facilitate literature-based discovery methods by simplifying and improving retrieval and aggregation of semantic predications at a large scale.

Multisource Feedback Driven Intervention Improves Physician Leadership and Teamwork

Jinwei Hu, MD¹,², Robert Lee, MD¹, Sarah Mullin, MS¹, Steven Schwitzberg, MS, MD¹,², Larry Harmon, PhD², Paul Gregory, PhD³, Peter L Elkin, MD¹
¹Department of Biomedical Informatics, JSMBS, University at Buffalo, Buffalo, NY; ²Department of Surgery, JSMBS, University at Buffalo, Buffalo, NY; ³Department of Psychiatry & Behavioral Sciences, University of Miami, Miami, FL

Introduction

Multisource feedback (MSF) provides a method of quantitatively assessing and potentially improving physician teamwork and leadership focused behaviors. First, we sought to determine whether tiered educational interventions can improve measurements of multisource feedback for physician across specialties. Second, whether MSF baseline measurements and improvements after intervention vary by specialty designation.

Study Design

We present survey data obtained over 15 years (2002-2017) using the proprietary PULSE 360 multisource feedback system to measure Leadership Teamwork Index (LTI) scores before and after a tiered educational intervention delivered based on provider scores. PULSE 360 assessments were performed on 1190 physicians from academic (34%) and community hospital (66%) settings in the United States and Canada. 25% of physicians were in primary care, 47% surgical subspecialties and 28% medical subspecialties.

Three tiers of intervention were used depending on baseline LTI score: (1) providing a web based feedback report, (2) debriefing via virtual coaching, and (3) individualized, web based curriculum and directed, continued coaching. Physicians then underwent a post-intervention PULSE 360 assessment 12-24 months after intervention. Statistical analysis was performed using R. We used quasi-likelihood generalized estimating equation models to account for the correlation between subjects across evaluations and assess the LTI score.

Results

Demographics of the 1190 physicians surveyed included 75% male and 24% female respondents. At baseline, there were an average of 2.78 ratings per provider. Surgeons started with the lowest baseline LTI score, and experienced a mean increase of 6.06 LTI points after intervention (p<0.001), whereas specialists had a mean increase of 3.13 LTI points compared to surgeons (p=0.0497).

Conclusions

Baseline multisource feedback scores vary by specialty and improve based on feedback and coaching. In particular, physicians who start with low scores have the greatest potential for improvement.
Cancer Patients’ Emotional Health Discovering: Influences of Health Literacy, Fatalism and Social Support

Pengwei Hu PhD†, Zhaomeng Niu, PhD‡, Shaochun Li
1IBM Research, Beijing, China; 2Rutgers Cancer Institute of New Jersey, New Jersey

Introduction

Cancer patients’ emotional health, which may contribute to their treatment and recovery, is critical to their overall wellbeing. However, cancer patients tend to feel diverse emotional issues such as anxiety, depression, and distress1. Almost 40% of cancer survivors reported having significant distress1. Emotional support from family and friends has been found to increase emotional health of cancer patients2. Cancer fatalism, the belief that death is inevitable when cancer is present, sometimes contributes to negative health outcomes3 and is negatively associated with health knowledge and education4. The current study aimed to investigate the association between health literacy, cancer fatalism, social support, and emotional health of cancer survivors.

Method

Survey data were drawn from National Cancer Institute's Health Information National Trends Survey 5 Cycle 1 (N = 479). HINTS is a nationally-representative survey that aims to collect data on the American public’s knowledge of, attitudes toward, and use of health-related information; and the questionnaires were distributed by mail. Structural equation model (SEM) was used to test the relationship between health literacy, cancer fatalism, social support, and emotional health of cancer survivors and multiple model fit indices were used to evaluate the model fit. Fatalism, social support, and emotional health were used as latent variables and health literacy was used as a manifest variable. HINTS are approved public datasets and are considered as exempt from institutional review board.

Results

Cancer fatalism mediated the effects of health literacy on cancer patients’ emotional health (Figure 1). Health literacy was negatively associated with cancer fatalism (β = -.083, p < .001) while cancer fatalism was negatively associated with emotional health of cancer survivors (β = -.583, p < .01). Social support was positively associated with cancer patients’ emotional health (β = .926, p < .05). The SEM model of the current study had a good fit: χ²(1) = 2.06, p < .001; RMSEA = 0.046; CFI = 0.953.

Conclusion

Health literacy level is negatively associated with cancer fatalism of cancer patients while lower cancer fatalism is associated with increased cancer patients’ emotional health. Therefore, health care providers and family or friend of the cancer survivors need to improve cancer patients’ health literacy and increase social support.

Harnessing Health Information Technology in Family Violence in the United States – Systematic review

Vivian C. Hui\textsuperscript{a}, Klem, M. L.\textsuperscript{a}, Rose E. Constantino\textsuperscript{a}, Young Ji Lee\textsuperscript{a,b},
\textsuperscript{a} Department of Health and Community Systems, School of Nursing, University of Pittsburgh, USA \\
\textsuperscript{b} Department of Biomedical Informatics, School of Medicine, University of Pittsburgh, USA

Introduction
Family violence, also dubbed as domestic violence (DV), is a global health vicious cycle that menacing the health and well-being of people around the world. It refers to a pattern of abusive behaviour in any relationship that is used by one partner to gain or maintain control over another intimate partner. Every 9 seconds in the US a woman is assaulted or beaten.\textsuperscript{1} The costs of domestic violence amount to more than $37 billion a year in law enforcement involvement, legal work, medical and mental health treatment, and lost productivity at companies.\textsuperscript{2} Recently, scholarly researchers showed that Health Information Technology (HIT) is an effective way to analyse trends across different populations, assist in developing more effective screening tools and improve the quality of life for victims of family violence.\textsuperscript{3}

Method
1332 Articles are extracted from four databases. 25 research articles met the inclusion criteria. Data abstracted and entered into a table to facilitate the evaluation process in an unbiased, reliable and valid way. Table variables were categorized into three dimensions, namely (1) Classification of intervention (purposes of the study, types of technology, types of intervention and abuse), (2) Descriptive details (sample size, location, and settings), and (3) Outcomes assessment (Measurement, data analysis and interpretation.)

Result
After the systematic review, 4 intervention features and 3 types of intervention outcomes has been found. As for intervention features, 5 mobile applications are included in this review serving as a safety decision, prevention and education aid regarding Intimate partner violence and domestic violence. Another five articles addressed the importance of online learning for healthcare professionals as a training module on how to report DV cases. While 3 articles compared the technology intervention of DV in rural and metropolitan areas, another 16 articles delineated different types of abuse. Elder abuse is the least one supported with technology intervention. Physical and psychological health outcomes are evaluated in 17 articles.

Conclusion
This research elicited data that HIT is effective in alleviating family violence. Future research should devise technology intervention in elder abuse and cyber abuse. More avenues can evaluate the behavioral health outcomes.
Comparison of Data Entry Time for Structured Data Entries and Free Text

Ji Eun Hwang, BS¹, Byung-Ook Seong, MBA², Sang-Oh Lee, MD, PhD²³, Soo-Yong Shin, PhD¹

¹SungKyunKwan University (SAIHST), Seoul, Republic of Korea; ²Asan Medical Center, Seoul, Republic of Korea; ³Asan Medical Center, University of Ulsan College of Medicine, Seoul, Republic of Korea

Introduction
The adoption rate of electronic health records (EHRs) has increased rapidly. However, most current EHRs depend on free text entries, which hinder data usage, especially in research. To overcome this limitation, structured clinical templates or natural clinical language processing are required. Since entering the meaningful data (structured clinical templates) is more important than cleansing the unstructured data (clinical natural language processing), we had interested in structured clinical templates. However, most structured data entries (SDEs) require more data entry time than free text entry¹. We monitored the total data entry time of SDEs and free text in the real clinical practice.

Method
We developed 4 structured pathology reports in the EHR of a Korean tertiary hospital from 2014 to 2015. Within limited time, we used bottom-up approaches to implement structured templates. So, at first, we design the template with physicians, and then SED for template is developed. Although this approach has a demerit of model granularity, it can substantially save the development cost.

We collected the data entry time for four representative pathology SDEs—stomach, lung, colon, and thyroid cancer structured templates—which have been used in clinical practice. We collected log data of SDEs from the deployment of each SDE to 2017 and log data of free text templates from 2011 to the deployment of each SDE. Log data consist of the timestamp from May to July (3 months) of each year (2011~2017) for free text templates or SDEs. Timestamps were collected from 06:00 to 18:00, excluding lunch break (12:00~13:00).

Result
Table 1 shows the comparison results of the average elapsed time between SDEs and free text entries. The interesting characteristics of SDEs with less data entry time are 1) minimizing structured components and 2) input patterns suitable for SDE. For example, the colon cancer SDE has only minimal necessary components based on previous experience, and the thyroid cancer template already has a standardized input pattern, which can be helpful when implementing SDE.

Table 1. Comparison of elapsed time between SDE and free text in the first year of applying SDE.

<table>
<thead>
<tr>
<th></th>
<th>Free Text</th>
<th>SDE</th>
<th>Time comparison</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Elapsed time</td>
<td>Collection year (Number of reports)</td>
<td>Elapsed time</td>
</tr>
<tr>
<td>Stomach cancer</td>
<td>12 min 58 sec</td>
<td>2011~2012 (1,130)</td>
<td>20 min 37 sec</td>
</tr>
<tr>
<td>Lung cancer</td>
<td>14 min 18 sec</td>
<td>2011~2013 (720)</td>
<td>16 min 01 sec</td>
</tr>
<tr>
<td>Colon cancer</td>
<td>16 min 55 sec</td>
<td>2011~2013 (1,002)</td>
<td>16 min 17 sec</td>
</tr>
<tr>
<td>Thyroid cancer</td>
<td>14 min 32 sec</td>
<td>2011~2014 (1,574)</td>
<td>12 min 50 sec</td>
</tr>
</tbody>
</table>

Conclusion
When designing SDEs, we should focus on the reduction of data entry time for successful deployment. As in the case of colon and thyroid cancer, well optimized and designed SDEs will reduce the elapsed time of data entry.

An Informatics Framework for Knowledge Representation and Reconciliation of Disease Pathways

Yulia Innokenteva¹², Olha Kholod¹², Fei He³, Duolin Wang¹, Richard Hammer²¹, Dong Xu³¹ and Dmitriy Shin²¹*

¹MU Informatics Institute, ²Department of Pathology and Anatomical Sciences, ³Department of Electrical Engineering and Computer Science and Christopher S. Bond Life Sciences Center, University of Missouri, Columbia, MO 65211, ⁴School of Information Science and Technology, Northeast Normal University, Changchun, 130117, China

Introduction

The practice of precision medicine requires fine-grained knowledge of biological processes to explain patient-specific clinical phenotypes. However, the vast majority of current knowledge bases (KB) contain canonical disease pathways and rarely include uncommon disease mechanisms and drug actions. Furthermore, state-of-the-art knowledge representation (KR) methods still lack a capability to enable uncovering of implicit relationships without applying more complex reasoning techniques. To address these challenges, we developed a novel informatics framework for KR and reconciliation of disease pathways for precision medicine analytics. The framework introduces a multi-perspective consensus method for processing concordant, contradictory, and complimentary disease mechanisms.

Method

To represent a disease pathway (DP) on the biological level we introduced a notion of a Disease Pathway Profile (DPP). There can be several profiles for the same disease pathway. A profile can be viewed as a specific perspective of a disease pathway. For instance, a newly reported disease pathway that describes a downstream effect of a genomic alteration such as a Single Nucleotide Polymorphism (SNP) in EGFR gene on its 20th exon known as T790M in Non-Small Cell Lung Cancer (NSCLC) can have several profiles. One profile can describe genomic alterations involved in the disease pathway and can be designated as DPP-Genomic_Alteration, another profile can describe regulation by the disease pathways of a specific cancer hallmark (cell survival, proliferation and differentiation or/apoptotic mechanism) and can be designated as DPP-Cancer_Hallmark. On the technical level, a disease pathway is represented as a network, where nodes correspond to molecular entities such as genes, proteins, chemical elements as well as molecular processes such as metabolic reaction, and links constitute interactions between these entities and/or processes. Nodes and links are linked to ontological terms. An elementary network unit is an interaction between a pair of molecular entities and/or processes (e.g. “kinase A phosphorylates protein B” or “metabolite C participates in metabolic reaction D”). When disease pathways from different articles can be meaningfully linked, an integrated disease pathway profile is formed. The main logic of the proposed multi-perspective consensus model is as follows. For each newly extracted disease pathway, the KB is queried to determine the status of the pathway. New disease pathway: If there are no profiles in the KB that exactly match the extracted disease pathway from the same perspective, then a new profile is created and the process is finished. Concordant disease pathway (aggregation): If the extracted disease pathway exactly matches a profile in the KB, it is aggregated with that profile and the profile’s evidence score is increased. Contradictory disease pathway: If the disease pathway partially matches a profile in a KB, a new profile is created, which constitutes an alternative annotation to the existing profile(s). Complementary disease pathway (integration): If there is an existing complementary profile in the KB, it is augmented by a newly created DPP and a new integrated disease pathway profile is formed and entered into the KB. We used an RDF store as the KB platform to store extracted disease pathways and provided retrieval capabilities using SPARQL language.

Results and Conclusion

We have tested our framework on a set of disease pathways reconstructed from 195 PubMed articles. Our method enabled formalization and inclusion into a KB a large spectrum of complex and heterogeneous biological mechanisms. Moreover, the multi-perspective model of the framework facilitated uncovering of a common mechanism of V600E mutation in BRAF gene in Melanoma and Hairy Cell Leukemia disease pathways in an explicit way. That link was previously reported in the literature and consequently validated. We, therefore, conclude that the proposed framework can improve health outcomes in individualized patient cases by efficiently bringing the latest biomedical discoveries into a precision medicine setting.
Mapping Medications to Standards with Machine Learning and Noisy Labels

Alvin D. Jeffery, PhD, RN, 1,2 Sharidan Parr, MD, MS, 1,2 Michael E. Matheny, MD, MS, MPH 1,2
1. TN Valley Healthcare System, U.S. Department of Veterans Affairs, Nashville, TN, USA
2. Department of Biomedical Informatics, Vanderbilt University, Nashville, TN, USA

Introduction

Medication information is commonly used in large-scale, observational studies. Attempts to map medications to standard terminologies have explored information extraction from clinical notes, order sets, problem lists, and other clinical records. However, mapping medications within large, multi-site databases is not routinely performed, and if it is completed, it might not be correct. Recent, novel algorithms to perform such medication mapping tend to be conducted in condition-specific settings (e.g., *C. difficile* infections) rather than in a generalized manner. Within the Department of Veterans Affairs (VA) national data, as many as 15% of prescription orders are not mapped to a standard terminology, and up to 60% of prescription orders cannot be directly mapped to a standard RxNorm concept unique identifier (CUI). Noisy labeling (i.e., using imperfect but available labels) combined with machine learning could provide a process for efficiently and accurately mapping medications to a standard terminology. Therefore, we sought to evaluate the performance of an algorithm that uses noisy labels to map medication data to RxNorm CUIs.

Methods

We developed a multi-class random forest classifier to predict generic RxNorm CUIs within observational data from the VA. We randomly selected 5 medical centers for preliminary testing and applied the classifier to initial prescription data for all patients with at least 2 encounters. We aggregated individual prescriptions by standard identifiers, drug names, strength, unit, and form, and calculated summary statistics for medication quantity, days-supply, refills, and price. We then converted the VA-specific identifier (VUID), the National Drug Classification (NDC) identifier, and the ingredient/strength/unit/form (ISUF) combination to RxNorm CUIs via RxNav. The resulting CUI served as the outcome in each model with the number of unique labels ranging from 5,739 (NDC-based) to 17,293 (ISUF-based).

We removed aggregated rows representing < 5 prescriptions from 2005 to 2018. We included all 43 numeric features (see Table) as predictors in each model. Each model also retained categorical predictors for the original VUID, NDC, or ISUF values (see Table). We used median imputation for numerical features and imputed the word “MISSING” for categorical features. Our hold-out test set comprised 100 manually- adjudicated cases reviewed by a nurse practitioner.

Results

All models yielded Micro F1 scores ranging 0.77-0.89 (see Table), indicating moderate to strong performance. The highest-performing models used the VUID as a predictor and either the VUID-based generic CUI or NDC-based generic CUI as the outcome. Accuracies ranged 0.71-0.89. In most models, the strongest predictor was the standard term (e.g., VUID to predict VUID-based CUI). The number of individual prescriptions an aggregated row represented (i.e., *counts*) and minimum price were frequently found in the top 5 strongest features.

Discussion and Conclusion

We have demonstrated the feasibility of using machine learning and noisy labels to map prescription-based medication information found in a large databases to a standard terminology. We achieved moderate-to-strong performance on a small set of manually-adjudicated cases. We plan to expand the manually-adjudicated test set, train the model on all 130 VA medical centers, and assess model performance on rows with unlabeled data using the manually-annotated test set. These final results will be presented at the AMIA conference.

Utility of the Business Process Model and Notation Standard to Represent Business Processes in the Arden Syntax

Robert A. Jenders, MD, MS, FACP, FACMI
Charles Drew University & University of California, Los Angeles, CA

Introduction

Arden Syntax is a formalism supervised by Health Level Seven International (HL7) for representation of procedural medical knowledge with the goal of sharing units of knowledge known as MLMs. An MLM, which may contain business processes, consists of 3 required categories: Maintenance (software attributes of the MLM such as author); Library (with Purpose and Explanation slots for unstructured descriptions of what the MLM does); and Knowledge (with Data, Logic and Action slots for explicit, structured encoding of executable knowledge). While Arden Syntax has a rich set of features for representation of clinical knowledge, it lacks explicit constructs for business process modeling. Sites using Arden have constructed workarounds to do this, such as EVOKE statements invoking EVENT mappings or WRITE statements to represent a business event, but these can end up incomplete, omitting details that are left implicit. Business Process Model and Notation 2.0 (BPMN) has been suggested representation of workflows, reflecting joint work with the Object Management Group (OMG) to use combinations of languages to represent clinical processes. BPMN represents entities such as events (things that happen, such as escalation and conditional), tasks (which are atomic activities that are part of processes) and sequence flows among them. Prior work has demonstrated the significant prevalence of business processes in MLMs, although commonly in narrative format or implied. In order to explore the utility of including the BPMN standard as part of the Arden Syntax, the present work assesses the representational adequacy of BPMN for business processes in the Arden Syntax.

Methods

A convenience sample of MLMs pooled from 5 sources—3 university hospitals and 2 vendors—was examined. Business processes, either structured in the Knowledge category or unstructured in the Maintenance category of each MLM, that align with constructs in BPMN 2.0 (such as events, activities and workflows) were identified.

Results

A total of 325 MLMs were examined. MLMs concerned mainly with lab tests were the most common (137/325 = 42%), followed by clinical assessment or classification (67/325 = 21%) and medication (41/325 = 13%). The remainder addressed administrative and miscellaneous topics. These included 430 trigger mappings that could be modeled as an Event such as Escalation or a Conditional Event, but often with incompletely defined workflow (e.g., responsible clinician, escalation pathways, etc). The most common entities of the Event type were hospital admission and a laboratory test result, while ordering of a medication or a laboratory test was the most common Task. In addition, 1027 output definition statements were identified, and these were representable by the Choreography Task element. For example, an alert issued via an Arden WRITE statement in the Action slot can be expanded into a Choreography Task, with explicit representation of the recipient role as Participant and the recommended action via a Message and messageFlowRef. Also, processes referenced in the Purpose and Explanation slots in the Library section of nearly all MLMs could be represented by the Choreography Task and Sequence Flow elements of BPMN. There were no business processes that could not be represented in BPMN.

Conclusions

Business processes are a common feature of knowledge represented in Arden Syntax MLMs. These processes are represented in part through explicit data mappings of events, activities and message output destinations. However, more nuanced processes are present only in narrative format because of the absence of specific formal constructs that would support their representation. BPMN is sufficiently robust to represent these processes in a computable format in the Arden Syntax. While it would be the subject of future work in HL7, as BPMN lacks an expression language of its own, it could be integrated in Arden through new native Arden operators or, as a version of the standard already exists in this format, via amendments to Arden’s XML schema.

Acceptance and Use of Home-Based Electronic Symptom Self-Reporting Systems in Cancer Patients: A Literature Review

Yun Jiang, PhD, MS1, Huiting Zhang, MSN1, Marcelline R. Harris, PhD1
1University of Michigan, Ann Arbor, MI, USA

Introduction
Electronic systems developed to support cancer patients’ self-reporting of symptoms from home have shown promising potential to support cancer symptom self-management. However, patients and families’ adoption of these systems, especially their long-term use of the systems, has not been fully understood. This purpose of this review was to gain an overview of cancer patients’ acceptance and use of electronic systems for symptom self-reporting from home, and to identify factors associated with patients’ acceptance and use of the systems.

Methods
The electronic database PubMed, Scopus, PsycINFO, CINAHL, and Cochrane library, from January 2003 to December 2018 were searched using the keywords: “self-report”, “patient reported”, “symptom reporting”, “adverse effect”, “telemedicine”, “mobile health”, “ehealth”, “technology acceptance”, “technology adoption”, and “cancer”. English articles were selected if the studies assessed adult cancer patients’ acceptance and use of electronic systems for symptoms self-reporting from home. Electronic systems only used in clinics or in clinical trials were excluded.

Results
A total of 569 articles were retrieved and 25 articles met the study criteria; most were short-term feasibility tests with small sample size (range 5–286). Among 17 electronic systems studied, the majority were internet-based (e.g. STAR, WebChoice, InCASA), and 4 mobile phone-based (e.g. ASyMS, Interaktor) and 4 Interactive Voice Response (IVR) telephone systems. Studies included patients with multiple types of cancer that self-reported symptoms related to chemotherapy, radiotherapy, or surgery. This review revealed inconsistent definition or measurement of patient acceptance and use of electronic symptom self-reporting system across the studies. Acceptance was assessed by patient participation rate, positive expectation, general satisfaction, perceived usefulness or easy-to-use, and intention to use. Actual use of the system was assessed by the percentage of participants that used (logged on) the system as intended, completion rates (of the study), full or minimal compliance (patient-days with all data or at least one parameter available), daily or weekly call adherence, etc. Inconsistent assessment makes the synthesis of findings difficult. In general, patients reported high satisfaction, positive perception of ease of use, and minimal technical issues such as internet connectivity. Four studies followed up with patients for 12 months or longer, indicating the greatest use in the initial 12 weeks; however, the compliance declined over time; and with a mean follow-up 34 weeks, 83% monthly compliance (self-report at least once per month) and 62% weekly compliance were reported; The studies with 1-year follow-up showed 77% patients logged on at least once and 63.6% logged on more than once. The greater use was associated with older age, higher education, high level of computer experience, and not having comorbidities. Common reasons for patients’ non-use of the system included perceived no benefits, feeling too sick, feeling too distressed, unwilling to use a computer, limited health literacy, high frequency of reporting, too many reporting questions, and no symptom to report. Facilitators of patients’ acceptance and use included: timely feedback from clinicians, peer connection or interaction, alert or reminder of use, user friendly interface, easy to access or use, informative content, linkage to self-management resources, and adequate health literacy.

Conclusion
Current studies lack the standardized assessment of patients’ acceptance and use of electronic symptom self-reporting system. More research is needed to increase our understanding of patients’ long-term adoption. A variety of barriers to patient use of self-reporting systems indicated the level of tailoring needs need to be improved, in order to develop personalized technology-based interventions to support cancer patient symptom self-reporting.

Review of Mobile Applications for the Detection and Management of Atrial Fibrillation

Victoria Jimenez, Samuel Isaac, Munther Alshalabi, Ruth Masterson Creber, PhD, MSc, RN, Meghan Reading Turcione, PhD, MPH, RN

Weill Cornell Medical College, New York, NY

Introduction: Atrial Fibrillation (AF) is a cardiac arrhythmia affecting an estimated 6 million people. Advances in smartphone technology and mobile health (mHealth) have made it possible for patients to monitor and manage their cardiac conditions at home. However, there is little guidance for patients and clinicians on which available mHealth applications (apps) are appropriate for managing AF.

Objective: This review of commercially available applications aimed to identify and assess the functionalities mHealth apps for monitoring and managing AF leveraging native smartphone capabilities.

Methods: We used an established methodology for this review. We identified relevant apps from three marketplaces: AppStore, Google Play Store, and Amazon Appstore with standard search terms (e.g. “Atrial fibrillation”, “ECG”, “Heart rhythm”, “Cardiac arrhythmia”). Apps underwent four rounds of screening, designed to identify AF specific patient-targeted apps (Figure 1). We evaluated the final list of included apps using the Mobile Application Rating Scale (MARS), IMS Institute for Healthcare Informatics functionality scores, and evidence-based guidelines. The MARS assesses the broad quality and performance of apps; while IMS functionality score evaluates the app against 11 functionalities. Evidence-based guidelines for general AF management were used in the absence of patient-specific self-management guidelines.

Results: We screened an initial 1,473 potential apps, and 13 met the final inclusion criteria. Apps were largely excluded based on content aimed at a clinical, non-patient audience; or content solely for entertainment purposes. While a portion of apps provided pulse data, they failed to measure cardiac rhythm (n=70); and they did not provide any further education regarding AF. The average MARS score of the included apps was 3.0 out of 5. Nine of 13 apps had scores of 3.0 or greater, which is the minimum acceptability score. There was high interrater reliability among the four reviewers (IRR=0.75-0.83). Of the apps evaluated, Afib Companion had the highest overall MARS score (4.1), followed by Qardio and Photo Afib Detector (both scored 3.6). The most common functionalities were record, display, and collect data; allowing patients to track cardiac rhythm and medication adherence data, and view trends in self-reporting (Figure 2). None of the apps adhered to all the evidence-based guidelines for AF management.

Conclusion: Despite the volume of relevant search results, few apps are actually leveraging native smartphone capabilities to provide patients-facing tools and education regarding AF. The apps identified had adequate quality scores but limited functionality, and did not adhere to evidence-based guidelines. Future app development and improvement of existing apps should aim to adhere with guidelines for AF management and offer greater functionality to better meet the self-management needs of this patient population.

LeukApp: Development of a Mobile Application for Clinical Decision Support in Acute Leukemia

Andrew Johnson¹, Stephanie Furniss, PhD¹, Matthew Burton, MD¹, Priya Radhakrishnan, MD², Jeffrey Schriber, MD², Anita Murcko, MD, FACP¹

¹Biomedical Informatics, College of Health Solutions, Arizona State University, Scottsdale, AZ; ²HonorHealth Virginia G. Piper Cancer Care Network - Cancer Transplant Institute, Scottsdale, AZ

Problem Description: Optimal and timely treatment of acute leukemia requires a complex evaluation of a patient’s prognosis and suitability for hematopoietic stem cell transplant (HSCT). HSCT offers the highest likelihood of long-term disease-free survival compared to standard chemotherapy and radiation treatment. However, HSCT is a more aggressive treatment pathway that also confers risks of treatment-related mortality and adverse events, especially in older patients, patients with multiple comorbidities, and patients with decreased functional status¹. Additionally, acute leukemias are highly heterogeneous diseases, which present varying risk categories based on clinical factors, French-American-British (FAB) classification, molecular and cytogenetic factors, as well as prior relapse or treatment². Given the difficulty and importance of timely diagnosis, complete testing and correct treatment, HonorHealth is developing a mobile application to enable clinicians to utilize clinical data to understand a patient’s prognosis and facilitate prompt referral for HSCT if indicated. This is part of a larger initiative to develop a specialized leukemia learning network, an educational program to support the inter-professional team at community based hospitals and critical access hospitals to improve care of patients with acute leukemia.

Methods: To develop the mobile app, HonorHealth partnered with clinical informaticists from Arizona State University. Eleven semi-structured interviews were conducted with emergency physicians, hematology/oncology specialists, hematopathologists, and primary care providers. These interviews were used to create workflow models outlining pathways for patient and information flow through initial work-up and leukemia diagnosis, specialized evaluation, treatment, and follow-up. These findings were used to generate use cases and identify target users for the proposed application.

Discussion: Based on our evaluation of interviews with physician experts, we identified two key use cases for the proposed app: (1) evaluation of a patient’s prognosis into key risk groups - favorable, unfavorable, and intermediate; and (2) determining a patient’s potential eligibility for HSCT based on demographic, clinical, and cytogenetic factors. We determined that oncologists and hematopathologists would be the target users, based on the physician’s level of involvement with reaching treatment decisions after the initial diagnostic work-up. The application would incorporate a knowledge base and implement a rule-based approach for assigning treatment prognosis and determining HSCT suitability using decision rules from the above factors. We plan to gather feedback on a prototype of UI mock-ups and screen maps using a focus group of nurses and physicians from HonorHealth and other institutions.

The impact of an automated digital navigation program for colonoscopy on bowel preparation quality and patient satisfaction: a comparative study

Sarthak. Kakkar, MS¹, Rajanshu. Verma, MD², Hallie. Jara, Degrees², Shashank. Garg, MS¹, Andy. Pfau, JD³, Cera. Jaffe, BS³, Shrawan. Patel, MBBS, BSc³, Virender. Sharma, MBBS², Ashish. Atreja, MBBS, MPH¹

Abstract

About 1 in 5 patients suffer from inadequate or poor bowel prep in advance of a colonoscopy.¹ Prior studies have shown that this leads to a decrease in adenoma detection rate, increased time spent in completing colonoscopy procedure, as well as an overall increase in cost of care from 13-20%.² There has always been a patient need to improve this aspect of care, however, with the shift towards value-based care in the American healthcare system, there is now a business case for urgent improvement. Digital care pathways linked through SMART on FHIR have potential to guide patients through complex periprocedural guidance in an intuitive manner.

OBJECTIVES To integrate and utilize a digital navigation program to automate and improve preprocedure navigation for colonoscopy and ascertain its impact on bowel preparation quality. METHODS A quasi experimental design was used to compare two cohorts of patients (usual care versus digital navigation) scheduled for colonoscopy at the Arizona Center for Digestive Health (AZCDH). The digital navigation cohort received usual care in addition to clinical rule driven time based messages leveraging specific content. These messages utilized multimedia education modules and were built on, and delivered through, RxHealth’s digital medicine platform. Patients received notification messages and education content from the day of appointment scheduling right through to one day post procedure completion. We then analyzed the characteristics of bowel preparation in the two cohorts, and patient satisfaction with the digital navigation intervention. RESULTS Of the 217 patients prescribed the digital navigation program, 20 (9.21%) patients had text messages undelivered (due to wrong number or landline), and 93 completed the procedure and had bowel preparation results documented in AZCDH's electronic endoscopic record system. Patients who received the digital navigation program (n=93) were significantly more likely to have good or excellent bowel preparation quality than patients in usual care (n=960, 87.10% vs. 64.79%; p<0.05). As shown in Figure 1, the digital navigation program cut down the rate of aborted procedures by more than half (1.07% vs 2.2%). Furthermore, 27 patients responded to the follow-up electronic satisfaction survey and 92.59% of them “strongly agreed” and “agreed” that the digital navigation program was helpful in preparing them for a colonoscopy.

CONCLUSIONS Our single site study showed that digital navigation for colonoscopy is well adopted by patients and can lead to better bowel preparation rate and significant reduction in rate of aborted procedures, while achieving high patient satisfaction. Future research should evaluate this in multisite trials and identify strategies to engage patients who are not digitally engaged in their care or lack the skills or resources to do so

Data-driven Study of Pain, its Predictors, Co-morbidities, and Characteristics using Nurse-generated Big Data

Youjeong Kang¹, PhD, MPH, CCRN;; Durga Prasad Sanugula², MS; Kriti Bagdi³, MS; Robin R. Austin⁴, PhD, DNP, DC, RN-BC; Karen A. Monsen²-⁴, PhD, RN, FAMIA, FAAN

¹ College of Nursing, University of Utah, Salt Lake City, UT
²Computer Science and Engineering, ³Institute for Health Informatics, ⁴School of Nursing, University of Minnesota, Minneapolis, MN

Introduction. Previous studies in health care industry have made use of big data across different clinical settings, disciplines and data sources. For example, nurse researchers have used the Omaha System, a multidisciplinary ontology and terminology for big data analysis to identify critical data elements in nursing documentation (1). The Omaha System includes three components designed for assessment (Problem Classification Scheme), care plan/services (Intervention Scheme), and evaluation (Problem Rating Scale for Outcomes) (1,2). Under the assessment component, there is a taxonomy of 42 health concepts called the problems including signs and symptoms used in clinical assessments (1,2). Although there is a long history of research using the Omaha System, the pain component has not been fully utilized. In general, there is a lack of pain research using big data approach (3). Thus, the aims of this study were to 1) using machine learning techniques, identify primary and secondary predictors of pain, 2) examine the likelihood of having pain across the population based on most common predictors identified in Aim 1.

Methods. This study used existing de-identified nurse-generated Omaha System data within the secure data shelter of the University of Minnesota Academic Health Center. The data include Problems, Interventions as well as Knowledge, Behavior, and Status (KBS) scores. Pain variables included 6 binary signs/symptoms, interventions addressing the Pain problem, and Pain KBS on admission and discharge. The Problem Rating Scale for Outcomes consists of three Likert-type ordinal scales for rating problem-specific KBS from 1 (most negative) to 5 (most positive). For Aim 1, we trialed Machine Learning algorithms like Logistic Regression with L1 regularization, Support Vector Machines (SVM), Multi-Layer Perceptron (MLP), Decision Trees (DT), Gradient Boosting (GB) and Random Forests (RF). Tree based models performed better as the data with 325,369 samples is very high-dimensional and the target variable was computed by having some conditions on independent variables. We used 80-20 train test split and 5 fold cross validation to determine the best model. Based on the following validation accuracies of various ML models (Decision Tree: 99.31%, Gradient Boosting: 98.31% and Random Forest: 95.01%) we chose Decision tree for extracting primary and secondary predictors of pain and derive optimal models and interpret findings specific to pain. These models were built using scikit-learn ML library. We used descriptive and inferential statistics to examine pain for cases with pain and other co-morbid problems.

Results. The sample (N=3,934) include 58.2% of female and 57.9% of white with a mean age of 74 years (SD=17.6). The strongest primary predictors of pain (normalized feature importance score=0.1) were the sign/symptom expresses discomfort/pain and the baseline Pain Status score. The strongest secondary predictors of pain were decreased muscle strength and gait/ambulation disturbance, both signs/symptoms of the Neuro-musculo-skeletal function problem, overall Status score at discharge, and the total number of signs/symptoms. For the entire dataset (N=325,369) cases with the Neuro-musculo-skeletal problem were 454 times more likely to have Pain vs. cases without the Neuro-musculo-skeletal problem; while patients with the Circulation problem were 204 times more likely to have Pain vs. cases without the Circulation problem.

Discussion. This data-driven, comparative study addressed the problem of understanding pain from a large nurse-generated dataset perspective overall, and for sub-populations within the big dataset. Results revealed new patterns in pain predictors. Future study needs to be replicated in other datasets with smaller dimensions to validate findings because it is easy to lose the important vector if the data are very high-dimensional. Further research is underway to examine pain, multi-morbidity, intervention effectiveness, and differential outcomes.

Conclusion. Little research has been conducted to explore pain using standardized nursing terminology data. This study demonstrated the potential for knowledge discovery related to pain within large nurse-generated datasets.

Life after cancer: After-Treatment concerns and peer-support among breast cancer survivors, portrayed on Twitter

Akshat Kapoor, PhD, MS\(^1\), Elizabeth Baker, MS\(^1\)
\(^1\)East Carolina University, Greenville, NC, USA

Introduction

The rigorous cancer treatments, including surgery, chemotherapy, and radiation can often have a debilitating impact on one’s physical, psychological, and social well-being. There is ample evidence on the benefits of peer-support interventions for cancer survivors, however, knowledge about the role and characteristics of peer support in an unmoderated online environment is still limited\(^1\). Analyzing tweets of breast cancer survivors can thus provide a meaningful insight into how cancer treatment-related symptoms impact the daily lives of survivors, and the various coping mechanisms they adopt to maintain their quality of life.

Objective

The objective of this research is to answer the following research questions: RQ1: What are the primary post-treatment concerns among breast cancer survivors as shared on Twitter?; and RQ2: What are the characteristics of peer-support and associated information-sharing among breast cancer survivors on Twitter?

Method

We utilize a random sample of 100 Twitter users comprising of breast cancer survivors. Survivors were identified as having tweeted about receiving breast cancer treatment at least once on their Twitter timeline. Only individual accounts were included, and organizations were excluded. We perform content analysis on the survivors’ original tweets (retweets were not included in the analysis) to identify post-treatment concerns and forms of support, as depicted in tweets. Concerns were further categorized as physical, psychological, or social. Similarly, forms of support in tweets were labeled as emotional, instrumental, informational, or appraisal support. Thematic analysis was performed to identify recurring themes. Tweets were aggregated using the Twitter4J Java library for Twitter API, and qualitative analysis was performed using NVivo.

Results

Approximately half a million tweets were included in the analysis. Survivors shared a variety of concerns, with sleep disturbance and weight gain being the most common physical concerns. Popular psychological concerns were depression, body-image, and fear of cancer recurrence, while financial burden of the cancer treatment was a very common social concern among survivors. There was also great variation in the types of support offered by survivors on Twitter. While informational support was the most frequent form of support, instrumental support was the least frequent. Further analysis of informational support revealed that survivors also shared several coping strategies with each other. Engaging in physical activity and spirituality were predominant among these.

Conclusion

Beyond the informational support provided on Twitter, peer survivors also offer positive reinforcement to fellow survivors that they are not alone. Peer support is known to be highly beneficial among cancer survivors. Online platforms such as Twitter can be vital in allowing one to network with fellow survivors, receive needed support, and share coping strategies, especially for those living in remote and/or rural locations.

Introduction
The general public’s perception of common health issues such as diet remains limited to survey-based studies. Publicly available Twitter posts have facilitated data collection and leveraged the research at the intersection of public health and data science that cannot otherwise be collected through traditional means of research (e.g., surveys, interviews, focus groups). Furthermore, analyzing Twitter data can help health organizations such as state health departments and large healthcare systems to provide effective health advice and track health opinions of their populations when needed. While previous studies have provided valuable insights, the geopolitical factor of diet has not been investigated on social media. To address this gap in the literature, this study utilizes a computational approach to characterize health-related opinions regarding diet based on the political orientation of the US states. These common perceptions can be used by providers and public health agencies to better understand the common opinions of their population denominators in regard to diet, and reflect upon those opinions accordingly.

Method and Result

Data Collection. We collected 2,348,229 million tweets using Twitter’s Application Programming Interface (API) from June 2016 to May 2017 using diet and #diet. Data Pre-Processing. This step removed duplicate tweets and retweets, stopword, and categorized the tweets based on different states. This process resulted in 857,277 tweets. Topic Analysis. Then we detected the hidden semantic structure using topic modeling in the collected tweets based on the political orientation of the US states.

Decoding Patterns. This phase utilized a qualitative approach to detect, decode, and interpret meaningful patterns with the help of public health experts. This phase removed nine unrelated and meaningless topics and provided 32 topics. Statistical Analysis. Finally, we compared the weight of topics based the political orientation of the US locations including Republican (Rep), Democratic (Dem), and Swing (Swi) states.

Result. We estimated and extracted 41 topics about different issues such as different types of diet, chronic condition, lifestyle, and health behavior. The following table shows that the weight of more than 60% of topics is statistically significant ($P - Value < .05$). Each value in this table shows the percentage of the topics whose weight was statistically significant between each of the categories in the columns. For example, the comparison between the diet topics posted on Republican and Democratic states shows that the average weight of 95.12% of the 41 topics was statistically significant.

Discussion
We found that there was a significant difference between Democratic & Republican, Democratic & Swing, and Republican & Swing states regarding diet-related topics. The key findings as follows. First, the difference of diet-related topics discussed on Twitter between Republican & Swing states is less than Democratic & Swing states. Second, the difference between Democratic & Swing is more than the one between Republican & Swing states and Democratic & Republican. The results are interesting because most Swing states voted for the Republican candidate in the 2016 US presidential election. So, there was a close relationship between Republican and Swing states based on opinions and beliefs.
The Effective, The Inefficient and the Ugly: Interface Elements in Nursing Order Management

Alexandra N. Kassis, Benjamin J. Duncan, MS, Lu Zheng, RN, MHI, MS, David R. Kaufman, PhD, Stephanie K. Furniss, PhD, Adela Grando, PhD, Karl A. Poterack, MD, Richard A. Helmers, MD, Bradley N. Doebbeling, MD, MSc

1 Biomedical Informatics, College of Health Solutions, Arizona State University, AZ, US; 2 Kern Center Informatics and Knowledge Management, Mayo Clinic, Rochester, MN, US; 3 Science of Healthcare Delivery, College of Health Solutions, Arizona State University, AZ, US; 4 Department of Anesthesiology, Mayo Clinic, AZ, US

Description of Problem
Electronic Health Record (EHR) designs that contain unused features put a burden on the user’s cognitive load by cluttering the screen and making navigation complicated. Published reports suggest current EHR design guidelines are not as effective as we need them to be. Investigating the current EHR-mediated workflow in pre-operative nursing order management (OM) at Mayo Clinic allowed us to identify usability problems and frequency of use in selectable features. Identifying the most frequently used functions will aid in the improvement of future OM design while eliminating unused functions will result in workflow optimization, efficiency, better usability and more effective patient care.

Methods
Pre-operative care observations were completed in one of Mayo Clinic’s tertiary hospitals. Usability issues were identified and categorized leveraging a set of 14 usability principles for evaluating health information technology (IT) from Zhang et. al. Problems were identified and categorized by two EHR usability expert informaticists using six of the 14 usability principles for evaluating electronic systems. Selectable features were identified in a system walkthrough and function frequency was calculated using eight recorded and analyzed OM cases. These issues were observed through screen capture using Morae™, a usability video capture software, to record users interacting with the systems in situ. The results presented here were based off observations of eight nurses using SurgiNet in PreOp OM instances at the Mayo Clinic Arizona campus.

Results
Table 1 shows the name of the system in which the usability problem occurs, the specific interface aspect where it occurred, a description of the problem being observed, and which usability principles are involved. There were six observed issues in the Cerner SurgiNet system. The problems with Cerner centered around the display issues including visibility, memory, consistency, and minimalism.

<table>

</tr>
</tbody>
</table>

Conclusion
The heuristic categorization analysis performed identifies specific usability problems and a description of usability principles violated. Through categorization, usability issues can be identified for further investigation on design improvement. Future work will involve further application of the TURF framework and function frequency on Epic to compare the two-systems interface design and usability. This comparison will allow usability barriers to be more easily identified and suggest future interface aspect redesigns.

The Promise and Perils of Pseudonymization

Mehmet Kayaalp, MD, PhD
Lister Hill National Center for Biomedical Communications,
U.S. National Library of Medicine, National Institutes of Health, Bethesda, MD

Abstract

Pseudonymization is the practice of replacing actual personal identifiers with realistic-looking faux identifiers. Its significance has grown immensely as it was adopted by the EU’s General Data Protection Regulation. This study provides a cost-benefit analysis of pseudonymization and concludes that the perils of pseudonymization when used as the default de-identification mode may outweigh the benefits.

Clinical text de-identification systems replace personal identifiers (e.g., James) with appropriate labels such as [Individual-1]. Pseudonymization goes one-step further and maps genuine identifiers to faux identifiers (e.g., James becomes John) within the text and sometimes across the entire collection of data. The resulting de-identified text would read more naturally. Furthermore, if the de-identification system fails to recognize an identifier, leaving it unmodified, the genuine identifier blended among others may remain unnoticeable.1 Due to these benefits, General Data Protection Regulation adopted pseudonymization as the default mode of de-identification.2

Genuine identifiers missed by the de-identification system would be glaringly obvious in the conventionally de-identified output. When one user observes the failure, the policy under which the institution operates should dictate that the incidence be reported immediately, so the underlying problem could be corrected for the entire dataset, preventing further exposure of the confidential information to others. In the same scenario, pseudonymization would only provide an illusion of privacy protection while confidential data could obliviously be distributed to a wider audience. Furthermore, the promise of added privacy protection via pseudonymization has a marginal value since the chance of patient re-identification from the output of a modern de-identification system is usually much less than 1%,3 and when it occurs, the chance that the research scientist knows that patient would be slim to none.

Modern de-identification systems rely on the feedback of their users since the characteristics of input change over time. Pseudonymization, however, may hinder this process in at least two ways: (1) the user may genuinely be unaware of the problem, or (2) without any serious risk of repercussion, the user may pretend to be unaware of the problem to avoid the overhead of reporting and the risk of an extended interruption of their study.

Some pseudonymization algorithms may use one-to-one mapping between actual and faux identifiers across the database for linking patient data longitudinally. If the algorithm or the actual map itself is hacked or revealed, all hidden identifiers could be exposed at once; therefore, such seemingly innocuous methods may pose high risk to privacy and their applications would require great care.

Pseudonymization may also inadvertently alter the actual scientific data by misjudging it as a personal identifier such as a date, age, telephone number, address location, or other numeric identifier. Since pseudonymization creates no sign of alteration, scientists could unsuspectingly use false data, producing erroneous results whose cost would be hard to predict.

In the final analysis, pseudonymization can be appropriate in select circumstances (e.g., sharing well-verified de-identified data to a large group of users); however, using it as the default mode of de-identification may cause more harm than good.

Representing the Intensity of a Physical Activity

1Yujing Ke, 1Arthur Zhao, 1William Gu, 2Hyeoneui Kim
1Department of Computer Science, 2School of Nursing; Duke University, Durham, NC

Introduction
Assessment and recommendation of a physical activity for a patient needs to specify frequency, duration, types and intensity of the activity. Consistent representations of these physical activity attributes should also be available to draw reliable insights into various health outcomes. Unlike the easily quantifiable attributes like frequency and duration, objectively describing activity intensity is challenging because it is a subjective experience. There exists a few metrics that offer a means to quantifying the intensity level of an activity: Metabolic Equivalent (MET) values can be adjusted to represent the intensity of an activity that a person experiences based on his/her resting metabolic rate1. Borg scale2 also provides a relatively simple but reliable way of assessing the intensity of an activity based on one’s perceived exertion. However, these methods are rarely used in everyday communications of assessment and recommendation of physical activities. This exploratory study investigated a few methods that are widely used to describe and communicate activity intensity information by analyzing standardized physical activity questionnaires.

Methods
We reviewed 1132 unique questions collected from 30 standardized questionnaires developed to assess physical activity habits of adult populations. We manually extracted various expressions describing activity intensity from the collected questions. For example, from a question “Does your work involve vigorous-intensity activity that causes large increases in breathing or heart rate like carrying or lifting heavy loads, digging or construction work for at least 10 minutes continuously?” we extracted three types of intensity descriptors: a general severity modifier “vigorous”, physical exertion “causes large increases in breathing or heart rate”, and activity examples “lifting heavy loads, digging or construction work.” We then analyzed the extracted intensity expressions to discover common patterns and inconsistencies in associating these expressions to different intensity levels of a physical activity.

Results and Discussion
Eighty seven of the 1132 questions contained activity intensity expressions. General severity modifiers were the most widely used method of describing activity intensity and found in 83 questions. We identified 9 severity modifiers such as light, mild, moderate, vigorous, strenuous, heavy, hard, light to moderate, and moderate to vigorous, which were deemed to need further standardization. Activity examples were the next most frequently used method for describing intensity, and were found in 68 questions. Simplified physical exertion levels were used in 36 questions and expressed with changes in heart rate, breathing, and sweating; each was attached with various degree descriptors (e.g., slight increase, faster than normal, soaked, etc.). These three types of descriptions were often used in combination. All three types of descriptions were found in 23 questions like the one provided as an example in the Methods section. A severity modifier was used in combination with activity examples in 41 questions, and with physical exertion in 8 questions. However, more than half of the questions analyzed in this study depended solely on the general severity modifiers to describe activity intensity. The associations made between physical exertion and severity modifiers in these questions were consistent. However, we noted inconsistencies in associating activity examples and severity modifiers to describe activity intensity. For example, bicycling was used as an example of a moderate activity in one question, but presented as a vigorous activity in another. Similarly, swimming and brisk walking were used as examples with both light and moderate intensity.

This study was done in a small scale and not powered to discover various patterns and inconsistencies in intensity descriptions thoroughly. Nonetheless this study suggests that the current methods of describing activity intensity information found in physical activity questionnaires can potentially lead to miscommunication. Describing activity intensity with general severity modifiers, simplified degree of physical exertion, and activity examples might not be a reliable way of conveying intensity information as they all involve in subjectivities in interpretation. This explorative study highlights the need to investigate how people perceive and interpret these commonly used methods of describing activity intensity, and consider adopting a quantifiable method of describing activity intensity.

Semantic Representations of Multi-Modal Data, NeuroInformatic Processing Pipelines, and Derived Neuroimaging Results in the Arkansas Image Enterprise System (ARIES)

Aaron S. Kemp, MBA 1,2, Jonathan Bona, PhD 2, Tracy S. Nolan 2, Linda Larson-Prior, PhD 1,2,3, Tuhin Virmani, MD, PhD 3, Lakshmi Pillai, MS 3, Mathias Brochhausen, PhD 2, Lawrence Tarbox, PhD 2, and Fred Prior, PhD 2
1 Psychiatry, University of Arkansas for Medical Sciences (UAMS), Little Rock, AR; 2 Biomedical Informatics, UAMS, Little Rock, AR; 3 Neurology, UAMS, Little Rock, AR

Introduction
Neuroimaging is among the most active research domains for the creation and management of open-access data repositories. Heavy emphasis has been placed on functional magnetic resonance imaging (fMRI) data for both disease specific collections and healthy brain function. The Cancer Imaging Archive (TCIA) has been the National Cancer Institute’s principal imaging resource and has encouraged and supported open-science research by acquiring, curating, hosting and managing collections of multi-modal information. The TCIA technology stack is currently being refactored into a more streamlined, easily maintained, containerized package which we have labeled PRISM: Platform for Imaging in Precision Medicine. One of the first applications of PRISM is the establishment of a neuroimaging research data management system at the University of Arkansas for Medical Sciences, which is known as the Arkansas Image Enterprise System (ARIES). As the first instantiation of the PRISM infrastructure, the ARIES project aims to explore the practical utility and usability of the full set of capabilities that this new platform provides. In particular, the integration of semantic representations of multi-modal data elements from a variety of disparate sources (e.g., imaging, behavioral, or cognitive assessments), across image processing stages (e.g., preprocessing steps, neuroanatomical segmentation schemes, analytic pipelines), as well as descriptions of the derived results would ensure greater reproducibility and comparability of scientific findings across large-scale neuroimaging research projects.

User Groups and Pilot Data
Pilot testing of the ARIES instantiation of PRISM is being conducted with three collaborating investigative teams who are using ARIES in a project designed to identify common pathways of neurodegeneration. The dataset for the pilot test includes neuroimaging measures (structural and functional MRI and EEG) as well as endophenotypic data obtained from a variety of assessments designed to measure neuro-motor integration (wearable body sensors, gait-assessment floor mat, digitized gloves, and handwriting/drawing assessments on a digitizing tablet) and neurocognitive functions (performance scores on standardized neuropsychological tests and cognitive activation tasks from functional imaging) in three unique study cohorts diagnosed with Parkinson’s disease (PD), Mild Cognitive Impairment (MCI), or Cancer-Related Cognitive Impairment (CRCI).

Semantic Integration Approach
To integrate and manage these data we are building semantic representations using axiomatically-rich ontologies. These will be used to instantiate a knowledge graph that combines the data from these unique study cohorts into a shared semantic representation that explicitly accounts for relations among these data. This amounts to providing queryable relationships across the source data sets. This knowledge graph is stored in a triple store database that supports reasoning over and querying these integrated data. We believe that these unique capabilities will facilitate the discovery of important new linkages among endophenotypic expressions of disturbed neural functions and discrete neuroanatomical markers of neurodegeneration obtained from the derived neuroimaging results.

Conclusion
Semantic integration of neuroinformatic processes in the ARIES pilot project demonstrates the capabilities of the PRISM infrastructure to effectively represent detailed neuroanatomical segmentation schemata and processing pipelines for image analyses, integrate a diverse set of multi-modal data elements, and provide detailed descriptions of the results obtained across the analytic processing stages and in relation to the supporting endophenotypic data. Such capabilities are essential to ensure greater reproducibility in large-scale neuroimaging research projects.

Sickle Cell Disease Phenotype Algorithm Performance in Adult, Pediatric, and Transitional Care

Mirza S. Khan, MD\textsuperscript{1,2}, Mark Rodeghier, PhD\textsuperscript{3}, Robert M. Cronin, MD, MS\textsuperscript{2}
\textsuperscript{1}U.S. Department of Veterans Affairs, Nashville, TN; \textsuperscript{2}Dept of Biomedical Informatics, Vanderbilt University, Nashville, TN; \textsuperscript{3}Rodeghier Consultants, Chicago, IL

Introduction
Sickle cell disease (SCD) is an inherited condition that is associated with increased healthcare utilization and mortality. This risk is greatest in adolescent patients due to the poor transition of care from pediatric to adult-based practice\textsuperscript{1}. Adherence to evidence-based SCD management is sub-optimal. To prevent complications, efficient methods are needed to monitor care practices in this population. Computable phenotype algorithms are a promising method to query electronic health record (EHR) data to discover patients with rare conditions, such as SCD.

Methods
We conducted a retrospective observational study using EHR data from 2012 to 2016 at Vanderbilt University Medical Center and Monroe Carell Jr. Children’s Hospital at Vanderbilt. This study was approved by the Vanderbilt University IRB. Similar to prior work, algorithm 1 queries pertinent ICD-9 and ICD-10 codes\textsuperscript{2}. Algorithm 2 uses relevant SNOMED terms and word matching. Algorithm 3 identifies cases satisfying both algorithms 1 and 2. We used clinical encounter metadata to categorize patients by clinical setting as pediatric, adult, and transition. The latter accounts for patients transitioning from pediatric to adult practice. SCD status was confirmed using a manually curated SCD patient registry. We calculated positive predictive value (PPV) and sensitivity with and without stratification by age group. We used the \(\chi^2\)-test to study SCD status between age categories and the Fisher’s exact test to compare PPV and sensitivity by age group for algorithms 1 and 2. Statistical analysis was performed using SPSS version 25.

Results
The study included 728 total patients; 87.2\% were black and 50.4\% were female. PPV ranged from 88.4-94.0\% and sensitivity from 89.2-100\% (Table 1). True SCD status between age groups is significantly different (\(p = 0.002\)). Sensitivity between age groups is different for Algorithm 1 (\(p = 0.009\)) and for Algorithm 3 (\(p = 0.034\)). There is no difference in PPV (\(p = 0.454\)) and sensitivity (\(p = 0.136\)) between Algorithms 1 and 2.

Table 1: Summary statistics, PPV and sensitivity calculated by age group for Algorithms 1, 2 and 3.

Conclusion
Computable phenotype algorithms are efficient, scalable and cost-effective alternatives to manual patient registries for identifying patients with rare conditions. Using SNOMED terms and word matching resulted in comparable performance to our algorithm that queried ICD codes. Furthermore, the PPV for each algorithm is not different across age groups, even among those undergoing care transition. Use of such algorithms to identify patients with rare diseases may aid population health monitoring and provides efficient cohort development for research studies.

A Review of Palliative Care Mobile Applications for Patients and Caregivers

Eugenia Kim, MS1,2, Fariha Ahsan, MPA1,3, Corinne Lamour-Romero, RN1,2, Chelsea Michael1,2, Ruth Masterson Creber, PhD, MSc, RN1
1Weill Cornell Graduate School of Medical Sciences, New York, NY; 2Memorial Sloan Kettering Cancer Center, New York, NY; 3NewYork-Presbyterian Hospital, New York, NY

Introduction

As the elderly population continues to grow, understanding how mobile technology can be used to improve end-of-life and palliative care for aging patients and to support their caregivers is becoming increasingly important. Within the United States, older people (ages 60 and over) are expected to outnumber children and young adults by 2030.1 While research shows that smartphone use and ownership varies by age, utilization of smartphones has grown most dramatically in the 60 and older age groups.2 However, to our knowledge, no studies have systematically evaluated consumer apps for palliative care. We reviewed mobile apps designed to improve palliative care of patients and support their caregivers.

Methods

In February 2019, a comprehensive review of mobile apps was conducted across three mobile app stores: Apple iTunes store using fnd.io, Android Google Play store, and Amazon Appstore. The following search terms were included: “palliative care,” “end-of-life care,” “hospice,” “hospice care,” “hospice caregiver,” “hospice support,” and “terminal illness.” Apps were evaluated using the Mobile Application Rating Scale (MARS), IMS Institute for Healthcare Informatics functionality assessment, and evidence-based guidelines for self-management based on the Supportive and Palliative Care Indicators Tool (SPICT) and Palliative Care Network of Wisconsin (PCNOW) guidelines, which included criteria such as symptom management and enhanced communication.

Results

We identified 1856 apps, of which 19 met the final inclusion criteria. Most applications were excluded because they were non-English, games/books, unrelated, for clinicians only, or medical information and education. The most common criteria that was addressed from the SPICT/PCNOW guidelines were reviewing plan of care and easing mental health suffering. Interrater reliability among four reviewers was substantial (0.58-0.79). The majority of apps did not meet the criteria recommended by the SPICT/PCNOW guidelines. The median MARS score was 2.6 out of 5, and eight of the 19 apps met the minimum acceptability score of 3.0. Across all our reviewed apps, the average IMS functionality score was 3.3 out of 11 with the most common features being inform (20%) and communicate (20%) (Figure 1). Overall, the Mind Your Loved Ones app scored highest on the MARS, IMS functionality, and SPICT/PCNOW guidelines. The most common behavioral change approach was to “Inform/Educate” (11 apps). Ten apps required web access to function and seven allowed sharing information from the app to loved ones or to popular social media platforms. Six required logins, but none offered data encryption.

Discussion & Conclusion

This review indicates that of the currently available apps, few meet the identified criteria for quality or functionality. Many of the palliative care apps were not grounded in theory or evidence-based guidelines. In particular, despite an emphasis on recommendations for symptom management in palliative care, there was a noted absence in the apps providing any such features to support patients and caregivers in doing so. These findings suggest that apps need further targeted development, and policy makers, app developers, and designers should work collectively to create both policies and apps that are founded on evidence-based clinical guidelines.

Developing computational phenotyping algorithm to classify lung cancer stages using common data elements

Min-Hyung Kim, MD, MS, Sajung Park, MD, Yu Rang Park, PhD, Wonjun Ji, MD, Seul-gi Kim, MA, Minji Choo, RN, Seung-sik Hwang, MD, PhD, Jae Cheol Lee, MD, PhD, Hyeong Ryul Kim, MD, PhD, Chang-Min Choi, MD, PhD

4 Graduate School of Public Health, Seoul National University, Seoul, Republic of Korea

Introduction

TNM stage is an important classification system for predicting prognosis and planning treatments in lung cancer. Unfortunately, TNM information is not available in ICD-9/10 systems, and this limits analyses of large-scale health databases. We aimed to develop computable phenotype algorithms to classify the TNM cancer stages of lung cancer patients using common data elements, including diagnosis, medication and procedure codes.

Methods

We first developed a rule-based computational phenotyping algorithm based on medication and procedure codes, according to the recommended treatment regimens in the U.S. National Comprehensive Cancer Network (NCCN) guidelines. Then we validated the base classifier in electronic health records of a tertiary referral hospital. The gold-standard staging information was attained by manual chart review for 2,907 lung cancer patients. We divided the patients into three random subsets and used the first subset for the initial validation. Then, we developed three additional rules: the second rule added limits based on prior non-pulmonary malignancy, the third rule added limits based on pulmonary comorbid conditions (ICD-10 A15-16, J10-18, J41-47, J84-85), and the fourth rule added limits based on both prior non-pulmonary malignancy and pulmonary comorbid conditions. The performances of all algorithms were evaluated in the second subset, and the third subset remains sequestered for future research.

Results

After reviewing the initial validation results (overall accuracy 0.75, pooled sensitivity 0.63, specificity 0.91, c-statistics 0.77), we developed the additional rules and validated the classification performance of each rule in addition to the base classifier in the second subset. In the secondary validation, the base classifier showed overall accuracy, pooled sensitivity, specificity and c-statistics of 0.77, 0.62, 0.92, and 0.77, respectively. When the second rule was added to the base classifier, the overall accuracy, pooled sensitivity, specificity and c-statistics were 0.79, 0.62, 0.91, and 0.77, respectively. When the third rule was added to the base classifier, the overall accuracy, pooled sensitivity, specificity and c-statistics were 0.78, 0.63, 0.92, and 0.78, respectively. When the fourth limit was added to the base classifier, the overall accuracy, pooled sensitivity, specificity and c-statistics of 0.79, 0.62, 0.91, and 0.77, respectively.

Discussion

In this study, we show validation results of rule-based computational phenotyping algorithm based on common data elements, including medication and procedure codes, which can be readily available in large-scale health databases. The phenotyping algorithm based on treatment patterns may have high sensitivities and specificities when there is an authentic clinical guideline that clinicians strictly follow. On the other hand, there are certain scenarios when clinicians make exceptional decisions in practice. This study highlights the opportunities of challenges in developing computational phenotyping algorithm to classify lung cancer stages using common data elements.

The Effectiveness of using mobile EMR with consultation process in EMR

Su Jin Kim¹, BA, Kwang Yul Jung, MD², Won Chul Cha, MD³

¹ Department of Digital Health, SAIHST, Sungkyunkwan University, Seoul, Korea
²Department of Emergency Medicine, Inha University School of Medicine, Incheon, Korea
³Department of Emergency Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea

Introduction

Consultation is critical part of Emergency Department (ED) function.[1] Delayed response from specialty physician results in disposition delay and ultimately attributed to ED crowding which has been critical concern to public health at the aspect of throughput process of ED crowding stages. Mobile electronic medical records (mEMR) is increasingly utilized by health care providers.[2] Several studies has proven that mEMR makes physician work efficiently. However, none of previous studies have evaluated the time efficiency in real clinical circumstances depending on the use of mEMR. In this study, we identified the relation between consultation response and frequency of mEMR.

Method

This retrospective study took place in an academic ED in Seoul, South Korea. We analyzed PC EMR and mEMR data from May 2018 to December 2018. From PC EMR, Request time for consultation from ED physician and record written time by other specialty physician were extracted. Frequency are extracted from log data of mEMR. We merged two data by physician ID and performed Pearson’s product-moment correlation to identify the association.

Result

During the study period, the total of 40,991 cases of consultant from ED physician occurred. 277 physicians received request of consultation. From the 277 physicians, 216 were mEMR users. We found that the frequent mobile EMR users respond more quickly to consultation from EMR. (coefficient: -0.25(-0.37 to -0.17), P-value< 0.001)

Conclusion

This study support that the use of mEMR can enhance the time efficiency in real clinical circumstances.

Cancer Type Classification by Jointly Using Words and Concepts from Electronic Health Record Text Notes

Youngjun Kim, PhD1, Stephane M. Meystre, MD, PhD1

1 Medical University of South Carolina, Charleston, South Carolina, USA

Introduction: Electronic health records (EHRs) contain a wide variety of data important to patient care management. The vector representation of this medical information has been increasingly applied to clinical text classification problems. This study investigates what information contained in the EHR contributes to classifying patient cancer types. Our task involves recognizing three types of cancer: breast cancer, gastrointestinal cancer, and lung cancer. The classifier assigns one of the three cancer categories to an EHR using its textual content. We show that document classification can be improved when the words and medical concepts contained in EHRs are jointly used. We also propose a method to extract synonyms from the medical knowledge-base by comparing two concepts that share the same meaning. The synonym list is used to refine the word vector embeddings (WV) for more accurate classification.

Methods: We used EHR text notes from 154 randomly selected cancer patients treated at the Huntsman Cancer Institute (Salt Lake City, Utah). We selected the 168 most frequently diagnosed medical problem at the University of Utah Healthcare in 2013. For each note, all mentions of these problems were annotated by medical experts with about 70% inter-annotator agreement. The corpus consisted of 495 notes used for training with 9,337 problems and 274 notes used for testing with 5,360 problems. To automatically identify notes from patients with breast, gastrointestinal or lung cancer, we created four different multi-class classifiers for document classification. We used the Vowpal Wabbit online learning library with 3-skip-trigrams that allow words to be skipped for each word in the document. One-vs-all classification strategy was applied to perform multi-class classification. We used fastText for the other three classifiers: one without pre-trained WV, one with pre-trained WV, and one with refined WV using concept synonyms from the UMLS Metathesaurus. We used all terms associated with UMLS concepts and created pairs of concepts. For each concept term in the pair, we removed common words that occurred in both terms. When only one word remained in each of the two terms, we considered them as synonyms. We rebuilt the WV representations by applying the refinement method proposed by Faruqui et al. with this list of synonyms. For all four classification methods, we implemented three different variations: using only words, only concepts, and both words and concepts.

Results: We report the accuracy of each model correctly identifying the type of cancer in each patient note. The fastText models showed higher accuracy than the corresponding Vowpal Wabbit models. Pre-trained word embeddings contributed to the accuracy when words were used for training. The fastText model, with refined word embeddings using synonyms produced the best accuracy at 93.5% when both words and concepts were used as features. The paired t-tests showed that the accuracy of this model was significantly better than models preceded by an asterisk (*) in Table at the p < 0.05 significance level.

Conclusion: Instead of using only diagnostic codes or only words found in EHR text notes, we demonstrated that jointly using words and standard terminology concepts can further improve document classification for identification of patients with specific cancer types. The automated extraction of synonyms from the standard terminology yielded promising results. Yet our study only covered one-word synonym terms. One direction for future research involves comparing pairs of synonymous terms with multiple words.

Acknowledgments: This research was supported in part by the National Cancer Institute (R41CA180190).

Abstract

The vast amount of data stored in a patient’s Electronic Medical Record (EMR) makes it difficult for clinicians to get the information they need. We use machine learning to predict which patient data a clinician is likely to seek, and we highlight those data in the EMR. In this poster, we report insights gained while developing and evaluating a Learning EMR system.

Methods

A Learning EMR observes clinician information-seeking behavior and applies it using machine learning to direct the display of data in future patient cases. Over the last five years, we have developed, trained, and evaluated a Learning EMR system. In the most recent work, we evaluated a Learning EMR system that was trained on the information-seeking behavior of 11 intensive care unit (ICU) clinicians (intensivists) when, in a laboratory environment using de-identified EMR data, they prepared to present about 200 patient cases at morning rounds. The evaluation consisted of 12 intensivists each performing the same clinical tasks for 18 patient cases, where the cases were presented using either the control “vanilla” EMR user interface or using an intervention “highlighted” EMR user interface. The experience of conducting this work culminates into insights into context-aware systems such as the Learning EMR.

Results

This poster presents insights into \textit{what}, \textit{where}, and \textit{when} data should be highlighted in a Learning EMR, and \textit{how} training data should be collected for a Learning EMR.

Conclusion

Data-driven approaches for adaptive EMR systems show promise for supporting clinical decision making and enhancing user experience with EMRs. These insights will help others pursuing similar problems involving context-aware learning.

Continuous Predictive Modelling for Sepsis, Organ Failure, and In-hospital Mortality in the Intensive Care Unit

Amber Kiser, BS¹, Devin Horton, MD², Karen Eilbeck, MSc, PhD¹, Samir Abdelrahman, MSc, PhD¹
¹Department of Biomedical Informatics, University of Utah, School of Medicine, Salt Lake City, Utah
²Department of Internal Medicine, Division of General Internal Medicine, University of Utah Medical Center, Salt Lake City, Utah

Introduction: Patients in the Intensive Care Unit (ICU) can deteriorate very quickly, leading to unexpected outcomes, including sepsis, organ failure, and death. Sepsis is a dysregulated host response to infection, which for this project is identified clinically as systemic inflammatory response syndrome (SIRS) plus infection. Most current clinical risk scores such as SOFA are calculated once a day. Because of this, there is little ability to know how things are changing in real time. Additionally, previous studies have demonstrated that clinical risk scores such as SIRS and qSOFA have lower positive predictive value (PPV), despite having acceptable area under the receiver operating characteristics (AUROC). Continuous predictive modelling, however, can identify negative trends early and may improve patient management and outcomes. The goal of this project is to develop continuous predictive modelling for each outcome, i.e., sepsis, organ failure, and in-hospital mortality, in order to monitor the patient’s status hourly. Several recent models have been developed to predict sepsis with at least one lacking precision when compared to the qSOFA score until 6 hours of data were incorporated into the model, demonstrating a need for continuous modelling. Our continuous modelling predicts sepsis along with sepsis-related outcomes, organ failure and mortality, using only 1 hour of data with greater precision when compared to the risk scores most appropriately matched for each outcome.

Methods: The data was retrieved from the MIMIC III database. Patients under the age of 18 were excluded. Only patients who were transferred to the ICU at some point during their hospital stay were included. In total, 38,439 unique patients were included, comprising 8,301,364 rows of hourly data. Vital signs and laboratory results were binned hourly for each patient. For each hour, the outcomes were determined from the vital signs and laboratory values, including whether the patient had sepsis, was in organ failure, or if the patient died. The final cohorts were prepared individually for each outcome. Vital signs, laboratory values, patient age, and some medication information were used as features in the model. In order to avoid biasing the models, some features were excluded from certain models because these measurements were used in defining the outcome. Observations from the previous hour were used to predict outcomes for the current hour. Several clinical risk scoring criteria were used to compare the PPV and NPV of the continuous prediction models. These included SIRS, used to compare with sepsis prediction, qSOFA, used to compare with organ failure prediction, and mEWS and NEWS2, used to compare with mortality prediction. Each hour, these clinical risk scores were calculated for each patient based on the published criteria and standard thresholds. The datasets were split into training and testing sets in an 80/20 split by hourly records. The training data was used to perform minimal hyperparameter tuning for 5 different algorithms, including Gradient Boosting, SVM, Logistic Regression, Naïve Bayes, and Random Forest. After training, the models were evaluated on the unseen test data and compared to the risk scores. Our hypothesis was that the continuous predictive models would have greater precision than their matched risk scores.

Results: For all outcomes, logistic regression underperformed against the clinical scores. However, Naïve Bayes did perform better than the scores in sepsis prediction and SVM performed better than the scores for organ failure prediction. For sepsis prediction, the gradient boosting (PPV = 0.348, NPV = 0.989, AUC = 0.877) and random forest (PPV = 0.358, NPV = 0.990, AUC = 0.961) models produced comparable results. Both surpassing the SIRS risk score (PPV = 0.001, NPV = 0.985). For organ failure prediction, the gradient boosting model (PPV = 0.266, NPV = 0.980, AUC = 0.754) surpassed the qSOFA risk score (PPV = 0.054, NPV = 0.980) in PPV and produced a comparable NPV. Finally, for mortality prediction, once again the gradient boosting model (PPV = 0.196, NPV = 0.999, AUC = 0.836) surpassed the mEWS (PPV = 0.006, NPV = 0.999) and NEWS2 (PPV = 0.002, NPV = 0.999) risk scores in PPV while again producing comparable NPV.

Discussion: This study served as a proof of concept for our hypothesis that continuous modelling would predict sepsis and sepsis-related outcomes better than clinical risk scores. Our hypothesis was demonstrated to be true as the top performing continuous prediction models resulted in higher PPV than the risk scores associated with the outcome. There are some limitations in comparing different study models which predict sepsis. For example, these studies often use different definitions of sepsis and predict different time periods prior to onset. However, given this caveat, our model performed better or comparable to four recent models, granted they are predicting different time periods before onset. Our best performing random forest model produced an AUC = 0.961, compared to Delahanty et al AUC = 0.96, Desautels et al AUC = 0.88, Nemati et al AUC = 0.85, and Taylor et al AUC = 0.860. In order to more accurately and appropriately compare the current study model to other similar models, we plan to incorporate the ability to predict sepsis onset more than one hour in advance, using data from more than just the previous hour. Additional future enhancements to our study include different validation methods, such as cross validation and a validation dataset, different feature selection methods, additional datasets including different patient populations, and more advanced techniques such as deep learning.

Virtual Reality: Exploring Methods to Improve Dietary Choices

William Kistler, MA1,2, Denise M. Goldsmith MPH, MS, RN, FAAN1, Patricia Flatley Brennan PhD, RN1,3
1National Institute of Nursing Research, Washington, DC; 2University College London, London, UK; 3National Library of Medicine, Washington, DC.

Introduction

Virtual Reality (VR) is showing promise in healthcare1 and may be of value in rehearsing self-management tasks for patients with complex disease such as heart failure (HF). Patients with HF experience difficult life-style alterations, including the need to follow a sodium restricted diet.2 As part of the development of an advanced visualization laboratory to investigate patient self-management, we conducted focus groups with experienced home care nurses to identify opportunities for patient self-care that could be investigated using VR. In this effort, we use the results of the focus group to explore a proof of concept VR environment wherein patients can select food according to their sodium restricted diet and receive feedback on their choices.

Methods

We invited four experienced home care nurses to participate in a series of two, ninety-minute focus groups designed to identify self-management concerns for chronically ill patients. Food choice selection was identified as a common challenge for patients with HF on a restricted dietary sodium regimen. To investigate whether a VR environment could facilitate food selection behaviors for patients on a sodium restricted diet, we drew storyboards to depict individuals confronted with a range of high and low sodium food choices. The use of VR to replicate and facilitate this type of real-world food choice selection process has been validated in earlier research, and we will leverage that work.3 This environment will be built using Blender 3D and Unity3D engines for use with the HTC Vive™.

Discussion

Proof of Concept Design Considerations: we chose to develop a shopping experience in a grocery store environment within VR store ex in VR that will allow the user to select food for purchase, and review choices. Periodically, the user’s selected foods will be calculated for sodium levels and feedback will be provided to the user. Users will be able to exchange foods or continue with their current selections. Our user experience and VR environment will expand on prior work in its use of feedback to user choices and monitoring user responses. Using VR enables experimental and experiential benefits. Of note, all VR participants are exposed to an identical visual and auditory experience. As such, investigators are given complete control of the environment and its experimental variables. VR environments can also provide quantifiable data for behavioral analysis, i.e. every food choice and body movement could be calculated and recorded in a way that permits detailed analysis. There are notable tradeoffs to using a virtual environment. It is relevant to note that there would likely be no sense of smell or touch available in our VR environment. These senses would be valuable for a food selection task; nonetheless, similar research in diet and food choice has shown success without requiring these sensory stimulations.3 Another barrier to our proposed virtual environment arises from the limited resolution of VR displays. Currently, smaller text sizes are difficult to read, even for individuals with normal vision. To effectively navigate this challenge, another form of interface with the nutrition information may be required, which may in turn reduce the veridical experience for the user. Future studies conducted in this environment may support the clinician’s ability to identify whether a patient understands their prescribed sodium restrictive diet and determine which mode of feedback to food choice could best prevent sodium overload or hospital readmission.

Detecting and mitigating clinical guideline interactions in multimorbidity patients using computer-interpretable guidelines and AEOLUS

Alexandra Kogan¹, BSc; Mor Peleg¹, PhD; Samson W Tu², MSc

¹Department of Information systems, University of Haifa, Israel
²Stanford Center for Biomedical Research, Stanford University, Stanford, CA, USA

Introduction. Clinical practice guidelines (CPGs) provide evidence-based recommendations for single diseases while addressing prevalent comorbidities and side effects. In previous work, we developed a decision-support system with a Controller component that can detect and mitigate interactions among computer-interpretable guidelines (CIGs) by reasoning on the CIG knowledge using predefined interaction-management design patterns. Our goal-based method utilizes knowledge of drugs’ physiological effects and therapeutic usage to combine knowledge from CIGs. It incrementally detects interactions and plans non-contradicting therapies. The Controller algorithm [1] uses patterns to check consistency and respond to events such as data enquiries, diagnoses, adverse events, recommended medications, tests, and goals. The method utilizes existing standards and CIG tools, including the Fast Healthcare Interoperability Resources (FHIR) patient data model, National Drug File - Reference Terminology (NDF-RT), and the PROforma CIG formalism with its Alium knowledge-engineering environment and PROforma enactment engine. In this work we expand the sources of knowledge used by the Controller to include, in addition to CIGs and NDF-RT, a repository of drugs’ side effects. We demonstrate the use of a design pattern that interacts with the side effect repository using a case study of a diabetes Mellitus (DM) medication causing a recurrent Fungal Infection (rFI).

Methods. In this study, we linked the Controller to the Adverse Event Open Learning through Universal Standardization (AEOLUS) [2]. This resource contains standardized reports and pre-computed statistics derived from the US Food and Drug Administration (FDA) Adverse Event Reporting System (FAERS). AEOLUS contains information about the Proportional Reporting Ratio (PRR). We defined a drug-disease-interaction pattern that directs the Controller to search for any drug-disease interactions encoded in relevant CIGs, and if no interactions are found, send a query to the AEOLUS database with the RxNorm ID numbers of each of the medications that the patient is currently taking. The query returns possible side effects for each of the medications. After consulting with our Medical expert, we decided to include side effects that have a PRR>2. The Controller compares the side effects returned with the name and ID of the new diagnosis and presents the user with the medications that could be the causes or contributing factors of the new condition, as well as the PRR statistics. In addition, an Adverse Event FHIR object is logged in the system, with the relevant medication and condition.

To demonstrate the Controller’s reasoning with side effects and conclusion of adverse events [3], we represented in Alium the DM and rFI CPGs and analyzed a case of a patient with DM taking Metformin and Gliflozin (SGLT2 Inhibitor), who develops rFI. The CPGs do not reference SGLT2I as a potential contributing factor of rFI.

Results

![Figure 1. The Controller’s dialogue for a patient with DM (Metformin+Gliflozin) who develops rFI showing detection of fungal infection as an adverse event in the AEOLUS knowledge base](image)

Discussion. In this study we demonstrated the behavior of a Controller that can detect and mitigate drug-disease interactions, using a case study involving two morbidities (DM and rFI), where the second morbidity is a potential adverse event of a medication prescribed to treat the first morbidity. The system that was developed based on [1] was evaluated with ten 6th year medical students and was well received. The detection of the potential adverse event supplies the physician with additional information that is not present in the guidelines and might be missed otherwise. This allows for a better treatment for the patient.

Acknowledgement. This project has received funding from Israel Science Foundation grant 906/16.

Chronic Condition Symptom Enrichment from Electronic Health Records

Theresa A. Koleck, PhD, RN1, Suzanne Bakken, PhD, RN, FAAN, FACMI1, and Nicholas P. Tatonetti, PhD1
1Columbia University, New York, NY, USA

Introduction
Symptoms are a significant source of burden for patients living with chronic conditions, but remain understudied and poorly understood. Electronic health records (EHRs) offer an opportunity for longitudinal data-driven characterization of symptoms after chronic condition diagnosis. Our previous efforts to analyze symptoms of chronic conditions using structured EHR data have proved largely uninformative due to the over influence of symptom documentation related to emergency room (ER) visits (e.g., chest pain, dizziness) rather than the condition itself (e.g., fatigue). Therefore, the purpose of this work is to evaluate symptom enrichment in four common chronic conditions – chronic obstructive pulmonary disease (COPD), heart failure (HF), type 2 diabetes mellitus (T2DM), and cancer – via normalization.

Methods
We identified patients with ≥ 2 International Classification of Diseases, 9th and 10th Revisions (ICD-9/10), diagnosis codes on different days for COPD (490-492, 494, 496; J44), HF (428; I50), T2DM (250; E11), or cancer (140-209; C00-97), using structured inpatient and outpatient EHR data at Columbia University Medical Center from 2007 to 2017. For these patients, we extracted ICD-9/10 codes for 80 symptoms (780-799; R00-69) occurring after the initial date of condition diagnosis. We calculated the percentage of distinct patients with ≥ 1 code for each symptom by condition. We then generated 20 datasets of 50,000 randomly selected patients from the entire EHR population with ≥ 2 codes documented between 2007 and 2017. We used the mean and standard deviation of the percentage of distinct patients with ≥ 1 code from the random datasets to generate z-scores for each symptom. We compared top symptoms for the four chronic conditions before and after normalizing by population-level symptom documentation.

Results
The sample sizes and percentage of patients with ≥ 1 symptom documented for COPD, HF, T2DM, and cancer were n=18,219, 75.1%; n=29,569, 74.4%; n=52,837, 76.1%; and n=53,392, 53.0%, respectively. The mean percentage of patients with ≥ 1 symptom documented from the random datasets was 29.3%. The number of symptoms out of 80 that occurred at a significantly greater (Bonferroni corrected p<0.00016) percentage in the condition than in the population was 60, 57, 61, and 56 for COPD, HF, T2DM, and cancer, respectively. Table 1 shows the top 5 symptoms based on percentage before normalization and based on z-score after normalization.

Discussion
We determined enriched symptoms for COPD, HF, T2DM, and cancer after diagnosis from structured EHR codes by normalizing using population-level EHR symptom documentation. The percentages of patients with symptoms documented were higher for each chronic condition both overall and for the majority of individual symptoms compared to the randomly selected datasets. Normalization resulted in emergence of symptoms not traditionally associated with ER visits, including debility and nocturia. Of particular interest is the transition from chest pain to other malaise and fatigue as the top enriched symptom for cancer. While the magnitudes of the z-scores suggest the need for additional refinement of controls, normalization will be an essential step of our future symptom characterization analyses. A Review of Older Adults’ Personal Health Information Management Processes, Needs, Challenges, and Tools

Malgorzata Kolotylo-Kulkarni, PhD Candidate¹, Cynthia M. LeRouge, PhD¹, Deborah E. Seale, PhD²

¹Florida International University, Miami, FL; ²Des Moines University, Des Moines, IA

Introduction & Background. Patient access to, and effective management of their personal health information (PHI) are critical in supporting patients in their health management. Due to their growing healthcare needs, effective PHI management (PHIM) may be particularly helpful for older adults. In order to ensure effective PHIM and to provide functional PHIM technology, we need to have a thorough and comprehensive understanding of the idiosyncratic PHIM practices by the respective target groups. It is therefore critical to establish a comprehensive view of their practices and needs to examine whether older adults differ in their PHIM practices, needs and preferences from other age groups.

To tailor PHIM technology to an aged population, it is also important to explore whether the differences in older adults subgroups with regard to their healthcare needs and practices (for instance due to life transitions – retirement and associated with it insurance changes, caregiving – or adequately, requiring a caregiver) materially affect PHIM needs, challenges, and practices, and the implications on technology design. Notable subgroups include 1) consumers aged circa 50 to 69 years old (including baby boomers); and 2) the elderly - consumers of age 69 and above (presently The Silent Generation and The Greatest Generation).

While a few reviews of PHIM literature exist, not many have focused on older adults, and more so, none of them have provided an overall view of the various factors which play a role in PHIM. Literature related to older adults remains fragmented and does not provide a comprehensive understanding of PHIM among this subpopulation and its nuances. This study aims to address the need to better understand PHIM for older adults through a systematic literature review covering current empirical evidence of the practices and tools which older adults use for PHIM, their PHIM needs, and the challenges they face. We will address this purpose by answering the following research questions:

• What idiosyncratic PHIM attributes for an older adult subpopulation is revealed by the literature?
• Do the aspects related to PHIM differ across the two recognized age-related subgroups among older adults?

We adopt the Patient Work Model¹, which references 1) person-related factors; 2) socio-organizational aspects; 3) tasks carried out; 4) physical environment; and 5) tools used and information managed.² as comprehensive lens to organize extant findings and to establish current knowledge on the elements of PHIM by older adults.

Methodology. This study carries out a review of literature from 2008 to 2018, adopting adopt the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) model. The literature search process in our study consists of 2 stages: 1) systematic search using online databases; and 2) backwards and forward citation analysis of the full papers found during the search and subject to eligibility analysis. We have so far completed the first stage of this process, and have run a systematic search in 13 databases, with a keyword search of “health information management” OR “personal health information management”; OR “consumer health information management” in papers’ titles or abstracts. Inclusionary criteria incorporate: empirical papers published between 2008 and 2018, written in English, full-text available, peer reviewed, conference papers and abstracts, address one or both age subgroups, and examine one of the constructs in the Patient Work Model. Analysis of the literature is being carried out using qualitative methods according to the Patient Work Model and using Dedoose©.

Early Research Findings. At present stage of the study our review has identified n=15 papers. The final sample of articles is anticipated to provide a comprehensive view of the empirical evidence on PHIM by older adults and systematize it by the elements of older adults’ patient work system³. Preliminary findings indicate that PHIM by this population is highly complex in terms of the various environmental aspects: 1) older adults face particular challenges (e.g. having experiential health knowledge may impact their health information needs); 2) social and organizational support (such as training/education) are important for older consumers; 3) PHIM tasks they engage in are intertwined with health – and medication management activities; 4) PHIM activities occur in various locations, at home and away from home, (e.g. physician’s office or while traveling); 5) specific tool design features can be helpful for older adults (e.g. built-in aids to support information comprehension may help overcome age-related cognitive decline).

Discussion. Based on these insights, we aim to propose a research agenda with respect to the themes from the Patient Work Framework and from an overall perspective on the phenomenon.

Title: Longitudinal modeling of prescription refill records to predict medication use

Authors: Kimberley ES Kondratieff*, MS; Candace D McNaughton†, MPH, MD, PhD; Michael E Matheny*, MPH, MS, MD; Thomas A Lasko*, MD, PhD

Description of Work: A majority of Americans now live with chronic diseases requiring long-term management with medication. Successful therapeutic outcomes—reduction of symptoms, reduced morbidity and mortality—require adequate adherence to medication. Similarly, after-market exposure research requires good data on when patients were exposed to medications, including doses received and timing of doses relative to outcomes of interest.

Researchers often use pharmacy refill records as an objective proxy for medication-taking behavior because they are easy to obtain and lack reporting biases. Recent studies[1] suggest analyzing these records as trajectories of adherence instead of single-number summaries improves models predicting patient outcomes[2]. Yet models that predict patient medication adherence trajectories over time remain elusive, requiring months of patient medication records—which may not be available to clinicians—to make accurate predictions[3].

One possible reason for this shortcoming is the dichotomizing of medication trajectories required by current prediction methods. Herein we investigate the use of more granular trajectories to model the association between patient refill behavior and laboratory values over time.

Methodology: Our initial code development project created trajectories for a convenience sample of fifty patients. We then performed in-depth chart reviews for a small number of patients as spot checks on the trajectories’ validity. This included an extended review for one patient where medication lists present in clinical notes were compared to the patient’s calculated supply of medication on the dates of those notes.

For future research, we propose methods for computing granular refill trajectories for two medications (Synthroid and coumadin) and modeling the relationship between these trajectories and longitudinal changes in related laboratory values (TSH/T4 levels and prothrombin time, respectively). We will additionally quantify the level of adherence to these medications—determined from refill records—required to cause clinically significant changes in their associated lab values.

Initial Results: In the in-depth chart review over a single patient, 52% of notes with medication lists neglected to mention a medication the patient had supply for, and 50% of notes included a medication the patient did not have supply for. A spot check comparing another patient’s longitudinal refill pattern of warfarin with INR values over the same time period showed that refill persistence less than 70% tended to correspond with INR values below therapeutic range, suggesting the method’s potential utility.

Introduction

Development of just-in-time adaptive health interventions (JITAI) requires reliable technologies for accurate monitoring of physiological parameters in ambulatory settings. While many consumer-grade wearable sensors enable continuous and unobtrusive in-situ heart rate (HR) monitoring, their manufacturers do not sufficiently characterize sensor accuracy. Consequently, researchers independently evaluate HR sensors against electrocardiographs (ECG), using highly heterogeneous and at times inappropriate (1) methods. Thus, harmonization of relevant findings and comparison of sensors evaluated across studies are often limited. To ameliorate this issue, we identified and reviewed suitable methods, characterized their appropriateness for validating HR sensors against ECG, and proposed guidelines.

High veracity of HR estimates is critical for health state estimation, intervention efficacy, and patient safety. Resting HR (RHR) and HR recovery (HRR) are strong, modifiable predictors of cardiovascular health and mortality (2,3). Exercise at 75% of maximum HR helps restore executive function (4): overestimating HR by 10 beats (~5%) can decrease intervention efficacy. This degree of error may put cardiac rehabilitation patients at risk. Small inaccuracies in RHR and HRR estimates may lead to biased health state inferences when comparing patients to clinical benchmarks.

Methods

First, we identified HR sensor validation methods by reviewing literature found in PubMed and Google Scholar by using combinations of the following terms: heart rate, wearables, smartwatches, validation, assessment, accuracy, methods. We excluded articles that focused only on heart rate variability. Second, we applied the methods to synthetic and empirical data collected in an ambulatory setting (5) to rigorously characterize their accuracy and robustness.

Results and Guidelines

HR sensors are validated against ECG using a myriad of methods including various combinations of Pearson's and Spearman's correlation coefficients, t-test, intraclass or concordance correlation coefficients (ICC, CCC), Bland-Altman’s plots, limits of agreement (LoA), and descriptive statistics. Our results indicate that due to its statistical properties, CCC is a preferred method for assessing accuracy. For clinical relevance, LoA should augment CCC. Computing both estimates over a short window may enable using a regression to relate CCC and LOA to motion and HR strata resulting in a better characterization of sensor’s performance. Time lags required for signals’ alignment should be reported as they can jeopardize JITAI’s effectiveness.

Conclusion

The results suggest the importance of CCC, LoA, their regressions on HR strata and motion, and time lags in HR sensor validation studies.

Descriptive Comparison of Patient Cohorts with Cognitive Function Testing Results from Structured vs Free-Text Clinical Notes

Aaron Kub1 B.A., Amanda Yoho1 Ph.D.
1 IBM Watson Health Analytics Innovation

Methodology
We used the IBM Explorys Therapeutic Dataset of over 62M patients to identify those with Mini-Mental State Examination (MMSE) and Montreal Cognitive Assessment (MoCA) observations. 89,018 patients were identified as having taken any of the two assessments; of these, 16,355 had cognitive assessments from structured EMR fields, while 75,885 had assessments extracted from free-text clinical notes, and 3,204 patients had both types. We compared the age, shared diagnoses, and utilization of patients with any cognitive function testing record from a structured field to those with a record from a clinical note, observing that 3,204 patients were represented in both categories. We further broke down the cohort into those with MMSE structured (MMSE-S) or note (MMSE-N) data and MoCA structured (MoCA-S) or note (MoCA-N) data to compare diagnoses of depressive or neurodegenerative disorders, in order to assess possible impact to studies where cognitive functioning information is important.

Results
Four out of the five most frequent diagnoses for the structured and note cohorts were shared between the two - Depressive disorder, Hyperlipidemia, Hypertension, and Urinary Tract Infection. Uncommon in the two were Anxiety Disorder for the structured cohort and Vitamin D Deficiency for the clinical note cohort. Neurodegenerative diagnoses and depression disorder showed a split between the assessment-specific subgroups, which are outlined in Table 1.

<td>6.80</td>
<td>0.58</td>
<td>0.63</td>
</tr>
<tr>
<td>Note</td>
<td>10.80</td>
<td>0.16</td>
<td>0.67</td>
</tr>
</tbody>
</table>

We found that 70% of MMSE-S records originated from inpatient psychiatric encounters while 66% of MMSE-N were recorded during office visits. The majority of MoCA scores originated from office visit encounters with 56% and 86% for MoCA-S and MoCA-N, respectively. In total, 50% of all structured records came from inpatient psychiatric encounters and 73% of all note records came from office visits. The note cohort also skewed older, with the average age of patients for structured and note cohorts being 60 and 75, respectively.

Conclusions
In both MMSE and MoCA test types, neurodegenerative disease is more common in patients that have results recorded in clinical notes. Meanwhile, depression disorder is more common in patients with structured results. Suggestions to administer MMSE tests to patients with behavioral emergencies may explain this difference, especially in the context of the increased inpatient psychiatric care utilization observed in the data. Although the patient profiles had considerable differences, more research is required to determine whether these patterns exist in other real-world EHR datasets.

An Informatics Infrastructure for Remote Monitoring and Management of Symptoms in Cancer Patients

Gilad J. Kuperman, MD, PhD, Yeneat Ophelia Chiu, MHA, Margarita Rozenshtein, Melissa R. Zablocki, MPH, Claire E. Perry, Abigail Baldwin-Medsker, MSN, RN, OCN, Amandeep K. Dhani, MPH, Brett A. Simon, MD, PhD, Robert Daly, MD, MBA
Memorial Sloan Kettering Cancer Center, New York, NY

Introduction

Patients receiving chemotherapy frequently develop symptoms that, if not managed effectively, require treatment in emergency or inpatient settings. At our institution, 36% of patients started on antineoplastic treatment have an ED visit in 6 months. Previous studies have demonstrated that continuous monitoring of patients’ symptoms can improve outcomes including overall survival. We set about to implement an operational infrastructure to capture patient symptoms on a daily cadence and support the workflows of the dedicated team assigned to monitor and manage these symptoms.

Methods

This work was completed at a single large comprehensive cancer center. Clinical experts developed an interactive questionnaire to capture 15 symptoms from high-risk patients beginning chemotherapy (pain, fatigue, nausea, etc.). The technical components of the infrastructure are: (i) a risk stratification engine that uses ~400 clinical variables to identify patients most at risk for requiring an emergency room visit within 6 months of initiation of therapy, (ii) electronic features that notify the physician that the patient is eligible for -- and allow the physician to enroll the patient in -- the program, (iii) a cohort manager application that keeps track of the patients who should be receiving a daily survey, (iv) a questionnaire driver, housed in our internally developed patient portal, that makes the questionnaire available to the patient, (v) a notification engine that sends electronic messages to the clinical team about concerning symptoms, (vi) a workflow application that allows the clinical team to review symptoms and the list of enrolled patients, and (vii) interfaces to the EHR to create a patient list and other workflow support.

Results

A pilot program went live on October 15, 2018. As of January 23, 2019, 28 patients had been enrolled in the program (average age 65; 36% male). In that time, 1,350 daily questionnaires were sent to patients of which 840 were completed (62%). 548 questionnaire responses included concerning symptoms. The technical platform is performing as intended though minor remediation has been required to assure that the various components interoperate robustly. A dedicated design team is examining user needs to identify opportunities to enhance the workflow support tools.

Conclusion

We were able to architect an environment to deliver questionnaires to patients on a daily basis. The optimal workflows to support capture and management of patient data still are being explored.

Improving Clinical Decision Support System by Analyzing Prognostic Factors of Colorectal Cancer Stage IV Patients

Hyunjin Kwon¹, Youngho Lee, PhD¹, Jinhyeok Park, BS¹, Sunjin Sym, PhD², Jeong-Heum Baek, PhD²
¹Gachon University, Gyeonggi-do, Republic of Korea; ²Gil Medical Center, Incheon, Republic of Korea

Introduction

Watson for Oncology (WfO) is a medical software created by IBM that combines Big Data and Artificial Intelligence. It is one of the Clinical Decision Support System that provides a suggestion of treatment to the oncologists based on past clinical cases, medical journals, and specialized data. WfO's treatment suggestion shows a high concordance rate with clinicians but shows low concordance rate to metastatic disease. This is because WfO has a critical flaw that does not reflect the EMR data. Thus, this research was done as preliminary research on improving the performance of WfO. To increase the low concordance rate of WfO, not only general guidelines but information based on actual EMR data is needed. To acquire the information from the actual EMR data, we analyzed the prognostic factors that affect the overall survival in patients with stage IV CRC.

Method

In this study, we used the EMR data of Gil Medical Center where first adopted WfO in Korea. We retrieved EMR data of 229 patients with stage IV CRC for analyzing prognostic factors of survival rate. We analyzed the median overall survival using the Kaplan-Meier method. We also identified the prognostic factors which affect the survival rate by using the Cox proportional-hazard models and tested the proportional hazards assumption using Kaplan-Meier curves as well.

Result

The median survival was 1.75 years. The univariate analysis demonstrated that age, number of harvested lymph node, positive rate from harvested lymph node (Ratio), lymphatic invasion, post-operation and chemotherapy (Post OP Chemo) were significant factors affecting survival (p < 0.1). The multivariate Cox regression analysis revealed that age, Ratio, and Post OP Chemo were associated with survival (Table 1).

</tbody>
</table>

Conclusion

To overcome the limitation that WfO does not reflect the EMR data, the information based on analyzing real EMR data is required. In this study, we have identified the prognostic factors affecting the survival period of patients with stage IV CRC. On multivariate analysis, we demonstrated that age, Ratio, and Post OP Chemo were prognostic factors for overall survival of stage IV CRC. In future studies, we expect that if this result is applied to WfO, it will be possible to offer an improved treatment suggestion in the field of stage IV CRC.

Addressing the Medical and Business Challenges in the Creation of the CureCloud™, a Prospective, Linked, Direct-to-Patient Multiple Myeloma Registry

Steven Labkoff, MD, FACP, FACMI, FAMIA, Christopher Williams, Shaadi Mehr, PhD, MS, Eugene Hui, Devon Bush, Scott Longley, Esme O. Baker, Simone Maiwald, David Voccola, Charles Tirrell, Leon Rozenblit, JD, PhD

Multiple Myeloma Research Foundation, Norwalk, CT; Broad Institute of MIT and Harvard, Cambridge, MA; Prometheus Research, New Haven, CT

Introduction: Understanding the onset, progression, and outcomes of patients with multiple myeloma requires linked data from disparate sources. The CureCloud™ is a follow-up project to the Multiple Myeloma Research Foundation’s landmark 1043-person CoMMpass study [1, 2]. The CureCloud Direct-to-Patient Registry (CC-DTP) (NCT03657251) is a prospective, longitudinal, linked data set. The CC-DTP’s goal is to accumulate data on 5000+ multiple myeloma (MM) patients to better understand and characterize this disease and to provide a comprehensive data view for patients, researchers, and clinicians [3]. CureCloud is currently slated to be a $20M effort, approximately $3M of which is earmarked for the informatics infrastructure.

Methods: After IRB approval, workflows were designed to obtain four types of data, patient self-reported data, EHR abstractions (from Cota Healthcare and Tempus), myeloma-specific gene panel sequencing (from the Broad Institute), and exome genomic sequencing (from Tempus) for the initial instantiation. Patients are solicited to join the program in multiple ways: direct outreach via social media, direct-to-patient emails from the MMRF database, and via direct outreach to patients via a partner’s (Tempus) outreach to treating MM physicians and their patients. Developing an overall data architecture became necessary to ensure the complex design with many partners would satisfy all intended use cases. Working with Prometheus Research, a comprehensive work- and dataflow architecture was designed and implemented [3]. This architecture considered major issues such as patient consent, the obtaining and processing of biospecimens for sequencing and biobanking, electronic health record (EHR) data abstraction, and data privacy and stewardship concerns. The final architected program will support large-scale data collection, analysis and reporting.

Results: The overall architecture of the CC-DTP, once designed, was tested with 25 pilot patients. These patients were selected to represent diverse geography in order to test the speed and completeness of the Cota EHR abstraction process. Patients successfully navigated informed consent and biospecimen donation workflows. Pan-cancer genomic and a MM multi-gene panel sequencing were performed; those data were matched with the EHR abstractions and entered into the registry. By late 2019 or early 2020, a planned, CLIA-approved patient report and customized visualizations will be provided back to participants. At the time of this writing, the CC-DTP contains 73 patients and is expected to grow to over 5000 over the next 5 years. Additional matched data sources are planned, including proteomic immune data from existing biospecimens, validated patient-reported outcomes and medical insurance claims. Because the CC-DTP is serving 3 distinct end-user groups, careful segregation of access privileges to preserve patient security and privacy is critical.

Conclusion: The creation of a nationwide, prospective, multi-data type, direct-to-patient registry requires thoughtful architecture. This architecture defines how data will be made available to the right end users with proper attention to patients’ privacy. Researchers will have a comprehensive data set upon which to study disease progression prospectively, to identify new biomarkers, validate therapies, and test new hypotheses to find a cure.

MPath Non-NGS: Software for Analysis of Clinical Fragment and Qualitative Polymerase Chain Reaction (PCR) Assays

Sean Lachhander, MS, John Ziegler, MS, Shoham Das, BS, Paulo Salazar, BS, Nana Mensah, MT, MBA, Ivelise Rijo, BS, Lissette Fernandez, MPH, Lin Dong, BS, Daniela Elezovic, BS, Ahmet Zehir*, PhD, Maria Arcila*, MD

1Department of Pathology, Memorial Sloan Kettering Cancer Center, New York, NY

Abstract
Molecular diagnostic laboratories are a critical part of patient care and are inundated with paper records. Every test, sample, and record increases complexity and makes it more difficult to meet pressing deadlines with accuracy. Furthermore, keeping paper records renders data mining virtually impossible. MPath Non-NGS is a comprehensive set of web-based applications that enables gathering, analysis, reporting and mining of a series of Non-NGS assays performed in MDS at MSKCC.

Introduction
While the next-generation sequencing (NGS) based assays have inherent support from a computational and informatics point of view, the traditional Non-NGS assays have not benefited from this digitization. Here, we describe our implementation of MPath Non-NGS, a set of software systems designed to address this deficiency, at the Molecular Diagnostics Service (MDS) in the Department of Pathology at Memorial Sloan Kettering Cancer Center (MSKCC).

System Overview
MPath Non-NGS software suite targets all stages of clinical workflows, integrating into the laboratory information management system (LIMS), and addresses the needs of lab technologists and supervisors with tools for efficient test setup, result tracking, and supervisor/QC (quality control) review. Subsequent stages of the assays are handled via a molecular result analysis and sign-out application. On these applications, molecular fellows and attending pathologists can view, annotate, and analyze the results of each clinical sample. Some key features include: (1) automated graphing of discrete Short Tandem Repeat (STR) test values and tools for calculating chimerism, (2) one-click human-readable annotation and reporting of high-density single nucleotide polymorphism (SNP) array results based on post commercial software analysis, (3) retrieval and curated views of historical results on a per-patient basis, and (4) automated diagnosis of HER2/IQFISH samples. Once each sample is reviewed, results are stored and indexed for future retrieval and clinical report generation.

Figure 1: Sample result visualization for STR testing
The applications are built utilizing a modern software development stack that includes a non-relational database deployment, python web APIs, and an intuitive web user interface built with Javascript/ES6. MPath Non-NGS is currently deployed on-site at version 2.4 and supports the processing of approximately 750 samples per month across 18 clinical assays. In total, MDS staff has used MPath Non-NGS to process over 26,000 samples in the past three years. Utilizing the software suite has shown to decrease the amount of human errors seen in assay workflows, and has resulted in significant time savings for lab technologists and reviewers. Overall, we are able to report results in an average of two days sooner versus using traditional written records, and have seen a 76% reduction in paper records. Additionally, lab technologists save over an hour per batch of samples. The next steps include supporting additional assays in the MDS and using back-end APIs to share the data across the institute.

Conclusion
In this presentation, we will walk-through typical workflows from the perspective of various users, including molecular pathologists, analysts, lab technologists, and supervisors. We will also provide an understanding of the software development processes and frameworks utilized to build these systems, as well as discuss some of the conclusions drawn while implementing at a large-scale in MSKCC.
Challenges of Data Abstraction to Characterize Contrast Media Reactions and Identify Potential Risk Factors in a Cancer Patient Population.

Cesar Lam, MD1; Christina Eldredge, MD2; James E. Andrews, Ph.D.2; Randa M. Perkins, MD1
1H. Lee Moffitt Cancer Center Research Institute, Tampa, Florida; 2University of South Florida, School of Information, Tampa, Florida

Introduction: Contrast imaging plays a pivotal role in the diagnosis, staging, and treatment of cancer. Cancer patients are frequently imaged to assess response to established complex treatment regimens and, in some cases, to continue in clinical cancer trials. Cancer patients may be at an increased risk for contrast media reactions (CMRs) due to the frequency of exposure to contrast media during these exams1. Additionally, these patients often undergo multiple treatment regimens, which may cause metabolism and immune system changes, potentially placing them at a greater risk for developing CMRs. We sought to use a data-driven approach to determine potential risk factors for these reactions; however, several challenges to automated data abstraction were identified. Furthermore, evaluation of current contrast allergy notes lacked the standardized CMR diagnostic criteria, recommended by the American College of Radiology (ACR)2.

Objective: To identify and address challenges in data abstraction to characterize potential risk factors in patients undergoing imaging at a cancer center.

Methods: The dataset included patients imaged in the radiology department at a cancer center between 2013 and 2017. The quality improvement department registry of CMRs occurring in this time period was used as the basis of the query. The following data points were queried in electronic medical record (EMR) system for the cohort of patients in which CMRs had occurred during the time period: (1) demographics; (2) cancer type and location; (3) treatment; (4) time from first treatment to CT scan reaction date; (5) allergies at time of CT scan reaction date; (6) creatinine at CT scan reaction date; and (7) medications at CT scan reaction date. These factors were collated and descriptively analyzed. To address gaps in data elements, event contrast allergy event notes were also evaluated.

Results: Between 2013 and 2017, a total of 122,997 contrast enhanced CT scans were performed. During this 5 year period, 150 CMRs were documented. The cohort median age was 67 years old with 52% female. Multiple CMRs occurred in 6 patients. The distribution of cancer types were as follows: gastrointestinal 40 (27%); genitourinary 30 (20%); soft tissue 17 (11%); breast 17 (11%); gynecological 8 (5%); endocrine 8 (5%); lymph node 6 (4%); oral 4 (3%); and 2 (1%) were unknown. In 16 reactions (11%) cancer descriptors (data elements) were missing. In the dataset, the abstraction method created duplication of CMR events in patients having multiple cancers (13 patients). Additionally, in 17 patients, no EMR data was identified. Finally, each queried data point was abstracted as a separate Excel spreadsheet making it difficult to analyze without merging it manually.

Conclusion: The key challenges to identifying and characterizing CMRs include lack of a systematic/standardized approach to data collection, duplication of events, and missing data points within the EMR system. Furthermore, the queried output of several pages of data necessitated the formation of a new data spreadsheet manually abstracted, increasing the potential of data entry error.

Future Work: We will analyze the etiology of missing data points and correct systemic flaws. Furthermore, we will evaluate and improve the current data collection and abstraction process using a standardized data abstraction tool with the aim of creating a single comprehensive data set.

Towards a learning health system for contraception care: Representing knowledge for tailored clinical practice feedback

Zach Landis-Lewis, PhD, MLIS1, Veena Panicker, BDS1, Dahee Lee, MHI, RN1, Marisa Wetmore, MPP2, Roger Smith, MD2, Michelle Moniz, MD2
1University of Michigan Medical School, Ann Arbor, MI, 2Program on Women's Healthcare Effectiveness Research, Ann Arbor, MI

Introduction
Learning health systems possess advanced knowledge management capabilities that refine knowledge, often in computable forms, through learning cycles. A key step of the learning cycle is the transition from knowledge to practice (K2P), in which refined knowledge is used to generate interventions to influence healthcare professional practice. Clinical practice feedback, delivered via quality dashboards and reports, is a widely used strategy to change practice with a growing evidence base. Using the learning cycle as a conceptual framework, we explore the development of computable knowledge for learning about clinical practice feedback interventions, applied to the implementation of a new practice of offering immediate postpartum long-acting reversible contraception (IPLARC) to patients. Clinical practice feedback about IPLARC includes hospital-level performance measures based on percentages of eligible women who are a) offered contraception, and b) provided with IPLARC at time of childbirth.

We draw from two domains to explore a foundation for computable knowledge in tailored practice feedback: user stories and behavior change interventions. In a prior study we explored the affordances in adopting user stories to manage requirements for the design of 11 tailored performance feedback messages with a collection of 9 user stories for IPLARC. User stories associate a specific software function (what) with a specific user (who) and a rationale (why). Tailored feedback messages could be matched with the recipient’s characteristics, specified in user stories, to deliver appropriate and actionable feedback. Behavior change interventions are “policies, activities, services, or products designed to induce or support people to act differently from how they would have acted otherwise”2. Components of behavior change interventions are specified in the Behavior Change Intervention Ontology (BCIO)2.

Methods
To understand the potential of BCIO for developing and managing computable knowledge about tailored feedback messages, we conducted a preliminary mapping exercise that related IPLARC user stories with BCIO constructs.

Findings
User stories were associated with the following BCIO constructs: Content (n=9); Population (n=7); Engagement (n=2) and Delivery (n=2). For example, the user story "As an attending physician, I want to receive a performance feedback report within the body of an email so that I can spend less time opening attachments" was mapped to Population (Context), Delivery (Intervention) and Engagement (Exposure) constructs. BCIO constructs were useful for organizing requirements and recognizing opportunities to formally specify tailored feedback message knowledge, based on individual and situational difference characteristics captured in the user stories.

Conclusion
User stories and BCIO may be useful as a foundation for computable knowledge representations of tailored performance feedback reports in learning health systems. Future work is required to understand implications for their management at large-scale.

Using EHR Data to Evaluate CPOE Safety
Angela L. Laurio, DrPH, RN, Aaron S. Dietz, PhD, Jean M. Scott, MS, CPHIMS, David C. Classen, MD, MSc
1Informatics Patient Safety, U.S. Department of Veterans Affairs, Washington, DC
2University of Utah, Salt Lake City, UT

Abstract
In 2018 the VA piloted the University of Utah EHR Flight Simulator CPOE evaluation tool at three hospitals to assess medication ordering safety and found it insightful, but too time and resource intensive to scale across all 130 hospitals on a recurring basis. This study demonstrates the feasibility of using EHR data to automate and scale CPOE evaluation across the enterprise as a more efficient and sensitive alternative to simulation using fewer resources.

Introduction
Despite the implementation of CPOE, medication errors still occur, often during order entry. The University of Utah EHR Flight Simulator uses simulated order entry to evaluate CPOE performance. The Department of Veterans Affairs (VA) piloted the Simulator at three hospitals in 2018 and found it took 4.5 to 6.5 hours per facility to complete entry of 48 orders. Orders were entered into a test system by one to two providers per site. This study demonstrates the feasibility of using EHR data to automate and scale CPOE evaluation across an enterprise as a more efficient and sensitive alternative.

Methods
The VA Corporate Data Warehouse contains EHR and system setting data. Some settings in the VA EHR are customizable and configuration varies between hospitals. Allergies, inpatient medication orders, and order checks were analyzed for the period 1/1/2017 to 12/31/2018 for the three hospitals that participated in the Simulator pilot. Overall order check counts and reasons were examined. Order check rates were compared for four allergy-drug pairs between simulated order entry and EHR data. Allergy, medication orders, and order check counts were generated for each hospital (Table 1).

Results
Data for 154,438 medication orders and associated order checks from the three hospitals were retrieved in under four minutes. Allergy-drug interaction was the third most common reason for an order check to “fire” (Figure 1). Analysis found a higher order check rate for allergy-drug interaction in EHR data than with simulation at one hospital, but lower order check rates at the other two (Figure 2). Drug classification prevented some order checks from firing, e.g. Sulfa classified as an antibiotic vs. an antacid. Disabled system settings could prevent order checks from firing, but no cases were identified in these data.

</tbody>
</table>

Conclusion
Data collection time was reduced by 99% using EHR data versus simulation, while the number of orders analyzed increased by over 3000%. Use of EHR data provides a more realistic assessment of CPOE performance over simulated order entry using test accounts. Further analysis is needed to determine why some order checks didn’t fire and to assess patient outcomes.

GeoService: Bridging Clinical and Public Health Informatics

Adam M. Lee, MBA
University of North Carolina, Chapel Hill, NC

Introduction

The North Carolina Translational and Clinical Sciences (NC TraCS) Institute set to establish a service, dubbed “TraCS GeoService”, for researchers at the University of North Carolina - Chapel Hill offering geocoded information along with other clinical data extracted from the UNC Healthcare system Epic electronic health record. This service has three aims 1) Link census data associated with subjects about their census tract from the available variables. 2) Deliver “as the crow flies” distances between a subject’s coordinates and various UNC locations using the Haversine formula. 3) Derive longitudinal data about a subject’s geographical location and census data tracking the number of moves, distance moved, and frequency.

Methods

TraCS GeoService implemented geocoding with the following methods:

1) Reference data are updated and verified. SAS provides street address files for download on a yearly basis, and ZIP codes quarterly. The census demographic data are loaded as of 2014.

2) Addresses are formed and extracted from the clinical data warehouse. Addresses are not cleaned or altered, but invalid ZIP codes are omitted, which remove non- U.S. locations.

3) SAS code executes to process the extracted addresses into batches and runs SAS PROC GEOCODE on each batch.

4) Each batch of addresses are geocoded and imported into the clinical data warehouse as they process, resulting in latitude, longitude, and Federal Information Processing Standards (FIPS) Census Tract codes.

5) Linkages are completed ad hoc for researchers’ data provisions.

Researchers may utilize geocoded data as additional data attributes for data sets, and/or use geocode or census data as inclusion/ exclusion criteria for cohort identification, i.e. recruitment cohorts may require subject to be within 50 miles of a specific facility or target patients in tracts with a certain percentage indicated as ‘Below Poverty Level’

Results

The geocoding process results in street level matches of 74.4% of the population, with three categories for accuracy, ‘Accurate, Minor Error, and Major Error’ matches with matching percentages found in Table 1. The Zip level matches account for 25.5% of the population, and is the general default for non-matches due to poor address formation or lack of information.

Discussion

The primary discussion for the TraCS GeoService is the omission of cleaning addresses. While accuracy could increase with properly collected and formed addresses, it was crucial to the service that data remain as natural as possible as extracted from the clinical system. Notably, these results facilitate the capabilities of each aim and allows researchers to associate clinical data with socioeconomic data. Additionally, results of this process permit further capabilities such as identifying urban/rural areas, and allows tertiary linkages such as environmental data.

Conclusion

Overall, TraCS GeoService established reliable processes for geocoding and meaningful data linkage from census data to add levels of information to patient populations enhancing UNC research informatics pipeline.
How Personalized Are Personalized Order Sets? Measuring Variation in Physician Use of Electronic Order Sets

Jaehoon Lee, PhD1,2; Nathan C. Hulse, PhD1,2

1 Intermountain Healthcare, Salt Lake City, UT; 2 University of Utah, Salt Lake City, UT

Introduction Computerized Provider Order Entry (CPOE) systems and electronic order set libraries are key components in modern EHR systems that support care standardization by reinforcing best practice through templates. However, enterprise standardized order sets often do not cover ad-hoc needs, exceptional cases, and other provider-specific needs. Personalized order sets (‘favorites’) are designed to address these issues and have been implemented in several CPOE systems, affording users flexibility to modify contents from the standard order sets. An important management point in maintaining these libraries is to control personalization within the originally intended use of order sets so as to prevent clinical misuse, avoid potential safety issues, or the proliferation of redundant content. As a baseline study to better address this issue, we studied two research questions: 1) How are our providers tailoring standard and personalized order sets during routine use? and 2) How can we quantitatively measure such variation?

Methods To measure variation from library templates during CPOE usage, we modeled order set use data set as two character strings: 1) the first string consisting of characters for each orderable item in an order set, and 2) the second one consisting of characters for each representing order instances derived from the order set. With this representation strategy, a gap between the two strings is indicative of whether an element of an order set was used as designed or not. To measure the gap, we adopted the concept of Hamming distance, which is a count of differences in positions for which the corresponding symbols are different between two strings of equal length 1. We normalized the measure by dividing by the overall size of the individual order sets as formulated below.

Hamming distance = #orderable items weren’t actually ordered / size of order sets (# of items)

We used data from a CPOE system in our enterprise data warehouse at Intermountain Healthcare. In the CPOE system, providers can order from standard order sets created by clinical departments but can also choose to create and order from personalized order sets that they create themselves to tailor to their needs. We extracted 1,244,950 order sessions (Feb 2015 – Feb 2019) and divided them into two user groups: standard (933,456) and personalized (311,494) in 28 clinical categories. We excluded very small order sets and those ordered less than 100 times. In mapping orderable items to character strings, we only included those are in prechecked status by default.

Figure 1. Distribution of Hamming distances by order sets (colored by clinical category) shows clearly distinguished pattern of standard radiology order sets (ranges 0.5-1), compared to the rest clustered around 0-0.4.

Conclusion Average Hamming distance of personalized use was 0.23 whereas that of standard is 0.306. Our findings are 1) Use of standard radiology order sets exhibited wide levels of variation in use. 2) Excluding that, there was no significant difference in variation during the use of standard and personalized order sets, and 3) The size of order set templates has no strong correlation with overall variation during order set use. Since the aggregation used in this study has limitations, we will conduct deeper analysis at the level of individual order sets, specialties, and providers.

**Integrated Research Information for patients (IRIS): Creating a Patient Centric Clinical Trial Experience**

Vincent Lee, MBA; Cathy Knowlton, BS; Sai Sindhu Kurra, BS; James White, BS; Katherine Luzuriaga, MD; Jomol Mathew, Ph.D

University of Massachusetts Medical School, Worcester, MA.

**Introduction:** Timely accrual is a challenge for many clinical trials. In a study of 787 phase II/III adult National Clinical Trial Network sponsored trials launched between 2000 and 2011\(^1\), Bennette *et al.* reported that 18% of the studies closed with low accrual or were accruing with less than 50% of target three years or more after initiation. These non-acquiring trials consume resources for setup and operation without contributing to research findings. Lack of awareness and timeliness of information and misconceptions about clinical trials on the part of prospective patients have been attributed to be amongst the root causes of the problem\(^1\). The main public source of clinical trial information (clinicaltrial.gov) contains complex scientific language that is often difficult for the general public to comprehend\(^2\). Additionally, the lack of tools that connect research teams to interested subjects has also remained a significant barrier to clinical trial accrual. ResearchMatch and Trials Today\(^2\) have made significant improvements. A complementary clinical trial portal that can be locally installed at sites with the latest trial information in simplified language would be the key to raising awareness and engaging patients and providers in catalyzing clinical and translational research.

**Methods:** We leveraged the basic principles of the **Attention, Interest, Desire, and Action** (AIDA) model of advertising and marketing to develop a universally adoptable platform – **Integrated Research Information for patients** (IRIS)- for clinical trial sites to advertise trials to patients, connect them to study teams and analyze the site traffic information. Each trial listing can be composed of the **most critical information relevant to patients** such as trial description in layman’s terms, eligibility, time commitment, and required study procedures. Prospective patients can perform **keyword searches** based on a disease group, specific conditions or provider names and retrieve the most relevant trial information. Furthermore, the system **directly connects patients with study teams** by allowing patients to explicitly express their interest in certain trials and provide permission to be contacted by the study teams. The platform’s capability to **integrate with Clinical Trial Management Systems** (CTMS) allows each active trial to be synched up with CTMS so that the most up to date information is available to patients and providers. Finally, patients are encouraged to register and sign up to receive email notifications when new clinical trials open that match their area of interests, thus increasing patients’ ability to discuss trials with their providers when making clinical care decisions if necessary.

**Results & Discussion:** We have currently launched the IRIS platform (conqueringdiseases.org) for all trials at the University of Massachusetts (UMMS). We have established baseline recruitment information to our current trials and will be collecting overall recruitment data from all trials and recruitment rates for selected trials for a year. Data will be used to compare baseline and post-launch enrollment to assess impact. We are currently designing patient and provider surveys and organizing focus groups to obtain feedback from users to further improve the system. Our future development plans for IRIS include volunteer registry, alerting patients who have expressed interest in a disease area about new trials, geographically oriented trial matching, social media based content presentation and EHR integration of IRIS for providers to search for trials that suite their patients.

Dialog Act Classification (DCA) for Automated Classification of Online Health Communities

**Young Ji Lee, PhD, RN**, Grace Campbell, PhD, RN, **Victoria Han**, Hyeju Jang, PhD

1University of Pittsburgh, Pittsburgh, PA; 2University of British Columbia, Vancouver, Canada

**Introduction**: Patients and caregivers are using online health communities (OHCs) to seek and follow information from others who have undergone similar experiences. By learning about the topics discussed on OHCs, health care providers can prioritize patients and caregivers’ concerns and are able to develop interventions for the target population. Our long-term goal is to design an automated system to classify needs of patients and/or caregivers written in the OHCs; however, there is no framework for guiding system development. As a first step, we applied the discourse dialog act classification (DCA) to develop the framework for the system.

**Method**: Data comes from the OHC of ovarian cancer sponsored by the American Cancer Society Cancer Survivors Network (http://csn.cancer.org). The forum contains approximately 55,000 posts written by 2,000 users between 2006 and 2016. We selected initial posts of all users, then excluded the ones that were replies to other posts. The process resulted in a dataset of 856 posts in total. We manually identified whether a post was written by a patient or a caregiver. Then, these posts were classified by 12 needs based on the literature (Physical, Psychological/emotional, Family, Social, Interpersonal, Practical, Daily living, Spiritual, Health information, Patient – clinician communication, Cognitive, Miscellaneous), and only included postings with the most common need (health information need; n=447). Each post was broken down the unit of sentences. Two annotators (YL, VH) annotated each sentence with a dialog act classification, Requesting Information, Explaining Information, Expressing an Opinion, Describing an Experience, Providing a Suggestion. Inter-rater agreement was measured between the two annotators using F1 score, a measure of a test’s accuracy.

**Result**: Among the 447, 229 were written by patients and 179 were written by caregivers. Inter-rater agreement of the classification was 0.51. Most of the disagreement came from “explain information” and “describing an experience”. “Request” was most agreed upon. Main difference between the patient posts and the caregiver posts was the sub classification of describing an experience. Patients mostly discussed their own experience (1,213 vs 42) while caregivers discussed another’s experience (808 vs 45) compared to their own.

| Table 1. Result of Dialog Act Classification on Online Health Community among Ovarian Cancer |
|----------------------------------|--|------------------|
| Category                        | # of sentences (patients) | # of sentences (caregivers) |
| Requesting Information           | 473                        | 283                      |
| [1] why this is happening        | 268                        | 172                      |
| [2] what to do                   | 205                        | 114                      |
| Explaining Information           | 1006                       | 401                      |
| Expressing an Opinion            | 107                        | 45                       |
| Describing an Experience         | 1,255                      | 45                       |
| [1] self-experience              | 1,213                      | 808                      |
| [2] someone else’s experience    | 42                         | 853                      |
| Expressing Emotion               | 114                        | 44                       |
| [1] what happened/is happening   | 86                         | 4                        |
| [2] what is going to happen      | 29                         | 48                       |
| Suggestion                       | 2                          | 0                        |
| Other                            | 184                        | 117                      |

**Conclusion**: Only a moderate agreement between two annotators suggests that dialog acts must be clarified before moving forward, particularly “describe” and “explain”. Difference in subcategory between patient and caregiver posts suggests separation between the two is necessary for accurate prediction in the computational model. “Suggestion” category did not use very few times and it will be a category extremely hard to predict when using automated classification. This is the first step of the algorithm development, and DCA will guide us what to consider for the algorithm development. We will improve our classification framework for the future algorithm.

A User-Centered Model for Electronic Patient-Reported Outcomes Visualizations in Clinical Practice
Cynthia LeRouge, PhD¹², Jenney Lee, MA¹, Courtney Segal, BA¹, Elizabeth Austin, MPH¹, Danielle Lavallee, PharmD, PhD,¹
¹University of Washington, Seattle, WA; ²Florida International University, Miami, FL

Introduction: Clinical integration of Patient Reported Outcomes (PROs) augments routine healthcare, quality improvement initiatives, and population health management with direct insight into the patient experience. As use of PROs increases across healthcare settings, there is a need to develop electronic PRO (ePRO) tools that provide patients the means to answer PRO surveys electronically, efficiently integrate data into clinical workflows, and incorporate effective mechanisms (e.g., visualizations) for reporting PROs to providers. Indeed, many providers perceive ePROs as a potentially valuable addition to augment their patient care processes if it meets preferences for reporting visualizations and if ePRO workflow is streamlined. Robust literature exists to guide the design of visualizations in other domains, but available models do not adequately address considerations specific to the unique nature of ePRO reporting in clinical practice. The objective of this qualitative study is to develop a stakeholder-informed model of critical design considerations for ePROs visualizations that support successful clinical integration of PRO data. This model will assist both ePRO developers and implementation teams in key decisions regarding the content, design, and functions associated with ePROs across a healthcare system.

Methods: As part of a larger project on health system governance, implementation, and reporting of ePROs, our multidisciplinary team performed a review of published literature on reporting and visualizations for ePROs in clinical settings (n=82 manuscripts). We then performed key informant interviews with 20 providers who had experience using a wide range of PROs, using a semi-structured interview guide to explore providers’ design needs and preferences for ePRO reporting. Interviewees spanned 11 medical and surgical specialties at a large academic medical center, making this endeavor the broadest cross-disciplinary examination of PROs use to our knowledge. Interviews were recorded and transcribed. The literature was coded inductively (open coding) for insights about ePRO reporting. Emergent themes pertained to report content, functionality, and visualization design. This analysis formed an a priori coding schema for the interview data, with codes added as additional key concepts emerged. Purposive, axial analysis of the combined literature review and interview code sets resulted in themes supporting the components of our ePRO reporting design model. Constant comparison methodology and 100% code review (by a non-coder) was used to establish rigor and enhance validity for all qualitative analysis.

Findings: Analysis of the literature and key informant interviews resulted in 12 key themes comprising three critical domains related to 1) data and information (i.e., what type of data is provided), 2) system function and interactions (i.e., which capabilities are provided), and 3) presentation (i.e., how data is visually represented), for ePRO tools. Our integrated framework is summarized in the figure below. Details associated with each of these themes highlights key commonalities where standardization is possible as well as situational nuances where flexibility may be needed.

Conclusion: Our findings reveal 12 core areas that providers consider critical to the usefulness and usability of ePRO reporting tools. The integrated framework we propose represents an important contribution to the PRO literature by highlighting common targets for ePRO tools as well as key points of customization needed to support various specialties and provider preferences. Findings also help to position ePRO visualization design among human computer interaction literature related to health informatics. This work examines providers as stakeholders in designing ePRO reporting tools because as “front line” users they are key to successful clinical integration of ePROs. Future work should address the needs and preferences of additional stakeholder groups (including patients). Future work should also consider the applicability of these findings across other medical and surgical specialties.

Data Requirements for a Patient-Centered Learning Health System

Lysanne Lessard, PhD1, Antoine Sauré, PhD1, Agnes Grudniewicz, PhD1, William Gardner, PhD, MS, AB1,2, James King, MSc, MD, FRCP1,2, Wojtek Michalowski, PhD1, David Murphy2, Kathleen Pajer, MD1,2, Elyse Schipper3, Sinthuja Suntharalingam, MD, FRCP1,2, Raphaël Ménard-Grenier1, Michael Cheng, MD, FRCP 1,2
1University of Ottawa, Ottawa, Ontario, Canada; 2CHEO, Ottawa, Ontario, Canada; 3Parent’s Lifeline of Eastern Ontario, Ottawa, Ontario, Canada

Introduction
This research is part of an ongoing effort aiming at transforming healthcare organizations into learning health systems (LHSs)1. LHSs create organizational and technological structures that can leverage the vast amount of patient data stored in electronic health records (EHRs) to improve the safety, efficiency, and effectiveness of traditional health systems. Despite the widespread acknowledgement that LHSs should ultimately improve patient outcomes, current models of LHSs are not truly patient-centered2. Existing EHRs do not support the collection of data related to the preferences and goals of individual patients, nor do they provide the means for measuring whether they are achieved. Child and youth mental health (CYMH), which poses a massive burden on society, is a prime target to benefit from patient-centered LHSs; unfortunately, current processes and tools in CYMH care do not enable continuous and rapid learning leading to patient-relevant outcomes.

Data Requirements for a Patient-Centered Learning Health System
This project aims at identifying the data requirements and characterizing the data lifecycle for a patient-centered LHS for CYMH. It will focus on learning about which treatments are most likely to have positive impacts from the patient’s perspective. We propose to use Design Thinking, an approach that provides methods to engage patients’ families and care providers as equal partners in the study1. This project will be organized in three phases:

1. Understand stakeholders’ challenges and perspectives. This phase aims at developing a deep understanding of obstacles faced by patients’ families and CYMH care providers in relation to choosing among treatment options and learning from treatment outcomes. Design thinking sessions comprised of individual interviews and activities such as the creation of journey maps and prototype decision-support tools to overcome perceived obstacles will be conducted with these stakeholders. Data collected during design thinking sessions will be analyzed through thematic analysis.

2. Ideate and prototype potential solutions. This phase aims at developing conceptual and practical solutions for implementing a patient-centered LHS for CYMH. We will use the results from Phase 1 to articulate data requirements and a data lifecycle that can leverage the capabilities offered by advanced analytics in order to move from patient-identified goals to rapid and continuous learning that improves patient-relevant outcomes. Process mapping and conceptual data model design will be used to identify the data requirements for this learning cycle. Identified requirements will be used to create a representative data set of cases of CYMH patients amenable to predictive and simulation modeling.

3. Iteratively improve solutions based on stakeholder feedback. This phase aims at arriving at validated data requirements. A set of design thinking sessions following principles of user studies will be held to gather feedback from stakeholders. Participants will be asked to interact with treatment predictions and learning cycle mock-ups in order to assess if they meet their needs and expectations regarding a patient-centered LHS. The mock-ups and underlying requirements will be revised until stakeholders assess them as being adequate for their needs.

Conclusion
The results of our project could be integrated into EHRs to ensure that they support the achievement of patient goals alongside clinical ones. They thus stand to improve health outcomes and patient satisfaction in CYMH care without imposing additional strain on the limited resources available to face the growing needs of this population.

Finding the evidence base using citation networks: Do 300 to 400 U.S. physicians die by suicide annually?

Tiffany I. Leung, MD, MPH, FACP, FAMIA, Sima Pendharkar, MD, MPH, FACP, Chwen-Yuen Angie Chen, MD, FACP, FASAM, Michel Dumontier, PhD

1 Faculty of Health, Medicine and Life Sciences, Maastricht University, Maastricht, The Netherlands

3 Department of Primary Care and Population Health, Stanford University, Stanford, CA, USA
4 Institute of Data Science, Maastricht University, Maastricht, The Netherlands

Introduction

An eye-catching estimate declared and parroted in scholarly work and popular media is that “300 to 400 U.S. physicians die by suicide annually.” Reported physician suicide incidence varies depending on method of ascertainment, country, specialty, stage of profession, and gender. However, the data and methods on which this claim is based have not been clearly cited. Valid citation of scientific evidence in an ecosystem of enormous volumes of literature is important to mitigate the propagation of inaccurate claims. Citation distortion occurs when a claim is stated as fact yet actually has no supportive empiric evidence. How can we keep track of the provenance and accuracy of claims regarding physician suicide? One approach is to construct a citation network, representing claims made in publications, their supporting references, data, and other components. By tracing the lineage of a single scientific claim, citation distortion can be demonstrated with successive publications. We constructed a claim-specific citation network focusing on one claim about physician suicide deaths. This is a proof-of-concept to capture evidence that can be used to track estimated rates of physician suicide.

Methods

Claims were extracted from a corpus of articles obtained from a scoping review of peer-reviewed literature on physician suicide. The review had included a variety of article types published between 1903 and 2018 from 37 countries. We manually curated from each article the claim (about the number of physicians who die by suicide annually), claim attribute (author), cited reference(s), and cited data or methods, if provided. Each set represents a type of micropublication, which is a semantic model for scientific claims and evidence that enables knowledge discovery and inference across networks of information. We constructed each micropublication using extracted data, and then combined them into one citation network representing the claims, their relationships, and supporting references and data.

Results

Twenty-three articles, including 14 opinion articles, were identified; 11 cited zero references in relation to their claim about the number of physician suicide deaths annually. Four articles claim a different number of annual physician suicide deaths than the claim of interest. Tracing the claim’s lineage back in time in a manually constructed citation network, based on Greenberg, reveals inadequately supportive data or methods.

Discussion

The medical community and advocates need accurate and trustworthy estimates to communicate the urgency of addressing physician suicide. This study is remarkable because: (1) citation networks have never been applied to suicidology, especially among physicians, and (2) this analysis suggests that the oft-quoted claim that “300 to 400 U.S. physicians die by suicide annually” does not have adequately cited supporting data or methods. These findings suggest that inadequately supported claims about physician suicide can easily propagate through publications. Also, advocates and researchers in this area should be vigilant of potential information distortion. A key limitation is that we traced a single verbatim claim, which in future work, will include additional incidence data and calculated estimates. Our approach of building citation networks about physician suicide appears promising for future studies and for ensuring preserved accuracy of scientific work in this field.

Ethical Considerations for Social Media Research
Deborah Lewis, EdD, CRNP, MSN, MPH, Walden University, Minneapolis, MN
Patricia Salai RN, MSN, CNN, CRNP(retired), VA Medical Center, Pittsburgh, PA

Overview
The adage that a “picture is worth a thousand words” illustrates that a single photograph can convey complex meaning. This concept easily translates to visual data produced by social media platforms such as Instagram. Instagram provides a unique visual window into individuals’ lives and can provide insights into the meanings represented by the visual images posted.

As part of an ongoing research project, Instagram images were collected to identify the meaning of those images for rheumatoid arthritis, a chronic disease. Because the information is considered public and did not require any communication with the individual who posted it, by definition this project did not involve human subjects and was approved, as such, by the University IRB. This poster represents one aspect of our ongoing research that raised questions related to the methodology and ethical nature of social media findings.

Problem Identified
Anyone 13 years of age and older can create an Instagram account to share photos and video. The user chooses their user name and decides the level of privacy associated with their account. Collecting Instagram images, for research, using the public search tool, should not result in access to any information marked as private by the individual who posted. Users may choose to post their personal user information publicly, which could be collected via a public search.

For our current study, Instagram images were collected, coded, and analyzed independently by two coders. The initial intent of the research was to identify the meaning represented by the images. As the research progressed, the coders encountered an element of ethical discord, and while adhering to all current ethical standards, became uncomfortable with the idea of sharing human images as part of the results. We ultimately chose not to present images that included human faces. We reviewed the literature and found that in other published research using Instagram images, the images were altered to obscure the identity of human faces to protect the privacy of the persons who posted.

Questions for Future Research
Visual ethnography, our methodology, provided an opportunity to examine the meaning of the visuals utilizing the entire image. While providing rich information, this methodology also raised some unanticipated questions. Was it appropriate to share the full images? Would sharing the complete image, including the facial expression, strengthen the conclusions? If the research consumer only sees blurred or blocked images or no images at all, how can they fully understand the findings of a study based on visual data? Even though social media platforms are in the public domain, and include privacy notifications, are individuals who post images fully aware that their images may be used in research? How is the collection of social media images for research different than photographs taken in public settings? If Instagram images are personal art, are they protected by copyright?

In any qualitative approach, the trustworthiness of findings can also be a challenge. Using public social media searches makes it difficult to identify the origin of the images; therefore, it is difficult to member check with the individual who posted the image. If you don’t member check with the individuals who posted are you accurately reflecting the meaning represented by the image shared? Are the images truly posted by those who have the disease? Ongoing research is important in understanding how social media may contribute to health information sharing and the impact on health outcomes. Future research needs to examine the best approaches for ensuring ethical research methodologies and the best ways to share visual data that results from social media healthcare research.

Increasing Transparent and Accountable Use of Data by 
Quantifying the Actual Privacy Risk in Interactive Record Linkage 
Qinbo Li\textsuperscript{1} Adam G. D’Souza\textsuperscript{2} Mahin Ramezani\textsuperscript{1} Cason Schmit\textsuperscript{1} Hye-Chung Kum\textsuperscript{1} 
\textsuperscript{1}Texas A&M University, College Station, TX \textsuperscript{2}University of Calgary, Calgary, AB, Canada

Introduction

In biomedical research, there is a constant tension between the need to leverage data to promote social good and the legal requirements to protect patient privacy by guarding against unnecessary disclosure and use. Record linkage, or patient matching, poses a particular difficulty for information privacy. The goal of record linkage is to integrate heterogeneous databases lacking a common identifier, in order to reliably combine patient data from multiple sources.

Recently, there has been increasing interest in using encryption-based privacy-preserving record linkage methods when there are no better alternatives. However, these methods are primarily designed to compute a predetermined linkage function in a secure manner. In reality, in many projects the linkage function cannot be predetermined without interacting with the data being integrated, making it difficult to have good match rates. In fact, in most record linkage projects it is very important to have someone interacting with the data to clean and standardize the data, build training datasets, tune parameters, and resolve ambiguous links. Typically, the amount of data being disclosed during this interactive linkage process is only a small fraction of the data being linked.

Objective

In this poster, we investigate how to best monitor and quantify the actual privacy risk that occurs during this interaction with the data. We first demonstrate the desired properties of a privacy risk score for interactive record linkage that will allow project managers to better communicate and decide on the best tradeoff points between information disclosure and accuracy of record linkage for a given project. We then propose a measure, k-Anonymized Privacy Risk (KAPR) score, and prove that it meets all the required properties. We further illustrate the utility of KAPR via an example and its use in a prototype privacy enhanced interactive record linkage system called MINDFIRL (MInimum Necessary Disclosure For Interactive Record Linkage).

Methods

There are several desirable properties of the measure for quantifying the privacy risk in interactive record linkage. First, it must measure the actual identity disclosure risk based on only the data that has been disclosed to someone during the interactive record linkage process. Second, the measure should range from 0 (when no data is disclosed) to 1 (when all data has been disclosed and identified). Third, it should be a norm (a non-negative, homogeneous function of a suitable representation of the information disclosure state that obeys the triangle inequality) so that it can be assigned the geometrical interpretation of the “length” of the information disclosed, where “longer” means “higher risk of identity disclosure”. The norm property guarantees that the measure is only dependent on the information disclosed by the user, and not on the precise order of disclosure.

Results

We propose the k-Anonymized Privacy Risk (KAPR) score, which is based on the anonymity set size and the total information disclosed. The anonymity set size is the total number of records that share the same information that has been disclosed. For example, if there are 10 patients named Bob, than disclosing Bob would result in the anonymity set size being 10. The KAPR score is formally defined as $K(\kappa; X) := \frac{\kappa}{ND} ||X||_{1,1} = \frac{\kappa}{ND} \sum_{i=0}^{2n-1} \frac{1}{k_i} \sum_{j=0}^{D-1} |p_{ij}|$, where $X$ is the suitably-defined information disclosed from a total of 2n records with D attributes, $p_{ij}$ is the proportion of characters of attribute $j$ of record $i$ disclosed, $\kappa$ is the minimum allowed anonymity set size and $k_i$ is the anonymity set size of record $i$ based on the current information disclosed.

Conclusion

KAPR score is one of the main components of the MINDFIRL system design. To the best of our knowledge, MINDFIRL is the first system designed to meet the legal requirements for minimum necessary disclosure by disclosing only the needed information for high quality record linkage using an interactive on-demand incremental interface and then to quantify the actual privacy risk based on what PII was disclosed. In addition, it supports setting a pre-specified limit on the total level of disclosure by using the agreed on KAPR budget. We have conducted multiple user studies that have demonstrated that use of MINDFIRL reduced privacy risk to only KAPR=7.85%, compared to 100% when all data is disclosed, with little to no impact on decision quality or completion time.
A Bibliometric Analysis of Research Publications that Adopted the Medical Expenditure Panel Survey (MEPS) Data

Jiacheng Liu, BS, Fei Yu, PhD, MPS
University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA

Abstract

The Medical Expenditure Panel Survey (MEPS) is a large publicly available information source provided by the Agency of Healthcare Research and Quality (AHRQ). We systematically retrieved, screened, and conducted a bibliometric analysis for the research publications that adopted MEPS data. Through a bibliometric approach, this study meant to provide insights to inform policy makers, grant agencies, and researchers of the landscape through the research effort that MEPS data have supported.

Introduction

Since 1996, the Agency of Healthcare Research and Quality (AHRQ) has conducted Medical Expenditure Panel Survey (MEPS) by taking samples of households throughout the United States. MEPS data provide an unparalleled degree of details about the use and payment of health care services. Although more than one thousand publications have used MEPS data in the past two decades, it still shows the lack of an overview on the research effort that MEPS data have supported. This study aimed to systematically survey the research publications that adopted MEPS as the sole or one of the datasets by a bibliometric approach. The findings meant to provide insights to policy makers, grant agencies, and researchers in terms of data collection and organization, funding, publishing, and collaborations.

Methods

This study systematically searched peer-reviewed articles from 1996 to 2018 which adopted the MEPS data in two research databases (PubMed & Web of Science (WoS)). JL and FY independently screened the title and abstract fields of each retrieved publication in Covidence\(^1\) based on a set of inclusion and exclusion criteria. The full citation records of the included publications were obtained by matching records in WoS using PMID, DOI, and title fields. WoS analytics, Microsoft Excel, and VoSviewer\(^2\) were utilized for quantitative and bibliometric network analysis, including the number of publications by year, research categories and topic clustering, journal sources, other datasets co-used with MEPS, funding sources, and co-authorship (i.e., organizational and country collaboration).

Results

A total of 1670 publications from 1996 to 2018 were included in this study. The publications that adopted MEPS data grew steadily with an average of 75 articles per year and reached a peak in 2017. The top research categories were healthcare services, public environmental occupational health, health policy, and internal medicine. In addition, 235 key terms were extracted from the title and abstracts of the included publications and formed three major topic clusters (i.e., health quality and cost, healthcare accessibility and disparity, child and family care). Additional 24 datasets were identified that were frequently co-used with MEPS by the included studies such as Nationwide Inpatient Sample and Truven MarketScan. National Institute of Health was the top grant agency for the included studies. More than 3200 authors contributed to the included publications, and they were from 25 countries and 1074 institutions or organizations.

Discussion & Conclusion

Although MEPS focuses on the representative samples of domestic households and researchers in the U.S. contributed the most to the included publications, the MEPS data have inspired cross-country collaborations. Our results illustrated the broad landscape of research efforts that MEPS data have supported and substantiated the value of AHRQ’s effort of providing the MEPS data to the public. The findings will help stakeholders with informed decision making.

4Department of Biomedical Engineering, Tufts University, Medford, Massachusetts, USA

Abstract

This paper aims to investigate doctor of medicine students’ perceptions regarding a clinical informatics course at West China School of Medicine, Sichuan University. Students were surveyed to evaluate their perceptions and satisfaction of the course. Semi-structured and open-ended questionnaires were used to explore the students’ perception of the course. A total of 95% (195/205) completed questionnaires were returned on October 21-23, 2018. The results showed that students were satisfied with and received benefits from the course.

Introduction

With the expanding interest and investment in health information technology by hospitals, health systems, and practitioners, physicians will be practicing in a digital world. Therefore, clinical informatics course will be of paramount importance for physicians [1,2]. It is important for students in medicine and health care to be taught clinical informatics. This pilot study collected and analyzed quantitative and qualitative data to evaluate doctor of medicine students’ perceptions about a clinical informatics course at West China School of Medicine, Sichuan University. West China School of Medicine is one of the most famous medical schools in China.

Methods

We developed a 9-question with close-and open-ended questions, web-based, anonymous survey in consultation with medical educators and informatics experts. Completion of the questionnaires was voluntary and anonymous. We surveyed all students (205) joining the course on October 21-23, 2018.

Results

The survey response rate was 95.12% (195/205), of which 154 (75.12%) answered the open-ended question. 52.68% of the respondents were male. 94.36% (184) were very satisfied while 4.62% (9) were satisfied. The mean overall satisfactory was 4.92 ± 0.35 (5-strongly agree to 1-strongly disagree); “the course benefits your career” was 4.92 ± 0.39. 94.87% (185) strongly agreed and 3.59% (7) agreed (Table 1). The main responses to the open-ended questions were “clinical informatics is very important”, “I hope to increase the opportunity of clinical informatics learning”.

Conclusion

Findings gleaned from this study suggests that 98.98% (193/195) of the students were satisfied with the clinical informatics course. 98.46% (192/195) of students agree that the course will benefit their career. Clinical informatics is a very useful subject for the doctor of medicine students.

One Size Does Not Fit All – Lessons Learned from Developing Algorithms for Decision Support for Symptom Management in Cancer Patients

David F. Lobach, MD, PhD, MS1; Mary E. Cooley, PhD2; Barbara Halpenny, MA2; Jennifer Ligibel, MD2; Andrea Enzinger, MD2; and Janet L. Abraham, MD2

1Klesis Healthcare, Durham, NC; 2Dana-Farber Cancer Institute, Boston, MA

Introduction
Cancer survivors represent 5.0% of the United States population, and their numbers are projected to increase by 29% over the next 10 years to more than 21 million individuals.1 Most cancer patients are afflicted with distressing symptoms that are undertreated and not managed in accordance with evidence-based practices leading to increased morbidity, mortality and cost.2 Clinical decision support (CDS) can facilitate symptom management in cancer patients; however, studies of CDS have been limited in their scope and scalability.3,4 This study is part of a larger project funded by the National Cancer Institute (NCI) to promote care continuity across clinical settings through CDS for evidence-based cancer symptom management. Development of algorithms for fatigue and constipation were specifically requested in the NCI contract. We engaged clinicians from multiple disciplines who manage patients with cancer symptoms in a variety of contexts to develop generalized algorithms for the management of constipation and fatigue across the continuum of care. This poster reports on feedback from the clinical experts who created the algorithms and from multidisciplinary clinicians who reviewed the completed algorithms.

Methods
We leveraged our previous approach for adapting research evidence and guidelines into clinical algorithms for cancer symptom management using the ADAPTE process specifically targeting fatigue and constipation.5 To receive input from the continuum of clinical settings in which cancer care is provided (i.e. from primary care through acute cancer treatment and end-of-life care), we formed two panels of eight clinicians and other stakeholders, one to address constipation and the other to address fatigue. Panel members included medical oncologists, oncology nurse practitioners, palliative care physicians, integrative care specialists, psychologists, social workers, pharmacists, primary care internists, gastroenterologists, nutritionists, and patients who are cancer survivors. Panel experts were provided current research evidence and guidelines. They interacted in three virtual sessions and one in-person session to review draft clinical algorithms. Themes and observations resulting from these sessions were recorded by study team personnel and used to modify the algorithms. Each modified algorithm was then reviewed with 8 to 10 multidisciplinary clinicians (MDs, PAs, NPs) through structured interviews.

Results
Salient observations from sessions with clinical experts and interviews with multidisciplinary clinicians included:
1) Cancer symptom management guidelines from different reputable sources are conflicting, inconsistent and need more specificity in order to be used for clinical decision support.
2) Recommendations need to be based on a patient’s place on the cancer care continuum, care setting, and patient preferences/goals of care, treatment status/regimen, age, and cancer type.
3) Primary care clinicians desire a general symptom management guideline that is applicable to all patients.
4) Patients of hospice clinicians may have different goals from those of actively treated or advanced cancer patients.

Discussion
Study observations have implications for cancer care delivery models that extend across the care continuum, especially if fewer patients follow-up through oncology clinics as the number of cancer survivors increases. Implications are that CDS for patients being treated for cancer may not generalize to primary care providers, and thus primary care providers should be explicitly included in usability testing. Implications for managing cancer patients in hospice programs are that guidance needs to be aligned with overall care goals and tailored to the changing status of patients as they approach end-of-life. This study is limited in that it reflects only the opinions of 16 clinical experts and 17 multidisciplinary clinicians, and that it focused only on fatigue and constipation.

Conclusions
While CDS can be helpful with promoting evidence-based cancer symptom management, the CDS systems providing care recommendations will need to be specifically developed to fit the patient characteristics and context.

Classification Types: A New Feature in the SPECIALIST Lexicon

Chris J. Lu, PhD1,2, Amanda Payne, PhD1,2 and Dina Demner-Fushman, MD, PhD1
1National Library of Medicine, Bethesda, MD 2Medical Science & Computing, LLC, Rockville, MD

Introduction

The SPECIALIST Lexicon (thereafter, the Lexicon) [1], distributed by the National Library of Medicine (NLM) as one of the Unified Medical Language System (UMLS) knowledge sources, supports popular NLP tools, such as SemRep, MetaMap, cTAKES, CSpell, and the SPECIALIST Lexical Tools, as an underlying resource. A new enhanced feature called the classification type (CT) is a proposed addition to the Lexicon. These classification types can be archaic, source, informal, or other. First, terms classified as archaic, such as cozen, colde and benight, are considered no longer in common use in modern corpora (such as MEDLINE). These terms may have modern equivalents in the same lexical record (colde for cold) or in separate ones (ye for the). Second, normalization on spelling variants from foreign English into US English is needed if the source is from a foreign country. For example, British English (analyse, leukaemia, tumour) can be normalized to US English (analyze, leukemia, tumor). These terms are classified as source. Third, consumers often use informal language when they ask questions. For example, bomb for success, or grandpa for grandfather are used primarily in colloquial contexts. The performance of automated consumer question understanding could be improved if the Lexicon provides informal terms with their cross-referenced (CR) formal terms (synonyms). Four CTs and their syntax are shown in Table 1.

Table 1. Enhanced Features of Four Classification Types.

</tr>
</tbody>
</table>

Classification Type Implementation

CTs are added to new lexical records during lexicon building by NLM linguists through a Web-based tool, LexBuild. New GUI components for adding CTs and the enhanced LexCheck software for validating syntax and contents of CTs are integrated in LexBuild. CT tagging on existing lexical records is also done through LexBuild. First, class_type=unassigned is added to all existing records, and removed after it is tagged. Computer-aided features for retrieving records by specified patterns, like suffix, substring, category, etc. are implemented for systematic tagging. Finally, post-process programs are implemented to generate new Lexicon tables, including archaic terms, spelling variants with originated sources and informal terms with their formal synonyms, for the Lexicon annual release.

Applications and Conclusion

The performance of NLP applications that use the Lexicon is expected to be improved with the new CTs. First, archaic terms can be excluded when dealing with modern corpora. Second, foreign English can be normalized to US English with source CTs. Third, the performance of automated question understanding on consumer health can be improved. For example, grandpa (no concept found in UMLS) can be effectively mapped to grandfather (C0337475) with query expansion by substituting formal synonyms for their informal terms [2]. The Lexicon is distributed by NLM via an Open Source License agreement and is available at: https://umlslex.nlm.nih.gov/lexicon.

Dissemination of HIV-HCV-STD Clinical Evidence through Guideline-Driven Interactive Case Simulation Tools – An Assessment of User Engagement

David Lukacs, MS; Meredith Abrams, MPH, MS; Dongwen Wang, PhD
Arizona State University, Scottsdale, AZ

Abstract

Engaging clinician users in educational initiatives is critical for effective knowledge dissemination. We analyzed the usage of five interactive case simulation tools in a statewide HIV-HCV-STD clinical education program to assess user engagement. We have found that interactive, patient-specific simulation can engage clinician users more effectively when compared to hyperlinked text or static cases. The results from this study will guide the future development of online resources for more effective dissemination of clinical evidence.

Introduction

Interactive case simulation tool (ICST) is an important vehicle to disseminate clinical evidence. The New York State HIV-HCV-STD Clinical Education Initiative (CEI) has developed various guideline-driven ICSTs and disseminated them to thousands of clinicians. User engagement is critical for effective dissemination of online resources. Here we report a study to assess the engagement of clinicians through analyses of ICST usage in the CEI program. The findings from this study will guide future development of online resources for more effective knowledge dissemination.

Methods

We selected five popular ICSTs from the CEI program for analyses: HIV Pre-Exposure Prophylaxis, Anal Dysplasia and Cancer, Substance Use, HIV Exposed Infants, and HIV Testing. Each ICST has three main components: (1) recommendation, which is presented as hyperlinked text; (2) my case, which is user-defined patient case through an interactive, algorithm-based process to explore different options for patient management; and (3) sample case, which is similar to (2), except that the patient case is pre-defined and the decision algorithm is presented as a whole without step-by-step user interactions. We tracked all user interactions with the ICSTs, such as click of a hyperlink and hit of a button, and recorded the usage data during a study period from October 2013 to November 2015. To assess user engagement, we leveraged a network analysis approach to obtain the number of disengaged users during interactions with ICST and the specific location and context when a user left. For statistical analyses, we compared the proportions of disengaged users among the three components of ICST, i.e., recommendation, sample case, and my case. We used Chi-square test, with Fisher’s exact correction when applicable, to examine the significance of the differences.

p-value – Sample Case vs. My Case: 0.6956, 0.2728 ↑, 0.0747 ↑, 0.0126 ↑, 0.0300 ↑
p-value – Recommendation vs. Sample: 0.0159 ↑, 1.0000, 0.4028 ↑, 0.9173, 0.6843

↑ indicates that the difference is in a direction consistent with the hypothesis. Bold font: p-value < 0.05.

Conclusion

This study provides empirical evidence on impact of usability design to user engagement. Interactive case simulations likely could engage users more effectively when compared to general recommendations delivered in hyperlinked text. User-defined, interactive case simulations could engage user slightly better than pre-defined, static cases. No significant differences found between pre-defined, static cases and general recommendations. Future research is required to examine the generalizability of the findings to other domains and problems.
Automatic Identification of Social Determinants of Health from Clinical Records

Kevin Lybarger1, Mari Ostendorf, PhD1, Ozlem Uzuner, PhD3, Meliha Yetisgen, PhD2
1Department of Electrical Engineering, 2Department of Biomedical and Health Informatics, University of Washington, Seattle, WA
3Department of Information Sciences and Technology, George Mason University, Fairfax, VA

Abstract
Social determinants of health (SDOH) negatively impact morbidity and mortality especially in marginalized and vulnerable populations. For clinical care, it has long been practice to record SDOH as part of social history during clinical care as this history impacts not only diagnosis but also treatment options. SDOH information can improve public health through secondary use applications, like clinical decision-support systems; however, SDOH must first be automatically extracted from unstructured clinical narrative text. In this work, we apply automatic SDOH extraction methods to two publicly available datasets, namely i2b2 Obesity Challenge dataset [1] and MIMIC-3 dataset [2], and present prevalence of SDOH information in these corpora.

Introduction
SDOH focuses on social factors related to health. In our work, these factors include substance abuse (alcohol, drug, tobacco), living situation, and occupation information. Each of these determinants is characterized through status predictions and multi-word spans. Determinant status has the possible values of unknown, none, current, or past. Substance abuse is characterized through the entities: amount (e.g. “minimal” or “three drinks”), frequency (e.g. “daily” or “occasionally”), exposure history (e.g. “since 1990” or “more than 35 years”), quit history (e.g. “four years ago” or “in 1985”), and type (e.g. “wine” or “illicit”). The living situation entity is method (e.g. “lives with her husband” or “lives alone”). The occupation entities include type (e.g. “carpenter” or “running a day care”), method (e.g. “unemployed” or “retired on disability”), and location (e.g. “Florida” or “XYZ Medical Center”).

Methods
We trained a multi-task model SDOH from clinical text. Details of the multi-task model based on bi-LSTM can be found in [3]. To train our model we utilized our publicly available corpus of 364 social history sections (YV-Notes) extracted from 516 history and physical notes downloaded from the MTSamples website [4]. We applied the trained model to 61,472 social history sections from 59,652 discharge summaries and 141,624 physician notes from MIMIC-3 dataset. We also applied the trained model to 472 social history sections from 1237 notes from i2b2 obesity challenge (both training and test sets).

Results
Extraction performance of our multi-task model on YV-Notes is presented in Table 1. We identified SDOH information in both i2b2 and MIMIC-3 datasets. The resulting statistics are provided in Table 2.

Conclusion
The social history section in clinical text indeed contains a wealth of SDOH information, which can be used in both clinical care and in clinical research. The extraction software and automatically generated annotations on MIMIC-3 are released at https://github.com/Lybarger/clinical_extraction. These resources facilitate robust correlation studies between social history factors and disease outcomes. We will manually validate the automatic annotations on the i2b2 obesity challenge to generate a gold standard for a future community challenge.

Value Set Development for Studies Involving Historical Data

Kristin A. Lyman, JD, MHA, Melanie Canterberry, PhD, Elizabeth Crull, MPH, Jason Denton, BS, Fern FitzHenry, PhD, RN, Qiaohong Hu, MS, Sharidan K. Parr, MD, MS, Amy M. Perkins, MS, Dina Zein, MHA, Michael E. Matheny, MD, MS, MPH, Jason N. Doctor, PhD, Daniella Meeker, PhD

1Louisiana Public Health Institute, New Orleans, LA; 2Tennessee Valley Healthcare System, Veteran’s Health Administration, Nashville, TN; 3Vanderbilt University Medical Center, Nashville, TN; 4University of Southern California, Los Angeles, CA

Introduction

Through participation in the National Patient-Centered Clinical Research Network (PCORnet), the REACHnet and pSCANNER clinical research networks were funded to develop the PCORnet Opioid Surveillance Demonstration, a rapid response study that leverages PCORnet Common Data Model data (EHR data) across 5 PCORnet clinical research networks. The overall goal of the study is to create an EHR-based surveillance framework to complement existing CDC and other national and regional surveillance data sources. As an integral part of the study, the study team was required to develop medication, diagnosis, procedure, and lab value sets to be applied when querying historical data from the time period 2010-2017. The goal of this poster is to highlight the challenges and solutions associated with the development of value sets for studies and surveillance models that leverage historical data.

Methods

Value sets were developed for the following: 1) Medications (RxNorm CUI and NDC) - opioids, benzodiazepines, naloxone, buprenorphine, naltrexone, and methadone; 2) Diagnoses (ICD9CM and ICD10CM) - cancer, mental health conditions, substance use disorders, opioid overdose, smoking, HIV, hepatitis B virus, hepatitis C virus, suicide, and neonatal abstinence syndrome; 3) Procedures (CPT, HCPCS, ICD9CM procedure codes, ICD10PCS) - chemotherapy, radiation, and urine drug screening; 4) Labs (LOINC) - urine drug screening.

Several techniques were employed to augment completeness and relevance of value sets for this study. First, multiple published value sets were combined to provide a starting point for further value set augmentation and fine-tuning, including Value Set Authority Center value sets, other published value sets (i.e., those published for endorsed quality measures), Athena OHDSI, and RxNav. Second, current and historical code releases were manually reviewed to ensure that all codes within relevant ranges were captured. Third, in some cases published reports regarding specific historical code changes were reviewed to provide additional validation. Finally, value sets were reviewed manually to ensure that codes align with use of the value set within the larger analytics model that aims to characterize and assess relationships between opioid epidemic risk factors, processes, and outcomes of interest. Any study or surveillance model would benefit from the application of these methods to the development of value sets.

Results

The development of value sets for this study highlighted several challenges that are generalizable to the development of other studies and surveillance models. First, when leveraging value sets for studies involving historical data, value sets must include codes that have been deleted or replaced, including temporary codes. Second, value sets must often be fine-tuned based on a study’s specific aims and population of interest. In developing the value set for mental health diagnoses most often associated with opioid use, misuse, or abuse, it was determined that ICD10CM code R63.2 (Polyphagia) should be deleted. Third, the level of granularity of certain codes may not be appropriate given the level of data present. Naloxone RxNorm CUIs with IN term type were removed due to the potential to include Buprenorphine/Naloxone combinations for sites that had RxNorm CUI coded at the ingredient versus a more granular level. Finally, certain value sets may not include the full scope of codes applicable to a certain concept. A number of published value sets for HIV did not include the ICD9CM code 044.9 (HIV infection, unspecified).

Conclusions

The challenges encountered in the development of value sets for the PCORnet Opioid Surveillance Demonstration are not unique to the opioid use case. Methods can be easily generalized to any study or surveillance model that leverages historical data and requires tailoring of value sets to specific research questions and/or populations of interest.
Scalable Dimensionality Reduction in Patient Medication Domain: A Use Case for ATC Terminology Mapping for Machine Learning Models

Sina Madani, MD, PhD, Colin G. Walsh, MD, MA, Joseph A. Huenecke, PharmD, Jeff Byrd, Asli Weitkamp, PhD
Vanderbilt University Medical Center, Department of HealthIT

Introduction

Machine learning models classify or predict an output likelihood or class from input data. Recent machine learning applications show great potential in patient care where hundreds, if not thousands, of predictor variables co-exist together. However, input data like medications usually contain highly dimensional attributes that may negatively affect algorithm performance or model fit. Patient medication modules within Electronic Medical Record (EMR) systems often identify a drug both at the drug name and dosage/route levels, while, at the latter level, dosage and route of administration information are also included in the name. For example, Clindamycin, Clindamycin 150 mg capsule, Clindamycin 300 mg capsule, and Clindamycin 1% Lotion, are typically represented with four unique identifiers where the last three with dosages/routes information are linked to the parent drug name Clindamycin. The legacy medication authoritative repository at Vanderbilt University Medical Center (VUMC) captured patient “current medications” as part of patient summary services. We are operationalizing multiple machine learning algorithms at VUMC such as suicide risk prediction which rely on legacy data. The Anatomical Therapeutic Chemical (ATC) Medication Terminology has been shown to be effective in dimensionality reduction for suicide attempt risk prediction. ATC translates dosage/route level to higher levels of abstraction. While medication names in the legacy repository show minimum variations, the difference in their dosage and route of administration levels are noticeable among prescribed medications. We hypothesized that by leveraging existing crosswalks and medication classifications in our newly migrated EMR system, we could translate historical information entered in the legacy EMR to the ATC terminology and reduce the dimensionality for clinical prediction in a scalable way while supporting the translation of published suicide attempt risk predictive model to clinical practice.

Methods

We have identified all instances of legacy patient medications (n=15.6 million) between 2008-2017 from 1.8 million patients at VUMC. This dataset corresponds to 61,809 unique medication codes at drug name and dosage/route levels. We leveraged National Drug Data File Plus (NDDF) coding schema to crosswalk from our legacy prescribed medication codes to ATC Terminology (v2018). If multiple mappings existed for a given medication, we aggregated all the ATC codes for that drug. For example, based on the crosswalk, Salicylic Acid would map to three ATC codes representing Salicylic Acid Preparations, Wart and Anti-Corn Preparations, and Other concepts in ATC terminology.

Results

Most medication instances in our legacy dataset were mapped to 2,357 ATC codes (Figure 1). All medications at the dosage/route level were mapped to only 1 ATC code (if there were any), while 3% of the medications at the name level were mapped to more than 1 ATC code (n=1,985). Despite the fact that some of the drugs in the unmapped set had an NDDF Plus code assigned to them at the name (22%) and dosage (9%) levels, no equivalent ATC code was available for such medications. For example, Lutein with a valid NDDF Plus code has no equivalent ATC code in the crosswalk (v2018) that we used for this analysis. We intend to apply pattern matching algorithms in future to the unmapped corpora to find the nearest ATC concept.

Discussions

This study validates the feasibility of using NDDF Plus schema for reliable mapping of legacy patient medications to ATC codes for drug classification in an operational environment for a machine learning algorithm designed for predicting risk of suicide attempts. We will also use this framework in applications such as clinical decision support systems, that rely on higher level of abstractions represented in a standard fashion, to create sharable and reusable knowledge objects within the healthcare enterprise.
Drug-drug Interaction Extraction via Transfer Learning

Yuqing Mao, PhD¹, Kin Wah Fung, MD¹, Dina Demner-Fushman, MD, PhD¹
¹Lister Hill National Center for Biomedical Communications, National Library of Medicine, National Institutes of Health, Bethesda, MD, USA

Introduction

Drug-drug interaction (DDI) is an unexpected modification in the effect of a drug when taken in combination with another drug. It has the potential to cause significant harm to the patient. The U.S. Food and Drug Administration (FDA) and the National Library of Medicine (NLM) have worked collaboratively on transforming the content of Structured Product Labeling (SPL) documents for prescription drugs into machine-readable data. To inform future FDA efforts at automating important safety processes, the Text Analysis Conference (TAC) 2018 DDI track¹ has provided unique datasets for testing the performance on extracting DDI information from SPL documents of various natural language processing (NLP) approaches.

Recently, deep learning approaches have made significant progress in many NLP tasks. The most important advantage of deep learning approaches is that they do not need manually defined lexical features. More breakthroughs in NLP area were achieved via transfer learning in last year. Transfer learning for NLP tasks includes two steps: the first step is to pre-train a model on large amounts of unlabeled texts; the second step is to transfer the learned general language knowledge to a specific NLP task through fine-tuning. Pre-trained model can improve performances on NLP tasks also because the context can be encoded in its textural representations. In this work, we focus on building a transfer learning framework with BERT², one of the best publicly available, large-scale, pre-trained models, which we used for extracting DDI information from SPL documents.

Methods and Results

The TAC 2018 DDI track includes four shared tasks, and our model is designed to tackle the first two tasks. Task 1 is to extract mentions of interacting drugs/substances, interaction triggers and specific interactions at sentence level. Task 2 is to identify interactions, including the interacting drugs, the specific interaction types: pharmacodynamics (PD) pharmacokinetic (PK), or unspecified, and the outcomes of PD and PK interactions. Since the second task requires the output of the first task, we model them jointly by encoding the associated interaction type for each precipitant drug. Our framework contains three major components: an encoder for contextual embeddings, a BiLSTM-CRF to recognize all entities including precipitants, triggers and effects, and a CNN with two separate dense output layers (one binary classifier for PD interactions and one multiclass classifier for PK interactions) to predict outcome. We utilize the pre-trained BERT model as the context encoder, and compare its performance with one of the state-of-the-art models in TAC 2018 DDI track, which has the same architecture but uses a Bi-LSTM encoder that composes a context representation and character-CNN composed representations. The results of evaluation on TAC 2018 DDI track datasets are shown in Table 1. It is clear that the integration of the pre-trained BERT model can improve the performance of DDI extraction tasks.

Table 1. F1-scores of our BERT-based model and the SOTA model based on Bi-LSTM + CNN.

</tbody>
</table>

Conclusion

Transfer learning shows improvements in DDI extraction tasks. The performance can potentially be further improved if the pre-trained model could learn biomedical domain specific knowledge through training with a large set of unlabeled texts such as SPL documents and PubMed Central full-text articles.

The My Diabetes Dashboard: Preliminary Results of a Prospective, Longitudinal Usability Study
William Martinez, MD, MS; Gerald Hickson, MD; Kenneth Wallston, PhD; S. Trent Rosenbloom, MD, MPH; Tom Elasy, MD, MPH
Vanderbilt University Medical Center - Nashville, TN

Background
We recently applied user-centered design sprint methodology and key strategies for patient engagement to develop a patient web portal intervention for patients with diabetes called the My Diabetes Dashboard (MyDD). It was designed to help patients better understand their diabetes health data as well as support self-management. The dashboard uses graphics to visualize and summarize patients' diabetes health data, incorporates motivational strategies (e.g., social comparisons and gamification), and provides literacy-level sensitive educational resources.

Objective
This study aimed to assess the acceptability and usability of the MyDD over time among patients with type 2 diabetes mellitus (T2DM) as well as users’ attitudes about specific features and potential improvements (e.g., additional functionality) to help patients better understand their diabetes health data and support self-management.

Methods
To accomplish this objective, we conducted a prospective, longitudinal usability study. We recruited 60 adult patients with T2DM who completed the study. Patients were recruited from the Vanderbilt University Medical Center Adult Primary Care (VAPC) clinic and Eskind Diabetes Clinic both located in Nashville, TN. Participants were given one month of access to the My Diabetes Dashboard embedded within Vanderbilt’s patient web portal, My Health at Vanderbilt, run on Epic’s MyChart platform. Data were collected on dashboard usage. At the conclusion of the study, participants completed a questionnaire including a validated measure of usability, System Usability Scale (SUS), and questions about their experience using the MyDD including attitudes about specific features and potential improvements.

Results
Participants’ mean age was 58 (33% were 65 or older), 55% were female, 72% were Caucasian, 18% had limited health literacy, 40% were taking insulin, and the average hemoglobin A1c level was 7.5% (range: 4.9 to 12.5). All participants reported they intended to continue to use the dashboard going forward. The majority of participants (80%) visited the dashboard 3 or more times and 50% spent a total of 15 minutes or more on the dashboard during the one-month study period. Participants’ mean SUS score was 77.9 (SD ±15.2) and significantly greater than the threshold value of 68 indicative of ‘above average’ usability (P<0.001). Participants most commonly identified MyDD’s literacy-level sensitive educational resources as a feature that contributed to improved understanding of their diabetes health data as well as those that would make the dashboard more useful (65% and 73%, respectively).

Discussion
Our study describes the usability of a patient portal intervention designed to help patients understand and manage their diabetes. All participants found the dashboard acceptable (i.e., intended to continue using it). Participants’ SUS scores indicated significantly ‘above average’ usability. Participants identified key features that contributed to improved understanding of their diabetes health data as well as those that would increase MyDD’s usefulness.

A Review of ER Case Reports for Potential Anchoring Bias

Roni Matin, MSc1; Amy Franklin, PhD1

1University of Texas Health Science Center, School of Biomedical Informatics, Houston, Texas

Introduction
Research into sociotechnical systems in healthcare indicate the majority of adverse events involve either system errors, cognitive errors or both.1–3 and medical errors due to faulty diagnostic reasoning frequently involve cognitive factors.4 Decision making is widely considered to be a dual process model of system one processes, which are fast, intuitive, often termed heuristics, and system two processes, which are slower, deliberate and effortful. Under time pressure clinicians may defer to heuristics for making diagnoses. While heuristics typically serve the decision maker well, they represent a source of cognitive bias. One such bias identified as impacting clinical reasoning is anchoring bias, which is described by Croskerry as “the tendency to lock onto the salient features of a case too early in the diagnostic process” and failing to adjust from this view.5,6 Emergency departments represent pressured, stressful settings, where clinicians are required to provide prompt diagnosis and treatment to patients, many with life threatening conditions. Additionally, they may not have timely access to all the medical information pertaining to the patient under their care. Unsurprisingly, 65% of ED malpractice claims involve diagnostic error.7,8 Some diagnoses may involve transitions of care and the use of handoff protocols is not consistently universal. Here we reviewed a set of ED case reports involving adverse patient events due to diagnostic error, in order to infer whether anchoring bias may have contributed to the incorrect diagnosis and thereby discover gaps for further study.

Methods
A review of a limited set of case reports was conducted from articles retrieved by ad hoc manual searches in PubMed, and Google Scholar using the search terms “case reports” AND (“missed diagnosis” OR “delayed diagnosis”). Article titles and abstracts were reviewed and ten articles related to cases of missed or delayed diagnosis of patients presenting in ER settings, were selected for full text review and analysis. Case reports where an error had occurred and was caught late in the process or not all resulting in patient harm, were selected and reviewed to note diagnosis and follow on actions reported for each case. Data regarding the patient presentation, the tests, treatment and medications the patient was given following the initial diagnosis, as well as the final diagnosis reported, what prompted the final diagnosis and the case outcome were noted.

Results
The articles (n=10) were from case reports of self-declared diagnostic failures published between 2005-2019 were retrieved and reviewed. Of these, four cases resulted in the death of the patient, four resulted in delayed surgeries and two had outcomes where the patient was left severely disabled. Half the cases involved senior patients and six involved patients with multiple pre-existing chronic conditions such as diabetes, renal failure and HIV. In eight of the ten cases the error in diagnosis was not caught in the initial ED admission and the final diagnosis was reached following tests post transfer to other units or on readmission to the ED. These failures were due to anchoring on patients’ pre-existing conditions or erroneous patient-provided medical history, despite the presence of clinical evidence suggesting otherwise. Also, in eight cases the treatment given was consistent with the initial diagnosis. In two cases, the diagnosis and treatment of the patient occurred over ED shift changes and the authors suggest failures in the handoff practices promoted anchoring bias in the diagnosis.

Conclusion
The articles were heterogeneous in terms type of information and the level of detail reported regarding exact timings, the decision makers involved and the content of communications. Consequently, the findings can only infer the occurrence of anchoring bias involvement in these cases. Of particular interest were the two cases where issues in ED handoffs were identified as contributing to anchoring bias. These two studies contained very detailed reporting of the cases enabling better reflection of the events that occurred. Anchoring effect is recognized to be involved in ED diagnosis errors and these findings suggest may be more prevalent with patients who are elderly or already have complex chronic conditions. The manual selection of the articles does bias the results and limits the generalizability of the findings of this review. However, the findings do suggest further study of the anchoring bias in ED handoffs presents an opportunity of future research to inform the development of handover tools and de-biasing strategies for both medical training and practice.

Acceptability of Text Messaging to Help African American Women Manage Anxiety and Depression

Terika McCall, MPH, MBA¹, Todd Schwartz, DrPH²,³, Saif Khairat, PhD, MPH¹,²

¹Carolina Health Informatics Program, University of North Carolina at Chapel Hill, Chapel Hill, NC; ²School of Nursing, University of North Carolina at Chapel Hill, Chapel Hill, NC; ³Department of Biostatistics, Gillings School of Global Public Health, University of North Carolina at Chapel Hill, Chapel Hill, NC

Introduction

The rates of mental illness among African American women are comparable to the general population (18.6% vs. 18.9%), however they significantly underutilize mental health services compared to their white counterparts (10.6% vs. 23.4%) (1). Previous studies revealed that telehealth interventions are effective, and can be used to increase access to services (2). The aim of this exploratory study is to gauge the acceptability of utilizing text messaging to deliver mental health services to help African American women manage anxiety and depression.

Methods

A self-administered web-based survey was launched in June and closed August 2018. Eligible participants were African American women (≥ 18 years of age), regardless of mental health history. Participants were recruited through convenience sampling methods (including snowball sampling), via email or social media posts. Respondents were provided an anonymous link to the online questionnaire. The survey consisted of 53 questions, and the following subjects: sociodemographic characteristics, attitudes toward seeking professional psychological help (3), mobile phone use, and acceptability of using a mobile phone to receive mental health care.

Results

The results of this exploratory study (N=101, 90% completion rate) showed low acceptance of the use of text messaging to communicate with a professional to receive help to manage anxiety and depression (< 50% endorsed). Fifty-one percent agreed that having the option to use text messaging to communicate with a professional if they are dealing with anxiety would be helpful. Similarly, 49% agreed that having the option to use text messaging to communicate with a professional if they are dealing with depression would be helpful. Over 50% of respondents indicated having concerns about using text messaging to communicate with a professional. No statistically significant associations were found between age and agreement with the use of text messaging (all p > .05).

Conclusion

The use of text messaging was not highly endorsed by African American women as an acceptable mode of communication with a professional to help them manage anxiety or depression. Concerns around privacy, confidentiality, and the impersonal feel of communicating about sensitive issues via text messages must be addressed in order for this mode of communication to be a viable option. The findings of this study demonstrated the need for additional research into the use of mobile technology to provide African American women with more accessible and convenient options for mental health care.

Nurses’ SNOMED CT and Physicians’ SNOMED CT have little overlap in terms

Smruti Mehta, BS, Miguel Colon, BSN, Zachary Warren, BS, Karen Dunn Lopez, PhD, Andrew D. Boyd, MD
Department of Biomedical and Health Information Sciences, College of Applied Health Sciences, University of Illinois at Chicago, Chicago IL USA

Introduction:
The objective of this study was to measure the discrepancies within the interdisciplinary documentation of hospital staff within the Electronic Health Record (EHR). The electronic health records allow health information to be electronically shared and viewed by all the members of the healthcare team; however, many times different members will use different terms to describe the same care, which can lead to confusion⁠¹ between the team. This study evaluates the terminology between nurses and physician in patient documentation using SNOMED CT.

Methods:
We analyzed 10 heart failure patient discharge summary notes that were transformed to SNOMED CT using Natural Language Processing program MedLEE¹. Nursing documentation was coded¹ in NANDA-I, NOC, and NIC in HANDS© (a nursing documentation software) and then translated to SNOMED CT². SNOMED CT terms were labeled by provider if the term was used by a nurse or a physician. The relationships between SNOMED CT terms were extracted from SNOMED CT². The relationships between the terms were graphed using Cytoscape 3.6.1 (https://cytoscape.org/) to evaluate similarity and distance apart. In SNOMED CT all terms are seven nodes apart from the root term, so to evaluate similarity in this study if the nurse and physician terms are two nodes or less apart than they are considered to be similar between the professions.

Results:
From the 10 patient discharge summaries, around 15.6% of terms did not map to SNOMED CT. Out of over 300 terms, only two SNOMED CT² terms (pain and cardiology procedures) overlapped within two nodes between the professions. In figure 1, a graph represents interdisciplinary documentation terms of patient care from the EHR. In the graph, the red nodes represent nurse terms, and blue nodes physician terms. All other patients have similar sparse branching patterns.

Discussion:
Based on the results, physicians and nurses used different terms to record the care on the same patient. Although SNOMED CT is a universal health terminology taxonomy, the provider terms were in completely different areas of the SNOMED CT hierarchy². The structural difference represents the fact that physicians and nurses have different scopes of care. The use of different terms even within the same terminology can lead to misunderstanding amongst the caregivers. Within UMLS’s network on average 4 terms per patient were within 2 terms¹, in this study the average was approximately 0.

Conclusion:
From the 10 patients discharge summaries only two SNOMED CT² terms (pain and cardiology procedures) overlapped within two nodes between the professions. The discontinuity between the two professions can be seen through these results. While continuing with this study, we hope to create a better understanding between physician and nurse's documentation even when using the same terminology.

An Analysis of Advance Directive Documentation at Memorial Sloan Kettering Cancer Center

Chelsea L. Michael\textsuperscript{1,2}, Anjali V. Desai, MD\textsuperscript{1,2}, Gilad J. Kuperman, MD, PhD\textsuperscript{1}
\textsuperscript{1}Memorial Sloan Kettering Cancer Center, New York, NY; \textsuperscript{2}Weill Cornell Graduate School of Medical Sciences, New York, NY

Introduction

Incorporating patient values into treatment planning is critical for the delivery of high-quality care. Important aspects of the patient’s decision-making preferences are highlighted in advance directive documents (ADD). Making ADD easier to access can help ensure that clinical decisions are aligned with the patient’s wishes. As part of an effort to facilitate goal-concordant care by improving usability of ADD and other values-related data in the electronic health record (EHR) [Desai, A V. J Oncol Pract. 2018;14(12):e775-e785], we sought to understand which types of ADD are present in Memorial Sloan Kettering Cancer Center (MSK)’s EHR.

Methods

MSK is a large, single dedicated cancer center. For ADD, a patient may use an MSK health care proxy (HCP) form (with optional living will and organ donation sections) or an ADD from an outside source. The care team forwards completed ADD (and other hard copy documents) to a central scanning group within the medical records department. This scanning group abstracts the document execution date and, for outside documents, identifies the document type.

Having obtained IRB approval, we randomly identified 100 patients who had at least one ADD scanned into our EHR within the last year (2017-2018). We then reviewed all ADD in the EHR for those patients. We classified each ADD by source (our institutional form or outside documents), duplicate scans (multiple scans of the same document) and incomplete or combined documents. We identified elements present in each document (i.e., HCP, living will, organ donation). We compared the abstracted execution date to the execution date documented on the scanned form.

Results

Of the 100 EHR charts reviewed, 49 patients had a single ADD scan (scan), and 51 patients had multiple scans. Of 192 scans in total, 151 were unique documents and 41 were duplicates. Of the 192 scans, 8 were missing pages, and 4 contained more than one document in a single scan.

Characteristics of the 151 unique documents are summarized in Table 1. The majority constituted a HCP form, while living will and organ donation elements were included in a minority of forms. All documents were health-related (i.e., no financial-only power of attorney documents), and 45 documents replaced prior ADD (e.g., a change in health care agent, updated contact information and/or married name), 2 documents re-executed prior ADD with errors, and 1 document voided an older document without specifying updated directives. The 42 outside documents had varied formats and sources, including forms from 2 state health departments and 3 non-profit organizations; lawyer-drafted text documents from 3 states; and 24 forms and text documents from unknown sources. For the 192 scans, the abstracted date did not match the document execution date for 67 scans (35%). Most date offsets were short, but some were much longer (median = 7 days, range = 1-6364 days).

Conclusions

The ADD in our EHR contain multiple elements relevant to the patient’s wishes. Currently, we can only identify these important elements through manual review. Challenges related to paper documentation (e.g., missing pages, multiple copies, incorrect abstraction dates) are frequently present. To improve usability, we first aim to facilitate ADD retrieval from the most used EHR components. Anecdotes suggest that low ADD accessibility in the EHR leads to quality issues (e.g., duplicates). We could also leverage the patient portal for ADD upload and/or review. Analyses of ADD workflows and charting are ongoing. There are many opportunities to improve management of advance directive data as we seek to leverage our electronic systems to facilitate the delivery of high-quality, goal-concordant care.
Machine learning for personalized decision support with patient-generated health data

Elliot G. Mitchell, MA\textsuperscript{1}, Lena Mamykina, PhD\textsuperscript{1}, Matthew E. Levine, BA\textsuperscript{2}, Esteban G. Tabak, PhD\textsuperscript{3}, David J. Albers, PhD\textsuperscript{4}

\textsuperscript{1}Columbia University, Department of Biomedical Informatics, New York, NY; \textsuperscript{2}California Institute of Technology, Pasadena, CA; \textsuperscript{3}Courant Institute of Mathematical Sciences, New York, NY; \textsuperscript{4}University of Colorado, Departments of Pediatrics and Informatics, Aurora, CO

Introduction

We all seek to make informed decisions; in complex domains like health, it can be difficult for individuals to anticipate the consequences of daily choices. This is especially true for diseases with high individual variability. Clinical guidelines only apply to the average individual.\textsuperscript{1} Machine learning and patient generated health data can find patterns and offer insights at the individual level.\textsuperscript{2}

Here, we apply attributable components analysis (ACA)\textsuperscript{3} – a recently developed non-parametric density estimation method based on optimal transport theory – to type 2 diabetes (T2D) self-monitoring data. ACA identifies patterns of association between nutrition and changes to blood glucose (BG) after a meal, and we compare the method to linear regression to explore its potential advantages to support individualized decision support.

Methods

We used data for 15 individuals with T2D collected using a custom smartphone application in prior research. The data included meal records and BG readings recorded before and two hours after each meal. The glycemic impact of a meal was calculated as the difference between post- and pre-meal BG. Each meal was evaluated by a registered dietitian (RD) using a standardized protocol to assess the calories and macronutrients (carbohydrates, protein, and fat) in grams. Each data set included a median of 67 meals (range: 34 to 293), and participants were an average of 54 years old (SD=7.8) with a body mass index of 36.6 (SD=11.9). Analysis with ACA and linear regression were performed on each individual patient’s data set, as well as subsets by meal type (breakfast, lunch, and dinner) for a total of 60 (4 * 15) n-of-1 experiments. To estimate uncertainty and generate confidence intervals (CIs), we used a bootstrap procedure to run each method multiple times on random subsamples of the data.\textsuperscript{4} To compare the performance of the two methods, we produced a series of plots examining the shape of the relationship between each individual macronutrient and BG impact. To measure the quality of the CIs, we calculated the percentage of data points that fell within the CI.

Results and Conclusion

ACA was more robust to outliers, was able to find non-linear relationships, and importantly provided broader, more informative confidence intervals. As shown in Table 1, a much larger percentage of data points fell within the CI for ACA than linear regression. Because uncertainty is intrinsic to the practice of medicine, making ML useful for clinical decision support necessitates accurate and informative uncertainty estimates.\textsuperscript{5} Our results demonstrate the promise of ACA for uncertainty-aware machine learning with patient-generated data.

Three Rs of Clinical Data Quality – Relevance, Robustness, Repercussions

Sandra H. Mitchell, RPh, MSIS, FASHP\textsuperscript{1}, Gay E. Stahr, BS\textsuperscript{1}, Todd E. Turner\textsuperscript{2}

\textsuperscript{1}US Department of Veterans Health Information Exchange, Contractor – J P Systems, Inc., Clifton, VA; \textsuperscript{2}US Department of Veterans Health Information Exchange, Office Health Informatics/Clinical Informatics Data Management Office, Washington, DC

Introduction

Healthcare interoperability brings new challenges to your EHR data quality. Exchanged data reflects data quality programs across enterprises. When the data is shared, wide variances in adherence to standards means data content is in flux. Thus, leading to challenges in data ingestion/transformation in the data not being usable in the receiving applications.

Three years ago, the Veterans Health Information Exchange (VHIE) pioneered a clinician viewpoint analysis of HL7 message exchanges with the end goal of increasing native ingestion of external data. From a completeness and content perspective the results of the analysis, where they even exist, can be overwhelming. Clinical content improvement comes from focusing on Relevance, Robustness, and Repercussions.

Relevance

Clinicians expect content appropriate to their needs from external sources, but often experience misplaced, miscoded, and missing content.

“To be useful, EHR data from disparate sources need to be aggregated, mapped and harmonized into a single collaborative environment to ensure full visibility of the patient population.”\textsuperscript{1}

Robustness

Robustness refers to what makes data trustworthy, including accuracy, completeness, timeliness, and accessibility. Loss of the “clinical intention”, due to missing, misplaced or miscoded data can make the clinician spend more time with the technology than the patient or can lead to the clinician missing key patient clinical issues.

Repercussions

Data is a business resource and needs to be valued as such. Poor data can result in duplicate testing, incomplete research projects, and impact bringing new drugs to market. If the underlying data is poor, then all dependent applications are impacted.

Patient safety risk increases if poor data is added to the local Electronic Health Record (EHR) or if data requires transformation into local value sets. Without quality data, initiatives such as Artificial Intelligence (AI) or Clinical Decision Support (CDS) can’t perform to expectations. Complete and accurate data is not only a financial imperative, it is also an ethical imperative (e.g. patient safety, access to protocols based on relevant and robust data).

Conclusion

Opportunities exist to rectify the situation. The enthusiasm of the vendors to understand the challenge and adopt the VHIE Interoperability Data Quality process is leading to improved data exchange today. Without complete and high-quality clinical content exchange, the potential of Clinical Decision Support and Artificial Intelligence cannot be realized, research projects will take longer to complete, clinicians will continue to suffer burnout. Improved clinical content within the healthcare interoperability space is the true key to success.

Synthetic Data for Teaching Data Integration in Informatics Graduate Program

Hedyeh Mobahi, MS, Hua Min, PhD, Janusz Wojtusiak, PhD
George Mason University, Fairfax, VA

Introduction
Data integration is an important part of the health data analysis process, and a prerequisite to application of any analytic tools. It is critical for students in health informatics and health data analysis programs to become familiar with the required skills to perform such tasks. In Mason’s health informatics curriculum (MS and PhD), students learn these skills with SQL and Python as part of Health Data Integration course. Students learn increasingly complex approaches to data integration: first simple process in which a master patient index (MPI) exists is covered. Then, students need to search and match patient IDs that use different coding systems and conversions are needed. Finally, students learn and apply statistical matching methods. In all of the exercises, students also learn and apply evaluation methods used to check/confirm successful integration.

One challenge for instructors teaching data integration is to provide the right datasets which are realistic but at the same time do not contain any sensitive identifiable patient information. The approach that guarantees this requirement is use of realistic synthetic data. In the presented work, we algorithmically generated synthetic datasets that resemble real ones, yet do not contain any real patient information.

The presented study had two main goals: 1. Generate a usable realistic synthetic dataset for the education purposes; and 2. Ensure that the data shows the challenges needed to study complexity of data integration.

Methods
Synthetic datasets were created to resemble medical claims and cancer registry. The starting point of the process of generating synthetic data was extraction of real deidentified datasets from two independent sources. The extracted subsets from claims data included demographics, diagnosis (ICD9), procedures (HCPCS) and billing information. Cancer registry data included demographics and cancer diagnosis information only.

Records in the synthetic data were generated by randomly selecting age within ±3 years for each patient. Payments were randomly generated within ±10% of the real patient values. HCPCS and ICD9 codes were generated consistently with respective hierarchies for these codes. HCPCS categorization is broad, hence the following strategy was applied: if the code consisted only of digits, a random code was picked from range [10 codes before, 10 codes after] of the real value, if it starts with a character, a random code was picked from codes starting with the same character, and if a code ends with a character a random code from same category was chosen. To generate ICD9 codes, we have used the standard groupings suggested by CDC. For each code, two different thresholds were used. If the code reached the lower threshold the digits before dot were replaced by using a random code from the same category, and if the higher threshold was reached the digits after dot were replaced by picking one random code from the subset starting with the same digits. Race and gender were selected from original data. Finally, the two generated synthetic datasets were matched using statistical matching based on age, gender, race, and cancer diagnosis. Synthetic patient identifiers were generated that link across both datasets.

Generation of the synthetic data was done using Python 3.6 and PostgreSQL.

Results
Using the described process 1,655,574 synthetic claims were generated for 14,977 patients. The total number of 10,392 distinct ICD9 codes, 8,452 distinct HCPCS codes were used and 1,655,574 payments were generated. In the synthetic cancer registry data 37,198 cases of cancer were generated for 35,191 patients. After statistical matching 5,110 patient records remained. The additional 39,948 unmatched records were left in the data to provide students with realistic scenario in which not all records can be matched.

The final dataset is provided to students in five comma separated files: 1. Claims demographics; 2. Claims diagnoses; 3. Claims procedures and payments; 4. Cancer registry demographics; and 5. Cancer registry diagnoses.

Conclusion
The described process allowed us to create synthetic data that is realistic, yet do not contain any real patient information. Such data can be used in teaching data integration and databases without need of providing special security and data access control. It is important to note that such synthetic data are not intended for more advanced analytics courses including health data mining or machine learning as the data are random beyond the possibility of finding useful patterns. We specifically designed it only for the purpose of patient matching.

**HemOnc.org: Evaluation of Information Models for Cancer Therapy Representation**

Zachary H. Moldwin, BA\(^1\), Harry Hochheiser, PhD\(^2\), Jeremy L. Warner, MD MS\(^3\)

\(1\)University of Illinois at Chicago College of Pharmacy, Chicago, IL; \(2\)University of Pittsburgh, Pittsburgh, PA; \(3\)Vanderbilt University, Nashville, TN

**Problem Description**

HemOnc.org\(^1\) is a cancer therapy wiki and knowledge base with many possible applications for clinicians, researchers, and clinical decision support systems. Expansion of its functionality requires that it be readily accessible and maintainable, as well as semantically sound and interoperable with health information systems. Tools must be developed to simply, safely, securely, and consistently edit concepts and relationships. Easily navigable user-facing EHR and CDS applications should have access to well-built and defined information representation models. We compare four information models for maintainability, usability in health and research systems, and compatibility with related ontologies, standards, and terminologies.

**Methodology**

With permission of HemOnc.org LLC, the HemOnc.org content was obtained in HTML format, and portions were transformed into an OWL ontology in JSON format. This was converted to XML and parsed into a SQL Server relational database (HemOncDB). The HemOncDB data model uses a standard normalized multi-table domain architecture, derived by analyzing the knowledge representations in the OWL ontology. Forms were created in C# to allow editing of HemOncDB and to display the relationships between concepts. HemOncDB was then transformed into a Neo4j graph database using a Python script and the py2neo library. Portions of the HemOncDB content were also transformed into several denormalized tables using the OHDSI OMOP concept-relationship data model.\(^2\)

**Evaluation Results**

For semantic modelling in the ontology, excessive pre-coordination has been generally avoided because it could limit the flexibility of the derived products/tools and also overly complicate the model. Importation of ontology identifiers into HemOncDB generated data integrity issues because the ontology relied upon meaningful string identifiers rather than Concept Unique Identifiers (CUIs). For example, in the OWL ontology format, ‘Cyclophosphamide’ appears both as a parent element (containing brand names, etc.) and as a child element of many different regimens, and no CUIs were present to ensure that ‘Cyclophosphamide’ the parent and ‘Cyclophosphamide’ the child were semantically the same. Additionally, duplicate instances of many parent concepts, often with differing case or spelling and with differing child elements, were found.

Population of the Neo4j and the OMOP OHDSI databases were relatively straightforward because they are close in structure to the original OWL export format; design of a custom domain model was not necessary. In contrast, HemOncDB has a domain-specific design with unique identifiers and promotes data integrity, concept uniqueness and referential integrity. Therefore, HemOncDB was useful for data cleanup from the original ontology, such as detection of concept duplication. For the non-domain model architectures (OWL ontology, Neo4j and OHDSI OMOP), n-ary relationships were difficult to represent and/or enforce. As an example of a relationship that is difficult to represent/enforce, a treatment regimen used in one disease subtype may be supported by evidence from one publication, whereas the same treatment regimen used in a different disease subtype may be supported by another publication.

**Conclusion**

The HemOncDB data integrity features readily detected OWL dataset irregularities that were not detected through the non-relational models. The Neo4j model provided useful graph traversal and visualization tools that were not readily available in HemOncDB. Representation of regimen data in HemOncDB, OWL, Neo4j and OHDSI formats will increase their availability for oncology research and may allow easier integration with EHR and clinical decision support systems.

A Comparison of Online Consumer Medication Information from Canada, Denmark, and the United States of America

Helen Monkman, PhD¹, Thomas Schmidt, PhD², Christian Nohr, PhD²
¹School of Health Information Science, University of Victoria, BC, Canada; ²Maersk Mc-Kinney Moller Institute, University of Southern Denmark, Denmark

Introduction

Many people around the world take prescription medications: some for short durations (e.g., antibiotics) others continuously on a daily or multiple times daily basis. Taking any prescription medication inherently has both benefits (i.e., alleviating symptoms) and risks (e.g., side effects, contraindications, interactions, overdoses) for consumers. This study compared the content and design of online Consumer Medication Information (CMI) from three sources: one Canadian and one American pharmacy, as well as the Danish national resource minmedicin.dk. The investigators identified strengths and weaknesses of each of the three online CMI sources revealing opportunities for improvement.

Methods

We independently analyzed online CMI from three countries (Denmark, Canada, United States) for three medications (an inhaler, a tablet, and an intravenous medication), for a total of nine CMI. We assessed the content of each CMI against Monkman and Kushniruk’s¹¹ content utility criteria to assess whether important topics were present. We also assessed the design of the three online CMI resources by critically examining how each one presented information and how users interacted with the site.

Results

Content: Generally, all nine online CMI addressed the majority of the content criteria. The American CMI was the most comprehensive and the least comprehensive was the Danish CMI. However, each country’s CMI had its shortcomings. We found no drug interaction information in the American CMI, no information concerning missed doses in Danish CMI, and no overdose information in the Canadian CMI. Directions for use varied considerably from very brief to elaborate descriptions. Only the American CMI provided patient to patient medication information using summary statistics drawn from PatientsLikeMe. Finally, only Denmark provided specific information about the frequency of experiencing side effects (e.g., <10 in 100 people). Design: Each online CMI source relied on content structuring using templates. Navigation varied between the three CMI sources. Canada used in-page anchor links, with all content visible on page load. In contrast, both the USA and Denmark leveraged expandable text boxes. When expanded, the American text boxes were lengthy blocks of text. Both the American and Danish sites displayed pictures of the medications. However, only Denmark offered used slideshows and videos to convey directions for use.

Discussion and Conclusion

This analysis of online CMI from three countries, highlighted interesting differences in both the content and design of online CMI. Research dictates that online text should be concise and easily scannable² and pages should not be too long.² However, American and Canadian online CMI violated these guidelines which impedes their usability and likely use as well. Both Canada and Denmark equipped consumers with actionable information to empower consumers, whereas the USA prompted them to consult their healthcare providers. Yet, only the USA provided peer experiences. Denmark’s online CMI demonstrated unique benefits, which may be associated with its streamlined single national CMI approach, rather than relying on pharmacies to provide their own. In summary, each country’s online CMI demonstrated unique strengths and weaknesses and we found opportunities for improvement.

Adaptation of a Natural Language Processing Algorithm Following Implementation of a New Electronic Health Record

Sungrim Moon PhD, Vinod Kaggal, Sungwan Sohn PhD, Hongfang Liu PhD, Rajeev Chaudhry MD, Adelaide M. Arruda-Olson MD, PhD
Mayo Clinic, Rochester, MN, USA

Introduction: A rule-based natural language processing (NLP) algorithm has been developed to identify patients with peripheral artery disease (PAD). Subsequently, the NLP algorithm was delivered via the institutional near real-time NLP infrastructure for extraction of relevant patient-specific knowledge from clinical narratives. However, the institution migrated to a new Electronic health record (EHR) system and the PAD-NLP algorithm lost functionality. This study describes the process of adaptation of the PAD-NLP algorithm to restore performance following deployment of the new EHR.

Methods: Two separate versions of the PAD-NLP algorithm using MedTagger software were deployed to process clinical narratives of the new EHR system at Mayo Clinic. The first algorithm was the original PAD-NLP version and the second was a revised version which was modified for use with the new EHR (EPIC). The original PAD-NLP algorithm identified a cohort of 2,574 patients using near real-time NLP infrastructure between October 8th and December 6th, 2018. The algorithm performance was evaluated by manual review of the NLP output for patient classification. The NLP algorithm was revised with updated rules and keywords. "Medical Specialties" and “Note Types” in clinical narrative of the new EHR were mapped to equivalent information in the historical EHR (see Table 1). This revised algorithm was then applied to the same set of clinical narratives. Clinical narratives of 50 randomly selected patients (25 PAD cases and 25 non-cases) identified by the revised algorithm were used for evaluation. These narratives were manual reviewed by two trained annotators following written guidelines for standardization.

Table 1. Mapping of specialties and note types of the 2 EHR systems.

* Underlines represent the mapping between historical EHR and new EHR

Results: In the new EHR lexical variations in clinical narratives were different for representation of the same medical concepts compared to the historical EHR system. After implementation of the new EHR system, there were changes in clinician workflow and clinicians also changed terms used for documentation in the new EHR. For example, the original PAD-NLP algorithm contained the exclusion keywords “deep vein thrombosis” (DVT) or “deep venous thrombosis”. However, in clinical narratives of the new EHR system the concept of DVT was represented as “thrombosis deep vein”, which lead to erroneous exclusions with increase of false-positive results. The revised PAD-NLP algorithm identified only 715 PAD cases (27.78% of 2,574 patients of the cohort identified by the original version of the algorithm. Most of these 2,574 patients were false-positive cases.) In a randomly selected sample (n=50) for evaluation the refined NLP algorithm had accuracy of 98% (95% CI, 89.35%-99.95%), sensitivity of 96% (95% CI, 79.65%-99.90%), specificity of 100% (95% CI, 86.28%-100.00%), positive predictive value of 100% (95% CI, not applicable) and negative predictive value of 96.15% (95% CI, 78.56% to 99.42%).

Conclusions: Migration of EHR systems significantly impacts operation and performance of analytic tools installed in the near real-time NLP infrastructure. This study describes the process to restore functionality and for further refinement of the NLP algorithm mitigating the impact of the EHR migration. Updated rules and keywords as well as mapping of specialties and note types were essential to adapt a rule-based NLP algorithm to the new EHR.

Residential neighborhoods and walking: An Informatics Approach to Walkability
Stephen J. Mooney, PhD, Department of Epidemiology, University of Washington, Seattle, WA
Philip Hurvitz, PhD, Urban Form Lab, University of Washington, Seattle, WA
Anne Vernez Moudon, Dr es Sc., Urban Form Lab, University of Washington, Seattle, WA
Brian E Saelens, PhD, Seattle Children’s Research Institute, Seattle, WA

Background and Methods
Walking is the most common form of physical activity among adults. Numerous studies have assessed the potential impacts of assorted neighborhood characteristics on walking. In practice, measureable neighborhood characteristics are often highly inter-correlated. We took an informatics approach to identifying neighborhood environment predictors of objectively measured walking.

We used data from the Travel Assessment and Community (TRAC) study, a 3-wave cohort study of adults living in King County, Washington. In 2007-2009, each adult carried a Global Positioning System (GPS) device and Accelerometer device for 7 days. Using a previously validated algorithm, we identified periods of time the adults spent walking (‘walk bouts’) from these data. We developed the Automatic Context Measurement Tool (ACMT), a piece of R code to compile 146 measures of neighborhood characteristics including population demographics, commute mode, educational attainment, and land cover from publically available data sources with 833 meters (∙½ mile) of each participant’s home address. Following a Neighborhood Environment-Wide Association Study (NE-WAS) design, we used negative binomial regression to model the number of walk bouts each participant completed in 7 days as a function of each neighborhood measure individually, adjusting for selected participant characteristics. Next, we compared predictive accuracy of a model predicting walk bouts using conventional walkability measures to a model predicting walk bouts from the first principal component of the 146 measures.

Results
After Bonferroni correction, many neighborhood characteristics were associated with number of walk bouts (Figure 1). Proportion measures (e.g. proportion of residents commuting by car) were more strongly associated with walking than count measures (e.g. number of residents commuting by car). The model using principal components explained more of the variance in the total number of walk bouts than the models using conventional walkability measures did (Figure 2).

Conclusions
Informatics approaches to identifying residential neighborhood determinants of walking hold promise. Future work will extend the number of measures included, explore other modeling techniques, attempt to replicate findings in other geographic contexts, and explore how results may be of use for public health intervention.

Enhancing Accessibility of a Molecular Oncology Almanac for Precision Cancer Medicine

Nicholas S. Moore, BA¹,²,³, Brendan Reardon, BS²,³, Eric Kofman, BS²,³, Nathanael Moore, BS⁴, Eliezer Van Allen, MD²,³
¹Harvard Medical School, Boston, MA; ²Dana-Farber Cancer Institute, Boston, MA; ³Broad Institute of MIT and Harvard, Cambridge, MA; ⁴Indiana University School of Medicine, Indianapolis, IN

Problem
Cancer care is increasingly informed by molecular alterations that predict therapeutic sensitivity, therapeutic resistance, and prognosis. Clinical and preclinical studies continue to identify somatic and germline alterations that impact clinical decision-making, increasing the complexity of interpreting tumor molecular profiles for patient care and research. Increasing access to point-of-care molecular profiling holds great potential for patients but will only translate to improved outcomes if clinicians and researchers are able to interpret patient data in the context of a rapidly changing and broadening research landscape.

Towards solving this problem, we have built and continue to extend the Molecular Oncology Almanac, an open-access combined genomic interpretation algorithm, knowledge system, and web portal for informing treatment decisions through rapid assessment of tumor actionability. Analysis encompasses not only single nucleotide variants, insertions/deletions, and copy number alterations, which are commonly used at the point of care, but also anticipates growing application of fusions, mutational burden, mutational signatures, microsatellite instability, and aneuploidy. A major obstacle to maintaining an up-to-date knowledgebase of actionable alterations lies in the difficulty of incorporating relevant assertions from the literature as soon as they are available. To improve the accessibility of these assertions for the wider oncology research community, we adapted the Molecular Oncology Almanac by implementing open API endpoints and a browser extension for the purpose of rapid assertion acquisition.

Aims
1. Increase accessibility of the Molecular Oncology Almanac precision medicine knowledgebase through open-access API endpoints.
2. Implement a user-friendly interface for submitting actionable alterations to the knowledgebase directly from journal websites.

Methods
RESTful API endpoints for getting and posting alteration-action relationships to the Molecular Oncology Almanac were developed within the existing Flask web framework. Endpoints were designed within the OpenAPI 3.0 standard and documented in Swagger. Using these endpoints, a Google Chrome browser extension for posting alteration-action relationships was developed. Every submitted assertion includes a citation, class of alteration, cancer type, alteration effect, and level of evidence; gene, alteration, and therapy may also be included where relevant. Testing of endpoints and the extension was performed by multiple users in the Van Allen Lab. Submitted assertions are reviewed by site administrators prior to final incorporation into the database.

Results
The Connector browser extension was submitted to the Google Chrome Web Store, with final release pending approval. Multiple test users have submitted assertions through the pre-release extension. The Connector streamlines the process of submitting actionable alterations while reviewing the literature, reducing the effort required for knowledge base maintenance.

Conclusion
Open access tools for posting and retrieving assertions, sources, genes, and specific alterations expand the scope of the Molecular Oncology Almanac for integration into external interpretation resources. These developments represent a step forward in providing accessible clinical interpretation of tumor molecular profiling to clinicians and researchers. The Connector will be presented to cancer research audiences aiming for wide adoption in the community.
Measurement of physician burden in EHRs: a systematic literature review

Amanda J. Moy, MPH1, Sarah Collins Rossetti, RN, PhD1
1Columbia University Department of Biomedical Informatics, New York, NY, USA

Introduction
Public policy discussions associate EHRs with increased documentation burden resulting in burnout. While validated measures of burnout exist (e.g., Maslach Burnout Inventory), burden has largely been ill-defined.

Methods
We used PRISMA guidelines to conduct and report our systematic review. We searched PUBMED from 1/1/1995 to 2/9/2019 for all English-language studies investigating EHR documentation burden among physicians in mixed practice settings. Search terms were: (burden) AND (documentation OR note) OR ehr OR emr) AND (physician OR clinician OR doctor). After removing duplicates, titles/abstracts were independently assessed by two reviewers. Studies were restricted to the U.S. due to its unique socio-political context and healthcare ecosystem. A priori inclusion criteria were: U.S. studies utilizing any documentation burden metric (e.g., perception of time, event logs). A priori exclusion criteria were studies: outside the U.S., not involving physicians, without mention of burden, neither descriptive, observational nor interventional.

Results
Of the 732 articles retrieved, ten studies met criteria. After full-text review, two additional studies were incorporated based on in-text references for a total of 12 studies. Several specialties were examined; half of the studies involved internists and family/primary care. Study designs varied (Table 1), and distinct time constructs were measured: observed time elapsed, “time block[s]” constructed via EHR login data, EHR login/logout time, EHR event logs, self-reported time as a relative metric (i.e., more or less time), self-reported proportion of burden or time, and observed documentation time for notes. We identified six main proxies of burden (Table 1). Physician burnout was mentioned in 41.7% (5/12) studies, but only one used a validated burnout assessment. Only one study distinguished burden from burnout; independently, only one explicitly mentioned generating a quantitative measure of burden.

Table 1.

</tbody>
</table>

Conclusion
EHR documentation burden among physicians of diverse specialties remains a challenge in both inpatient and ambulatory settings. Targeting burden as the subject for quality improvement strategies and interventions requires quantifiable measures that are comparable and consistent across time, settings, and contexts—a metric that isolates the problem area, as well as its magnitude and directionality. However, research utilizing concrete, validated measures of burden are lacking. Given the multitudinous definitions for both burden and time, this review suggests evidence is fragmentary. Further research is needed to reliably operationalize the concept of burden, explore how it is best measured, and standardize its utilization.

Designing a biomedical information system for clinical assessments and subsequent interventions for mental health and substance abuse YMSM patients of color with HIV utilizing Multidimensional Scaling Analysis and Paired Comparisons Techniques

Sukrit Mukherjee, PhD, MSE1, 2, Eric Houston, PhD2

1Center for Biomedical Informatics, Charles R. Drew University of Medicine and Science, Los Angeles, CA, USA; 2Department of Psychiatry and Human Behavior, Charles R. Drew University of Medicine and Science, Los Angeles, CA, USA

Abstract

In mental health and substance abuse treatment, individualized assessments provide information on the specific thoughts and cognitive processes influencing a person’s behavior, emotional responses, and psychological functioning. Given the lack of automated assessment procedures or individualized clinical interventions in the growing health disparities in the South Los Angeles of USA, we developed a novel system using idiographic techniques to automatically and quickly generate individualized patient assessment data for use in clinical interventions.

Introduction

Depression is widespread and disproportionately affects people living with HIV and other chronic health conditions (Ali et al, 2006). A study based on a nationally representative sample of people living with human immunodeficiency virus (HIV) in the United States found that 36% of participants had a probable diagnosis of major depressive disorder, a rate nearly five times greater than that of the general population (Bing, 2001). Receiving treatment for depression becomes critical for those HIV patients but for many people living with HIV (PLH), depression remains largely untreated (Asch, 2003; Shippy, 2004). This low percentage of treatment for depression in the HIV patient population have led to several factors, including the stigma including tendency of individuals to avoid or not to engage in treatment for depression as well as non-participation in depression intervention research (Shippy, 2004; Earnshaw et al, 2013; Nichols, 2002; Reece, 2003). Little research has focused on how to reach and engage patients with depression and HIV who may be at the intersection of multiple social identities faced with stigma. Paired comparisons techniques and MDS analyses are two data analytic techniques that have traditionally been used in statistics and research (Zhu, 2009). But to date, paired-comparisons techniques and MDS have not been combined for use in either automated assessment procedures or individualized clinical interventions. We intended to fill this gap by utilizing novel use of such idiographic approaches that may be particularly valuable in clinical settings that lack staff trained in clinical interviewing or individualized assessment techniques.

Methods & Results

We followed a mixed method research design in this study. The study called, Project STEP (“Steps Towards Embodying Positivity”) was targeted to conceive a new cognitive training intervention system to address depressive symptoms and suboptimal HIV treatment adherence among African American and Latino YMSM (ages 18-29) in the Los Angeles metropolitan area. The system consists of 2 stages. The first stage was designed using Java Server Pages (JSP) as frontend, Java as middle tier and MySQL as backend on a Linux platform with statement session of the input data (paired-comparisons ratings) from a participant and it processes the data using MDS analysis and transforms the data into display of a n-dimensional spatial configuration and provides stress values, a least distance measure and R values of the individual user. The 2nd stage that is designed with ASP.Net as frontend, C# as middle tier and MS SQL Server as backend on a Windows platform receives statements, ratings, dot location and emotion values from first stage and generates stimuli for use in ABM training interventions, particularly individualized ABM interventions. The automated nature of our assessment approach and the relative speed with which the information can be applied is novel and has much potential in addressing gaps in the delivery of care.

Conclusion

We have attempted to solve the problem of clinical assessment for mental health and substance abuse patients belonging to YMSM of color with HIV across the continuum of care by creating a novel system that automatically and quickly generates individualized patient assessment data for use in clinical interventions like attention bias modification training with strong market potential.
Variability in User Response to Custom Alerts in the Electronic Health Record: An Observational Study

Naveen Muthu, MD1, Eric D. Shelov, MD, MBI1, Marc C. Tobias, MD2, Dean J. Karavite, MS1, Evan W. Orenstein, MD3, Robert W. Grundmeier, MD1
1Children’s Hospital of Philadelphia, Philadelphia, PA; 2Phrase Health, Philadelphia, PA; 3Children’s Healthcare of Atlanta, Atlanta, GA

Introduction

Computerized alerts in electronic health record (EHR) systems are intended to bring evidence to clinical practice and improve the safety of patient care. The adoption of EHRs that meet the requirements for the Meaningful Use incentive program has allowed organizations to build custom alerts in the EHR. These custom alerts, as opposed to medication alerts that are often purchased from third-party vendors, remain poorly characterized. Therefore, in this study, we aimed to describe the incidence of and user response to these custom EHR alerts at Children’s Hospital of Philadelphia.

Methods

We examined data for all interruptive custom alerts from October 1, 2017 to December 31, 2017. Non-interruptive alerts were not included. Data were obtained from the institutional clinical data warehouse. One author (N.M.), a pediatrician and board-certified clinical informatician, reviewed the display text of each custom alert and determined if 1) an actionable intervention was available for the user to choose in the alert itself and 2) if an actionable intervention was available, categorized which of the potential alert responses constituted alert acceptance and alert overrides.

Results

137 unique interruptive alerts were displayed on 395,161 occasions to users of the EHR in the study period. Of all the alert instances in the study period, 51.6% were seen by nurses. Prescribers (residents, fellows, attending physicians, nurse practitioners, physician assistants) saw 28.6% of alerts. Pharmacists, who are often targeted by medication prescribing alerts, receive only 7.1% of custom alerts. Of the 137 unique alerts, 70% included an actionable response within the alert itself, and these alerts accounted for 69% of all instances when a user saw an alert in the study period. When an actionable option was offered to the user, users accepted the alert recommendation 11% of the time and overrode the alert 89% of the time. Although most alerts have an acceptance rate of 10% or less, a subset of alerts are accepted more than 30% of the time (Figure 1).

Figure 1. Number of alerts by alert acceptance rate. The majority of alerts have an acceptance rate less than 10%. However, there is a subset of alerts that have an acceptance rate over 30%.

Conclusion

There appears to be a substantial range of alert acceptance for custom alerts, suggesting that despite the potential for alert fatigue, providers consider alert recommendations. Further study of the contextual and display characteristics that explain the variability in provider response to alerts is needed in order to effectively design and use alerts.

Improving Automation and Access Using the Vaccine Code Set Management Service

Stuart Myerburg, JD, Centers for Disease Control and Prevention, Atlanta GA
Millie Malai, MPH, Deloitte Consulting, LLP, Atlanta, GA

Problem Addressed:
The use of data standards is not uniform across healthcare providers affecting the quality of information exchanged with public health entities. Specifically, for immunization registries, outdated or incorrect information can affect the accuracy of public health coverage assessments used to make immunization program decisions. This service aims to provide a centralized source for vaccine-related codes to ensure that the mappings between codes, attributes, and metadata are sound, and then offer a web service to facilitate more automated updates.

Description of our service:
The Centers for Disease Control and Prevention (CDC) deployed a centralized service to provide immunization information systems (IIS) and provider EHR systems with comprehensive and consolidated mapping services for vaccine and vaccine-related codes. The codes represent components of vaccine ordering, inventory management, and the documentation of vaccines administered to patients, and are managed by diverse governmental and non-governmental agencies such as CDC (CVX and MVX codes), Food and Drug Administration (NDC codes), and the American Medical Association (CPT codes), amongst others. The centralized service maps CVX, MVX, CPT, NDC (unit of use and unit of sale), Global Trade Identification Numbers (GTIN), vaccine lot numbers (unit of use and unit of sale), and Vaccine Information Statements (VIS) codes, along with metadata associated with the codes. The leading-edge application allows for a more streamlined management of the codes and more automated access to the codes via web service.

The Vaccine Code Set Management Service (VCSMS) was established to explore and implement new tools for management and delivery of these code sets. The tools and data foundations have been implemented for managing and curating catalogs and maps. In April 2019, the service deployed an end-user web service to facilitate more automated use of the information published by CDC.

The main objectives of the service are:
Improving data management and quality – Increase automation to improve process efficiency and quality, establish consistently-applied data editorial policies, and improve sourcing of external reference data used for code set maintenance and mapping.

Expand content structure – Deliver new content data files specifically designed to aid integration with electronic systems.

Provide automated data access – Provide new options for direct delivery of content to end user organizations via web-service and desktop client.

Poster will describe:
The poster will describe the centralized service and how terminologies are managed through the system interface, the changes to the workflow to manage the content, the public health organization’s workflow and how it has changed to improve automation using the service, and lessons learned that other organizations can use when deploying a web service or similar functionality.
Systematic Review of Patient-Facing Visualizations of their Personal Health Data

Annie Myers, MA¹, Samuel Isaac, BS¹, Ruth Masterson Creber, PhD, MSc, RN¹, Meghan Reading Turchioe, PhD, MPH, RN¹

¹Div. of Health Informatics, Dept. of Healthcare Policy and Research, Weill Cornell Medicine, New York, NY

Introduction and Purpose

Tools that allow patients to generate and view health-related data have grown in recent years. In parallel, health-related data is being returned to patients and consumers with increasing frequency, towards the goal of increased engagement, education, and shared decision-making. In the setting of varied literacy, health literacy, and numeracy levels, visualizations may aid patients and consumers to better interpret and act upon health-related data. However, there remains a need to understand best practices for visualizing health data to patients. The purpose of this systematic review was to review and evaluate the state of the science of patient-facing visualizations of their personal health data.

Methods

In December 2018, we searched five scholarly databases (Pubmed, Embase, Scopus, ACM Digital Library, and IEEE computation index) for articles reporting patient-facing visualizations for personal health data, including data originating from both patients (i.e., patient-reported outcomes) and clinical settings (i.e., lab values) published between 2013 and 2018. We used search terms such as patient/consumer/user and visualization/graphic. Three reviewers systematically screened retrieved articles using prespecified eligibility criteria in Covidence (covidence.org), and independently assessed quality of included articles using the Mixed Methods Appraisal Tool. Characteristics of included articles and visualizations were extracted and synthesized following Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines.

Results

Of the 2,300 articles retrieved, 39 were included in this review. Most articles were excluded for including visualizations of non-health data (n=870) or visualizations intended for a clinicians or researchers (n=834). Sample sizes across the included studies varied drastically (369 ± 1,255). On average, participants were middle-aged (51 ± 11), non-Hispanic White (70%), female (60%), and had high education (77% college or higher). Few studies measured health literacy (n=5), numeracy (n=3), or graph literacy (n=2). Approximately half of the visualizations supported chronic condition monitoring and management while half were for general health maintenance (for example, lipid profiles). Visualizations included line graphs (35%), number lines (25%), bar graphs (16%), and icons (12%). Overall 77% of the visualizations used color; a traffic light color scheme was used most frequently. Many displayed longitudinal data (47%), 32% included legends, and 40% offered sentence-based interpretations of the data. Articles reported a range of methodologies and measures for assessing the visualizations, from qualitative explorations of patient attitudes and preferences to quantified measures of risk perception and comprehension.

Conclusion

Although findings suggest certain visualization types (number lines, icons) and components (color, contextual information) promote comprehension, the homogeneous patient samples, limited reporting of health literacy, numeracy, and graph literacy, and range of methodologies and outcome measures reported make assessment of optimal visualizations difficult. The informatics community and others engaged in this work would benefit from efforts to standardize best practices for the design, development, and evaluation of patient-facing visualizations.

This work was supported by NINR of the NIH under Award Number R00NR016275 (PI: Masterson Creber).

Similarity of Medical Concepts among Submitted Questions in Community-Driven Consumer Health Websites

Hamid Naderi, PhD1, Sina Madani, MD, PhD2, Behzad Kiani, PhD1, Kobra Etminani, PhD1
1Mashhad University of Medical Sciences, School of Medicine, Department of Medical Informatics, Mashhad, Iran; 2Vanderbilt University Medical Center, Department of HealthIT, Nashville, TN, USA

Introduction: Online Question and Answering (Q&A) communities are rapidly growing in World Wide Web. One of the major issues in these communities is duplicated questions, which result in a large number of analogous questions being posted on the websites. Hence, repeated questions make the search and browse for healthcare consumers quite frustrating. The ability to automatically categorize submitted questions based on structured topics on these websites and suggest similar Q&A to the users could potentially reduce the number of redundant questions. This study aims at comparing inter and intra-topic likeness amongst Q&As by incorporating concept-based similarity computing.

Methods: We randomly selected 3,000 Q&As from three popular online health communities including NetWellness, WebMD, and Yahoo Answers. Then, Unified Medical Language System (UMLS) concepts relevant to a set of selected questions from various topics were extracted by MetaMap (v2016) where the data source was limited to Consumer Health Vocabulary data source. Subsequently, Concept Unique identifiers (CUIs) were weighted by Term Frequency Inverse Document Frequency (TF-IDF) values. Finally, the cosine similarity among weighted vectors of UMLS concepts was computed (Figure 1). We also randomly selected 400 answered questions from NetWellness by 20 subject matter experts (20 Q&A for each expert) in order to compute expert-expert similarity scores. We generated profile for some experts based on answered questions. Then the similarity between profile of experts in same (expert-expert intra-topic similarity) and different topics (expert-expert inter-topic similarity) was computed.

Results: The average of intra-topic similarity in NetWellness, WebMD, and Yahoo Answers (0.095, 0.192, and 0.110 respectively) was about 10 times higher than the average of inter-topic similarity within the same communities for selected questions (0.012, 0.025, and 0.018 respectively). Similarity scores between the content of questions answered by subject matter experts in the same and different topics were calculated as 0.51 and 0.11, respectively.

Discussion: Comparing the results of intra-topic similarity and inter-topic similarity indicate the similarity between questions from same topics is significantly higher than the similarity between questions from different topics. It means the overlap between extracted concepts of questions from different topics is little. So using concept based method can classify questions of different topics automatically. Also Expert-expert intra-topic similarity shows there is considerable overlap between profiles of experts in the same topic. So concept based system can suggest users similar experts in a specific topic who have similar profiles. So concept-based similarity computing methods can be used in the development of intelligent Q&A retrieval systems with auto recommendation functionality for identification of comparable healthcare related questions as well as subject matter experts. Moreover, such methods can help community programmers define a process for automatic classification of questions and experts by topic, while integrating the content of several communities where healthcare consumers can find additional information from analogous questions that have been already asked and answered.

Electronic Phenotyping of Patients with Heart Failure from a National Clinical Information Database

Masaharu Nakayama, MD, PhD¹,²; Chiaki Otomo, RN¹; Ryusuke Inoue, MD, PhD¹
¹Medical Informatics Center, Tohoku University Hospital, Sendai, Japan; ²Department of Medical Informatics, Tohoku University School of Medicine, Sendai, Japan

Introduction
A database of clinical information collected from several medical institutions, including national university hospitals and private hospital groups, and the Medical Information Database NETwork (MID-NET), have been available to the public in Japan since 2018 [1]. Tohoku University Hospital is one of the cooperative medical institutions of the MID-NET project. To collect clinical events known as electronic phenotyping, it is important to correctly extract data from clinical information, combine multiple pieces of information, and define the target disease. Herein, we examined a study to find patients with heart failure and to validate the accuracy of using MID-NET data.

Methods
A criterion to describe heart failure cases was determined according to clinical guidelines that were released by the Japanese Circulation Society, which is the largest community of cardiologists in Japan [2]. The data that we studied were based on the records from April 1 to December 31, 2013. The initial search conditions (initial rule) were based on disease names, examinations, and medications related to heart failure. We extracted and analyzed clinical data from MID-NET and found patients with heart failure. Two doctors, including a cardiologist, reviewed medical records and verified which cases were true. Precision and recall rates were calculated after the case assessments. Next, we examined a method to identify the elements to extract true cases correctly using machine learning with XGBoost in R (v3.4.1).

Results
There were 5,282 cases extracted by disease names that were related to heart failure. Of these, 2,799 cases corresponding to the initial rule were retrieved, and 200 cases were randomly sampled and assessed. There were 70 true cases. Thus, the precision rate was 0.350 and the recall rate was 0.912. A machine learning method using XGBoost revealed the correlation of heart failure with several factors, including the value of serum b-type natriuretic peptide (BNP), the linkage between the disease name start date and actual date of hospitalization, and medications for treatment of heart failure. Using this information, we were able to determine conditions contributing to improving the validity of the cases with heart failure. In this way, patients were extracted using the disease name as it related to heart failure and hospitalization within two weeks after the disease name starting date. Furthermore, the candidates were categorized into three groups according to the value of their serum BNP (High, Middle, and Low ranges). The high group was labeled “heart failure,” and the low group was excluded. In the middle group, candidates were additionally categorized according to their prescribed medication for heart failure. Our analysis indicated that the precision rate increased to 0.878, while the recall rate decreased to 0.697. The F-measure also increased from 0.506 to 0.777.

Conclusions
To find target cases from a large clinical database, precise electronic phenotyping is indispensable. A machine learning method can improve the accurate extraction of patients with heart failure. Leveraging large amounts of clinical data may be beneficial for making progress in medical research.

Automated classification of mobility activities in free text clinical narratives

Denis Newman-Griffis, MS,1,2 Ayah Zirikly, PhD,1 Pei-Shu Ho, PhD,1 Jonathan Camacho Maldonado, MD,1 Maryanne Sacco, MA,1 Alex Marr, BA,1 Albert M. Lai, PhD,3 Eric Fosler-Lussier, PhD2
1National Institutes of Health Clinical Center, Bethesda, MD; 2The Ohio State University, Columbus, OH; 3Washington University in St. Louis, St. Louis, MO

Introduction
Gathering and analyzing information on whole-person functional activities is an important part of assessing and improving an individual’s quality of life. However, reliably extracting information on activities from free text clinical records has proven challenging, in part due to a lack of coverage in controlled terminologies [1]. Recently, a dataset of 250 physical therapy records was annotated for descriptions of patient mobility [2], one category of whole-person activities defined in the International Classification of Functioning, Disability, and Health (ICF). Each of the 2,867 Action descriptions in the dataset was assigned one of thirteen 3-digit ICF codes indicating the type of mobility activity. The code names in the ICF match only a small subset of these descriptions, and a lack of integration with other controlled vocabularies limits their use for normalizing these codes. In this work, we formulated the normalization problem as multi-class classification, and experimented with a variety of popular classification models to understand what types of linguistic features can best distinguish different mobility activities.

Methods
We experimented with unigram text features and continuous word embeddings for classification, using both the words in the Action string and words within a fixed context window. We utilized several popular classification algorithms: Naïve Bayes (NB), k-Nearest Neighbors (KNN), Support Vector Machine (SVM), and Deep Neural Networks (DNN). In addition, we also investigated the use of concept embeddings derived from averaging word embeddings for the definitions of each 3-digit code in the ICF. We compared these ICF code embeddings to the word embedding features derived from Action texts and contexts and chose the code with highest cosine similarity as the prediction. Finally, we used a deep neural network that took word embedding features of a specific context and ICF code embeddings as input and calculated a linear transformation of the code embedding for classification with the cosine similarity model.

Table 1. 10-fold cross-validation results, in %, for classifying Action mentions with 3-digit ICF codes. VecSim denotes vector similarity model; +DNN adds the context-sensitive linear transformation.

Overall micro accuracy and macro F1 (averaged over ICF codes) from our experiments are given in Table 1. Both the unmodified vector similarity model and the version with context-sensitive linear transformation outperform the other classifiers by a large margin, indicating that using embedding representations of the codes is more helpful for the normalization task than treating each as an orthogonal class label alone. In addition, using the context-sensitive transformation improves overall performance significantly ($p=0$, McNemar’s test). However, as shown by comparing the Micro Accuracy performance (weighted by sample) to Macro F1 (weighted by code), all methods are sensitive to skew in the dataset. Of the 2,867 total actions, 1,088 are labeled with the most frequent code (d450 – Walking), while the three least common codes each have fewer than 10 samples.

Conclusion
We found that neural concept embeddings achieved the best performance on classifying the type of mobility Actions, and that a context-sensitive projection of concept embeddings improved classification significantly. This indicates the importance of context-sensitive models for mobility information, and offers a potential direction for improving general clinical information extraction. Our results also indicate that robustly classifying rare codes is an important area of future work. This research was supported by the Intramural Research Program of the National Institutes of Health, Clinical Research Center and through an Inter-Agency Agreement with the US Social Security Administration.

Roudebush VA Medical Center, Indianapolis, IN; 4Department of Medicine, Indiana University School of Medicine, Indianapolis, IN;

Introduction
Poor design of Pharmacogenomics clinical decision support tools (PGx-CDS) can introduce errors and create alert fatigue instead of improve treatment efficacy and safety for patients1,2. The objective of this study was to develop and evaluate a prototype of a PGx-CDS interface with user-centered design methods.

Methods
This study had two phases: In phase I, we conducted qualitative interviews to assess providers’ information needs from two healthcare systems. Interviews were audio recorded and transcribed for analysis through a combination of inductive and deductive qualitative analysis to develop design requirements for a PGx-CDS user interface. In Phase II, we conduct usability evaluates of the prototype in a simulated examination room. Physicians, specializing in oncology and gastroenterology, completed two fictitious patient scenarios involving PGx-CDS for thiopurine methyltransferase (TPMT). Qualitative data were collected via Morae® video and audio recording using a “think aloud” technique and debriefing interviews. Quantitative usability data were measured on four established measures: learnability, usability errors, efficiency, and satisfaction utilizing the 19-item Post-Study System Usability Questionnaire.3

Results
Fourteen providers participated: 10 were interviewed in phase I and 7 provider completed usability testing in phase II (3 providers participated in both phases). Most (90%) providers were interested in PGx-CDS systems to help improve medication efficacy and safety. Interviews yielded 8 themes (Table 1) sorted into two main categories: health care provider’s views on PGx-CDS and 2) important design features for PGx-CDS. Usability testing showed high provider satisfaction from the prototype (Table 2).

Longitudinal Satisfaction with Information for Breast Reconstruction Patients

Krista M. Nicklaus, MSE1,2, Mary Catherine Bordes, BS2, Jun Liu, PhD2, Deepi Chopra, MBBS, MPH2, Greg P. Reece, MD2, Summer E. Hanson, MD, PhD2, Mia K. Markey, PhD1,2

1The University of Texas at Austin, Austin, TX; 2The University of Texas MD Anderson Cancer Center, Houston, TX

Introduction

Prior studies have demonstrated psychosocial and quality of life benefits for patients who undergo breast reconstruction after mastectomy, but patients’ decision-making about breast reconstruction is challenging, especially with respect to the available preoperative information1. The goal of this study is to investigate patients’ satisfaction with the information they received from their healthcare providers over multiple time points after their initial reconstruction surgery to identify unmet information needs and factors associated with information gaps.

Materials and Methods

We have previously collected health data, image data, and psychosocial measures from 505 breast reconstruction patients from The University of Texas MD Anderson Cancer Center from 2011-2014 (funded by NIH R01CA143190 and R01CA203984). This study used the BREAST-Q v.1 Post Reconstruction Satisfaction with Information module, which includes 15 items to rate satisfaction with information provided by the plastic surgeon about issues such as healing time, complications, and new breast look and feel. This module was administered at four time points after patients’ initial or definitive reconstruction surgery.

For initial analysis, we selected 118 patients who had satisfaction with information scores at the first two time points and complete demographic data, including assessments of preoperative body image investment (ASI-R) and body image concerns (BIS). We used cluster analysis to look for trends in how satisfaction with information changed over time. Figure 1 demonstrates the results of k-means clustering based on the satisfaction with information scores at T1 (3 months postoperative) and T2 (12 months postoperative) as well as the difference between the scores at T1 and T2.

Results and Conclusion

Cluster analysis of longitudinal satisfaction with information revealed patterns that are not simply a reflection of differences in preoperative body image investment or body image concerns. For example, women in cluster #1 and cluster #2 had similar ASI-R and BIS scores, but different satisfaction patterns over time. The clusters are being further investigated with the aim of identifying preoperative characteristics that predict which patients are mostly likely to benefit from postoperative information interventions, such as just-in-time delivery of information about surgical complications. This study represents the use of patient-reported outcomes and psychosocial data to improve healthcare information delivery to breast reconstruction patients.

Using Electronic Health Record Data to Identify Patients with Prediabetes

Thomas J. O’Byrne, MAS1, M. Regina Castro, MD2, Che G. Ngufor, PhD1, Gyorgy Simon, PhD3, Pedro J. Caraballo, MD2

1Department of Health Science Research and 2Department of Medicine Mayo Clinic, Rochester, MN; 3Department of Medicine, University of Minnesota, Minneapolis, MN

Introduction

It is estimated that 30% of the population suffers from pre-diabetes, in which glucose levels are above normal but still below current criteria for diabetes. Pre-diabetes represents a state of increased health risk and is an important risk factor for the development of overt diabetes. Current evidence shows poor recognition and limited management in routine clinical practice. There are challenges to identify patients with prediabetes including lack of knowledge, confusing glucose levels, lack of documentation in the electronic medical record, etc. Current national clinical guidelines recommend screening and management of patients with prediabetes as the most cost-effective intervention to confront the growing diabetes epidemic. Our aim is to define algorithms to accurately identify patients with pre-diabetes by using available electronic health record (EHR) data obtained during routine care. Herein, we present our initial findings related to feasibility, validation of the algorithm and clinical categorization.

Methodology

The study included 48,038 adult (≥ 18 y-o), non-pregnant residents of Olmsted County, Minnesota, who received primary care at Mayo Clinic between 1999 and 2014. We used electronic searches to gather data and used “fasting” glucose, A1c, diagnoses and medications related to diabetes in an algorithm to allocate all subjects into 4 mutually exclusive and exhaustive categories: “Diabetes”, “Pre-diabetes”, “Normoglycemia”, and “No-data” (no available data applicable to the other categories). Validation of the algorithm was performed using a powered sample of patients (n=159) with blind and manual clinical review of the comprehensive EHR by an expert clinician. To evaluate agreement, we used Kappa, Weighted Kappa and secondary measures of agreement. Two sensitivity analyses were performed to examine the ability of the algorithm to correctly categorize patients. The first sensitivity analysis used only 1 indicator of diabetes disease instead of 2, as used in the main analysis, and the second sensitivity analysis used 3 indicators.

Results

The proportion of subjects allocated to the 4 categories in the large cohort, Diabetes, Pre-diabetes, Normoglycemia and No-data were 9.5%, 29.6%, 28.5% and 32.4%, respectively. The random sample had similar characteristics to the rest of the cohort except for having lower mortality. There was a strong agreement between the algorithm and the manual clinical review, Kappa 0.85 (95%CI 0.78-0.92, p<0.0001) and Weighted Kappa 0.90 (95%CI 0.84-0.96, p<0.0001). The results of the sensitivity analyses are shown in the Figure. The proportions of No-data and Normoglycemia were similar between the manual clinical review and both sensitivity analyses. However, proportions of Diabetes and Pre-Diabetes were different. The changes made to the algorithm for the sensitivity analyses affected classification of patients only into the Diabetes and Pre-Diabetes categories.

Conclusion

Our data showed that it is feasible to identify clinically helpful phenotypes describing the different levels of dysglycemia by using EHR data obtained during routine clinical care. The use of discrete clinical categories should facilitate implementation of clinical decision support and longitudinal plan of care, using tools currently available in most widely used EHR. These interventions would support current best strategies to minimize the impact of the diabetes epidemic and associated devastating complications.
Building a LVEF Extraction Pipeline for SOAP Notes
Adetomiwa Oguntuga, MS¹, Jordan Overcash MS¹, Nam Nguyen, MS¹
¹Veradigm, San Francisco, CA

Introduction
Congestive Heart Failure is a common chronic medical condition that affects the pumping power of muscles in the heart. Left Ventricular Ejection Fraction (LVEF) is a quality measurement recommended by the American College of Cardiology Foundation, the American Heart Association and the Physician Consortium for Performance Improvement, to access pumping power of the left ventricular wall of the heart.

We build a prototype information extraction pipeline in python, using natural language processing (NLP) techniques to identify and extract these assessments from SOAP notes on Practice Fusion EHR data.

Methods
500 SOAP notes from Practice Fusion’s EHR database were identified as possibly containing LVEF scores, using keyword search. The keywords used were: left ventricular ejection fraction, lv ejection fraction, ejection fraction, e.f, ef, heart failure reduced ejection fraction, hhref, heart failure preserved ejection fraction and hhpief.

These notes were run individually through a prototype extraction pipeline, coded in Python 3 (version 3.6)².

This pipeline used functionality from the spacy NLP library (version 2.0)³ to chunk notes into a list of sentences. Sentences containing LVEF assessments were chunked further based on the presence of commas or semi colons into smaller chunks. Commas present in dates are ignored and the dates are converted into a numerical MM/DD/YYYY or MM/YYYY format. The final list of chunks is then processed by using regular expressions, to extract the LVEF assessment and the date associated with the assessment (if present in the note).

LVEF assessments come in three types: a percentage (e.g. 45%), a range of percentages (e.g. 40-50%), or a relative percentage (e.g. >40%). Precision, recall and F1 score were calculated by assessment type.

Results
The results presented in the table below are from sentences identified as containing an LVEF assessment (Table 1).

Table 1: Precision, Recall and F1 Measure Score for Prototype Pipeline

Discussion and Conclusion
Our overall goal is to build a tool that can extract LVEF assessments from our unstructured data sources to enrich our structured data to better enhance our life science analysis studies. We have been able to extract LVEF scores and dates from identified sentences with a high degree of accuracy. Though some data had an associated date, the majority of extracted LVEF scores did not. Future work will focus tying the extracted LVEF score to an encounter. In addition, we need to access the recall and precision of the logic that identifies sentences with LVEF.

Determinants of Medication Adherence in Sickle Cell Disease Using the World Health Organization Model

Kinsley E. Ojukwu1, Christopher Simpson1, Amol Utrakar, MD2, Whitney Allen3, Laurie Novak, PhD, MHSA1, Robert M. Cronin, MD1
1 Vanderbilt University, Nashville, TN, USA, 2 Columbia University, New York, NY, USA, 3 Meharry Medical College, Nashville, TN, USA

Introduction
Over 100,000 individuals in the United States are affected with sickle cell disease (SCD)1, and the disease has great prevalence among those with healthcare and healthcare information technology disparities. Hydroxyurea is a medication that decreases morbidity and mortality in SCD, yet has poor adherence2. In a 2003 report on adherence to long term medical therapies, the World Health Organization (WHO) described a model that organized determinants of medication adherence into five interacting dimensions3. There are limited data exploring both barriers and promoters of medication adherence in SCD, and none analyzed these determinants of medication adherence in the context of the WHO model.

Methods
A mixed methods approach was used for this study. Participants were selected via a convenience sampling of patients seen at outpatient clinics affiliated with the Vanderbilt-Meharry Center for Excellence in SCD. Demographic data was collected through the use of surveys. Semi-structured interviews were conducted between September 2016 – July 2017. Interviews were audio recorded, transcribed, and analyzed using Dedoose Version 8.1.8. Analysis was done with an inductive-deductive approach4. Open coding methodology was utilized, and a codebook developed to identify promoters and barriers of medication adherence. These codes were subsequently categorized based on the WHO Model. Codes were reviewed by two independent coders, and categorization done via consensus of three authors (KEO, CS, and RMC).

Results
Forty-six participants ranging from age 14-61 were enrolled. All participants carried a diagnosis of SCD. The median age was 28.5, and a majority were female (n=24). Most self-identified as Black or African American (n=42). Fifty distinct codes were applied with 38 barriers, and 14 promoters. Twenty-six were patient-related factors (e.g., fear of addiction – barrier), 11 social & economic (e.g. theft of medications – barrier), six condition related (e.g. subjective feeling of well-being – promoter), five therapy related (e.g. dosing schedule – barrier), and four health system (e.g., a phone application to track medications or appointments – promoter) (Table 1). Some codes fit multiple categories, (e.g., sense of responsibility) – a barrier in younger ages, but a promoter in older ages, and stigma, both a barrier and promoter, and categorized into both social/economic and patient related categories.

Conclusion
This study found that although a majority of determinants were patient-related in nature, about half came from other dimensions, showing the multi-dimensional nature of medication adherence in SCD. We also discovered unique determinants in this population, such as the barrier of medication theft. Limitations to this study include being performed at a single center with a convenience sampling method of individuals from clinic, which may lead to lack of generalizability and selection bias respectively. However, many determinants extracted from our research are concordant with determinants previously described in literature, such as forgetfulness and concerns about medication side effects. Using the WHO framework to understand medication adherence determinants in SCD, a disease affecting those with healthcare and healthcare information technology disparities, can enable the creation of informatics solutions that can help increase medication adherence, and potentially help bridge the digital divide.

Introduction

Accurate surveillance is needed to combat the growing opioid epidemic for effective resource mobilization. Current methods primarily rely on diagnostic codes, which are specific, but not sensitive, potentially resulting in many opioid overdose encounters being missed by current surveillance methods. Recent application of Natural Language Processing (NLP) to clinical notes indicates there is a wealth of untapped, opioid-specific information that could be used to improve surveillance. To investigate the potential volume of missed opioid overdoses, we compare the number of overdose encounters identified by diagnostic codes and a rule-based NLP pipeline from two different medical systems.

Methods

Emergency department (ED) opioid overdose (OOD) encounters between 9/1/16 and 9/1/17 for patients 18 years or older were identified using two methods: 1) claims data using ICD-10-CM codes and 2) ED notes using NLP. Encounters identified by claims data were associated with one or more overdose-related ICD-10-CM codes. NLP processed the first 24-hours of ED notes using a rule-based approach. Briefly, we utilized CLAMP v1.5.0 to construct the NLP pipeline, which includes standard pre-processing NLP modules, a custom dictionary utilized by the Named Entity Recognition module to identify terms associated with OOD, and a section identification module. Pre-processed notes were subjected to rules that included removing all annotations from patient education sections, and identifying the patients response to Narcan. Virginia Commonwealth University (VCU) and Loyola University (LU) ran both methods for a cross-institutional evaluation using the same NLP pipeline and ICD-10-CM codes.

Results and Discussion

At both medical institutions, the NLP pipeline was able to identify more than 60% of the encounters found using ICD-10-CM codes plus additional encounters not identified by the claims data. At VCU, 1,228 encounters were classified as OOD with claims data identifying 566 versus NLP’s 1,011 (349 were found by both methods). At LU, 2,584 encounters were classified as OOD with claims data identifying 84 and NLP 2,556 (56 were found by both methods). The additional encounters identified by NLP had ICD-10-CM codes related to altered mental status and opioid abuse/dependence, indicating that NLP is identifying OOD-related encounters missed by claims data. Random sampling of 30 encounters at VCU revealed about 45% identified by NLP were false positives. These included chronic pain patients and patients with poor mental status from other medical conditions who received Narcan as empiric treatment prior to definitive diagnosis.

Conclusion and Future Work

Our analysis showed that the NLP pipeline was able to successfully capture additional OOD encounters missed by claims data. Refinement of the NLP pipeline by implementing additional rules that do not rely on Narcan administration and ignoring all annotations in the prescription section should aid in eliminating false positives. Additionally, the completion of an annotated gold-standard data set will provide concrete performance metrics and highlight additional areas in need of improvement. Incorporating sophisticated NLP and machine learning techniques into current diagnostic code-based methods has the potential to improve surveillance and obtain more accurate information on the incidence of opioid overdoses.

†SAMHSA opioid-related death specifications minus “adverse effect” codes and adding T40.69 and T40.60.
Evaluating Interactive Clustering for Biomedical Information Retrieval

Michael Segundo Ortiz¹, Kazuhiro Seki, Ph.D.², Javed Mostafa, Ph.D.¹
¹University of North Carolina, Chapel Hill, NC;
²Konan University, Kobe, Hyogo, Japan

Problem

Large biomedical research databases such as PubMed rely on keyword-based queries and ranked-retrieval methods. This method is an emerging barrier in advancing research due to the large body of publications, even within specialized sub-fields. For instance, a single search in PubMed for “breast cancer” returns a long list of more than 380,000 articles. It is a non-trivial task for researchers to go through a ranked list and digest content, let alone establish logical connections within the content. A possible solution is to employ a system with a cluster-based browsing interface which potentially enables more effective concept and document retrieval.

Objectives

Our objectives for this work were to carefully create document collections (data sets) by considering underlying topic groups manually assigned by human experts (MeSH), and identify essential components and methods for discovering quality document clusters in order to enable the production and use of a dynamic cluster-based browsing system.

Methods

We retrieved PubMed articles related to breast cancer with the query "breast neoplasms" on September 21, 2018. It should be clarified that the MeSH labels were only used to create the data sets and then to evaluate downstream clustering. The methodology of clustering itself is unsupervised, therefore class labels were removed for the experiments. We hypothesized that full-text data may offer more lexical diversity and, consequently, may result in higher quality clusters. For document representation, we used a vector space model. Additionally, we explored the effectiveness of dimensionality reduction, specifically latent semantic analysis (LSA). For cluster analysis we used the maximin (maximum-minimum), k-means++, and spectral clustering algorithms. As an internal criterion, we adopted the silhouette coefficient. For external criteria, purity and adjusted mutual information were used.

Evaluation

We observed that k-means++ combined with keyword discovery methods and LSA worked the best compared with other parameter configurations. Contrary to our expectations, full-text data did not help increase the cluster quality despite that it required around 13–20 times more processing time. Also, the increased lexical diversity of full text made the clustering process more complex and the results less precise. Overall, using abstracts appeared to achieve a better balance between lexical diversity, cluster quality, and time complexity.

Conclusion

Although our work sheds light on the fundamental components of evaluating cluster quality for biomedical information systems, optimum parameter values and combinations depend on input data, which dynamically change in the cluster-based browsing paradigm. There is a need for a mechanism to automatically and intelligently adjust parameters for highly variable inputs to achieve externally valid results.

Future Plans

We are currently building a prototype biomedical information system for dynamic cluster-based browsing based on our findings. Follow [http://vzlib.unc.edu/dcb2/](http://vzlib.unc.edu/dcb2/) to explore the prototype.

Investigating female–male differences in risk factors for myocardial infarction using OHDSI tools

Anna Ostropolets, Linying Zhang, Jami Jackson Mulgrave, George Hripcsak
Department of Biomedical Informatics, Columbia University, New York, USA

Background
Coronary heart disease (CHD) has been the leading cause of mortality and disability across the world. There is no consensus regarding the sex-specific influence of additional risk factors on outcomes of CHD: while Millett et al. and Anand et al. reported higher risk of myocardial infarction associated with diabetes mellitus (DM) type II in women compared to men, Shah et al. found no significant sex-specific difference. Similar disagreement has been observed for obesity, smoking and atrial fibrillation (AF). We tested the assertion that given a complex study result from the literature, we could quickly reproduce the study, mimicking the variables by generating matching phenotype definitions using standard vocabularies, and carrying out the statistical analyses on electronic health record data. We choose Millett’s study for its nested hypothesis that compares the relative effects in two groups.

Methods
We performed our analysis on the Columbia University Medical Center database that contains de-identified electronic health records of 6.3 million patients stored in the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM). We studied patients aged at least 30 years old as of 01 January 2012 (index date) who had never experienced major cardiovascular events (stroke, transient ischemic attack, myocardial infarction (MI), episodes of angina) prior to index date. To study the impact of risk factors, we leveraged the OMOP Standardized Vocabularies to obtain the comprehensive list of SNOMED diagnosis codes for hypertension, AF, obesity, DM types I and II, and smoking status. Additionally, for obesity we used LOINC codes for measurement of body mass index of 30 kg/m2 or higher. We used Observational Health Data Sciences and Informatics (OHDSI) Atlas web interface to generate phenotype definitions. We used a Cox proportional hazard model adjusted for age, hypertension, DM, obesity, and smoking status to estimate the baseline hazard ratio for MI comparing to men. To determine the hazard ratios for the risk factors, we created interaction terms between the risk factor and sex. Like Millet et al, we adjusted diabetes and hypertension for each other and for smoking status; obesity and use of lipid-lowering medications; AF for DM, hypertension, obesity, smoking status, and use of lipid-lowering medications; and obesity for smoking status. Additionally, we studied the effects of risk factors in different age groups by splitting patients into three age groups (<50, 50–59 and >60 years old). To obtain the ratio of hazard ratios for women comparing to men we used the interaction terms between these risk factors and sex.

Results
We identified 3,076,220 eligible patients (57.6% women and 42.6% men), with the mean age at index date 52±14.1 and 54±14.0 respectively. Baseline prevalence of diabetes, hypertension, obesity, and reported smoking in men and women did not differ significantly. Of 17661 incidents of MI that were recorded, the majority belonged to men (64%). We found that women had a lower overall risk of MI than men (women-to-men ratio of HR 0.45, 95% CI 0.44 – 0.46) after adjusting for the risk factors and age. This trend attenuated with increasing age (ratio of HR 0.53, 95% CI 0.48 – 0.59). Smoking was associated with an increased risk of MI in both women (HR 2.94, 95% CI 2.54 – 3.39) and men (HR 2.23, 95% CI 3.02 - 4.42); the difference between men and women was not statistically significant. We observed the same pattern for obesity: obese women developed a higher risk of MI (HR 4.62, 95% CI 4.11 – 5.2) compared to men (HR 4.02, 95% CI 3.55-4.57), although the women-to-men ratio was not significant. Hypertension, DM type I and type II and AF were also associated with higher attributable risk in women than men, with a women-to-men ratio ranging from 1.5 (DM type I) to 1.88 (AF). Presence of DM type II, hypertension, or AF was associated with a higher risk of MI in both sexes: hazard ratio varied from 2.0 (DM type II) to 2.19 (AF) in women and from 1.16 (AF) to 1.34 (hypertension) in men.

Conclusion
We were able to duplicate the study on electronic health record data stored in OMOP CDM. The phenotype definitions were based on logical and temporal constructs applied over classes from the OMOP Standardized Vocabularies using OHDSI’s Atlas web interface. Overall, we found tighter confidence intervals that overlapped the original intervals. From our experience, OHDSI Atlas facilitated phenotype generation and reduced the effort on initial data analysis. On the other hand, we could not fully implement the statistical model in Atlas, so it took several iterations to parallel the study’s statistical analysis in R. Therefore, the lesson for OHDSI is that the phenotyping component of Atlas is sufficient, but the statistical analysis component must be expanded.

Developing an Ontology for Daily-Living Routines of Patients with Chronic Conditions

Mustafa Ozkaynak, PhD

1University of Colorado | Anschutz Medical Campus, Aurora, CO

Introduction

Individualized therapy plans for chronic disease management require accounting for the daily-living routine of patients. Daily-living routines can be an effective operationalization of social determinants of health, which play an important role in health outcomes. If these routines can be captured and integrated into electronic health records (EHR), embedded decision support tools can utilize data from these routines (along with other patient information e.g. laboratory results, co-morbidities), to support clinicians develop individualized treatment plans. However, integration of these daily routines into the EHR, first requires their representation in a machine interpretable way. Such representation can be accomplished using ontologies. An ontology facilitates development of individual instances of well-described classes or concepts that constitute a knowledge base. The purpose of this study was to develop an ontology for daily-living routines of patients with a chronic condition requiring anticoagulation therapy.

Methods

Protégé1 was used to develop an ontology based on qualitative data collected to examine health management of anticoagulation therapy. Data was obtained from 39 patients from a single clinic through interviews and journaling. The first step of ontology development was conceptualizing daily-routines as workflows. The temporal features of the concept of workflow is beneficial to characterize daily-routines. The second step was a middle-out strategy for ontology development i.e., starting from salient and moving to general and specific concepts and relationships. We defined classes, properties of classes (slots), and subslots by qualitatively analyzing data and conducting a review on workflow in health informatics, human factors, and ergonomics literature. Previously developed ontologies (i.e. HELIS2 and SPHERE3) informed the specification, knowledge acquisition, conceptualization and integration of the ontology.

Results

We developed a preliminary ontology that represents daily-living routines and health management activities within these routines for patients on anticoagulation therapy. The ontology included: (1) activities, roles, use of information, and use of tools; (2) temporal organization of activities and rules in the form of constraints; and (3) physical, organizational, social, and cultural contexts. To evaluate the flexibility of the ontology, we developed instances for 16 of 39 participants with different characteristics in terms of age, gender, annual income and duration of therapy. The ontology is based on a corpus of qualitative data, as opposed to an expert panel, is the more common approach.

Conclusion

Future EHRs will have to include extra-clinical health-related workflow information4. The developed ontology allows production of machine-interpretable knowledge and makes possible clinical decision support that is sensitive to the patient’s daily-living routine and contexts. The therapy plans that are assisted by such decision support, can yield better adherence, hence improved patient outcomes. Future work includes validating the ontology by exploring the application of this ontology in patients with other chronic conditions. This study was supported by AHRQ under award number R03HS024092 (PI: Ozkaynak).

Development and Usability Evaluation of a Facebook-based Program for Pediatric Cancer Patients

Bu Kyung Park, PhD, RN
1Kyungpook National University, College of Nursing, Daegu, Republic of Korea

Abstract
The aim of this study was to develop and evaluate the usability of a Facebook-based program (“Healthy Teens”) for pediatric cancer patients. The process of the program’s development and evaluation was 1) focus group interview for needs assessment with 12 pediatric cancer patients and 12 of their family members, 2) content development and expert review, 3) usability evaluation with 11 pediatric cancer patients. The program was perceived by pediatric cancer patients to be usable and useful in improving their health-related interventions.

Introduction
Social networking sites such as Facebook have become a popular venue for teenagers. Concurrently, the prevalence of smartphones among youth and the expansive reach of the Internet have enabled various new educational methods. With the increasing survival rate of pediatric cancer patients, there is a greater need for education about self-management at home after discharge.

Objective
The aim of this study was to develop and evaluate the usability of a Facebook-based educational program (“Healthy Teens”) for pediatric cancer patients.

Methods
Program development and evaluation progressed as follows: 1) focus group interview for needs assessment, 2) content development and expert review, and 3) usability evaluation. First, we conducted a focus group interview with 12 pediatric cancer patients and 12 family members. Qualitative content analysis using the inductive coding approach was performed on the interview transcripts. Second, an expert panel developed the program content, based on social cognitive theory.1 Then, three experts in the field of pediatric cancer reviewed the program content. Lastly, we conducted a usability evaluation of the Facebook-based program with 11 pediatric cancer patients. We improved the program’s usability through iterative cycles of evaluation and adaptation. We measured participants’ perceived usability with the Perceived Health Web Site Usability Questionnaire (PHWSUQ)2 and their eHealth literacy with the Korean eHealth Literacy Scale (K-eHEALS)3.

Results
Based on the results of the focus group interview and expert review, we finalized the Healthy Teens program to contain eight modules comprising multimedia, printable materials, quizzes, and discussion topics.

Results of the usability evaluation indicated that participants (age range: 13 – 20 years old) deemed the appearance and content of the program appropriate, and the program itself, easy to use. Most participants recommended to add more graphics and explanations on medical terms used for their treatment. Participants’ perceived usability of the program was 60.09 (range: 12-84), and their eHealth literacy was 27.55 (range: 8-40).

Conclusion
Overall evaluation of the Healthy Teens program on Facebook revealed that pediatric cancer patients perceived the program to be usable and useful in improving their health-related interventions for self-management at home.

A Case Study of Remote Monitoring Processes in Texas

Sulki Park, MS¹,², Hye-Chung Kum, PhD¹,², Mark Lawley, PhD²
¹Health Policy & Management, Texas A&M School of Public Health, College Station, TX
²Industrial and Systems Engineering, Texas A&M University, College Station, TX

Introduction

Remote monitoring (RM) is likely to be implemented more widely as policy makers break down legal and regulatory barriers, as well as providers focus on improving RM services to meet the needs of patients and caregivers. Medicare expands reimbursement for RM releasing new procedure codes in 2019. Some states pursue their own unique set of reimbursement policies in their Medicaid programs. Texas Legislature has passed several bills since 2013 to establish RM for patients with hypertension or diabetes as a reimbursable health service under Texas Medicaid. Designing cost-effective RM processes, for both the automated computer processes and human processes, is the key to a successful implementation.

Objective

The purpose of this research was to evaluate RM processes by conducting a case study of one RM company in Texas. This study will provide further insight into understanding the key elements of the RM processes.

Methods

We conducted a population-based descriptive analysis of the processes for RM using a company data from 2016-2018. Only hypertensive or diabetic patients, enrolled in Medicaid, were eligible for this study. Blood pressure (BP), blood glucose (BG), or both were monitored daily after enrollment. Automated alerts were generated when 1) physiologic parameters were not transmitted on time (i.e., adherence alerts), or 2) the vital sign was out of acceptable range (i.e., clinical alerts), set by the physician. Both alerts were followed up with a phone call to the patient or caregiver. Non-clinical staff followed up on adherence alerts to trouble shoot in order to receive the daily reading. Clinical staff followed up and classified the clinical alerts as red, yellow, or green, depending on their severity and followed set protocol (e.g., red and yellow means, follow-up should occur both over phone and email to the clinical contact, and green should follow up over email). Weekly reports were transmitted to primary physicians with the vital signs and alert classification. In our study, daily records and alerts were analyzed.

Results

A total of 2,075 patients got monitored daily for BP, BG, or both from 2016-2018 by 66 physicians. The average age of the patients was 72 (SD ± 12), with 66% being female and 78% living in the South Texas area. On average, patients were authorized for monitoring for 363 days (SD ± 240). Of the authorized days, on average, 46% of these days (167 days ((SD ± 151)) required non-clinical follow-up to troubleshoot (e.g., battery issues, transmission issues) or remind patients take a reading. With these follow-up efforts, on average, 76% of the days (274 days (SD ± 201)) actually had a vital sign sent to the company for monitoring. Of the patients being monitored for BP, on average, 39% of monitored days (107 days (SD ± 107)) got clinical alerts, having a record that is out of acceptable range, and of BG patients, on average, 6% of the days (16 days (SD ± 35)) got clinical alerts. 93% of BP patients set diastolic/systolic BP as 60/90-90/160 mmHg to be an acceptable range and 89% of BG patients set 60-350 mg/dL to be acceptable range. On average, 87% of BP clinical alerts (93 days (SD ± 96)) and 75% of BG clinical alerts (12 days (SD ± 28)) were classified as being green, which means no clinical intervention needed, whereas red or yellow require clinical intervention.

Discussion and Conclusion

On average, about half of the authorized days required follow-up to maintain daily monitoring. These non-clinical calls with the patients constitute the largest time interacting with patients at the company. Even with these calls, on average, patients missed 2.4 of 10 days transmitting their vital sign. In addition, most automatic clinical alerts were classified as green that required no clinical intervention pointing to the difficulty of relying only on daily vital signs to detect clinically meaningful events. Thus, to establish an effective RM platform, it will be important to provide for non-physician clinical expertise to interact with the patients to differentiate between automatic alerts that need physician intervention and those that do not as well as non-clinical time to troubleshoot and maintain daily monitoring.
Extracting and Standardizing Social Determinants of Health Diagnosis from Problems List from a Large Ambulatory Electronic Health Record (EHR) Database

Svati Patel, MHS MS
Nam Nguyen, MS
Allscripts, Chicago, IL
Practice Fusion, San Francisco, CA

Introduction
There is increased recognition that social determinants of health (SDH) outside and within the traditional healthcare setting play a powerful role in shaping patient health outcomes (1,2,3). We developed a methodology to extract and analyze both structured and unstructured SDH diagnosis from problems list data from a large ambulatory EHR database.

Methods
Problems list data from an Allscripts EHR database containing deidentified health information for nearly 34 million unique individuals was mined for SDH diagnoses recorded in the ambulatory setting. 24% of the problem list diagnostic data was recorded as un-coded, unstructured free text. ICD-10, ICD-9, and SNOMED codes were used to extract SDH from the structured problem list data. SDH was extracted from unstructured data using a pattern matching search algorithm that utilized keywords, word pairs, and exclusion words. We also developed a mapping algorithm using the SDH framework found in ICD-10 codes Z55-Z65 to standardize captured data.

Results
Extraction methods yielded 1.45 million unique SDH diagnoses recorded within the Allscripts EHR database. These diagnoses were obtained using 96 icd-10 codes, 45 icd-9 codes, 619 SNOMED codes, and 1,008 unstructured SDH terms. 77% of the diagnoses were recorded as structured data; 23% of were recorded as unstructured data. 90% of the diagnoses found within the Allscripts EHR database were mapped to 14 (out of 81) SDH diagnoses. The top three SDH recorded were issues associated with divorce or separation, death or disappearance of a family member, and unemployment. Further, 90% of the SDH diagnostic data was recorded by 87 unique health systems (31%).

Discussion
Analysis reveals that SDH information can be recorded within a patient’s list of medical diagnoses, the problem list. However, the vast majority of the diagnostic SDH data is being recorded by only a small percentage of health systems represented in the Allscripts EHR database and regarding only a small percentage of SDH topic areas. Extraction of this data requires use of techniques that identify both structured and unstructured methodologies.

Conclusion
Though the problem list yields mineable SDH data, a full exploration of other EHR data is needed to understand the amount of SDH data available from ambulatory EHRs. Other possible sources of SDH data from ambulatory EHR databases that warrant exploring include SOAP notes and chief complaints. Future work will improve the recall and precision of the extraction from problem list data, adapt the extraction methodology to work with SOAP notes and chief complaint data, and access the full amount of SDH data that is currently recorded in ambulatory EHR data.

A Dataset Recommendation System for Researchers based on Publications

Braja Gopal Patra, PhD\textsuperscript{1}, Kirk Roberts, PhD\textsuperscript{2}, Hulin Wu, PhD\textsuperscript{1}

\textsuperscript{1}School of Public Health, \textsuperscript{2}School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX

Introduction

Many repositories and knowledge bases have been established to ease data sharing. Most of these solutions are domain-specific and none of them recommend datasets proactively to researchers. Further, there has been an exponential increase in the number of datasets added to dataset repositories in the past last two decades. For example, in the Gene Expression Omnibus (GEO) repository, an average of 34 datasets were added to GEO daily in the last five years (i.e. 2014 to 2018). This gives a glimpse of the increasing number of datasets being made available online, considering that there are many other online data repositories as well. Naturally, it is challenging for a researcher to track repositories for potential use. The aim of this work is to proactively recommend datasets to researchers based on their profile who could potentially reuse the datasets. In the experiments, 101,279 datasets (title and summary) as of April 10, 2019, were selected from GEO. Researchers’ publications (title and abstract) were collected from PubMed after verifying collected publications with CV (obtained using a web portal) to handle the author disambiguation as shown in Figure 1.

Methods

From initial experiments, it was observed that the datasets recommended for a researcher by combining all publications together were biased towards a single research area where the researcher’s publications were most concentrated. Our insight is that the more publications a researcher has, the more interests or areas of expertise he/she likely has as well. We propose to employ the non-parametric Gibbs Sampling based Dirichlet Process Mixture Model (DPMM)\textsuperscript{1} to cluster papers into several groups of expertise. The publications and datasets were converted into vectors using TF-IDF. The publications in each publication cluster were converted into a single vector using equation: $v_c = \frac{1}{N} \sum_{p \in P_c} \lambda_{pc} v_{pc}$ and $\lambda_{pc} = \frac{1}{\exp(\frac{0.05 \times t}{1})}$, where $t$ is the difference between the current year and year of publication; and $N$ is the total number of papers in the cluster. For each publication cluster vector, top similar datasets were recommended to the researchers using cosine similarity as shown in Figure 1.

![High level architecture of researcher’s publication extraction and proposed dataset recommendation systems.](image)

Results

We asked researchers who already worked on the datasets from GEO and published papers on these to rate each retrieved dataset using one to three stars (1: not relevant, 2: partially relevant, 3: most relevant) based on their publication clusters. The system achieved partial and strict precision at 10 of 0.65 and 0.51, respectively, based on the judgments from three researchers with 53, 48 and 32 papers.

Conclusion

This work is the first step toward developing a dataset recommendation tool to connect researchers to relevant datasets they may not otherwise have been aware of. This will hopefully lead to greater biomedical data reuse and improve scientific productivity. The next goal is to identify the clusters which are not related to datasets. We plan to implement other embedding methods and test the dataset recommendation system on more users.

Using JATS and GraphML as a Standard Form for Clinical Practice Guidelines

Michal Patriak, Daniel R. Schlegel, PhD
SUNY Oswego, Oswego, NY, USA

1 Introduction

Clinical practice guidelines (CPGs) are distributed in a variety of formats, though rarely are they easily computer processable. This is problematic as there is a continued push for the creation of computer interpretable guidelines (CIGs), and efforts to automate this task require the input files to be in a standard, easily processable, form. Most guidelines contain textual information, formatted as a structured document with sections, headings, lists, and figures. Many guidelines also contain figures meant to illustrate portions of the diagnosis or care algorithm, often using graphs of some sort. In order to represent guidelines in a standard form, we have developed transformation guidelines for the task of translating guidelines into an XML format using the Journal Article Tag Suite (JATS) [1] and GraphML [2].

2 Methods and Discussion

The two guidelines used in the development of our transformation guidelines, ADA Standards of Medical Care in Diabetes 2017 and NCCN Non-Small Cell Lung Cancer, were distributed as PDF files. The ADA guideline takes the form of a journal supplement or book, with several chapters and using a standard layout including sections and subsections of prose along with tables and figures. Recommendations are found in highlighted boxed subsections. The NCCN guideline begins with several pages of graphs representing the diagnosis, staging, and care algorithms. The graphs are heavily footnoted, and contain links to other graphs and document sections. After the graphs is a prose discussion, including a section on recommendations. Levels of evidence are indicated in guidelines in different ways.

The document structure was encoded in the JATS format. The tag suite allows for a significant subset of HTML formatting in addition to including tags for the document structure. Tags such as ⟨publisher⟩ and ⟨title-group⟩ capture article metadata. Others such as ⟨sec⟩, ⟨list⟩, and ⟨p⟩ maintain the article hierarchy. Other tags such as ⟨title⟩, ⟨year⟩, and ⟨article-id⟩ refer to specific types of data found within the article. Tables are represented using HTML. References to figures, tables, sections, and bibliographic references use ⟨xref⟩ tags.

GraphML is used to represent graphical data, principally found in figures and NCCN graph algorithms. Raw GraphML is rather basic, allowing for the representation of nodes, edges, and simple data annotating these. The format may be extended to allow structured data inside ⟨data⟩ tags, which we have done to allow embedding JATS tags in nodes.

We have resisted re-structuring the guideline data, instead preferring to encode it in the XML format exactly as it is written or drawn. Our eventual goal is to do automatic CIG generation, and we wish for the XML documents to be as faithful to the original document as possible, even when the produced form is not as intuitive as what would be possible should this have been the original target format. The ADA guideline evidence level is shown in a lighter color after the recommendation, so we wrap it in ⟨font⟩ tags. A table is used for the NCCN evidence blocks.

This work is being used in a system for automatic clinical guideline understanding. Using the XML structure, software produces logical representations of the structural propositions in a form subsuming the Document Content Ontology, adding to it linguistic features from the underlying text.

Comparing Nurse and Physician Perspectives on Health IT Adaptation

Nicole Pearl, BS1, Todd E. Tussing, DNP, RN, CENP, NEA-BC2, Esther Chipps, PhD, RN, NEA-BC2,3, Cynthia J. Sieck, PhD, MPH4, Po-Yin Yen, PhD, RN1,5

1Institute for Informatics, Department of Medicine, Division of General Medical Sciences, Washington University School of Medicine, St. Louis, MO; 2The Ohio State University Wexner Medical Center, Columbus, OH; 3College of Nursing, The Ohio State University, Columbus, OH; 4College of Medicine, The Ohio State University, Columbus, OH; 5Goldfarb School of Nursing, Barnes-Jewish College, BJC HealthCare, St. Louis, MO

Introduction

Since 2009, several policies, such as the Health Information Technology for Economic and Clinical Health (HITECH) Act, have sparked increased implementation of health information technology (IT) in healthcare settings, especially electronic health record (EHR) systems.1,2 Due to the difference in clinical duties among nurses and physicians, it is possible that they adapt, or modify existing conditions to achieve alignment,3 to new technology differently. This pilot study aims to identify factors associated with health IT adaptation, and compare nurse and physician perspectives.

Methods

We invited clinicians with varying clinical, IT, and leadership positions at a mid-west academic medical center. We asked each participant about their experiences and thoughts about health IT adaptation. All sessions were audio recorded and transcribed verbatim. Data analysis was conducted using a thematic analysis approach. Each transcript was coded by two researchers. Disagreements were discussed in meetings for consensus. Open codes were grouped into common categories from iterative discussion. Selected codes reflect the health IT adaptation processes for nurses and physicians. ATLAS.ti 8, a qualitative data analysis tool, was used for data management and analysis. Nurse and physician codes were compared to identify similarities and differences between their perspectives.

Results

Individual interviews were conducted with 13 registered nurses and 7 physicians. Preliminary results indicate themes from both groups can be grouped into 4 different categories: 1) adaptation factors, 2) outcomes resulting from the use of health IT, 3) outcomes from poor adaptation, and 4) outcomes from adequate adaptation. Both physicians and nurses feel that having off-unit training before implementation and on-site support from super users or peer experts is useful in their adaptation. Additionally, when leadership monitors health IT usage and provides feedback to users, it helps ensure the health IT is being utilized properly by physicians and nurses. Most participants would like to see increased clinician involvement in the design and implementation of health IT. Physicians specifically feel the need for more personalized training catering to individual provider roles. Physicians and nurses both recognize decreased face-to-face communication between both colleagues and patients as a result of the general nature of health IT usage, and many nurses felt frustrated regarding other clinicians’ use of copy and paste functions for notes in the EHR. Nurses and physicians also don’t have consistent access or permissions to view notes in the EHR. Ineffective and disorganized communication between providers and workarounds have resulted from poor adaption of health IT, or not using it as designed. Finding relevant patient information in the EHR has also become difficult and time consuming. Nurses and physicians expressed that when using health IT correctly, patient safety is generally increased due to decreased errors. Health IT can also lead to increased efficient communication between providers when consistently used as designed.

Conclusion

Interviews were conducted to capture health IT adaptation processes among nurses and physicians. Their perspectives were compared and grouped into 4 main themes: adaptation factors, outcomes of the general nature of health IT, outcomes from poor adaptation, and outcomes from adequate adaptation. Future studies should further investigate how nurses and physicians utilize health IT differently to allow clinical and IT leaders to facilitate innovative plans to increase adaptation across all provider roles as efficiently as possible.

Adapting a Patient-Reported Outcome App and Practice Model into Primary Care for Treatment of Asthma

Sofia Perez,1 Anuj K Dalal, MD,1,2 Jessica Sousa, MSW, MPH3, Robert S. Rudin, PhD3

1Brigham and Women’s Hospital, Boston, MA 2Harvard Medical School, Boston, MA 3RAND Corporation

Introduction: Asthma is largely controllable through symptom monitoring and treatment adjustment to avoid clinical deterioration and emergency care. Useful tools for symptom monitoring, such as patient reported outcome (PRO) questionnaires, have the potential to improve adherence to guidelines, but have not been widely adopted. The purpose of this study is to adapt a mobile health (mHealth) app and practice model that leverages electronic PRO questionnaires for asthma symptom monitoring that was previously developed for subspecialty care, for use in a primary care setting.

Methods: We are working with 4 ambulatory clinics affiliated Brigham and Women’s Hospital in Boston, MA to adapt our intervention to primary care. To guide our design process, we are using the NASSS framework, developed specifically to ensure scalability and sustainability of the intervention1. We are engaging multiple stakeholders during every step of the adaptation process: primary care providers (PCP), patients, nurses, clinic leadership, venders, and administrative staff who are responsible for technical infrastructure. We are employing a user-centered design approach (design sessions, low-fidelity/high-fidelity wireframes, surveys) to identify user requirements; understand workflow for patients, nurses, and clinicians; and determine how to integrate our intervention with our vendor electronic health record (Epic Systems, Inc.). Design sessions comprised of interview questions which were recorded, transcribed and summarize in consensus of two members of the research team.

Results: Based on 7 individual design sessions (6 physicians, 1 patient) conducted to date, we have identified several new requirements (Table 1) for scaling our intervention to primary care.

Table 1: User Requirements by Intervention

<table>
<thead>
<tr>
<th>Intervention Component</th>
<th>Previously Developed</th>
<th>New Requirements for Primary Care</th>
</tr>
</thead>
</table>
| Invitation             | • Patients receive a letter from their PCP inviting them to participate  
                          • Research staff calls patients and schedules in-person meeting. | • To facilitate enrollment and improve scalability, patients should be able to send a text message or email directly to address or phone number directing them to REDCap enrollment link |
| Weekly questionnaire and option to request a call-back from a nurse | • Patients receive weekly 5-item questionnaire and can request a call-back if symptoms deteriorate.  
                          • Nurses receive an email notification to login to dashboard | • Patients without active symptoms should respond to just 1 question  
                          • Nurse receives message in EHR ‘inbasket’ when patients request a call-back and should follow an institutionally supported triage protocol |
| Patient self-management | • Patients can view their previous reported symptoms on a graph | • Patients can view/enter notes, peak flows, triggers. |
| In-person visit        | • PRO data is available in a recent physician note prior to a visit | • Clinicians should be able to access PRO quickly from the EHR (e.g., one-click) and receive an alert when PRO data is available to review  
                          • Patients should receive a reminder about in-person visits through the app and are encouraged to review their symptoms with physicians |

Conclusion: Design sessions require feedback from all stakeholders as they play a crucial role in determining new requirements for integration. Adaptation of a relatively simple mHealth app and practice model for asthma symptom monitoring in the primary care setting still requires an extensive design process due to the need for integrating with clinical processes, leveraging available health system infrastructure, and reconciling many user requirements. The NASSS framework has been a helpful tool that has enabled us to prioritize requirements for primary care.

INTRODUCTION

REDCap uses user-defined fields and instruments to create custom databases. Records can be imported to a REDCap database from a variety of sources, including a comma-delimited (CSV) file or an excel spreadsheet. Current methods for preparing records for upload to REDCap generally involve manual transformation of data. At Memorial Sloan Kettering, we are working on efforts to remove manual steps when entering data into REDCap projects. REDCap Linter is a wizard that walks a user a multistep process of rapidly cleaning up errors in source data before loading it into REDCap. First, the user matches spreadsheet headers with REDCap fields and cleans up errors found in any column’s data. Many tasks like aligning REDCap fields with spreadsheet column headers and matching REDCap fields with permissible values and their corresponding column in a datafile are tedious and error-prone. Some fields such as checkboxes and dropdowns require a set of permissible values. For example, a study may have a ‘Demographics’ instrument with a field for ‘Gender’ that contains the set of permissible values (Male | 1, Female | 2). These fields need to be recoded with appropriate permissible values before upload. REDCap Linter 1.0 generates a cleaned csv file that is ready for upload to REDCap. However, there were still some additional features that were lacking if this cleaning (aka linting) process were to be less manual.

NEW FEATURES

With REDCap Linter 2.0 we build on our previous submission by introducing new features that enable the continuous flow of data into REDCap projects. REDCap Linter 2.0 introduces:

1. The ability to export and import a mappings file that stores information connecting spreadsheet columns to REDCap fields. The mappings file also stores steps used to clean up errors found in column data.
2. An API to call on REDCap Linter services programmatically.

The ability to save project mappings is an important feature for projects that receive updated spreadsheets in a consistent format. The feature allows a quick load of the new spreadsheet without having to manually re-map the columns again to the fields in REDCap. If additional errors not already stored in the mappings file are found in the new spreadsheet data, they can be added to mappings file.

The API to call Linter allows automation. Input parameters would include mappings file, data dictionary and spreadsheet data. Automation pipelines can create the mappings file for each spreadsheet sent to the Linter and receive back a cleaned CSV file for upload into REDCap.

CONCLUSION

At Memorial-Sloan Kettering, we are working on solutions to dynamically pull data into REDCap projects, however REDCap Linter is a general approach and is agnostic to the data source. REDCap Linter is open-source and we welcome any contributions from the community.

Introduction. Despite ongoing standardization efforts in healthcare, the goal of consistent data semantics has remained elusive. First, by their nature standards are often focused on elements of the domain that are broadly agreed-upon, and thus often struggle to account for the idiosyncrasies of specialized use cases, forcing users into expensive and time-consuming workarounds. Second, while advances in data-driven techniques have shown promise for eliciting robust semantic models from existing Electronic Health Record (EHR) data, blueprints on how to align the “top-down” development approach employed by standards organizations with “bottom-up” data-driven approaches are sparsely described in literature. Finally, downstream applications often have very pragmatic data needs. Standards that are too complex or abstract lead to implementation challenges and high costs – or the abandonment of standards altogether in favor of more one-off, pragmatic approaches. Semantic models must be easily consumable and able to be integrated into existing healthcare systems. In this work we propose three components of a framework to combine data-driven techniques with domain standards to produce interoperable semantic models. The components of the framework are enumerated below. Our intent for this work is to outline the high-level features of our system, setting the scope and direction for future research efforts in this area.

Component 1: Extract and standardize clinical concepts from narrative text.
Description: Using data-driven Natural Language Processing (NLP) techniques including sublanguage analysis and the transformation of text into SNOMED CT Expressions, the goal of this component is to extract and catalog concepts from clinical notes. This will output a data-driven “glossary” of how clinical concepts are defined in practice.

Component 2: Mine domain models for clinical concepts by combining data-driven and standards-based approaches.
Description: By leveraging ontology extraction techniques with Web Ontology Language (OWL) models, this component will mine domain models specific to the concepts extracted in Component 1. Standard, expert-curated domain ontologies will be used to bootstrap our data-driven approach, as well as to contrast the data-derived results with standard representations to quantify the differences – bridging the gap between standards and data.

Component 3: Automate the creation of Fast Healthcare Interoperability Resources (FHIR) Profiles based on clinical concepts (Component 1) and associated ontologies (Component 2).
Description: FHIR Profiles are an effective way of creating enforceable, unambiguous data contracts between applications. This component uses the inputs of Components 1 & 2 and outputs semantic models as FHIR Profiles.

Agent Based Model to Evaluate Simple Behavioral Changes on Individual Health Over Time

Andrew B. Phillips, PhD, RN\textsuperscript{1}, Margarita Sordo, MSc, PhD\textsuperscript{1,2,3}
\textsuperscript{1}MGH Institute of Health Professions, School of Nursing, Boston, MA, \textsuperscript{2}Department of Medicine, Brigham and Women’s Hospital, \textsuperscript{3}Harvard Medical School, Boston, MA

Introduction
For any disease, symptom, or condition, the underlying goals are to identify it as early as possible, understand its pathology, and employ an intervention that ameliorates symptoms, and/or eliminates the disease/condition (cures it). Health interventions are often born by the patient – changes in diet, exercise, smoking, routine monitoring, etc. The ability to improve our understanding of patient behaviors can ultimately lead to improved interventions with increased rates of success. Agent Based Models (ABM) represent an approach to modeling complex patient behaviors over time. An ABM is defined by individual agents (typically individuals) with their own attributes (descriptors) and behaviors (actions) residing within a simulated environment. The simulation produces an emergent behavior of the system based on the interaction of the defined attributes and interactions of its individual agents and the environment. ABMs can see the cumulative effects of negative or positive individual (patient) behaviors over time.

Methods
We selected exercise as an example as it represents a significant contributor to preventive health. The model used a simple set of rules. Our population mirrored the US population by age and sex. Each time point in the model represented a week and the simulation stopped after 5000 weeks (approximately 96 years). The ABM was guided by the following assumptions:

A – Exercise positively impacts health
B – Health impacts desire to exercise
C – Desire to exercise impacts exercise
D – Reduced impact of age over time on desire to exercise and overall health and exercise intensity, including probability of death.
E – Random element of overall health. For example, an individual could develop a chronic disease which impacts desire to exercise.

General Model Assumptions
1 - Individual health decays over time
2 - Individual Life expectancy per CDC
3 - Desire to exercise declines with age

Results

| Vigorous exercise increases health score, even over the extended period of time in the model. Other levels of exercise still have positive affect compared to no exercise, but health score decreases over model time frame. | Even though desire to exercise declines with age, the drop over time is influenced by health level. Good health will slow down the decline, whereas poor health will accelerate it. |

Discussion
Individual behavior is an important determinant of health. Changes, even small ones, to our individual behavior, in the form of simple actions, i.e. physical activity, can have positive altering effects over time. ABM models provide an opportunity to apply new tools to simulate and model individual behavior that evaluate the consequences of simple behaviors over time. Our model highlights two important aspects of individual behavior: a) simple actions have a direct cumulative effect over time; with b) cascading, feedback loops as part of a chain of cause-effect. As shown by our model, simple actions chained into cascading feedback loops, promote other actions/behaviors with their own consequences, while allowing agents to reach their own equilibrium. Under this approach, we can assess the short- and long-term impact of behavioral health interventions, and their cascading effects. Physical activity is a simple, modifiable behavior with a positive impact on health. Good health has a potential positive impact on desire to exercise, which in turn has an impact on the actual intensity of exercise. Although, conceptually simplified, our model captures the essential nuances and effects of a simple behavioral intervention in the overall well-being of an individual, that, when sustained, can have lasting benefits over time.

Clinical Decision Support Systems in Pediatric Surgery: a Scoping Review

Michael R. Phillips, MD1, Christopher J. Tignanelli, MD2, Saif Khairat, PhD, MPH1, Arlene E. Chung, MD, MHA, MMC1
1University of North Carolina, Chapel Hill, NC, USA; 2University of Minnesota, Minneapolis, MN, USA

Introduction
Electronic clinical decision support systems (CDSS) are systems designed to facilitate decision-making during the diagnosis and treatment of a medical condition. Pediatric surgeons treat a variety of surgical conditions in neonates to young adult patients. During episodes of care, pediatric surgery patients are also exposed to many different providers in outpatient and inpatient settings. This heterogeneity of patient demographics, providers, and clinical settings makes effective CDSS critical for high quality care. However, little is known about the usability or effectiveness of CDSS in pediatric surgery.

Methods
To review the literature in CDSS for pediatric surgery, the Pubmed database was searched using a combination of MESH terms related to pediatrics, children, surgery, and clinical decision support or clinical decision support systems. Studies were included if they met the following criteria: published in English, journal articles or conference papers that described the prospective use of any electronic CDSS in children (≤18 years old) with surgical conditions. Exclusion criteria were articles without electronic decision support, and articles on clinical diagnostic scoring systems. Two reviewers performed initial abstract screening, and all authors reviewed included articles for clinical relevance and findings.

Results
There were 69 articles that met the search criteria. After initial screening, 12 papers were included (inter-rater reliability between two reviewers=93.9%). Upon final review of the 12 papers, four additional papers were unanimously excluded, two for the retrospective use of the CDSS tool, one for duplicate data from another included study, and one that focused on adults treated in a pediatric intensive care unit. Eight papers were included in the final scoping analysis. Papers analyzed the following topics: order sets for appendicitis (2), medication selection and dosing assistance (2), electronic triage tool for abdominal pain (1), computer analysis of orthopedic conditions compared to expert opinion (1), alerts to assist with anesthetic management of traumatic brain injuries (1), and a home monitoring system for pediatric liver transplant patients (1). None of the papers examined the effect of the CDSS system on patient outcomes. Five of the papers reported user satisfaction or acceptance with rates of 69-100% and 20-30%, respectively. Of the studies examining satisfaction and acceptance, one examined electronic antimicrobial stewardship, one provided diagnostic and therapeutic recommendations during anesthesia for neurosurgical procedures, one compared an ad hoc order set to a systematically developed order set, one embedded clinical advice within an order set, and one evaluated acceptance of medication dosing alerts within a computerized order entry system. All of the studies that examined user satisfaction reported increased satisfaction with clinical decision support. Of the two studies examining practice changes, only one paper could connect practice patterns directly to CDSS. This study demonstrated similar changes in practice between pediatric and non-pediatric providers, but that pediatric trained providers were more likely to ignore an alert and less likely to cancel an order for medications outside the recommended dosing range. Three studies reported the diagnostic accuracy of CDSS (37.5%), including: one study comparing electronic vs. expert evaluation of clubfeet deformities (86% concordance), one examining the rate of detection of brain-injured patients to receive anesthetic treatment alerts during surgery (79%), and one measuring the rate of correct triage for patients with abdominal pain in the emergency room using a mobile app (70%).

Conclusion
The effectiveness of CDSS tools in pediatric surgery is an emerging area of research. This study is limited by the heterogeneity of the CDSS tools studied and the inconsistent reporting of variables examined. There was no study that examined the effect of the CDSS tools on patient outcomes. Studies examining user satisfaction demonstrated improved scores compared to historical practices. It appears that improving CDSS tools in pediatric surgery may increase user satisfaction with the electronic health systems; however, further research is needed to determine which types of CDSS provide the most improved satisfaction and make the most impactful changes to clinical practice.
Implementing Data Governance for Precision Health

David J. Pierce, BA¹, Kun Huang, PhD², Paul Biondich, MD MS³, Shaun Grannis, MD MS⁴, Burke Mamlin, MD⁵, Peter Embi, MD⁶

¹Indiana University, Indianapolis, IN; ²Indiana University, Indianapolis, IN; ³ Indiana University, Indianapolis, IN; ⁴ Indiana University, Indianapolis, IN; ⁵ Indiana University, Indianapolis, IN; ⁶ Indiana University, Indianapolis, IN

Introduction

The Indiana University (IU) Precision Health Initiative is a five year multidisciplinary project that aims to: cure at least one cancer, cure one childhood disease, prevent one chronic disease, and prevent one neurodegenerative disease. In order to achieve these goals, data from multiple systems and sources are being combined to support various research projects.

The research projects supported by the initiative require clinical, genomic, environmental, and other data such as information about biospecimens. The required data is spread across multiple systems and is owned by various data providers. In order to support the research project, an effective and transparent process had to be implemented that would allow for this type of broad data sharing.

Methods

Initially, the initiative approached data sharing by working through each data provider’s process. This approach resulted in delays in accessing the data and was too onerous for all parties involved. Instead of working through each data provider’s process, the initiative set forth a set of guiding principles for data governance. Four committees (Figure 1) were chartered with specific mandates to implement and monitor progress against the guiding principles.

![Data Governance Committee Structure](image)

The Executive Committee sets overall data policy for the initiative and resolves high level policy issues. The Data Provisioning Committee ensures that all required agreements are in place to allow data sharing. The Security and Compliance Committee defines security standards that meet all data providers’ and regulation requirements for data security. The Data Quality Committee is responsible for setting data standards and driving data quality improvement projects.

Each committee has representation from each data provider, which increases engagement from the data providers. The chairs of the sub-committees sit on the Executive Committee and provide regular reports on progress and challenges.

New projects are evaluated by the sub-committees and when necessary are escalated to the Executive Committee. Project submission templates were created for the researchers that guide them through the submission process to reduce delays.

Conclusion

Strong data governance is required in order to support data sharing across multiple institutions at scale. Standardizing the approach to data governance across the data providing organizations has allowed the initiative to more efficiently respond to new project requests thus increasing the speed of research.
Augmenting Quality Assurance Measures in Radiation Oncology with Machine Learning

Malvika Pillai1, Karthik Adapa, MPH, MBBS1

1Carolina Health Informatics Program, University of North Carolina, Chapel Hill, NC

Introduction

According to the current nationally regulated approach to quality assurance (QA), the physicist or dosimetrist manually chart checks multiple metrics for each patient before administering radiation therapy. Chart checking is time intensive, involves high cognitive burden, and is only 60% effective in detecting high severity incidents (1). Presently, in-house QA tools augment chart checking by automating standardized second checks, thus improving efficiency and reducing cognitive workload (2). The research objective is to improve the effectiveness of chart checking and reduce cognitive workload by flagging cases requiring additional manual and cognitive scrutiny. The analysis demonstrates a classification algorithm that categorizes the radiation treatment plans as hard, medium, and easy based on cognitive scrutiny involved.

Methods

We collected data from pre-treatment and weekly chart checks for treatment plans of each patient, encompassing all cancer sites. Data used in this analysis was collected from August 2018 to June 2019. A clinician and a physicist selected data attributes based on clinical relevance, contribution to plan complexity, and quality assurance metrics. The degree of difficulty of treatment plans, an outcome variable, was collected as a subjective rating by physicists on a scale of 1-10 from physics pre-treatment chart checks. 898 patient plans were used as a training set, where a patient could have multiple plans. All analysis was done using Python sklearn packages. A majority voting classifier was used in predicting the degree of difficulty of radiation treatment plans and classifying them as easy (1-3), medium (4-6), and hard (7-10). The class distribution of the dataset was: 52% easy, 38% medium, and 10% hard. The majority voting classifier consisted of 5 algorithms: support vector machine (SVM), decision tree, random forest classifier, adaboost, and k-nearest neighbor (KNN) where k is 2. Before predicting the degree of difficulty of plans, forward feature elimination was utilized to incorporate only variables of importance into the predictive algorithms (3). 17 attributes were used as input, and forward elimination was used for decision tree, random forest, and adaboost. The common variables selected for decision tree, random forest, and adaboost were: age, number of fractions, number of beam sets, number of images, and plan check completion time (ie 12:34 pm). Random forest and adaboost additionally selected organ count and site name as variables, while adaboost also used dose per monitor unit (MU).

Results

As the project is in progress, a blind test set has not been used yet to validate results. The training set of 898 patient plans was split into 80% for training and 20% for testing. Accuracy with 95% confidence intervals (CI), positive predictive value (PPV), and sensitivity were collected for each of the algorithms in the majority voting classifier (Table 1).

<td>0.76</td>
<td>0.90</td>
</tr>
</tbody>
</table>

Conclusion

We present a majority voting classifier in predicting difficulty of radiation treatment plans and flagging cases requiring extra cognitive scrutiny. The project utilizes clinical, plan complexity and QA data in generating knowledge about components of the radiation therapy plan that contribute to plan difficulty and in predicting the effect of plan components on cognitive workload. Further research on the project will consist of addressing limitations such as missing data, class imbalance, and using another classifier instead of adaboost.

Developing an Electronic Chart Review Tool to Identify and Assess Diagnostic Errors in the Acute Care Setting

Nicholas Piniella¹, Kerrin Bersani¹, Kumiko Schnock, PhD, RN¹, Pamela Garabedian, MS¹, David W Bates, MD, MSc¹,², Jeffrey L Schnipper, MD, MPH¹,², Anuj K Dalal, MD¹,²
¹Brigham and Women’s Hospital, Boston, MA; ²Harvard Medical School, Boston, MA

Introduction: Diagnostic error in acute care represents an unresolved safety issue: error rates range from 4.8 to 49.8%. Though chart review tools to determine the presence of diagnostic error have been validated in the ambulatory setting, these have not been validated for acute care. The purpose of this study is to describe our approach to developing a chart review tool that can be used to assess the presence of diagnostic errors in the acute care setting, as well as their potential for harm and categorize types of failures in the diagnostic process.

Methods: We used REDCap, an electronic data capture tool, to design and develop a chart review tool that clinician adjudicators could use to determine the presence of diagnostic error and diagnostic process errors in acute care. After conducting a literature review, our team decided to utilize both the Safer Dx Instrument and the Diagnostic Error Evaluation and Research (DEER) Taxonomy. Next, we gathered feedback from clinicians and researchers with expertise in studying diagnostic errors to adapt these tools for use in the acute care setting. Specifically, we made slight wording changes to the Safer Dx Instrument questions to assess the diagnostic process from admission to discharge. We adapted the DEER Taxonomy to capture specific types of failures in the diagnostic process during hospitalization: most notably, we added 2 domains, one to capture failures in care team communication and collaboration, and the other to identify issues related to patient experience. Finally, we asked physicians to use our tool to conduct electronic chart review of selected cases of potential diagnostic error. Based on their feedback, we iteratively refined our tool and chart review process, addressing issues that were identified.

Results: The final chart review tool (Table 1) has 4 sections that ask clinician adjudicators to identify and assess diagnostic errors during acute care. To create a workflow that would not be prohibitively long for reviewers, we used branching logic, based on the admission and discharge diagnoses and whether appropriate treatment was initiated within 24 hours, to guide the reviewer through the chart review process. For example, if there was preliminary evidence of a delayed diagnosis (i.e., discharge diagnosis substantially different than the admission diagnosis), then the tool encouraged the reviewer to focus on timestamps for diagnostic tests, labs, medications, and consultation orders. We also decided that reviewers would identify and enumerate all diagnostic errors that occur during a patient’s hospitalization, and identify DEER failure points in all reviewed cases, regardless of the presence of diagnostic error.

Conclusion: We created an electronic chart review tool and process to facilitate identification of cases of diagnostic error in acute care. Our next steps are to validate this chart review tool by: 1) retrieving cases of potential diagnostic error from the EHR using a variety of triggers (e.g., transfer to intensive care); 2) having two clinicians independently review charts of previously hospitalized patients who have one or more trigger to determine the presence of diagnostic error; and 3) calculating the sensitivity, specificity, and positive predictive value for trigger positive cases.

Improving Post-traumatic Stress Disorder (PTSD) Detection and Treatment After Traumatic Brain Injury (TBI)

Christie Pizzimenti, PhD1, Claire Ramey1, David Dorr, MD, MS1, Kari A. Stephens, PhD2
1Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR; 2Department of Psychiatry & Behavioral Sciences, University of Washington, Seattle, WA

Introduction

An estimated 2.8 million Americans sustain a traumatic brain injury (TBI) each year1 with an elevated (5.8 times) relative risk for Post-Traumatic Stress Disorder (PTSD)2. Estimates of epidemiological rates of PTSD following TBI range between 7 and 20%3, but healthcare organizations struggle to identify and treat PTSD. Subsequently, the costs of repeat hospitalizations and emergency department visits for PTSD-related symptoms go unmitigated. Electronic health record (EHR) data can be used to help identify patients with a high risk of developing PTSD following TBI and promote follow-up for appropriate treatment. We therefore explored the possibility of using EHR system data to understand the frequency of PTSD after TBI in treated populations at Oregon Health & Science University (OHSU).

Methods

ICD-10 codes were used to first identify patients diagnosed with TBI within the EHR, then patients also diagnosed with PTSD. Patients without a PTSD diagnosis, but with symptoms extracted from the EHR were also identified via standard PTSD rating scales (i.e., PTSD Check List –C and -5), given their high concordance with a PTSD diagnosis. TBI patients with subsequent encounters were identified via hospital admissions and appointments after the date of injury to assess opportunities to provide follow-up care.

Results

At OHSU, 3,475 patients with TBI were seen over the last 3 years. PTSD diagnoses were identified via ICD-10 codes in 49 patients (1.4%) and PTSD diagnoses were likely in 195 patients (5.6%) via positive screens. Indications of PTSD via screeners and not ICD-10 codes most closely represented expected epidemiological approximation of the rate of PTSD subsequent to TBI. It was also found that TBI patients were likely to seek care after TBI, with 45% returning via hospital admissions and 67% via office visits after the injury date.

Discussion

PTSD diagnosis and screening rates under-detected rates of PTSD in a TBI population, likely indicating better screening and treatment for PTSD is needed for patients with TBI. However, despite the low detection rate, EHR data, particularly via screener values, may be used to identify patients with TBI who are likely to be experiencing PTSD and likely to return to the hospital after TBI. PTSD screener values provide valuable information needed to facilitate effective treatment for TBI and PTSD. Additional refinement of this approach should target investigating common comorbid conditions and use of predictive analytics to drive better care.

Harmonizing Oncology Data from Multiple Institutions with the Observational Medical Outcomes Partnership’s Common Data Model

Joseph M Plasek, PhD1, John A. Weissert1, Kourosh Ravvaz, MD, PhD, MPH1
1Aurora Research Institute, Advocate Aurora Health, Milwaukee, WI, USA

Introduction
Semantic harmonization of disparate electronic health record (EHR) expedites multi-institutional clinical research as all data elements have a shared meaning. Common data models (CDM) with controlled vocabularies and a standardized structure provide a framework for achieving semantic harmonization. The Observational Medical Outcomes Partnership (OMOP) CDM enables systematic analysis of disparate data sources by transforming data into a common format with a common representation1. Limited prior use of OMOP CDM in oncology included cohort identification of prostate cancer2, among others. Using OMOP CDM, we aimed to test the feasibility of harmonizing multi-institutional non-muscle invasive bladder cancer (NMIBC) data, a disease noteworthy for a patient population with heterogeneous risk profiles and clinical outcomes. In doing so, we identified opportunities to improve the OMOP CDM for analyzing bladder cancer EHR data. Bladder cancer is the ninth most common cancer of which 70% of new cases present as NMIBC3.

Methods
From 1991 - 2017, two retrospective datasets containing 509 and 1331 patients with NMIBC were independently curated from the University of Wisconsin Madison and Aurora Health Care, respectively. We utilized OMOP CDM version 5.3.1 to transform the heterogeneous longitudinal datasets (consisting of cancer registry, pathology, and billing data) into a standardized format to enforce consistent structure and semantics.

Results
The OMOP CDM was insufficient for representing some aspects of the NMIBC data. Gaps identified revolved around the generalizability of OMOP CDM to represent oncology specific attributes, complex drug regimens, and time to outcome. Gaps: 1) The structure and/or vocabulary for storing oncology specific attributes (e.g., number of tumors, tumor size). These tumor characteristics were dispersed across multiple tables (e.g., condition occurrence, measurement, observation) without enough detail and linkages. 2) OMOP CDM lacked structure to express immunotherapy regimen elements (e.g., induction vs maintenance, cycle number) for drugs such as Bacillus Calmette-Guerin. 3) OMOP CDM does not allow for an explicit representation of time between recurrences for an individual patient. To address these gaps, we adapted existing concepts for tumor specification, repurposed partially related fields for drug regimens, and created temporary categorical representations of otherwise continuous data.

Conclusion
Despite the increasing attention and rigor of OMOP CDM, the growing multiplicity of EHR data sources, structures and thereby semantic harmonization may remain challenging in the foreseeable future. To improve OMOP CDM, we advocate for the development of more appropriate oncology vocabularies and table structures that can adequately represent continuous and temporal oncology data.

Using “Big Data” to Determine Prevalence of Side Effects of Chemotherapy in Breast Cancer Patients

Lu Pu, MD, PhD¹, David C. Kaelber, MD, PhD, MPH²
¹School of Medicine; ²Depts of Internal Medicine, Population and Quantitative Health Sciences, The MetroHealth System, Case Western Reserve University, Cleveland, OH

Introduction

One of the key factors affecting the care and mortality of breast cancer patients is the cardiotoxicity of chemotherapies. The cardiotoxicity of antimetabolites including 5-fluorouracil and capecitabine has been demonstrated in case reports, randomized control trials, and prospective and retrospective studies (1, 2), with incidence rates ranging from 1% to 68% (3). Aggregated and de-identified population data has been used for post-market surveillance of other non-chemotherapy medications (4). Here we present the first proof-of-principle study on post-market surveillance of cardiotoxicity of breast cancer therapies using the OHDSI (Observational Health Data Sciences and Informatics Collaborative)/OMOP (Observational Medical Outcomes Partnership) common data model (CDM).

Methods

De-identified health records of 2,740,000 breast cancer patients were obtained from five OMOP CDM-based electronic health record databases that were part of OHDSI. Data analysis occurred over a course of 10 hours using Atlas tools on top of the OHDSI databases (atlas.ohdsi.com). Diagnoses (breast cancer and medication side effects) were searched using, SNOMED terms and medications where searched using RxNorm for drugs.

Results

The incidence rate of left ventricular dysfunction (LVD) in breast cancer patients treated with antimetabolites was 2-3 times higher than left ventricular dysfunction with other therapies (Figure 1).

Discussion/Conclusion

Here we demonstrate that a medical school student (author LP) with limited exposure and training to large EHR data sets quickly (~10 hours of work) used tools to easily explore large data trends, in this case side effects related to chemotoxicity among breast cancer patients. Especially for relatively rare conditions this approach is attractive because other methods (case studies, randomized control trials, and traditional cohort studies) are not effective or efficient at assessing the overall frequency of correlation of rare events.

Large EHR databases, such as OHDSI and related analytics tools can be used to efficiently and effectively assess correlation between various chemotherapies and their potential side effects.

References

Figure 1. Incidence rates of LVD in patients with breast cancer and treated with: taxol (Taxanes, eg., paclitaxel), tam (endocrine therapy, eg. tamoxifen, anastrozole, letrozole), radiotherapy, her2 (HER-2 targeting therapies, eg., trastuzumab, pertuzumab), dox (anthracyclines, eg., doxorubicin, epirubicin), cisplatin (alkylating agents eg., cisplatin, cyclophosphamide), cdk (cyclin-dependent kinase 4/6 inhibitors, eg., palbociclib, ribociclib), and antimetab (antimetabolites, eg. 5-fluorouracil, capecitabine). Significance (by Chi-square test) is indicated (*: *p<0.05, **: *p<0.01).
A Modular Web Application Offers Flexibility and Adaptability to Cope with Frequent Structural Updates in Pathology Cancer Reporting

Zhenhong Qu, MD, PhD 1; Jason Guo Jin 2, Keran Zhao 3, Elaine Qu 4, Kimberly Pieters 1.

1. Department of Pathology, Beaumont Hospital, Royal Oak, MI.
2. University of Michigan, Ann Arbor, MI.
3. Department of Information and Decision Sciences, University of Illinois, Chicago, IL.

Introduction/Background
The American College of Surgeons Commission on Cancer (ACoS-CoC) mandates that pathology reports of cancer must include essential data elements and follow specific formats. An online application with dynamic forms has been an effective tool for pathologists to file cancer reports in compliance with the ACoS-CoC’s mandates. However, frequent updates of the reporting standards require corresponding back-end structural changes of the Web forms as reporting templates, which for more than a decade remains a daunting challenge in keeping the reporting templates up-to-date. No effective solution has been identified. Here we introduce a new method by which the users can 1) update/create reporting templates by combining dynamic form units as software modules on the Web via a simple drag-and-drop operation, and 2) file tumor reports with the updated reporting templates. This modular method effectively overcomes the challenge by greatly improving the flexibility in building cancer reporting templates and keeping them up-to-date when new reporting standards and requirements arise.

Method and Results
Our survey of more than a hundred of different tumor synoptic report forms by four different international professional organizations has identified a small number of frequently employed functionalities/features of Web forms (e.g. drop-down list, checkbox, free text box, etc.) that can meet nearly all format needs form reporting forms. Accordingly, we created Web modules for each of these functional form units as JavaScript Object Notation (JSON) Schema using ReactJS, a popular JavaScript library maintained by Facebook, Inc. (Menlo Park, California 94025). The JSON Schema defines Web forms. The final application uses JSON and HTML to create dynamic forms on the Web. The users can selectively upload multiple individual JSON files (i.e. form modules) via drag-and-drop on the Web page to create customized Web forms on the fly. The combined JSON file for a Web form can then be downloaded for future use as a reporting template or again as a module to merge with other form modules for updating or making new reporting templates. The resultant Web forms (templates) are used for online tumor reporting by pathologists. This platform is accessible at: http://www.essentialpathology.info/index.html?home by clicking icon “Create template …”

Conclusion and Discussion
This new modular method allows users to create and update tumor reporting forms easily in a Web browser without demanding programming skills of most users. It effectively overcomes the obstacle to timely updates of tumor-reporting standards mandated by ACoS-CoC. It is a simple method which solves a big chronic problem in the standardization of cancer reporting in pathology.

DSL-TEACH: Data Science Literacy Training to Enhance Approaches for Clinical decision-making in Healthcare

Samir Rachid Zaim, BA1,2, Ahyoung Amy Kim, BS3, Colleen Kenost, EdD1,2, Helen Hao Zhang, PhD3,6, Yves A. Lussier MD,1,3,7,8 Vignesh Subbian, PhD4,5

1Center for Biomedical Informatics & Biostatistics, 2Dept. of Medicine, 3Graduate Interdisciplinary Program in Statistics, 4Dept. of System and Industrial Engineering, 5Dept. of Biomedical Engineering, 6Dept. of Mathematics, College of Sciences, 7BIO5 Institute, 8UA Cancer Center,
The University of Arizona, Tucson, Arizona

Problem Statement

Prior studies1-3 surveying physicians indicated that many commonly-used statistical metrics, such as positive predictive value (PPV) or relative risk (RR), are not well understood, despite their coverage during medical training and subsequent use in clinical care. Indeed, Clinical Decision Support Systems (CDSS) implemented in Electronic Health Records (EHRs) are complex, dynamic data-driven healthcare tools that implicitly require a basic level of statistical literacy (e.g., PPV) for proficient development and utilization. However, new tools stemming from data science (i.e., case-based reasoning, machine learning-anchored practice-based evidence) are advancing the field of clinical decision-making4-5, demanding greater awareness for their utility and application in clinical care. Further, practice-based evidence derived from machine learning applied to big clinical data poses new challenges for clinicians. For example, the seminal NEJM on calculating risks of therapy from EHRs presented four relative risks without documenting their interdependencies, leading to a challenging interpretation6.

DSL-TEACH: Proposed Framework and Learning Modules for Promoting Data Science Literacy

To improve awareness and clinical utility of forthcoming data science tools in healthcare, we propose DSL-TEACH (Data Science Literacy Training to Enhance Approaches for Clinical decision-making in Healthcare), a framework for promoting literacy in data science and predictive analytics applied to clinical decision making. For example, components will include i) understanding data pre-processing and biases, ii) confounder-controlled observational study design, iii) strengths and limitations of feature curation and selection, iv) strengths and limitations of machine learning models, as well as v) fundamentals of probabilistic and case-based reasoning (e.g., understanding of risk reporting). Our current prototype is based on the above-mentioned components; however, we are in the process of conducting a needs assessment to better cater our framework to meet the specific needs of our audience. Once finalized, the polished prototype will be deployed as online learning modules, hosted via REDCap, which will be freely available at CB2.uahs.arizona.edu, along with any accompanying educational materials. In parallel, we will be developing and deploying monthly workshops as companion resources. For example, we currently offer a monthly “Orange for Beginners”, a programming-free introduction to this software on the basics of visualization and machine learning, which will be incorporated into the DSL-TEACH framework. The final product of DSL-TEACH will be a series of online learning modules along with in-person workshops, offered at varying learning levels. After a full year of implementation, we will conduct a program evaluation to assess its effectiveness.

Conclusion

We have developed a framework that covers the key components of data science along with a prototype of learning modules and assessments to illustrate its utility. DSL-TEACH provides healthcare professionals with the necessary data science conceptual skills to develop intuition and rationale for seamlessly interfacing with tools, such as CDSS, to improve patient care. DSL-TEACH is not a certified program, but rather a community resource covering concepts necessary for training healthcare providers in data science literacy in the context of healthcare decision making.

Evaluating EHR Data Availability for Cancer Pain Research
Christina Radloff, BSN, RN1, Jia-Wen Guo, PhD, RN1, Katherine Sward, PhD, RN1
1University of Utah, Salt Lake City, Utah, USA

Abstract

This study identified the availability of cancer pain research related data from the Veterans Affairs (VA) electronic health record (EHR). Two VA nurses independently reviewed 68 concepts and 50 scales identified in cancer pain literature and recorded where and how it is documented in the EHR. Approximately, 80% of the seen concepts are documented in unstructured free text. Techniques such as natural language processing are required to use EHR data for cancer pain research.

Introduction

Pain is one of the most distressing symptoms for cancer patients. The multifaceted, individualized, and dynamic nature of cancer pain necessitates a personalized care approach that considers the complexity and trajectory of cancer pain. The existing longitudinal patient data in the EHR may contain useful information for cancer pain research. However, it is unclear what EHR data are available to advance personalized cancer pain care research.

Methods

In our previous study, we used the Dynamic Symptoms Model to guide the identification of concepts describing cancer pain research. In that study, 68 concepts and 50 scales or measures were identified from literature and classified into 10 domains: including demographic, physiologic, psychological, social, spiritual, environmental, cancer pain intervention, overarching consequences, cancer pain symptoms, and cancer pain-related comorbidities. In the current study, we examined the availability of these cancer pain research related data in the VA EHR documentation systems, including Computerized Patient Record System (CPRS), Bar-Code Medication Administration (BCMA), and Essentris. Two VA nurses, one from the intensive care unit and the other from the general ward, independently reviewed all 68 concepts and 50 scales or measures. During the review, they recorded whether they have seen or documented the concept or scale. The datatype (e.g., structured or unstructured) and the documentation system (e.g., CPRS, BCMA, Essentris) would be further identified if the concept or scale was found in the EHR. Inter-rater reliability (IRR) was calculated to examine the degree of agreement between two nurses.

Results

The IRR results were almost perfect and moderate agreement for scales and concepts, respectively; discrepancies were resolved through discussion. Out of 68 cancer pain research related concepts, 89.7% (n=61) were documented or seen in the VA EHR. Of those 61, 80.3% (n=49) were represented as unstructured free-text. All 61 concepts are stored in CPRS, 8 are in BCMA, and 6 were in Essentris. The 7 concepts not found in the VA documentation systems were types of cancer pain interventions (i.e., cognitive behavior therapy, low-level laser therapy); quality of life; self-efficacy, barriers, and knowledge related to pain management; and social connection. Of the 50 scales or measures, only 8 were seen in the VA EHR: 6 for assessing pain, one for anxiety, and one for cognitive disturbance.

Discussion

This study provides information for researchers interested in using EHR data to study cancer pain. CPRS contains more patient data for cancer pain research than other VA documentation systems because it is the main system for documenting and storing patient records. The majority of the concepts were seen embedded in unstructured, free-text documentation. The concepts that were not seen within VA documentation systems may be found documented using terminology other than the stated concept name. For example, the social support concept was not seen in the VA documentation systems as ‘social isolation’. Social isolation may be documented using surrogate language. For example, ‘the patient lives in a remote area’ or ‘the patient is estranged from their family’.

Conclusion

Extracting EHR data for cancer pain research is not simple since many concepts are found within the unstructured, free-text documentation. Techniques such as natural language processing are required to extract the concept information from free-text. Also, some concepts are not clearly articulated within EHR documentation. Therefore, surrogate concepts and additional variables related to those concepts not seen in VA documentation systems. This will need to be explored in further research.
Addressing the Pressing Home Care Coordination Challenges and Opportunities: A Literature Review

Mohammad Ishtiaque Rahman, BSc, and Güneş Koru, PhD
University of Maryland, Baltimore County, Baltimore, MD

Introduction
Care coordination is pivotal for home health agencies (HHAs) as their participation in value-based purchasing (VBP) model of Centers for Medicare and Medicaid Services (CMS) is becoming mandatory by 2022.1 HHAs can ensure cost effective quality services to their clients which meet the criteria to be reimbursed through better care coordination. Analysis and synthesis of findings from previously published studies can help organizational initiatives aiming to achieve efficiency and effectiveness. Hence, this study has (i) identified the top challenges and opportunities to better coordination of home care services and (ii) derived initiative recommendations for HHAs to improve care coordination.

Methods
A literature review was performed, because such a review provides opportunities to analyze and synthesize information and results from a number of studies. To implement a systematic approach, the PRISMA guideline has been adopted.2 Keywords were developed according to the standard definition of care-coordination stated by AHRQ: Coordination, IT, collaboration, competency, discharge process, and home care giver.3 The relevant publications were selected based on a set of inclusion criteria: being published in US, written in English, only involving home health agencies and employees. Following this method, 7,423 papers were identified for preliminary screening searching IEEE, Pubmed and SAGE databases. A set of 30 papers were shortlisted for subsequent qualitative synthesis by examining the titles and abstracts.

Results
The conducted study reveals the followings as top challenges: (i) Power imbalance of communication among HHAs, physicians and hospitals, e.g., clinicians are not always confident while communicating with a physician and asking questions regarding important patient information. (ii) A lack of integration among EHR systems, as well as an inability to capture contextual information, e.g., EHR systems used in HHAs often do not interact with hospital EHRs and very few EHRs integrate NLP features to capture relevant contextual information. (iii) Alarm fatigue is also becoming relevant, e.g., hospitals and physicians often receive too many requests at once to handle. (iv) Often the HHAs receive lower priority and attention from the hospitals and physicians as they share information, e.g., in many cases HHAs received their requested patient history and medication data too late or did not receive at all. Sometimes, visiting clinicians are perceived as guests by the home care givers, i.e., home caregivers are not perceiving these clinicians as serious medical personnel to share patient information. Despite of these challenges, there are also opportunities which can bolster HHA coordination initiatives. Sharing photos and videos containing rich information using smart phones can increase patient-provider engagement. (i) Physicians are busy but generally willing to communicate, e.g., when contacted in person, physicians are sharing information. (ii) Clinicians enjoy and would likely to continue working in HHAs, reducing coordination problems regarding stuff overturn. (iii) More community resources are now available to the home care clinicians and care givers aiding care coordination, e.g., lists of shared durable medical equipment are publicly available.

Conclusion
The recommended directions emerging from this study are: Using online video streaming training, centralized portal to share and retrieve patient information reducing alarm fatigue, and meaningful use of social networks helping patients and care givers to find information resources. Further research is required addressing issues such as, EHR integration among HHAs and hospitals to improve collaborative effort. NLP research on health care domain will also be useful as right now EHR is not equipped enough to capture relevant contextual information.

Predicting Empiric Antibiotic Coverage based on Patient Factors

Protiva Rahman, BS, Erinn M. Hade, PhD, Courtney Dewart, MS, Yuan Gao, MS, Courtney Hebert, MD,MS
The Ohio State University, Columbus, OH

Introduction
While antibiograms provide pathogen-specific coverage details, physicians make syndrome specific decisions for empiric treatment. There has been preliminary work in modeling coverage for individual antibiotics using patient factors such as demographics, recent antibiotic exposure, etc. However, combining outputs of multiple models to recommend an ‘ideal’ one remains an open problem\(^1\). Selecting a high probability threshold can lead to prescribing broad-spectrum antibiotics, increasing antibiotic resistance in the community. In this work, we look at methods to identify the narrowest effective antibiotic for each patient.

Method
Our data consisted of adult patients admitted to an inpatient unit of an academic medical center from 11/11/11 to 6/30/16 with a urinary tract infection (UTI) and a positive culture in first 48 hours of admission (N=6,366, train = 5,093, test = 1,273). To rank antibiotics we used a mixed-methods approach of a survey followed by in-person discussion with the university’s antibiotic stewardship group\(^2\). We used the mean breadth score (on a scale of 100) from the 9 survey-responses as an antibiotic’s breadth. To model coverage, we used five penalized logistic regressions, one for each antibiotic (Cefazolin, Ceftriaxone, Ciprofloxacin, Cefepime, and Zosyn). As a first step in determining a recommended antibiotic, we selected the antibiotic with the lowest breadth score and an estimated probability above a specific threshold. For each patient, we further calculated the ‘ideal’ antibiotic as the narrowest (lowest breadth) antibiotic to which a patient was sensitive, based on lab results. We then trained hierarchical feed-forward neural networks with two fully-connected hidden layers to directly identify the ideal antibiotic.

Results
We evaluated the recommended antibiotic on two measures: the breadth score and the actual coverage (number of infections that would be successfully treated if the recommended antibiotic was prescribed). Figure 1 shows the actual coverage and breadth trade-off for varied thresholds of penalized and neural-network models in our test dataset. We also show results for physician administered and ideal antibiotic. A threshold of 0.65 covers 65% of infections at avg. breadth score of 60. Other thresholding schemes (0.65 for Cefazolin and Ceftriaxone, 0.7 for Cipro, 0.8 for Cefepime, otherwise Zosyn), result in covering 70% of UTI cases with breadth score of 62. Neural networks perform comparable to penalized models. As expected, increasing coverage, requires increasing breadth.

![Image of Figure 1](https://example.com/figure1.png)

*Figure 1. Coverage and breadth trade-off for different thresholds.*

Conclusion
We compare the trade-offs of different thresholding schemes when ranking antibiotics by combining predictions from five models. Our models are able to cover the same number of infections as the physician with a 5 point decrease in breadth, and they can cover 10% more infections with the same breadth as physicians. However, they are still far from the ideal scenario of covering 85% of infections at 43.5% breadth.

Approaches to Pilot Testing of Electronic Exchange of Infectious Diseases Case Report Data to Public Health Disease Surveillance System in Minnesota

Sripriya Rajamani, MBBS, PhD, MPH, FAMIA1,2,3; Ann Kayser, MPH1; Hanna Chakoian, BA1; Sarah Boneske, MPH1; Emily Emerson, BS1; Sarah Solarz, MPH1

1Minnesota Department of Health, St. Paul, MN; 2School of Nursing, 3Institute for Health Informatics, University of Minnesota, Minneapolis, MN;

Introduction

Public health agencies collect surveillance data on certain communicable diseases to assess disease trends, characterize affected population and prioritize disease control strategies. In Minnesota (MN), reportable diseases are determined by the Minnesota rules1 and communicable disease reporting is centralized. Reporting sources submit data to the MN Department of Health (MDH) and surveillance is supported by the Minnesota Electronic Disease Surveillance System (MEDSS)2. An estimated 71,995 cases were reported in 2017, most of which occurred through phone, fax, paper-based disease report cards and web-based data entry. With exponential growth of electronic health records (EHRs) in the clinical sector, there is increasing momentum to move towards electronic case reporting (eCR) to public health propelled by national initiatives. Currently, MDH is exploring a multi-modal approach to eCR to support stakeholders.

Methods

Driven by various factors ranging from national/local initiatives and the need to respond to time-dependent system changes by clinical data submitters, more than one approach was needed. Three different options (Table 1) for electronic exchange of case report data was considered. Preliminary steps/planning underway for the first one (Digital Bridge), with pilot test planned for later in the year. Last two options (HIE and eCR Lite) are under implementation.

Table 1: Approaches to Support Electronic Case Reporting

<table>
<thead>
<tr>
<th></th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Digital Bridge3                Nationally scalable, multi-jurisdictional approach with automated generation and transmission of case reports from EHRs to public health</td>
</tr>
<tr>
<td>2</td>
<td>Health Information Exchange   Data exchange supported by state-certified Health Information Exchange (HIE) service providers in Minnesota (HIE Oversight Program)4</td>
</tr>
<tr>
<td>3</td>
<td>eCR Lite2 (MN specific)        Customized MN approach that builds on national guidance along with additional data elements</td>
</tr>
</tbody>
</table>

Results

Rules for six nationally identified infectious diseases are currently being authored as part of Reportable Condition Knowledge Management System (RCKMS) which is integral to the national Digital Bridge initiative (option #1). A health system that is a MN-HIE certified entity (option #2) started reporting in early March 2019. This system decided to utilize eCR Lite approach (option #3) to submit their data. Regular data feeds (~8-12 cases/day) with relevant data (~84 out of 101 data elements in eCR Lite specs) extracted from their EHR through a reporting module are being submitted to MEDSS. A mid-sized provider clinic system was also able to successfully test eCR Lite (option #3) and is switching to that reporting method shortly. A customized data exchange method (part automated, part manual) was implemented to support receipt of data through option #3 in the short term.

Conclusions

MEDSS plans to move towards stream-lined and standards-based methods to support electronic data exchange of reportable case information. There is a need to share case studies and lessons learned to promote interoperability.

Clinical Trials Process Framework to Optimize Clinical Research Operations

Pallavi Ranade-Kharkar, MS, PhD1, Benjamin Chisum, BS1, Kathryn G. Kuttler, PhD1
1Intermountain Healthcare, Salt Lake City, UT

Introduction
Clinical research operations – from initial hypothesis to research publication and closeout – is complex, time-consuming, and resource-intensive. The operational processes are further complicated by regulatory requirements and involvement of multiple stakeholders, from siloed teams, some of whom are external to the organization. To improve efficiencies associated with administrative and other operational processes, it is crucial to define standardized workflows across departments and create a framework of measurement based on milestones defined at the appropriate level of granularity. Doing so, provides an opportunity to improve processes, provide transparency into workflows, track operational metrics, assist with resource estimation and optimum utilization, and provide data-driven rationale to leadership for requesting additional resources.

Method
We conducted semi-structured interviews with 37 stakeholders representing seven functional teams in the research pipeline (e.g. Institutional Review Board (IRB), contracts, billing compliance) and major research departments (e.g. Cardiovascular, Oncology, Women and Newborns) to understand their current workflows. We then created future-state workflows that identified critical milestones and their sub-processes (we called them actions) that: 1) indicate completion of an atomic activity (e.g. completion of the contract intake process); and/or 2) handoff responsibility from one team to another (e.g. initial billing plan essential documents uploaded where responsibility is passed from the research department to billing compliance); and/or 3) involve historically time-consuming processes (e.g. budget negotiation). We further defined sets of milestones for each of the types of studies, namely: sponsored, investigator-initiated, and data or sample study. We conducted three rounds of refinement to the milestones and actions. A detailed review of the milestones was completed with the stakeholders to ensure a balance between the need to record data points for tracking metrics and the data entry overhead for users. These milestones were implemented in a third-party Clinical Trial Management System (CTMS) that currently includes 502 studies. Stakeholders and users of the CTMS were interviewed post-implementation to evaluate ease of use of the process framework.

Results and Discussion
The clinical trial process framework is comprised of 12 milestones (Table 1). Users reported that completing data entry for the milestones and actions in the framework was easy to complete and involved minimal time overhead.

Table 1. Clinical research milestones and actions

eHealth in Military Primary Care: How Consumers Engage Electronically with the Military Health System

Stephanie J. Raps, MSN-BC, PhD Student
Graduate School of Nursing, Uniformed Services University, Bethesda, MD

Introduction

Primary care teams are becoming increasingly aware of the need to go beyond contemporary clinical approaches and include the use of patient engagement electronic health (eHealth) technologies to enhance patient-centered care. This awareness is emerging from, the effects of a major generational shift surfacing in primary care clinics. A recent study evaluating primary care providers found a split between consumers ages 18-29 ‘not’ having a primary care provider (45%), compared to older consumers 30-49 (28%), 50-64 (18%) and over 65 (12%)1. Consumers are increasingly seeking more convenient healthcare solutions – electronic health (eHealth), virtual visits, retail clinics, and urgent care clinics. However, despite a high consumer interest and expansion of eHealth tools, widespread adoption remains low2,3. The TriCare Online Patient Portal and Secure Messaging application is one of the highest utilized eHealth tools in the MHS and a focus of adoption efforts4. The MHS faces similar eHealth adoption issues while striving to increase engagement and maintain patient-centered, coordinated, and longitudinal relationships. The MHS reports 70.5 million annual visits across 375 outpatient clinics, but little is known about what portion of these visits are achieved by eHealth modes and how consumers interact electronically with the MHS. Our study investigated the utilization patterns of eHealth consumers in primary care within the MHS to describe the characteristics and patterns of use by high utilizers of eHealth and low utilizers of eHealth.

Methods

A retrospective review of the TriCare Online Patient Portal/Secure Messaging utilization metrics was completed. Two dependent variables were assessed: website login times a year and application used (Appointments, Blue Button, Service Separation, Secure Messaging, Nurse Advice Line, and RX Refill). Five independent variables were examined: Military Treatment Facility (MTF), TriCare region, sex, consumer type (Active Duty, retired, dependent) and age.

Preliminary Results

Preliminary data identify Army MHS consumers use the application more than other services. Additionally, viewing and downloading of health record data are the most used MHS eHealth functions. Non-Active Duty females between the ages of 25-35 are the highest users. (results pending April 2019)

Conclusion

These results are expected to have a vital positive impact that provides the missing knowledge to develop innovative education and technological designs that enable patients and providers to communicate satisfactorily and effectively.

Visualizations to Communicate Risk in Patient Reported Outcomes
Meghan Reading Turcchio, PhD, MPH, RN\textsuperscript{1}, Lisa V. Grossman, M.Phil\textsuperscript{2}, Annie C. Myers, MA\textsuperscript{1}, Ruth M. Masterson Creber, PhD, MSc, RN\textsuperscript{1}

\textsuperscript{1}Department of Healthcare Policy and Research, Division of Health Informatics, Weill Cornell Medicine, New York, NY; \textsuperscript{2}Department of Biomedical Informatics, College of Physicians and Surgeons, Columbia University, New York, NY

Introduction
Patient-reported outcomes (PROs) are gaining popularity as a means of supporting patient self-management. Recent research has begun to identify the smallest changes in PRO scores that are clinically meaningful (i.e., minimally important differences, or MIDs) for different patient populations\textsuperscript{1}. However few tools exist to communicate MIDs to patients with different health literacy, graph literacy, and numeracy levels. Communication of MIDs is critical for patients to understand and act on PRO scores. Visualizations of personal health data have the potential to convey risk to a diverse range of patients, but have predominantly been tested with data that have well-established boundaries for action (i.e., lab values)\textsuperscript{2}. The purpose of this study was to assess patients’ risk perception and behavioral intention in response to visualizations that display MIDs in PRO scores over time.

Methods
We recruited a purposive sample of hospitalized heart failure (HF) patients from an inpatient cardiac unit at an urban academic medical center to participate in individual interviews. Participants were English-speaking adults diagnosed with HF. A professional designer developed four visualizations (text only, text plus icon, text plus number line, and text plus line graph) depicting side-by-side comparisons showing worsening MIDs of PRO scores over time. We showed participants the colored, paper-based visualizations during their inpatient visit. Using the participants’ preferred visualization of the four, we evaluated subjective risk perception\textsuperscript{3,4}, objective risk perception\textsuperscript{5}, and behavioral intention. We then collected demographic and literacy-related surveys. Data were analyzed using SAS 9.4.

Results
Participants (n=40) had an average age of 61.3 years (±12.5) and were 22% female, 52% White, and 38% Latino. They reported having low education (high school or less: 45%), financial resources (43%), health literacy (55%), graph literacy (91%), and subjective numeracy (mean score 12.2 ±4.7). Most also had mild/moderate cognitive impairment (88%). Participants’ favorite visualizations were icons (31%) and number lines (41%). Subjective risk perception was generally high; 70% reported it was very/extremely likely their HF was getting worse and 54% reported they were very/extremely worried about their HF getting worse. However objective risk perception was mixed; 67% accurately recalled the gist of the visualization but only 10% accurately recalled the PRO scores verbatim. Regarding behavioral intention, most (82%) were very/extremely likely to act based on the visualization. The majority of these participants reported their next step would be to contact a healthcare provider or go directly to a hospital (84%), while fewer reported they would attempt to self-manage the symptom or search the Internet for health information (16%). The 8 participants who were unlikely to act reported it was due to their perception of low risk.

Conclusion
Visualizations of MIDs of PRO scores over time communicated risk to the majority of patients, who in turn reported being more likely to act. Patient decision-support may bolster patient skills and efficacy to self-manage, and minimize burden on healthcare providers, when patients perceive risk from PRO scores.

Technology-Mediated Adverse Events in Primary and Community Care

Chantelle Recksky, RN, MSN, PhD(c)1, Lorraine Blackburn, RN, MSN2, Allison Muniak, MSc2 Kathy Rush, RN, PhD3, Maura MacPhee, RN, PhD1, Leanne M. Currie RN, PhD1
1University of British Columbia-Vancouver, British Columbia, Canada;
2Vancouver Coastal Health, Vancouver, British Columbia, Canada;
3University of British Columbia-Okanagan, Kelowna, British Columbia, Canada

Introduction
A technology-mediated adverse event (TMAE) is a patient safety event with a potentially negative outcome (i.e., harm) in which health information technology played a role. The incidence of TMAE is increasing in parallel with high uptake of technology in healthcare. Most TMAE research has been conducted in acute care settings. A study of general practitioners in Australia found up to 6 TMAEs per practice over 19 months (with 6.6% having potential for harm). The purpose of this study was to examine rates of TMAEs in primary and community care settings.

Methods
This cross-sectional study was carried out in a Canadian healthcare region providing care for over 1 million people in urban and rural settings. Primary care is provided via an MD or NP. Community and public health care is provided at a clinic or the patient’s home. A web-based tool for voluntarily reporting patient safety events has been used since 2009. Reports include a narrative description, categorization of type (e.g., medication), and degree of harm. In 2015, a screening question derived from Magrabi et al.,’ was added: ‘Was the computer system a factor in the event?’ We analyzed reports from primary and community care from November 1, 2016 to October 31, 2018.

Results
Over 2 years, 105 events were tagged as “yes” to the screening question. These reports were investigated and verified by local supervisors. Of these, 19 (18%) had harm attributed – minor (n=13), moderate (n=5), and severe (n=1). Medication events represented 65% of reported events (n=68). Among the different areas of care, public health had the most reported events (n=38, 36%), yet 92% (n=35) of these events indicated no harm (e.g., vaccines administered outside of vaccine schedule). In contrast, 6% (n=6) of events were reported in home health, and half of events (n=3) in this setting indicated harm (e.g., missed care due to information loss in care transition).

Discussion
To the authors’ knowledge, this is the first study that reports on frequency of TMAEs in community care. Bias associated with self-reporting is a limitation. Qualitative data are being gathered and analyzed as another phase of this work. Healthcare leaders need to be aware of the potential for harm related to advancing technologies in practice, and encourage recognition and reporting of TMAE. These findings will guide the health region to establish a process to identify, analyze, and address TMAE in non-acute settings.

HomeSHARE: Implementing Multi-Site Smart Technology Infrastructure

Blaine Reeder, PhD\textsuperscript{1}, Haley Molchan, BS\textsuperscript{2}, Eric Gutierrez, MSPH\textsuperscript{1}, Ewelina Pena, BS\textsuperscript{1}, Kelly Caine, PhD\textsuperscript{3}, PhD, George Demiris, PhD\textsuperscript{4}, Katie Siek, PhD\textsuperscript{2}, Kay Connelly, PhD\textsuperscript{2}

\textsuperscript{1}University of Colorado, Aurora, CO; \textsuperscript{2}Indiana University, Bloomington, IN; \textsuperscript{3}Clemson University, Clemson, SC; \textsuperscript{4}University of Pennsylvania, Philadelphia, PA

Introduction

Smart home, wearable, and mobile sensor technologies are increasingly ubiquitous and have potential to enable previously unavailable opportunities to support research in daily living settings. However, investigators who conduct technology research in home environments face challenges of recruitment, generalizability of results, reusability and obsolescence of technology, data and algorithm transparency from proprietary devices, and sustainability of research efforts beyond funded study periods. The Home-based Smart Health Applications across Research Environments (HomeSHARE) project is a multi-site smart technology infrastructure initiative (NSF Award #s: 1629202, 1629468, 1625451, and 1629437) implementing a distributed testbed to integrate and evaluate a diversity of devices in participant homes and serve the needs of multiple research communities including those of informatics, gerontology, computer science, nursing, and public health. HomeSHARE sites are located at University of Colorado (Colorado), Indiana University (Indiana), University of Pennsylvania (UPenn) and Clemson University (Clemson).

The current HomeSHARE implementation relies on 1) a smart home system: sensors (motion and contact sensors) installed in the home that transmit activity data to a hub via wi-fi then to a project database via the internet; 2) system servers: servers located in a data center with a research console for project configuration, sensor data export, and remote hub management; 3) smart watch: wearable activity monitors that transmit activity data via bluetooth to a tablet computer (then vendor and HomeSHARE databases); and 4) participant portal: a tablet computer with touchscreen that allows researchers to collect electronic self-reported data from survey instruments and conduct remote video interviews. Participant self-reported survey data are transmitted to a REDCap database.

Methods

A cross-site infrastructure demonstration study using an identical mobility monitoring protocol\textsuperscript{1} in the homes of independent living participants 65+ years of age began in October 2018. Sensor and self-reported data are being integrated and analyzed for correlations. Technology implementation factors and feature needs are being documented for infrastructure improvement.

Results

Eighteen participants (n=14 Indiana; n=4 Colorado) are enrolled. Enrollment is ongoing with planned enrollment of 15 participants at both sites. Demonstration study results have informed requirements that will result in transitioning HomeSHARE to a new internet-of-things platform. Figure 1 shows a future state HomeSHARE architecture with backend features for improved integrated data reporting and remote technology management through a single research console.

Conclusion

We have successfully deployed a multi-site smart technology infrastructure designed for multiple research communities. An enhanced infrastructure study will scale HomeSHARE at Colorado, Indiana, UPenn, and Clemson (n=100 homes). Participant sensor data visualizations and implementation findings will be presented at AMIA 2019.

Initial Phase of Developing a Model to Predict Unplanned Readmissions in the Australian Private Healthcare Sector before they Occur: the Case of Hysterectomy

Daniel Reischel, MS1, Isabella Eigner, MS1, Freimut Bodendorf1, Jonathan L. Schaffer2, MD, MBA, Nilmini Wickramasinghe, PhD, MBA3
1FAU, Nuremberg, Germany; Cleveland Clinic, Cleveland, Ohio, USA; 3Swinburne University of Technology & Epworth HealthCare, Melbourne, Victoria, Country, Australia

Introduction: In the Australian private healthcare sector there is a growing pressure to reduce unplanned hospital readmissions, i.e., readmissions related to the initial indexed visit that were unexpected within 28 days of discharge, which are considered a quality of care indicator as well as a major cost driver1. The Australian Institute for Health and Welfare (AIHW) focuses on reducing unplanned readmissions post specific surgical procedures. Hysterectomy has been identified as the cause of the 2nd highest unplanned readmission within these procedures2; yet no model to predict unplanned readmissions following a hysterectomy exists. Australia has one of the highest rates of hysterectomy (27,586 procedures a year) in benign diseases as compared to other OECD countries3. Hence, this study focusses on developing a suitable predictive model which has lessons for other cases and contexts of unplanned readmissions.

Methodology: A double de-identified data set with 800 patient data records over 10 years at a private not-for profit tertiary healthcare facility is examined. To this data set, processes suggested by Shmueli and Koppius4 are employed to build a suitable prediction model. Clinical data, coupled with clinical insights extracted from focus groups were used. Inclusion criteria for assessing unplanned readmissions included readmission (based on DRG code) related to indexed initial visit within 28 days of discharge from indexed visit.

Discussion: Especially with imbalanced data, novel ensemble approaches promise a better performance in predicting the minority class. These approaches combine resampling techniques with either boosting or bagging. The most promising ensembles being RUSBoost or underbagging. To have a comprehensive benchmark also SMOTEBoost and Overbagging are added to determine the best performing approach in predicting unplanned hysterectomy readmissions. Since all ensemble methods need base classifiers, this study compares how decision tree (DT), artificial neural net (ANN) and support vector machine (SVM) classifiers perform in combination with these novel ensemble methods and their components. To identify the best model, the AUC-Score is used as performance measure.

<td>0.50</td>
</tr>
</tbody>
</table>

The best performing models are combinations of DT with random undersampled data or ensemble methods implementing random undersampling. The best performing model is RUSBoost with an AUC-Score of 0.94. The base ensemble methods bagging and Adaboost achieve worse scores than the novel approaches. Since Adaboost and its derivations RUSBoost and SMOTEBoost cause overfitting, underbagging should be preferred.

Conclusion: We built and compared multiple predictive models that indicate far reaching implications for theory and practice. We observe that novel ensemble approaches increase the predictive performance but note that these improvements. As this approach has far reaching implications it is therefore important to examine data sets from other healthcare organizations to confirm the obtained results which will form the basis of our future work.

Abstract
Clinical decision support (CDS) increasingly encompasses content to support patients and clinicians alike, such as decision aids for shared decision-making. Actions are therefore necessary to attain reliable and meaningful content for “patient-centered CDS” (PCCDS). The Patient-Centered CDS Learning Network led three parallel efforts to promote PCCDS: addressing issues of trust in PCCDS content; recommending standards for PCCDS; and developing an “action plan” for implementing PCCDS to manage chronic pain and opioids.

Introduction
PCCDS is CDS that directly involves or addresses patient-specific needs in partnership with caregivers. The Patient-Centered CDS Learning Network – funded by the Agency for Healthcare Quality and Research (AHRQ, Cooperative Agreement #5U18HS024849-03) – engaged numerous stakeholders from 2018 to 2019 to deliver products that inform vendors, policy-makers, patients (and more) about ways to structure evidence from patient-centered outcomes research and make it more trustable, standardized, and implementable within compelling real-world use cases.

Methods
The Learning Network formed three working groups (WGs) comprised of an array of stakeholders including patients, providers, policy-makers, content and electronic health record (EHR) vendors, and more. The WGs developed charters to govern themselves and define the outputs for promoting PCCDS-related actions. The WGs routinely met from February 2018 – January 2019 to address issues of trust, standardization, and implementation; and developed white papers that were community vetted, edited, and approved for release by AHRQ representatives.

Results
The three WGs identified a variety of challenges and developed recommendations that provide an overarching agenda for promoting PCCDS. The recommendations include the areas of policies, content authoring, implementation, and measuring impact. Table 1 summarizes the outputs from each WG.

<tr>
<td>Next Steps</td>
<td>Promote the recommendations as part of Learning Network efforts and integrate into learning health system scholarship</td>
<td>The Learning Network implements a set of core recommendations for piloting a standards-based patient-facing app in 2019</td>
</tr>
</tbody>
</table>

Discussion
The Learning Network developed a rich content base in three areas that are critical to the promotion of PCCDS: content trustability, technical standardization, and multi-stakeholder collaboration. The results provide elemental pieces to a broad ecosystem of policies and technological solutions that will be essential for sustaining PCCDS, and CDS more broadly. We believe our efforts contribute to a growing body of work pertaining to decision support solutions in clinical care as well as within learning health systems. The Learning Network will build upon these efforts and continue promoting PCCDS as a key area of development in the informatics sphere.
Racial Disparity in Clinical Decision Support Use for Acute Upper Respiratory Infection

Safiya Richardson, MD MPH1, Thomas McGinn MD MPH1, Simon Jones PhD2, Joseph Palmisano MD3, Sara Chokshi PhD2, Catherine Dinh-Le2, Rebecca Mishuris MD MA3, Linda Park PhD4, Paul D. Smith MD4, Ainsley Huffman5, Sundas Khan MD1, Rachel Hess MD5, David Feldstein MD MA2

1Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Hempstead, NY; 2New York University School of Medicine, New York, NY; 3Boston Medical Center, Boston, MA; 4University of Wisconsin School of Medicine and Public Health, Madison, WI; 5University of Utah School of Medicine, Salt Lake City, UT

Introduction: Clinical decision support (CDS) improves quality of care by improving diagnosis, treatment, and preventative care. CDS can standardize care and eliminate health disparities by providing unbiased care recommendations. CDS has been shown to eliminate racial disparities in child abuse screening and venous thromboembolism prophylaxis—in both cases White patients were receiving inferior care, lower screening and prophylaxis rates. The ability of these tools to reduce disparities depends on unbiased provider use. The objective of this study was to evaluate provider use of CDS by patient race in the context of a large randomized controlled trial.

Methods: This study was a part of a controlled trial, randomized by site, including 11 primary care practices at a large academic healthcare system in Wisconsin. Between October 2015 and June 2018 providers were presented with CDS to assist in estimating pre-test probability of group A strep pharyngitis and pneumonia with the goal of reducing unnecessary antibiotic prescriptions for acute upper respiratory infection. In patients with the chief complaint of sore throat providers were presented with a tool built with the Centor Score and in those with a chief complaint of cough or upper respiratory infection they were presented with a tool built with the Heckerling Rule for Pneumonia. Providers who completed the calculator portion of the CDS tool were considered users. Electronic health record data on provider and patient demographics and CDS tool use rates were collected for analysis.

Results: The intervention group included a total of 27,801 patient encounters with tool launch. The patient racial breakdown was: American Indian 0.68%, Asian 2.83%, Black 3.77%, Native Hawaiian and Pacific Islander 0.18%, White 91.57% and Other 0.97%. Overall CDS tool use was 9.4% (CI; 9%-9.7%). CDS use among Black patients was 13.4% (CI; 11.4%-15.5%). Providers were more likely to use the tool with Black patients (OR=1.51 (CI; 1.25-1.81), p <0.001) compared to White patients in a logistic regression model adjusted for age, gender and site clustering. Tool usage rates among the remaining race categories were similar to overall rates. In a model additionally controlled for provider type there was no racial difference in tool use. Antibiotic prescriptions were lower in Black patients (OR=0.84 (CI; 0.17-0.97), p=0.019).

Conclusions: Provider use of CDS in this trial varied by patient race. This may be explained by resident provider’s increased likelihood to use the tool and to see Black patients. Providers were more likely to use the tool with Black patients which could exacerbate a current disparity as White race is associated with higher antibiotic prescription rates for acute upper respiratory infection. Further study is needed to understand this difference in CDS use rates.
Semi-automated clinical data annotation framework using web-based RedCap and Jupyter Notebook Tools

Albert William Riedl, MS; Irene Cortes Puch, MD; Ernest Pierce Stewart, DO; Nicholas R Anderson, PhD; Jason Yeates Adams, MD

1: University of California at Davis. Sacramento, CA

Introduction: Secondary use of electronic medical record (EMR) data has proven more challenging than anticipated but is possible with careful curation. While developing an automated SOFA score annotation pipeline, the need for rapid cycle QA became apparent. The Sequential Organ Failure Assessment (SOFA) score is a tool to measure dysfunction in multiple organ systems, with higher scores associated with a higher mortality. While there are other illness severity scores (eg APACHE), one benefit of SOFA is that the data elements are, in theory, readily accessible. In practice, however, automated SOFA scoring requires integrating repeated measures, temporal data alignment, and handling charting errors. A rapid Quality Assurance (QA) cycle is necessary to increase experimentation velocity, enable iterative development, and provide benchmarks for success. We developed an extensible, web-based framework for consensus development and evaluation of gold standard annotation by interdisciplinary teams of clinicians and data scientists.

Methods: A RedCap form captures manually derived gold standard annotations from clinicians. Computed annotations were generated by a Python script and saved to a SQL database. The gold standard vs computed comparison was implemented as a Jupyter Notebook, a publishing format for reproducible workflows. The Notebook extracted computed annotations via SQL and gold standard annotations via the RedCap API (Figure 1). Annotations were index aligned via study identifier. SOFA organ system component scores were aligned pair wise by source (clinician vs computed) in columns to enable easy identification of discrepancies (Table 1).

Table 1: Index aligned, score pair visual review. Score pairs represent the 6 components of the SOFA score

</table>

Results: 80 critical care encounters were adjudicated via root cause analysis in interdisciplinary team meetings using this system to target anomalies, accelerating the development cycle and improving trust in computed annotations. The visual feedback helped classify errors as point failures or systemic issues. In our early work, we have found that most discordant scores are caused by errors in the gold standard annotation process itself; reviewers making errors that were not present in the computed scores.

Discussion: Accurate transformation of raw EMR data into meaningful information frequently requires algorithmic processing that must be guided by manually derived clinician gold standards. Gold standard data set development is time consuming and there are no widely adopted tools that facilitate rapid comparisons between clinician annotations and algorithmic output. This framework efficiently identified errors in algorithm logic, and importantly, in the manual chart review process rather than assuming that clinician annotations are inherently accurate. Future work will include adding a discrepancy resolution workflow in the Jupyter Notebook to facilitate consensus adjudication of scoring differences and descriptive statistics to better characterize algorithm accuracy relative to the final gold standard. This approach is extensible to any set of index aligned scoring comparisons.

Using Ontology-Driven Decision Support For Hereditary Cancer Risk Assessment

Jordon B. Ritchie,1 Lewis Frey, MS, PhD,1 Jean-Baptiste Lamy, PharmD, PhD,2 Heath Morrison, BS,1 Brandon M. Welch, MS, PhD,1
1Medical University of South Carolina, Charleston, SC,
2LIMICS, Université Paris 13, INSERM UMRS 1142, Sorbonne Universités, 93017 Bobigny, France

Introduction

Identifying patients who should be recommended for cancer genetic counseling and possible screening, relies heavily on family health history (FHx). FHx is comprised of family relationships, health related information for family members such as cancer history and demographic information, and is most often represented as a pedigree chart. This type of data represents a challenging data model to analyze. Additionally there are very specific evidence based guidelines, such as hereditary cancer guidelines from the American College of Medical Genetics\(^1\) (ACMG), that detail scenarios where patients should be recommended for counseling based on their FHx. These evidence based guidelines are complicated semantic rules that cancer genetic counselors (CGC) have to evaluate by hand. There are hundreds of rules in the ACMG guideline for hereditary cancer alone not to mention many additional guidelines. Currently CGCs are expected to evaluate hand-drawn pedigrees against hundreds of complicated semantic rules. This likely leads to failure to recommend patients, and family members of patients, for genetic counseling in cases where genetic counseling is needed.

Approach

Our proposed solution for storing collected FHx and applying evidence based semantic rules to determine whether patients or their family members should be recommended for genetic counseling hinges on Ontology Oriented Programming (OOP) and Semantic Reasoning. Ontologies have been around for a long time and are especially good at representing data that have important relationships that need to be preserved in the data. This is true for FHx. Ontologies allow the data to be stored in a graph model that depends on triples that define two objects (individuals) in the graph joined by their relationship (properties). This easily allows us to represent a family pedigree and their associated health information in the ontology. We can also define rules in our ontology that will guide semantic reasoners in reclassifying individuals of a given class into subclasses based on their properties that define their relationship to other classes in the ontology. Semantic reasoners evaluate triples and rule definitions to perform this classification process. The recent development of the Owlready\(^2\) API gives us programmatic access to our ontology and comes with built in access to the Hermit reasoner\(^3\) which is the industry standard reasoner that is also built into Protegé ontology editor\(^4\). This allows us to declare the ontological classes, properties, individuals, and rules and perform reasoning all in memory without using an editor such as Protegé.

The ability to programmatically define our ontology, store data in the ontology, and perform semantic reasoning allows us to create a service that consumes FHx and produces recommendations using ReST technology.

Introduction

Due to the paucity of health information exchange (HIE) evaluations employing causal study designs, demonstrations of positive effects of HIE implementations have largely remained theoretical. Our project presents the development of an enhanced methodology using a causal study design to evaluate the effect of HIE on healthcare processes and outcomes. We will apply this novel methodology to evaluating an innovative intervention that directly integrates HIE into electronic health records (EHR).

Objective

Our objective was to develop a novel and comprehensive method to evaluate CareView, an app integrating HIE information directly into Cerner\textsuperscript{1}, on user perceptions, and healthcare processes and outcome measures.

Methods

Our pragmatic evaluation applies a causal study design integrating objective measurements of HIE use with its qualitative context through surveys and focus groups to understand CareView’s impact. We will roll out CareView to 15 Indiana University Health emergency departments using a stepped-wedge cluster non-randomized study design that allows for each cluster to serve as a control. Clinicians and patients will be followed over time to connect the impact of HIE use to outcomes on a patient-by-patient basis, not only at a population-level as in previous studies. This mixed-methods evaluation is guided by a framework combining two models previously validated in the context of health technology interventions: the Unified Theory of Acceptance and Use of Technology II (UTAUT), and the DeLone and McLean Information Success Model. Data from clinician-user logs and patient records will be used to quantify HIE use. In addition, barriers to and motivators for using HIE will be uncovered through qualitative measures, providing context around specific use cases. We will relate these measures to care processes and outcomes including readmissions, and repeat tests and orders.

Policy Implications

HIE innovations to improve efforts toward meaningful integration of patient data must be guided by high-quality evidence provided by rigorous evaluations such as described for this project. This type of evaluation is necessary to provide evidence for continued financial and legislative support of interoperability by federal and state agencies, as well as other stakeholders.

Conclusion

Our proposed evaluation helps provide a practical and pragmatic roadmap to determine causal effects of HIE/EHR integration on meaningful HIE use, and its impact on improving healthcare processes, quality and patient outcomes.

Application of Semantic Web Technology to regulations

Mitra Rocca, Dipl.-Inform.Med¹, Rashed Hasan, PhD¹
¹US Food and Drug Administration, Silver Spring, MD, USA

Introduction:
The U.S. Food and Drug Administration’s (FDA) regulatory activities are based on federal law and Title 21 of the Code of Federal Regulations (21 CFR). CFR is an annual codification of the general and permanent rules published by the executive departments and agencies of the federal government of the United States. The entities regulated by FDA, including pharmaceutical, biotechnology, medical device, dietary supplement, food, cosmetics and tobacco companies, must follow the regulations in 21 CFR in all their operations under FDA jurisdiction. Depending on the product being regulated, these operations may include, but are not limited to, product manufacture and controls, nonclinical and clinical studies, submissions to the agency for human research or product marketing, labeling, and post-market safety reporting. By applying Semantic Web Technology (SWT), we developed a semantic model that enabled us to establish a linked resource for Part 11 of 21 CFR. This resource may be useful in clinical protocol design and phases of clinical development. The model can be extended to other parts of 21 CFR (and other regulations) to enable greater efficiency to the by providing a linked source of regulations.

Methods: For our project, we used AlchemyAPI [1]. AlchemyAPI uses Natural Language Processing (NLP) algorithms to extract metadata from the 21 CFR documents. We ran the application programming interface (API) over 21 CFR Part 11, which contains 10 sections. After discussion with domain experts, we considered only those phrases that were not longer than two words. We obtained 146 keyphrases of one or two words. Many of these, although highly ranked concepts, had nothing to do with the text, while seemingly obvious concepts in part of Alchemy’s library were not returned. Therefore, domain experts reviewed the 146 keyphrases and validated 86 of them, while classifying the remainder as false positives. Furthermore, to enable the system to automatically explore the relevant new datasets from the external sources, we connected the 21 CFR Part 11 keyphrases to the Linked Open Data (LOD) cloud. The proposed solution provides a visualization that shows how keyphrases are connected with each part and subpart of the regulation. This visualization provides a useful alternative representing relations.

Results: The system organizes the data into three layers: (1) User interface (UI), (2) Middleware, and (3) data source. The developed UI allows users to perform keyphrases search via a web page. In the Middleware, Solr does the analyses on the user input data and creates an index into the system. All of the Part 11 of 21 CFR section files were indexed in the Apache Solr indexing system[2], which is the foundation of the 21 CFR web-based query system. For better search functionality, we added NGram functionality (either NGramFilter-Factory or EdgeNGramFilterFactory) in the Solr configuration file. When the user performs full text searches, user-entered keyphrases will match any prefix of indexed text, rather than requiring the full word to be entered.

Conclusions: We have conducted an analysis of 21 CFR regulations Part 11. By applying Apache Solr indexing mechanisms and having subject matter experts validate keyphrases, we have demonstrated the potential to develop a usable search application. In addition, we presented an approach for publishing 21 CFR Part 11 keyphrases into the LOD Cloud and developed a search platform using Solr that supports users when searching documents by keywords. Future efforts may include expanding this work to other parts of 21 CFR regulations. Additionally, this approach may be applied to other FDA regulations and guidances, policy document from other health authorities, and the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH).

Introduction

The goal of our research is to develop and pilot a clinical decision support (CDS) tool that aims to optimize the current state of atherosclerotic cardiovascular disease (ASCVD) risk calculators. CDS has been shown to improve provider performance, with automated and workflow integrated CDS performing better than user initiated, nonintegrated CDS. The research team mapped clinician stakeholder’s workflow to leverage the ASCVD risk assessment tool and SMART (Substitutable Medical Applications, Reusable Technologies) on FHIR (Fast Healthcare Interoperability Resources) technology to integrate cardiovascular risk assessment into the electronic health record (EHR).

Methods

Participants were recruited for stakeholder interviews and clinical observations across a large Mid-Atlantic healthcare system to ensure diversity of care providers. Provider feedback, use cases, and observed tasks were used to better understand the desired features and functions of our novel health information technology ASCVD risk tool. By analyzing clinician workflow and needs, optimized functions were mapped to the appropriate technological capabilities needed to implement new functionality into a workflow embedded app.

Results

A total of 17 clinician interviews were conducted with an interdisciplinary group representative of the ASCVD surveillance process: cardiologists (n=6), primary care physicians (n=7), and care navigators (n=4). Additionally, 30 hours of clinical observations were conducted. Because of the physician workflow analysis, a critical objective of our optimization process for the ASCVD risk tool has become the auto population of ASCVD risk scores and guideline-based treatment recommendations to help decrease clinician burden.

Conclusion

The results of our research revealed implications for both technical design and development of the optimized ASCVD risk tool. Similar EHR tools used to aid recognition of abnormal blood pressure levels have seen an increase in recognition of elevated BP despite minimal app usage, leading researchers to believe workflow integration would maximize the usefulness of EHR CDS tools. The research team is expecting an increase in usage of the ASCVD risk calculator as a patient education tool during preventative cardiovascular risk discussion once fully integrated. The technical team continues to explore the use of SMART, SMART on FHIR, and CDS Hooks as well as native EHR integration methods (e.g., CCL, Smart Templates) to increase functionality.

PGxKnow: A Pharmacogenomics Educational Application in Augmented Reality

Don Roosan, PharmD, PhD; Western University of Health Sciences, College of Pharmacy, Pomona, CA, USA; Huy Truong, BS, PharmD Candidate; Keck Graduate Institute, School of Pharmacy, Claremont, CA, USA; Jay Chok, PhD, Keck Graduate Institute, Riggs School of Applied Life Sciences, Claremont, CA, USA; Moom Roosan, PharmD, PhD; Chapman University, School of Pharmacy, Irvine, CA, USA.

Background: Pharmacogenomics has the potential to reduce adverse drug events and improve health by individualizing medication therapy. Despite such potential, studies have shown that poor understanding of pharmacogenomics concepts by patients may lead to misinterpretation of the test results and decreased utilization. Simple videos or presentation materials were not very intuitive or interactive to grasp the complex genomics concepts for patients. We propose PGxKnow, an interactive pharmacogenomics augmented reality-based educational platform that can deliver information to patients in an engaging manner. The objective of the application is to educate patients on complex pharmacogenomics concepts to improve comprehension so that the patients recognize the lifelong implication of pharmacogenomics in medication therapy.

Overview of methodology: We conducted a human-factors-based methodology, cognitive work analysis (CWA), to create specific educational components that improve comprehension of pharmacogenomics concepts. Two pharmacogenomic trained pharmacists identified the important pharmacogenomics concepts. These concepts were further stratified into different frames for interactive features using 3D models for cells, nucleus, chromosomes, and proteins. Sequence of frames were arranged for better clarity through several iterations of feedback from the expert faculties. We used UNITY and Microsoft Visual Studio to transform the concepts into the interactive augmented reality PGxKnow application. Two pharmacists and two research assistants provided their initial feedback about the application on a quick usability study. We developed the application in a Microsoft Hololens device.

Results: We successfully created PGxKnow, an interactive application that shows frame by frame how mutations in genes may cause protein malformations with suboptimal function. Thus, these proteins contribute to increased or decreased drug metabolism leading to increased adverse events or treatment failure. The different visualizations and interactive features allow patients to have a broader understanding of how mutations from DNA can have a detrimental effect on drug metabolism. We incorporated feedback from the quick usability from the four participants and reiterated the design of the application.

Conclusion: In this study, we have successfully created an educational application, PGxKnow, for educating patients on pharmacogenomics concepts using augmented reality. In future, we plan to conduct usability testing of our application and assess how effective this application is in improving users’ understanding of pharmacogenomics concepts.

Retrospective analysis of electronic health records reveals the ineffectiveness of a prescribing intervention

Lauren M. Rost, BA¹, Erik S. Wright, PhD¹
¹Department of Biomedical Informatics, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Abstract
Antibiotic stewardship programs (ASPs) facilitate the appropriate prescribing of antibiotics within clinical care. These programs are recently mandatory in U.S. hospitals, and are upheld to certain standards, like utilizing health data for quality improvement. However, due to the nascent stage of these regulations, the field has not standardized the adoption of EHR data to inform and validate prescription interventions. We retrospectively analyzed outcomes associated with an implemented intervention to evaluate its effectiveness and inform future interventions.

Introduction
Antibiotic stewardship programs (ASPs) regulate unnecessary and inappropriate prescribing of antibiotics, and have been mandatory for U.S. hospitals since 2017¹. Part of this mandate includes the utilization of health data for the improvement of ASPs. However, due to the nascent stage of these regulations, most hospitals have yet to evaluate the effectiveness of their ASP². Electronic health record (EHR) mining presents an opportunity to standardize methods for evaluating and improving stewardship interventions.

Objective
In 2009, the University of Pittsburgh Medical Center’s (UPMC’s) ASP issued a stewardship intervention to switch from treating community-acquired pneumonia (CAP) patients with ceftriaxone plus azithromycin to ampicillin-sulbactam plus azithromycin, with the goal of decreasing the prevalence of C. difficile infections. We sought to determine clinician adherence and patient outcomes of this intervention.

Methods
We performed a retrospective analysis on EHR data from a cohort of CAP patients, identified through 70 ICD-9/10 codes, at 17 UPMC hospitals from 2004 to 2017. We determined adherence by assessing the distribution of antibiotics prescribed for the cohort. We calculated Cox proportional hazards for the effect of treatment on length of stay, in-hospital mortality, 30-day readmission rates, antibiotic duration, and time-to-therapy.

Results
Preliminary analyses have shown that there was low adherence to the intervention in 15 of the 17 UPMC hospitals, with the two hospitals that demonstrated adherence having more interactions with the ASP. We also found that the intervention did not have a substantial effect on the prevalence of C. difficile infections.

Conclusion
These findings emphasize the potential value of big data approaches to inform the impact of stewardship interventions. In advancing our analyses further, we seek to predict alternative successful treatment options using machine learning models.

Combining Forces for MRI Brain: Natural Language Processing of Radiology Reports with Structured Documentation

Justin F. Rousseau, MD, MMSc¹, Juan Diego Rodriguez, MS², Jared Abrams, PhD², Alex Liu, PhD², R. Nick Bryan, MD, PhD¹

¹University of Texas at Austin, Dell Medical School, Austin, TX; ²University of Texas at Austin, Applied Research Laboratories, Austin, TX

Introduction

There are tradeoffs with structured and unstructured approaches to healthcare documentation. Structured documentation offers opportunities for more accurate, complete, and computable data, while free-text allows physicians to expressively describe their thought processes. Galileo CDS® is a diagnostic clinical decision support (CDS) tool with an interface for radiologists to choose structured values for 12 imaging features for brain MRIs (e.g., FLAIR signal, contrast enhancement). The features are used to generate a probabilistic differential diagnosis and a standardized report¹². Free-text reports and structured data entry through the CDS tool follow two distinct paths of synthesis of images, clinical data, and medical knowledge, to produce an interpretation. We sought to understand how these paths might merge by converting radiology reports into the structured feature values via NLP for the CDS tool.

Methods

106 brain MRI radiology reports were assigned values for all CDS features by two non-clinician annotators who had received introductory training from an expert neuroradiologist. The reports were used to predict three inputs to the CDS tool using NLP methods: "increase" for Flair and T2, and "Yes" for Contrast Enhancement (CE). Inter-annotator agreement was measured with Cohen’s kappa coefficient (Flair: 0.47, T2: 0.61, CE: 0.53). All text was then preprocessed with Natural Language Toolkit (NLTK)³, including tokenizing, converting to lower case and removing stopwords. We experimented with both stemming and using term-frequency-inverse document frequency (tf-idf) weighting. Due to the limited amount of data, we focused on three text classifiers known to work well in low-data regime: logistic regression, multinomial naive Bayes, and complement naive Bayes, all implemented in scikit-learn⁴. We applied stratified 10-fold cross-validation 10 times and evaluated the methods with precision, recall, and F1 scores.

Results

Complement naive Bayes had both higher average F1 scores and less variance than multinomial naive Bayes and logistic regression. The best results were achieved using complement naive Bayes with stemming and tf-idf weighting in the preprocessing pipeline. Average F1 scores for the FLAIR, Contrast Enhancement, and T2 signal were 74.9%, 77.7% and 82.3%, respectively.

Discussion

Our methods of predicting the value of features based on NLP of radiology reports shows promise that feature values can be predicted using automated NLP techniques where with more data, predictions can be further improved.

Conclusion

Future work is needed to take further steps to extract additional features from clinical notes and evaluate methods of comparing the CDS tool with features extracted from the radiology reports. Future work is needed to compare NLP-extracted data to radiologist-entered data in the CDS tool and to compare mentions of diagnoses in the interpretations to the predicted diagnoses from the CDS tool and to true diagnoses vetted in the EHR.

Comparing De-Implementation Strategies: Education vs Removing Orders from Order Sets

Elise L. Ruan, MD¹, Joshua M. Pevnick, MD²

¹Albert Einstein College of Medicine, Bronx, NY, ²Cedars-Sinai, Los Angeles, CA

Introduction: Traditionally, order sets have been used to address issues of underuse by reminding providers of necessary orders. However, recent evidence suggests that order sets may contribute to overuse. In an era where overuse concerns loom large, we must evaluate the role of order sets in inadvertently encouraging overuse, and the potential role of order set modification in reducing overuse.

Methods: In our health system, we suspected overuse of creatine kinase (CK) testing. American College of Cardiology guidelines recommend against routine CK testing for asymptomatic patients on statins. Because CK ordering frequently came from an ambulatory order set used by one cardiology group, we removed the CK order from this order set. We then compared CK order frequency before and after order removal. We also compared order removal with an educational intervention applied to this cardiology group (Group A), as well as educational interventions applied to two other cardiology groups (Groups B and C) not using this order set.

All three groups received educational interventions, which included group and one-on-one talks about appropriate indications for CK testing (Table 1). We retrospectively defined a study period including one year before and after the date of order removal (9/21/17). For each provider, we extracted data on how many CK tests were ordered and whether orders came from the order set. To control for provider volume, we identified all ambulatory visits to each group. Finally, two investigators, including a cardiologist informatician, reviewed a random sample of 20 charts from encounters resulting in a CK order to evaluate order appropriateness.

Results: During the study period, there were 77,567 visits to all three groups and 6,906 CK orders. 403 of CK orders were placed through the order set. 5% of providers accounted for 66% of orders in the pre-intervention period. Without adjusting for provider volume, order set modification was the only intervention associated with a significant decrease in the order/visit ratio for providers (p=0.03). When adjusted, results showed that order set modification in Group A and the two educational interventions in Group C achieved significance. Order removal on average resulted in a 50% relative decrease (p=0.01) while the first educational intervention in Group C resulted in a 38% relative decrease (p=0.02). The second educational intervention resulted in a 90% relative decrease (p=0.02).

*Educational meetings were conducted with individual providers over the month; thus, no specific date is listed.

Discussion: Both order set modification and educational interventions were associated with decreases in test ordering. Advantages and drawbacks for each type should be considered when trying to change ordering behavior. Order set modification can theoretically be done without any additional involvement from providers who are often already limited in their availability. In cases where a small number of providers account for a large portion of inappropriate orders, a targeted educational intervention may be a simpler solution, but would not be as scalable as employing clinical decision support systems and order set modification. Similar to how both education and order sets are currently widely used to ensure important orders are not missed, there is potential for the same approaches to be applied to de-implementation and reducing overuse.
Leveraging temporal patterns in physiological variables for prediction of critical events in single ventricle infants

Victor M. Ruiz, PhD1, Jorge Galvez, MD1,2, Michael Goldsmith, MD1, Maryam Naim, MD1,2, Alejandro Lopez-Magallon, MD3, Ricardo Munoz, MD3, Fuchiang (Rich) Tsui, PhD1,2

1Children’s Hospital of Philadelphia, Philadelphia, PA
2University of Pennsylvania, Philadelphia, PA
3Children’s National Medical Center, Washington, DC

Introduction: Congenital heart defects (CHD) affect approximately 40,000 births annually in the United States. Single-ventricle (SV) defects are among the most complex CHDs, and infants in this population are at elevated risk of unexpected deterioration in the peri-operative period before stage-2 palliation.1

There is a scarcity of models for prediction of critical events (CEs) suggesting cardiopulmonary decompensation in SV infants, i.e., extracorporeal membrane oxygenation (ECMO), emergent endotracheal intubation (EEI), and cardiopulmonary resuscitation (CPR). State-of-the-art models2–4 achieved high performance (0.91 AUC) in the hour leading to CEs, but suffer from low early prediction performance, require significant technology investments from institutions, or ignore temporal trends in physiological variables. In this study, we extracted temporal information from longitudinal data of SV ICU admissions, and trained static and dynamic machine-learning classifiers for early prediction of CEs in SV infants. We hypothesized that leveraging longitudinal changes in routinely-collected physiological data would help predict the onset of CEs with up to eight hours of anticipation.

Methods: Dataset: We retrieved data from 271 SV infants who were admitted to the ICU before six months of age and before undergoing stage-2 palliation at the Children’s Hospital of Philadelphia between January 1, 2015 and September 30, 2018. Variables in the dataset included vital signs (e.g., heart rate, respiratory rate, blood pressure, oxygen saturation), and laboratory tests (e.g., creatinine, bicarbonate ion, base excess.) From these 271 infants, we identified 164 CEs as cases, and randomly selected 164 periods of non-eventful ICU admissions as controls. Patients with multiple CEs were considered as separate cases provided that they presented at least eight hours apart.

Longitudinal patterns: We extracted two sets of temporal features from longitudinal data. First, trend-summary features that summarize changes for each variable, e.g., slope of last two values, difference between apex and last values. Second, frequent temporal patterns (FTP), which capture trajectories of multi-variate temporal abstractions derived from longitudinal data, e.g., heart rate is high before oxygen saturation starts decreasing.

Modeling approach: We trained static classifiers, i.e., naïve Bayes, support-vector machine, decision tree, and random forest models from trend-summary and FTP features. We also trained long short-term memory models from raw time-series data. We trained and evaluated models at five prediction horizons, i.e., one, two, four, six, and eight hours before the onset of CEs. We measured predictive performance with the area under the ROC curve (AUC).

Results: Random forest classifiers trained with FTP features achieved the highest predictive performance, with AUCs of 0.86 (95% CI: 0.84-0.87), 0.84 (0.83-0.86), 0.84 (0.83-0.85), 0.86 (0.85-0.87), and 0.85 (0.84-0.86) at prediction horizons of one, two, four, six, and eight hours before CEs, respectively. At one hour and eight hours before CEs, the best model had sensitivities of 0.6 and 0.59, and PPVs of 0.87 and 0.86 at the 0.9 specificity level, respectively.

Conclusion: In this study, we leveraged the temporal information in longitudinal, objective data from SV infants admitted to the ICU to meet the need of accurate and early prediction of CEs. We achieved this by using data that can be extracted automatically from EHR systems, and that is routinely collected. Early prediction of CEs may enable clinicians to target interventions aimed at reducing morbidity, mortality, and healthcare costs associated with SV defects.

Reasons for Non-participation in an Inpatient Acute Health Portal Randomized Controlled Trial Among Hospitalized Patients
Beatriz Ryan-Lora, MPH1, Fernanda Polubriaginof, PhD1, Irma Alarcon1, Niurka Suero-Tejeda, Lisa Grossman2, Ruth Masterson-Creber, PhD3, David K. Vawdrey, PhD1
1NewYork-Presbyterian Hospital, New York, NY, 2 Columbia University Medical Center, New York, NY, 3Weill Cornell Medicine, New York, NY

Introduction and Background: Various studies have extensively examined the barriers and adherence to patient health portals in the outpatient setting. However, not many have examined barriers to use of patient health portals during hospitalization. We examined non-participant responses from a pool of participants who declined to be part of a randomized controlled trial (RCT) on Understanding Patient Information Needs During Hospitalization.1 The study aimed to randomize participants into three study arms: 1) usual care, 2) tablet with general access to the Internet and 3) tablet with an inpatient portal. We explained that the portal provided a variety of information ranging from vitals, basic medication lists, lab orders and results, and scheduled procedures such as CT scans or Ultrasounds.

Methods: Two bilingual (English/Spanish) research assistants recruited patients admitted to two separate step down units at Columbia University Medical Center between March 2014 and May 2017. Recruitment methods for the larger RCT are recorded in previously published work.1 Patients who declined to participate were asked if they approved to provide a recorded answer as to why they refused to participate. Research assistants used a script approved by the Institute Review Board. Participants who agreed to be interviewed were informed that their answers would be anonymous. They were asked to answer a 5-item survey that included open-ended questions about age, gender, race and reasons for non-participating. Answers were recorded on paper surveys and transcribed into excel format for further analysis. The open-ended questions were categorized into eight main categories and 22 subcategories of reasons for refusal. Descriptive statistics were calculated using SPPS.

Results: From the pool of recruited patients approached to participate in the RCT, 195 refused to participate but agreed to be interviewed about the reasons for their refusal. Of those interviewed, 62.1% were male, 59.5% were white, and 80% chose English as a preferred language. The median age of the respondents was 66-75 (28.2%) followed by 56-65 (26.7%). Categories of patient refusals are listed in Table 2. From our analysis we noted that the main reasons why patients refused to participate were due to General Denial (27.2%) because of pending discharge (12.3%) or generally not being interested in participating (12.3%). The second main category of refusal was listed under Vitality or Health reasons (25.6%), with 12.8% of non-participating patients expressing “worry regarding health outcomes.” The third category for refusal was Negative Feelings about Technology (17.4%), the main subcategories being “hesitation to use or adopt technology” (16.15%), “reluctance to use of technology” (5.13%) and “dislike of technology” (4.10%), with a small fraction stating they were “too old to learn” (3 participants) and preference of “face to face interaction” (1 participant).

Discussion: Previous studies have shown that admitted patients have a desire to access their medical information2,3 however, adoption and adherence to patient health portal use in the inpatient setting remains a challenge for many healthcare institutions. Despite many assertions that better-informed patients are more equipped to manage their medical care, some of our findings indicate that barriers remain in adoption of this type of technology by admitted patients due to pre-occupation with health outcomes and negative perceptions of technology.

A Novel Classification of Inherited Retinal Dystrophies

Hamideh Sabbaghi, MS1, Sina Madani, MD, PhD2, Hamid Ahmadieh, MD1, Narsis Daftarian, MD1, Fatemeh Suri, PhD1, Abbas Sheikhtaheri, PhD3, Farid Khorrami, PhD4, Proshat Saviz, BS3

1Shahid Beheshti University of Medical Sciences, Tehran, Iran; 2Vanderbilt University Medical Center, Nashville, TN, USA; 3Iran University of Medical Sciences, Tehran, Iran; 4Hormozgan University of Medical Sciences, Bandar Abbas, Iran

Introduction

Inherited retinal dystrophy (IRD) as one of the rare ocular diseases encompasses different types of hereditary retinal degenerations appearing by involvement of the different layers of the posterior ocular segment1-2. In respect of the importance of the classification systems regarding the recorded history of biologic and natural sciences3, there is no classification regarding the IRD diagnoses. Therefore, we aimed to present a novel classification in this regard.

Methods

For developing this classification, an expert group of two academic board certified retina specialists, one academic clinical and molecular geneticist, and five medical informatics specialists was formed. Initially, a comprehensive review was conducted on the reference text books in the field of ophthalmology focusing on the vitreous and retina, afterwards a primary classification of IRD diagnoses was developed. In the next step, a comprehensive search was conducted on different international classification systems including Unified Medical Language System (UMLS), Online Mendelian Inheritance in Man (OMIM), International Classification of Diseases (ICD-10 & 11), Systematized Nomenclature of Medicine - Clinical Terms (SNOMED-CT) and Orphanet Rare Disease Ontology. The primary classification was modified and finalized based on the consensus of working group members at several focus group meetings. Eventually, an organized hierarchy of IRD diagnoses was developed in the Protégé software. We classified our results as no matched, partially matched or completely matched. The IRD content was considered as term and concept matched if the term was completely in accordance with our search results. Further evaluation regarding concept matching was performed for no-term-matched IRD contents. Completely concept matched was also defined in cases with synonyms. In SNOMED-CT, we considered post-coordination if any synonym was not found. In fact, if there were possibilities to develop a concept post-coordinately, we considered that concept as “partially concept matched”. IRD contents with no possibility of pre- and post-coordination were considered as “completely no matched”.

Results

Based on the literature review, the primary classification including 55 IRD diagnoses had been provided in six sections. Afterwards, it was expanded to 1020 IRD diagnoses presenting by different international classification systems. As a result of the several panel group discussion, the final list containing 368 IRD diagnoses with consideration of both phenotyping and genotyping identifications in the eight sections was developed. Regarding the comparison between the five international classification systems, it was found that UMLS had the greatest coverage of 92.4%, while the lowest content coverage (24.7%) was obtained for SNOMED-CT. In general, all investigated systems had 12.8% overlap for IRD diagnoses. Furthermore, we found that 0.09% of diagnoses cannot be considered as IRD although they were categorized by other systems. All preferred names, synonyms or other alternative names and codes of each retinal dystrophy entity were extracted and documented, as well.

Conclusion

This specialized classification that is dedicated for different types of IRD diagnoses may be applicable in the ophthalmic practices and it can be considered as a preliminary step to develop an ontology for IRD concepts.
Workflow Pipeline for Medical Image Data Curation and Sharing

Sylvester Sakilay MS¹, Danne C. Elbers MS², Scott T. Doyle PhD¹, Luis E. Selva PhD²,
Brett R. Johnson PhD¹,²,³, Nhan V. Do MD²,³,⁴, Peter L. Elkin MD¹,³,⁵
¹University at Buffalo, Buffalo, NY; ²MAVERIC, VA Boston Healthcare System, Boston, MA; ³BD-STEP, VHA Washington DC; ⁴Boston University School of Medicine; ⁵VA Buffalo Health System

Introduction

Many advancements in medicine have been made possible by the collaboration between researchers and organizations via data sharing. Medical imaging is a critical source of data in research and patient treatment. Sharing the medical data with the external organizations has several important aspects to be taken care of. Most importantly, obtaining the patient consent to release their data and removing the PII (Personal Identifiable Information)¹. We have experienced several issues in handling the image data along the way and have gone through cycles of evaluation of various possibilities. This experience has helped us develop a pipeline that handles this process from the point of acquisition of imaging data to the point of delivery in a more efficient manner. The solution consists of an image de-identification tool and tools developed in python for filtering and QA (Quality Assurance). This work is being done as a part of PODR (Precision Oncology Data Repository) project, MAVERIC VA. Our idea is the method that we adopted would save a lot of time and effort for other researchers and organizations who are working on making their data available to external organizations and researchers.

Methods and Materials

We are using the CTP (Clinical Trial Processor) image de-identification tool from TCIA to remove PII from the DICOM files. Image Filter tool filters the images based on modality and type (original or derived) and queries the DICOM headers to produce manifest and metadata files. The data in these files is used to verify that only consented data is allowing to be shared. Unconsented data is not shared. Also, this step gives control over the type and modality of image data to be shared. After verification, the raw image data is sent to the CTP de-identification tool that scrubs PII data from the images. Once the de-identification process is complete, Final QA process is performed using a python tool. There are times when dose reports are embedded with images. This Final QA process guarantees that embedded reports are identified and removed from the data set prior to sharing with researchers. The de-identified DICOM data after successfully passing through these stringent QA checks is moved to the point of dispatch where a metadata file that contains the information such as Md5Checksum is generated using a python tool. From this point the image data is dispatched to the external organizations.

Conclusion

This pipeline helps sharing the data with the approved external researchers and organization while efficiently addressing the most important considerations like patient consent and PII which is a challenge as the image volume is huge and image data requires additional consideration in terms of format, access, and information extraction.

Crowdfunding Medical Care: An Exploratory Comparison of Canada, the United Kingdom, and the United States

Sameh N. Saleh MD¹, Ezimamaka Ajufo MD¹, Richard J. Medford MD¹²
1. Department of Internal Medicine, UT Southwestern Medical Center, Dallas, TX, USA
2. Division of Infectious Diseases, UT Southwestern Medical Center, Dallas, TX, USA

Background: Despite major differences in their healthcare systems, medical crowdfunding (CF) is now recognized as an important part of the healthcare funding landscape in Canada (CAN), the United Kingdom (UK), and the United States (US). Systematic comparison of the purpose, characteristics, and determinants of the success of CF campaigns in these countries may help to identify gaps in healthcare provision and potential inequities in the medical CF landscape in each setting.

Methods: GoFundMe (GFM) is the largest for-profit company in the medical crowdfunding arena, raising over $650 million dollars per year for healthcare costs. We conducted a cross-sectional analysis of GoFundMe (GFM) campaigns between February 2018 -2019 in CAN, the UK, and the US. Through web scraping, we directly extracted variables from over 1000 campaigns under the “Medical” subheading of each country’s GFM discovery webpage. We explored descriptive statistics for numerical variables extracted and evaluated the correlation matrix between these variables and amount raised. All monetary values were converted to US currency in dollars. We then performed a manual 2-person review of 10% of campaigns for each country to evaluate demographics, diagnosis, type of treatment, and if the campaign was primarily for treatment costs. Concordance was >90% in all categories.

Results: The vast majority of campaign beneficiaries in the three countries examined were non-black (CAN 99.1% vs. UK 99.1% vs. US 95.2%) adults (CAN 77.7% vs. UK 82.3% vs. US 76.6%). Campaign beneficiaries were more likely to be male in the US (60.5%) and CAN (59.8%), but not in the UK (39.8%). US campaigns set higher mean goals ($88,242; SD $180,758) compared to those in CAN ($31,149; SD $47,041) and the UK ($38,345; SD $87,309) and raised more mean funds ($48,647; SD $26,234) than campaigns in CAN ($17,447; SD $17,057) and the UK ($14,480; SD $28,674). Number of donors, GFM hearts, and fundraising goal were strongly positively correlated with the amount raised in all three countries, each with correlation coefficients >0.5. Facebook shares were strongly positively correlated with amount raised in the UK with a coefficient of 0.65, but only moderately correlated in the US and Canada with values of 0.32 and 0.38 respectively. Length of campaign and number of words or characters in the campaign text were not correlated with amount raised. In all three countries, cancer was by far the most reason for fundraising followed by neurologic conditions and trauma. While routine care was the most common reason for fundraising in the US (CAN 23.4% vs. UK 19.7% vs. US 72.1%), fundraising for experimental (CAN 31.9% vs. UK 46.1% vs. US 18.6%) and alternative therapies (CAN 19.1% vs. UK 11.8% vs. US 7%) was more common in CAN and the UK (Figure 1).

Conclusions: We show that GFM medical CF campaigns in the US set and achieved higher fundraising goals than those in CAN and the UK. CF for routine care was by far the most common reason for fundraising in the US, while campaigns for experimental and alternative care were more common in CAN and the UK. When comparing to the general population in each of the three countries, blacks were less likely to be beneficiaries of medical CF campaigns. Further work is required to determine generalizability of these findings in other CF platforms and to elucidate the factors that underlie these differences.

Figure 1. The graphs above display the type of treatment utilized per campaign for each country. The graph on the left reflects all campaigns and the graph on the right reflects only campaigns that were clearly to primarily fund treatment.
eReferral for Enrollment in Smoking Cessation Programs

Abraham Saraya, MD1, Simita Mishra, PhD1, Pat Folan, DNP1, Nathaniel Brown, MA1, Michael Oppenheim, MD1, Jan Horsky, PhD2

Introduction

Tobacco use remains to be a significant preventable contributor to morbidity and mortality in the United States. Referral of patients for counseling and brief personal consultations that clinicians have during office visits are effective interventions to increase cessation rate but long-term, intensive assistance to smokers yields better results.1 Completing a full patient referral and following progress, from enrollment into a cessation program to maintaining engagement over time, is time consuming and challenging for clinicians in the context of ambulatory care visits. We have implemented an electronic intervention (eReferral) to simplify and speed up initial referral to a cessation program and to establish a process to monitor and communicate updates on patient tobacco use. It is integrated into an EHR (Figure 1) and allows clinicians to send referrals to the Center for Tobacco Control (CTC) with two mouse clicks. Program counselors contact the patient by phone within 24-74 hours of the office visit, update the EHR record on the patient’s status (Z72.0) during the ambulatory care visit and follow the patient’s progress (eReferral) (Figure 1).

Methods

We queried the clinical data repository of a large healthcare delivery system for patients with newly documented smoking status (Z72.0) during a 21-month study period following the May 1, 2017 eReferral rollout. We counted the number of providers identifying patients as smokers and the proportion of those who used electronic cessation referral.

Results

There were 949 clinicians who identified 5,898 patients as new, active smokers in the first 21 months after rollout. Of those, 307 (32%) used eReferral for 1,892 smokers. The number of clinicians using the tool remained relatively static for the first five three-month periods after rollout before beginning to steadily increase (Figure 2).

Conclusion

We have found that the number of clinicians actively using eReferral initially plateaued after the rollout and the level of engagement started increasing only about a year and a half later. This change was likely due to our training initiative that looked to make more clinicians at new ambulatory care locations aware of this tool and explained the benefits of decreased workload for them and better care quality for their patients. A more routine and automated level of communication between the referring site and the CTC means that clinicians are always informed whether patients follow a path towards lower tobacco use and effectively closes the assessment-referral-treatment loop. The implication for the rollout process is that intensive knowledge dissemination and training are essential for creating conditions that lead to a larger proportion of clinicians using a quality-improvement electronic tool habitually and who can effectively incorporate it into their workflows and ambulatory practice.

References

Figure 1 eReferral screen in the ambulatory EHR results of their enrollment attempt and include a cessation care plan when a patient has joined the program. The objective of this study was to evaluate the frequency of eReferral use during the initial phase after implementation.

Figure 2 Number of providers and referrals of this tool and explained the benefits of decreased workload for them and better care quality for their patients. A more routine and automated level of communication between the referring site and the CTC means that clinicians are always informed whether patients follow a path towards lower tobacco use and effectively closes the assessment-referral-treatment loop. The implication for the rollout process is that intensive knowledge dissemination and training are essential for creating conditions that lead to a larger proportion of clinicians using a quality-improvement electronic tool habitually and who can effectively incorporate it into their workflows and ambulatory practice.

Lister Hill National Center for Biomedical Communications, U.S. National Library of Medicine, National Institutes of Health, Bethesda, MD

Introduction
Finding and accessing scientific literature in PubMed partially relies on indexing articles for MEDLINE® using Medical Subject Headings (MeSH®). Currently, more than 5,000 journals in MEDLINE are fully indexed, where the majority of articles published by these journals have MeSH indexing assigned. However, for approximately 130 selectively indexed journals, articles are only indexed if, after manual review, they are determined to be relevant to biomedicine and the life sciences. In recent years, the number of these articles has increased substantially; for example, in 2018 about 125,000 were added to PubMed. To reduce the number of articles that must be manually reviewed, we have developed the Biomedical Citation Selector (BmCS), a high recall machine learning system that identifies the articles that require indexing. Here, we manually evaluate BmCS’s automated predictions to better understand its performance in the indexing workflow.

Methods
For this evaluation, we manually reviewed 4,763 articles predicted by BmCS to be out-of-scope for indexing at a 99.5% level of confidence. We chose only articles from chemistry journals because BmCS has been shown to perform more poorly on these articles than it does on those from other disciplines. In a subsequent test, we selected 1,248 articles of any discipline, predicted to be in-scope at a 99.5% level of confidence. To manually review the articles, we designed a Microsoft Access form. The title and abstract of each article was reviewed by two of ten different reviewers, and a final label of in-scope or out-of-scope was assigned after considering both reviewers’ input.

Results
The human reviewers agreed with 4,612 out-of-scope predictions generated by BmCS and disagreed with 151. However, 147 of the misclassified articles were publication types that should always be classified as in-scope, such as comments or errata. Because BmCS will handle these with rules in the future, we removed them from the evaluation. Table 1 reflects this adjustment. The reviewers agreed with all 1,248 articles predicted to be in-scope. Accuracy for the in-scope class was computed to be 100% and for the out-of-scope class, 99.9%. Fleiss’ kappa, used to assess interrater agreement, was .981.

Table 1. Agreement, disagreement and accuracy between human reviewers and BmCS

<table>

<td>4</td>
<td>99.9%</td>
</tr>
<tr>
<td>In-scope</td>
<td>1,248</td>
<td>0</td>
<td>100%</td>
</tr>
</tbody>
</table>

Conclusion
In order for BmCS to effectively contribute to the indexing pipeline, it must infrequently label in-scope articles as out-of-scope. This is what we observed: After adjusting the predictions as discussed above, only 0.1% of the system’s out-of-scope predictions were incorrect. These results suggest that the system will effectively reject out-of-scope articles from the indexing pipeline. In addition, the perfect in-scope predictions indicate that we will be able to automatically send articles labeled as in-scope with 99.5% confidence to the human indexers, with relatively few false positives. In general, these results demonstrate that BmCS will reduce the number of articles from selectively indexed journals that require manual review by at least the amount we expect, 54%. Further development of BmCS will focus on exploring the effect of more permissive prediction thresholds, as well as integration into the indexing production environment.

Predicting adverse event reports in FDA's Adverse Event Reporting System (FAERS) more likely to be useful for causality assessment
Abhivyakti Sawarkar, MD, MMSc1; Robert Ball, MD, MPH, ScM1
1US Food and Drug Administration, Center for Drug Evaluation and Research, Silver Spring, MD, USA

**Background:** The US Food and Drug Administration (FDA) actively monitors the safety of drugs and therapeutic biologics from multiple data sources including FAERS, a database that contains adverse event reports, medication error reports, and product quality complaints resulting in adverse events, submitted to FDA. With an ever-increasing number of reports (> 2 million in 2018), making the review process more efficient so human safety evaluators can focus attention on assessing reports that contain the most useful information for assessing causality between a drug and an adverse event is an important goal.

**Objective:** To accurately predict the adverse event reports in FAERS more likely to provide information useful for causality assessment by safety evaluators using machine learning and text analytics. We hypothesized that certain subsets of reports (industry reports (IR), direct reports (DR), and literature reports (LR)) would have different linguistic patterns in the report narratives that might be useful to distinguish reports more likely to have information useful for causality assessment.

**Data:** Extending previous work, a set of 925 FAERS reports, classified for causality by FDA safety evaluators using a modified version of the World Health Organization–Uppsala Monitoring Centre (WHO-UMC) criteria for drug causality assessment, were coded as a binary classification task by aggregating the causality categories into two groups: group 1. *Certain*, *Probable*, *Possible* & group 2. *Unlikely*, *Unassessable*. Industry and published literature reports are submitted by manufacturers and direct reports are submitted by consumers and healthcare professionals directly to FDA.

**Methods:** Data was divided into train and test sets maintaining proportions of causality categories. We developed two machine learning models; classification & regression trees and random forest, to predict reports less likely to provide useful information regarding causality. We pre-processed the narratives in FAERS reports and used textual features (text length, term frequency, term frequency-inverse document frequency (TF-IDF), N-grams, singular value decomposition (SVD), and cosine similarity for terms in the report narratives among reports) in the models to see which features might predict reports containing useful information regarding causality. No other features were evaluated. We evaluated the accuracy (proportion of true results among the total number of cases examined) of trained classification models. We leveraged 10-fold cross validation and compared the overall model performance.

**Table 1:** Results: Comparison of accuracy of trained classification models using different features from textual data

<table>

<td>0.70</td>
<td>0.75</td>
</tr>
<tr>
<td>Literature Reports (77)</td>
<td>0.85</td>
<td>0.87</td>
</tr>
</tbody>
</table>

**Conclusions:** Our research using FAERS narratives shows that model accuracy improves when carefully selected linguistic features are applied in machine learning models. The random forest model was more predictive and two features; text length and cosine similarity for terms in literature reports, showed higher predictive power to discriminate between FAERS reports with more and less useful information for causality assessment. Further evaluation of this approach with a larger data set and deep learning techniques might improve performance over current machine learning approaches and enable better identification of discriminating narrative features and better predictive power to identify FAERS reports with more useful information for causality assessment.

Identifying Population Subgroups in Neuro-fMRI Using Unsupervised Machine Learning

Jenna M. Schabdach¹ MS, Vincent Schmithorst² PhD, Vince Lee², Rafael Ceschin¹,² PhD, Ashok Panigrahy¹,² MD

¹ Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA

Resting-state functional magnetic resonance images (rs-fMRIs) are often used to examine and evaluate the functional connectivity of different areas of the brain. Because of the MR protocol required to obtain these images, they are highly susceptible to motion. Researchers and clinicians have developed various behavioral and sedation-based protocols to prevent a patient from moving during image acquisition; however, these protocols fail to completely eliminate all sources of motion in an image. Acquired images must pass through one of many motion correction pipelines to account for the spatial and spin gradient effects of motion on the image contents. The combination of machine learning and image reconstruction techniques during and after image acquisition holds great promise for harmonizing images and recovering motion-corrupted data. However, there is little information about the relationship between unsupervised ML techniques and characteristics of rs-fMR images. We suggest that features indicative of high motion images may also be representative of different groups of subjects, but to obtain enough data to test this theory, we must employ the use of a multi-center study. In a multi-center study, the combination of motion artifacts and other factors such as protocol compliance, image harmonization, and subject populations can introduce sources of bias into the data. In our study, we examine rs-fMRI harmonization and motion in a set of complex congenital heart disease (CHD) case and healthy control adolescent subjects acquired through a multi-center neuroimaging study. We develop a set of features to represent global and local motion in each image. First, unsupervised machine learning techniques are used to ensure that the features extracted from the rs-fMRIs are not representative of other factors characteristic of each site, which confirms the success of the image harmonization technique. The unsupervised machine learning techniques were then used to identify other subgroups within the data set using different subsets of the motion feature set. This study suggests that the use of unsupervised machine learning techniques can not only inform harmonization characteristics of multi-center data, but also identify important features of motion artifacts for identifying subgroups within a patient population.
Improving Discoverability of Educational Resources for Clinical and Translational Scientists: Adapting the eagle-i Platform and a Proof-of-Concept Educational Resource Ontology

Juliane Schneider\textsuperscript{1}; Marc Ciriello\textsuperscript{1}; Jessica Zhang\textsuperscript{1}; Ankit Panchamia\textsuperscript{1}; Xavier Haurie\textsuperscript{1}; Thomas Naughton\textsuperscript{1}; Diane Keogh\textsuperscript{1}; Doug MacFadden, MS\textsuperscript{1}\
\textsuperscript{1}Harvard Medical School, Boston MA

Introduction
The Postgraduate Education Program in Clinical and Translational Science (PGE) at Harvard Medical School offers educational content through their Advanced Curriculum Compendium (ACC) and Educational Video Library (EVL). To improve discoverability of their resources, PGE sought to combine the two separate collections while making the resource data ontology-compliant for discovery via a novel search interface.

Making educational resources discoverable is an area of some effort in the Clinical and Translational science community, but there is no broadly-accepted solution, let alone a solution that follows semantic principles to enable data interoperability. The Harvard Catalyst team used the eagle-i platform adapted to use the N-Lighten educational resources ontology. The N-Lighten ontology was developed by Oregon Health & Sciences University in conjunction with Ohio State University to explore the possibility of developing an ontology for this domain area. The Harvard Catalyst team collaborated with PGE to 1) create the new search interface and 2) apply the N-Lighten proof-of-concept ontology in its first known practical application.

Methodology
Development and data requirements were documented with PGE after an analysis of the legacy systems and data. Desired search functionalities and filters for the user interface were identified. To leverage the N-Lighten ontology, both mapping of data from the legacy systems and selected ontology modifications were required. The N-Lighten ontology was extended to meet local needs by adding branches for the 0-5 Translational Levels, for course status (active/inactive), and for learning type (in-person or online). Ontological relationships (Part of/Has Part properties) were used to link videos to associated courses, thus connecting resources from the legacy systems.

Results
The N-Lighten proof-of-concept discovery tool was amended and the new search interface built according to local requirements. The new website-based search function as expected and a screenshot of the search interface is shown in Figure 1. Further development of the N-lighten ontology, if undertaken, may integrate the changes made to suit this local application to ease application to other institutions and uses.

**Simpler is Better: Case Studies of Clinical Decision Support for Laboratory Utilization/Stewardship**

**Thomas Schneider, MD**, **Ila Singh, MD PhD**1, **Bruce Darrow, MD PhD**1, **Joseph Kannry, MD**1

1Mount Sinai, New York, NY; 2Texas Children’s Hospital, Houston, TX

**Introduction:** Clinical Decision Support is best defined as anything that supports a decision.1 With that in mind CDS can involve other interventions in the EHR as simple as renaming order or changing the workflow. Clinical Decision Support (CDS) systems play a key role in Utilization Management/Stewardship programs.2 From 2014-15 an operational governance committee, the Laboratory Utilization Formulary Subcommittee, was charged with identifying tests that were clinically overutilized. The committee consisted of domain experts and EHR technical teams and was co-chaired by Informatics and the laboratory director. Seven laboratory tests were identified based on feasibility and suitability for EHR changes. The interventions were EHR test name changes, checking for duplicate test results in EHR, removal of tests from common order sets (collections of orders), removal from the list of orderable tests (aka Inpatient Preference List), and personal communications and information sessions with the biggest test utilizers. These interventions were applied to the following tests: Hemoglobin A1C, Hepatitis A antibodies, lipid panel, vitamin D, reticulocyte count, and a serum Iron + TIBC panel. Test utilization in the year prior to the intervention (2013) was compared to the year after the interventions with follow up evaluations a few years post-intervention in 2018. The interventions were restricted to inpatient laboratory test orders.

**Results:** For hemoglobin A1C, there were two interventions, a 90-day duplicate check and the removal of hemoglobin A1C from the insulin ordering pathway available to all inpatient clinicians. Vitamin D testing consisted of only two interventions, duplicate checking of less than 60 days and a name change. Vitamin D 1,25 Dihydroxy was changed to ‘Vitamin D 1,25 Dihydroxy (NOT for deficiency screening)’ and Vitamin D 25 Hydroxy was changed to ‘Vitamin D 25-OH (for deficiency screening).’ Hepatitis A antibody tests were renamed with “Hepatitis A Virus Antibody IgM” being renamed to “Hepatitis A IgM (Acute Infection)” and “Hepatitis A Virus Antibodies Total” being renamed to “Hepatitis A Virus Ab Total (immunization status).” Then more recently (2016) Hepatitis A Total Antibody was renamed to “Hepatitis A Virus Total Antibodies” and “Hepatitis A Total Antibody” was renamed to “Hepatitis A Total Antibody.” The standard lipid panel was subjected to two interventions: duplicate checking and personal communication sessions. Reticulocytes intervention consisted of only duplicate checking within 3 days of the order being placed. The two test panel, serum Iron + TIBC, had a 60 day duplicate check and was also removed from a daily

*Orders normalized to per 1000 discharges, in brackets are the number of discharges

**Conclusion:** Our case studies have demonstrated both successes and failures in clinical decision support in helping laboratory utilization. Laboratory test name changes were easier to implement compared to order set modifications. Duplicate checking led to variable successes, and clinician education led to a modest and sustained effect. Our largest success was in changing test names to those that added information needed to make the ordering decision.

Review of Medical Device Nomenclatures and Classification Systems

Martin Schotel,1 Karen M. Bavuso, RN, MSN,1 Melinda Wong, BS Pharm, RPh,1 Emily Chan, PharmD, RPh,1 Saverio Maviglia, MD, MS,1,2,3 Roberto A. Rocha, MD, PhD1,2,3

1Semedy, Inc., Waltham, MA; 2Harvard Medical School, Boston, MA; 3Brigham & Women’s Hospital, Boston, MA

Introduction

Different nomenclatures and classifications are used to categorize and identify medical devices. More than 20 nomenclatures and classification systems around the world are utilized to classify healthcare products and specifically, medical devices.1 Each nomenclature and classification system is typically utilized by different types of professionals based on specific needs, including procurement, adverse event reports, tariffs, among others.

An important difficulty resulting from these multiple nomenclatures and classifications is the inconsistency of the information that is ultimately captured, despite the growing need for more precise and reliable information about medical devices. This difficulty creates substantial overhead not only for healthcare institutions, but also for any medical device stakeholder, including providers, researchers, public health officials, and consumers (patients). The objective of identifying and tracking medical devices is essential when trying to determine which devices have been associated with adverse events, as well as efforts to coordinate and standardize care across institutions and settings.

Methods

We reviewed commonly used medical device nomenclatures and classifications, such as the Global Medical Devices Nomenclature System (GMDN),2 and the Universal Medical Devices Nomenclature System (UMDNS).3 Additionally, we reviewed a survey from the World Healthcare Organization (WHO) to identify device nomenclatures and their use.4 The intent was to identify properties used to describe, classify, and track devices.

Results

The WHO survey from 175 countries confirmed that 38 use GMDN or UMDNS, while 46 use a locally developed system. Six countries use multiple systems, while 85 do not use any classification.9 These variations were caused by multiple factors. For example, the FDA requires manufacturers to assign classification codes, while other countries adopted different methods. We are creating a property map showing inconsistencies across medical device systems.

Conclusion

Increasing numbers of medical devices are being used in healthcare environments, which creates a mandate for a unification effort. A fundamental goal of having a unified coding system is to allow proper descriptions and consistent sets of relevant details to standardize communication among all stakeholders. A set of essential properties describing medical devices and their clinical application is a significant requirement for such solution. A software platform able to detect and resolve inconsistencies at scale across nomenclatures and classifications is an important tool for cataloging medical devices and their use in any given type of institution or role.

**Associating Chief Complaints with Electronic Health Record Activity to Decrease Provider Administrative Burden**

John Schrom, MPH, Vijan Joshi, MD, Colleen Bouey, Allison Gilmore, PhD
One Medical, San Francisco, CA

**Introduction:** Physician burnout has become a widespread issue, with electronic health record (EHR) use known to be a major predictor of burnout[1]. The burden of EHRs has become so problematic that patients are now reluctant to engage in medical encounters due to the overuse of technology in the exam room[2]. The average physician spends almost six hours per day interacting with their EHR[3]. Machine learning and data mining can decrease this administrative burden through smart shortcuts, based on predicted user behavior.

**Methods:** Clinical encounters were gathered from a large, national primary care clinic system. The chief complaint was parsed into UMLS concepts using QuickUMLS[4], a clinical named entity recognition tool. These concepts were combined with patient demographics and clinical activities during the encounter: lab orders, prescriptions, diagnoses, and referrals. The apriori algorithm was used to discover association rules between these concepts. Performance was evaluated on a holdout dataset by removing a random concept and looking for a discovered association above a varying confidence threshold between the remaining concepts and the removed one. A control model was created by identifying the Top N most common diagnoses, prescriptions, and labs, and was similarly evaluated by looking for a removed concept in a Top N list, with varying N. The impact on physician administrative burden was estimated by number of clicks in the EHR, using the sample’s sensitivity and assuming one click reduction for medication and diagnosis, and two click reduction for lab orders.

**Results:** The dataset included 5,655,811 encounters, and association rule mining (ARM) discovered 3,019,661 rules. Many high-confidence rules involved direct correspondence of the chief complaint to the resultant activity (e.g., chief complaint of “bee sting” => new “bee sting” diagnosis). More nuanced associations — often symptom-based — also emerged (e.g., “broken condom” => STI testing; “motion sickness” => scopolamine prescription). Performance varied based on type of activity being predicted, with labs being the most performant (AUC = 0.69), followed by prescriptions (0.43) and diagnoses (0.41). The Top N models performed worse in all categories (see inset; labs: 0.36, prescriptions: 0.13, diagnoses: 0.14). We estimate this approach results in 3.2 fewer clicks per patient per year.

**Discussion:** This preliminary work demonstrates ARM as a method for identifying relationships between a patient’s demographics and chief complaint, and their provider’s EHR activity during the encounter. This approach performed better on lab ordering than medication prescribing or diagnosing. This may be due to larger number of classes being predicted, as well as more clinical variability in prescribing behavior and inconsistent diagnosis documentation. Even with its current performance, ARM is more predictive than a “Top 10 Most Common” style approach for the same activity. This suggests that implementing rules-based shortcuts in the EHR to allow single-click ordering, prescribing, and documenting would be more effective than listing the most common activity. Our approach would introduce opportunities to decrease clinical variation and improve documentation, while also saving the administrative burden of an estimated 4,800 clicks for a provider with a panel of 1,500 patients.

Neural Relation Extraction from Biomedical Literature
Elaheh Shafieibavani, PhD1, Antonio Jimeno Yepes, PhD1
1 IBM Research, Southbank, VIC, Australia

Introduction Genetic mutations are linked to diseases such as cancer and might be related to drug resistance. Curation from the literature into databases is typically done by human curators, which is slow and expensive. Text mining methods exist to identify mentions of mutation in text, such as T790M, which specifies a protein mutation in position 790. Position in a mutation mention is meaningless without a reference to a gene or protein. We propose linking mutations to the gene or protein mentioned in the scientific articles since this will provide a more complete contextualization of the mutations. In this case, T790M is linked to EGFR protein in MEDLINE document PMID:29448920.

Methods and Results We used the AMIA dataset available in1, with additional examples in the training set generated manually. The training/testing sets contain 2656/385 mentions of mutations and 2799/280 of genes/proteins and 1617/130 relations between genes and mutations. We extracted about %30 of our training set as the validation set. For further analysis and experiments, we also used the entity relations and chemical-protein datasets originated from the BioNLP2 and BioCreative3 VI shared tasks. Having mentions of genes/proteins/chemicals and mutations/diseases, the purpose is to automatically extract their relation within a sentence span. To this end, we have considered the following two approaches4: (i) Support Vector Machine (SVM) and (ii) Convolutional Neural Network (CNN), that model the input sentence as a linear sequence of word tokens. Each word token is then mapped to relevant vector space embeddings. The word vector, part-of-speech and entities features are directly produced from the information of each token. The distance and relative position features model the position of the token in the sentence. The path features mark the dependencies connecting each token to a token of interest. The shortest path features mark the set of dependencies forming the shortest path for a candidate relation. These embeddings are then concatenated together to be processed by a set of 1D convolutions with window sizes 1, 3, 5 and 7, and an applied global max pooling to each convolutional layer. The convolution output vector is fed into a dense layer of 400 neurons, which is connected to the final classification layer that uses sigmoid activation while the other layers use ReLU activation. Training multiple models with randomized initializations, we use the average prediction of the five best models ranked with micro-averaged F-score on the validation set. These ensemble predictions are calculated for each label as the average of all the models’ predicted confidence scores. In addition, a random combination of hyperparameters is picked from the ranges to be optimized. The adam optimizer with binary crossentropy is used with a learning rate of 0.001, dropout of 0.1, and up to 500 epochs, with early stopping once validation loss has no longer decreased for 10 consecutive epochs. Table 1 shows the performance of these approaches comparing against the human agreement for the AMIA dataset, and the corpora for the BioNLP and BioCreative relation extraction tasks.

Conclusion Experiment results show that it is possible to automatically extract the relations between mutations and genes/proteins with higher performance to human annotators from biomedical literature. Besides, we observe that the CNN F-score is superior to the SVM’s for different relation extraction tasks (AMIA, REL11, and CP17).

Predicting Acute Care Utilization (ER Visit and Hospitalization) due to Social Determinants of Health Factors

Soham Shah, MD MBA1,2,3, Peter Nguyen, MD1,2, Manisha K Shah, PhD3, Hamed Abbaszadegan, MD MBA FACP FAMIA1,2

1University of Arizona College of Medicine, Phoenix, AZ; 2Phoenix VA Health Care System, Phoenix, AZ; 3Mayo Clinic, Phoenix, AZ

Introduction: United States national health care expenditure was $3.5 trillion, representing 17.9% of the GDP [1]. There has been an increasing recognition of the influence of social, behavioral, economic, and environmental factors on overall patient health. It is suggested that social circumstances, behavioral patterns, and environmental exposures may have a combined contribution as high as 60% on an individual’s risk of premature death. Emergency room (ER) visits and hospital readmissions are part of indirect measures of health quality and have been a major focus due to their large contribution to healthcare costs. Studies have shown correlation between social factors and ER visits and 30-day hospital readmission [2,3]. Since social determinants of health disproportionately affect the population in lower socioeconomic status, strategies to improve healthy quality should focus on this population [4]. The rationale for this project then is to develop a more data-driven approach to proactively help patients with risk factors based on the social determinant of health list obtained from Arizona Health Care Cost Containment System (AHCCCS) [5]. The goal is to predict groups of patients at high risk from specific social factors for whom proactive care coordination and access to resources may be valuable.

Methods: The active patient population at the Phoenix VA Medical Center 10/1/2015 to 12/31/2018 were identified and a retrospective analysis was performed looking for ICD10 codes corresponding to social determinants of health risk factors. Annual number of ER visits and hospitalizations per patients were reviewed as outcome metrics. The social factors were based on a list published by AHCCCS [5]. Logistic regression models were used to identify correlations between the social determinants (ICD10 codes) and hospitalization or ER visits.

Results: Data from a cohort of 23,966 patients within the Phoenix VA system from different ethnicities, employment, and marital statuses were analyzed. The first outcome allowed for geographical analysis, identifying zip codes in the Phoenix Metro with increased acute care utilization. A standard correlation analysis between ICD10 codes and Hospitalization identified Z659 (problems related to psychosocial circumstances) and age as the top 2 and fulltime employment or active military as the least correlated events for hospitalization. Similarly, Z659 and Z596 (low income) as the top two and Marriage and Z642 (release from prison) as the lowest correlated for ER visits. Individually correlated ICD10 codes only yielded a maximum correlation coefficient of ~0.2. However, using machine learning and a logistic regression with ICD10 codes and demographics as inputs, our model was able to correctly predict no hospitalization 95.8% of time, and ER visits 78.8% of time.

Discussion: This work was able to predict no hospitalization 95.8% of time, ER visit 78.8% of time and correlate social determinants with acute care utilization, either through visits to the ER or hospitalization. The ability to predict these using machine learning would guide interventions towards a large patient population to prevent ER visits or hospital admissions. We believe this model can be used in real-time to facilitate better health outcomes and resource utilization, thus reducing overall cost of care while maintaining quality and value.

Enhancing Allergy Documentation in a Commercial EHR System
Sonam Shah1,2, Carlos Ortega1, Suzanne V. Blackley3, Kimberly G. Blumenthal4,5, Foster R. Goss6,7, Paige G. Wickner4,5, Diane L. Seger1,3, David W. Bates1,4, and Li Zhou1,4
1Brigham and Women’s Hospital, 2MCPHS University, 3Partners Healthcare, 4Harvard Medical School, 5Massachusetts General Hospital, 6University of Colorado Hospital, 7University of Colorado School of Medicine

Background: More than 20% of patients report at least one drug allergy. Adverse drug reactions (ADRs) occur in 1 in 4 outpatients and 1 in 5 inpatients. Complete and reliable patient allergy histories are critical to inform future prescribing. However, allergy documentation is often incomplete with reactions and reaction type specified only half of the time. Distinguishing reaction types (e.g., allergy vs intolerance) is important for patient care but challenging for general clinicians to determine. Another documentation obstacle is the reliance on commercial or local dictionaries whose adverse reaction lists are incomplete, ambiguous, static, and vary by location. Reactions lists from 6 institutions ranged from less than 20 to more than 100. EHRs support entry of structured/coded reactions, but free-text reactions remain common (1/6 of entries). We sought to improve reaction documentation beginning with the development of a more comprehensive, specific, and correctly classified reaction list.

Methods: We assigned a reaction type (i.e., allergy, contraindication, or intolerance) and minimum criticality (i.e., low, medium, or high) to each reaction in our institution’s reaction pick list. Allergy was defined as an immunologic hypersensitivity reaction of any possible Gell and Coombs type (i.e., Type I, Type II, Type III, Type IV). Intolerances were defined as development of non-immunologic symptom or sign from a substance. Contraindication was defined by a medical condition where a medication, food or other substance should never be used because of known harm that would occur. Reaction types were assigned by a clinical expert group consisting of pharmacists and physicians, including allergy specialists. Next, we used MTERMS, a multipurpose NLP tool for processing clinical text, to determine the prevalence of reactions including those entered as free-text. MTERMS extracted reactions from free-text comments using our previously developed value set of 4,300 reaction terms. The terms were then mapped to SNOMED-CT concepts, and the mappings were validated by clinical experts. The concepts were then further mapped to the EHR’s reaction list via exact match. Based on the frequency of free-text reactions without a corresponding coded reaction, clinical experts considered which reactions warranted coded entry in the existing reaction pick-list and classified reactions by type and criticality.

Results: The Partners reaction pick-list currently has 46 reactions (excluding “Other” and “Unknown”), with 26 of these reactions (56.52%) classified as allergies, 10 (21.74%) as intolerances, and 10 (21.74%) as contraindications. 24 reactions (52.27%) were considered high criticality, 11 (45.83%) were considered medium, and 11 (45.83%) were considered low. We identified 51 additional reactions with high frequency and clinical importance that warranted adding to the existing pick-list (Table 1). Of these, 22 (43.14%) were intolerances, 20 (39.22%) were contraindications, and 9 (17.65%) were allergies. Overall 34 of these reactions (66.67%) were high criticality, 8 (15.69%) were medium, and 9 (17.65%) were low.

Conclusions: Allergy documentation varies institutionally. We created an enhanced allergy reaction list informed by free text entries. We assigned reaction types and minimum criticality for all reactions to assist in improved allergy documentation. Future steps will include the implementation and evaluation of this enhanced reaction list.

National Working Group to Standardize the Identification of Sensitive Data Elements to Support Patient Privacy

Marianne Sharko, MD, MS1, Hannah Galvin, MD, FAAP2, Susan J. Kressly, MD, FAAP3, Joseph H Schneider, MD4, Fabienne Bourgeois MD, MPH5, Feliciano (Pele) Yu, MD6, Matthew Hong, MHCI7, Lauren Wilcox, PhD7, Jessica S Ancker, MPH, PhD1

1. Department of Healthcare Policy & Research, Weill Cornell Medical College, New York, NY, 2. Lahey Health, Burlington, MA, 3. Kressly Pediatrics, Warington, PA, 4. UT Southwestern Medical Center, Dallas, TX, 5. Harvard Medical School, Boston Children’s Hospital, Boston, MA, 6. Arkansas Children's Hospital, Little Rock, AR, 7. School of Interactive Computing, Georgia Institute of Technology, Atlanta, GA

Problem addressed:
In this age of electronic medical information collection, storage, analysis and exchange, it is important to protect patients’ rights to privacy over sensitive medical information. State laws and medical center policies governing privacy protection can vary and provide a complex backdrop for the standardization of sensitive data. It is important to consistently identify sensitive information in order to prevent the unintentional sharing of information through the electronic health record (EHR), patient portal or health information exchange (HIE).

Without standardization, medical organizations are left on their own to define the types of information identified as sensitive, and in need of heightened protection. This results in varying lists of sensitive data which can leave patients vulnerable to breaches of privacy. This is of particular importance to vulnerable populations, such as adolescents, patients seeking mental health or sexual reproductive care, or patients using proxies to manage their healthcare. HIE can provide challenges to data protection due to differing privacy policies. With limited ability to identify sensitive data in the EHR, many systems rely on individual professionals to provide this protection. The informatics community and industry have found it difficult to address these challenges due to its complexity and lack of business and regulatory drivers. However, it continues to be a clinical problem that impacts patients and providers daily.

Purposes of the working group:
A previous study found that many chief medical information officers (CMIO’s) welcome more formal assistance in the identification and control of sensitive data; however, national guidelines should be thoroughly vetted. The established standards should align with recommendations from medical associations and state laws, and should be adaptive enough to accommodate differing patient needs. We have developed a working group through a snowball recruitment process to define the problem and to brainstorm potential solutions. This group, working with the AAP Council of Clinical Information Technology and the Child Health Informatics Center includes pediatricians, adolescent specialists, CMIO’s, informaticists, researchers, and human-computer interaction specialists.

A primary aim of the group is to develop industry and expert consensus around recommendations for privacy protections at the data element level, a granularity previously thought to be too complex to address, yet which is necessary to support clinical use cases. Currently a clear list of sensitive data does not exist. To that end, we have begun categorizing data elements into levels of sensitivity through a small group consensus process to identify those with heightened privacy protection needs, such as from mental or sexual histories. We have also developed clinical use cases to demonstrate the need for standards development. Communication with vendors to delineate privacy expectations and create functional standards will help motivate electronic advancements, provide long-term consistency, and garner support from the ONC through their rule-making process. We look forward to sharing our processes, sensitive data lists and use cases to advance this conversation so that patients and families can benefit from the accurate exchange of information with confidence that their wishes regarding data privacy are respected.

Identification of Latent Subtypes of Patients with Opioid Misuse

Brihat Sharma, BA1; Dmitriy Dligach, PhD1; Robert Kania, BS1; Elizabeth Salisbury-Afshar, MD, MPH2; Niranjan Karnik, MD, PhD2; Cara Joyce, PhD1; Majid Afshar, MD1
1Loyola University Chicago, Chicago, IL; 2Rush University, Chicago, IL

Introduction: The aim of this study is to identify subtypes of opioid misuse using latent class analysis (LCA) on readily available structured electronic health record (EHR) data in hospitalized patients. Additionally, the clinical notes frequently contain free text about social and behavioral determinants of health that cannot be comprehensively examined manually due to high volume of data; therefore, topic modelling was applied to summarize the corpus of text. The goal is to identify distinct subtypes of patients with opioid misuse, and characterize the subtypes using topic modelling. We hypothesize LCA will identify distinct subtypes in our patient cohort with clinically meaningful traits.

Methods: This study utilized data from the EHR of an urban tertiary academic center between January 1, 2007 and September 30, 2017. An operational definition for opioid misuse was developed following the National Survey on Drug Use and Health criteria for opioid misuse. Among those with opioid misuse, latent classes were identified using demographics, diagnosis codes, and urine drug screen results, and model fit statistics were utilized to identify the appropriate number of latent classes. Pre-processing of all clinical notes was performed in the Apache clinical Text Analysis Knowledge Extraction System (cTAKES) with concept mapping to concept unique identifiers (CUIs). Latent Dirichlet Allocation (LDA) was used to identify the topics. The LDA model was trained on the full cohort of patients with opioid misuse and produced topics expressed as probability distributions over CUIs. The optimal number of topics was identified by examining a range of topics using model fit statistics for topic coherence.

Results: The health system had 228,884 inpatient encounters during the study period and 6,224 (2.7%) met inclusion criteria for opioid misuse. Fit statistics and model interpretability suggest a 4-class model was optimal. Class 1 represented high hospital utilizers with known opioid-related conditions (36.5%); Class 2 contained illicit users with low socioeconomic status and psychoses (12.8%); Class 3 consisted of those with alcohol use disorders with complications (39.2%); and class 4 had low hospital utilizers with incidental opioid misuse (11.5%). Classes 1 and 3 had highest likelihood for 30-day unplanned readmissions. In topic modelling, the final data corpus in the 6,224 patient encounters was comprised of 25,801 unique CUIs across 422,147 clinical notes. Twenty topics were identified for the cohort, with themes spanning from chronic medical conditions to behavioral conditions and healthcare services. LDA topics complemented the LCA findings (Figure).

Figure. Distribution of probabilities for each topic across the 4-class model

Conclusion: We identified a four-class model that identified clinically interpretable and relevant subtypes for opioid misuse, with good class separation and face validity based on documentation in the notes, structured data, and clinical outcomes. LCA using readily available class-defining substance use variables from the EHR may be applied as a prognostic enrichment strategy for targeted interventions (Research supported by NIH R01LM012973 Dligach).

Do Urban and Rural Patients Use Telemedicine Differently?

Lincoln R. Sheets, MD, PhD¹, Emmanuelle Wallach², Mirna Becevic, PhD¹
¹School of Medicine, University of Missouri, Columbia, Missouri, USA;
²PhD student, College of Engineering, University of Missouri, Columbia, Missouri, USA

Introduction

Telemedicine has traditionally been used in rural areas to improve access to specialty care.¹ However, telemedicine use is growing rapidly in urban areas,² and little is known about differences in urban and rural telemedicine use. We studied whether rural and urban patients in Missouri use telemedicine to access healthcare specialties at different rates.

Materials and Methods

We obtained Institutional Review Board approval to study de-identified electronic health records (EHR) from telemedicine visits at the University of Missouri from 2008 through 2017. We used Federal Office of Rural Health Policy (FORHP) classifications of patient zip code as rural or urban.³ Visits were categorized according to provider specialty: dermatology, child psychiatry, adult psychiatry, and other specialties which accumulated to less than 5% of all visits (anesthesiology, child development, endocrinology, family practice, neurology, oncology, vascular surgery).

Results

Of 5,411 telemedicine visits, 34% were from urban areas; these were 73% child psychiatry, 10% adult psychiatry, 13% dermatology, and 4% other, while rural visits were 35% child psychiatry, 19% adult psychiatry, 44% dermatology, and 2% other. Figure 1 summarizes these findings and Table 1 shows counts and demographic characteristics of telemedicine visits in each specialty, some of which were statistically (p<0.05) different between rural and urban visits.

* Significant (p<0.05) difference between urban and rural results.

Conclusion

Urban patients access telemedicine significantly differently, with a much greater demand for child psychiatry. Telemedicine may offer help for the critical nationwide shortage of adolescent psychiatry providers in rural and urban areas. Health systems should consider adjusting resources to meet the different needs of these two populations.

Leveraging a Data-Driven Strategy to Enrich Rare Disease Knowledge

Feichen Shen, Ph.D., Yiqing Zhao, Ph.D., Hongfang Liu, Ph.D.
Department of Health Sciences Research, Mayo Clinic, Rochester, MN, USA

Abstract

Existing resources to assist the diagnosis of rare diseases are usually curated from the literature that can be limited for clinical use. It often takes substantial effort before the suspicion of a rare disease is even raised to utilize those resources. The primary goal of this study is to apply a data-driven approach to enrich existing rare disease resources by mining phenotype-disease associations from electronic medical record (EMR).

Background

In this study, we focused on the Human Phenotype Ontology (HPO) [1] and Orphanet [2]. An annotation file that records associations between phenotypic terms from the HPO and rare disease terms from Orphanet were referred here as rare disease knowledge resource (HPO-Orphanet). We propose to enrich the HPO-Orphanet through mining association information between clinical phenotypes and diseases using EMR. Such enriched information, named as HPO-Orphanet+, can be used to link similar rare/common diseases and provide differential diagnostic decision support at the point of care for rare disease diagnosis.

Methods

We formulated the task of mining association information between clinical phenotypes and diseases as an association rule mining task. Specifically, patients are considered as transactions and their phenotypes and diseases are considered as items. The phenotype-disease association discovery can be defined as one item rule {Phenotype} → {Disease}. We first leveraged the support and confidence metrics to measure the importance of discovered associations. We then built a bipartite graph (HPO-Orphanet+ Graph) as an enriched knowledge graph to represent associations between diseases and phenotypes. We finally used Jaccard similarity on disease level to measure the similarity among diseases based on significant phenotypic features selected by odds ratio.

Results

All clinical notes during the years of 2010 to 2015 from Mayo Clinic EMR were used for the study. For each note type, we focused on the diagnosis section of the notes which summarizes problems for each patient. The resulting corpus contains 12.8 million clinical notes corresponding to about 730K patients. We first carried a use case study on Hodgkin lymphoma to compare performance on rare disease differential diagnosis for three different bipartite graphs, which are the original knowledge graph HPO-Orphanet, data-driven EMR Graph, and the enriched knowledge graph HPO-Orphanet+. We used ranked disease-disease similarity generated by the eRAM [3], an existing rare disease encyclopedia, as a gold standard to compare the three graphs with sensitivity and specificity as (0.17, 0.36, 0.46) and (0.52, 0.47, 0.51). We found HPO-Orphanet+ yielded the highest sensitivity. We also compared the top 15 diseases generated by HPO-Orphanet+ with eRAM and another widely used clinical diagnostic tool, the Phenomizer [4]. We found that the HPO-Orphanet+ graph identified 46.7% (7 out of 15) common diseases and 53.3% (8 out of 15) rare diseases. While differential diagnostic candidates provided by the Phenomizer are all rare disease. Similarly, the eRAM generates 93.3% (14 out of 15) rare diseases but only 6.7% (1 out of 15) common diseases. Compared to the Phenomizer and eRAM, the HPO-Orphanet+ graph is more capable of detecting link between common and rare diseases at the early time of diagnosis to assist in diagnostic decision support.

Conclusion

In this study, we proposed a data-driven approach to mine phenotype-disease associations buried in EMR so as to enrich current rare disease knowledge with extracted associations as well as differential diagnostic suggestions.

Abstract Familial risk criteria for common cancers rely on the age of cancer onset, which is documented inconsistently using structured and unstructured formats in electronic health records (EHRs). We operationalized a natural language processing (NLP) system to extract disease onset information from free-text EHR fields with recall and precision ranging from 98% to 100%.

Introduction

Family health history (FHH) is useful for identifying patients with increased cancer risk. Evidence-based criteria for patients who may benefit from the genetic evaluation include the age of cancer onset in family members (e.g., first or second degree relative with breast cancer and age of onset (AOO) <45 years old). However, the AOO is often recorded in free-text and is not readily available for standardized health information exchange and computational purposes. We investigated a natural language processing (NLP) approach to (i) extract AOO from a free-text comment field in an electronic health record (EHR); and (ii) structure the AOO to comply with the Fast Healthcare Interoperability Resources (FHIR) standard to allow inter-organization information exchange.

Methods

We queried the University of Utah Health (UHealth) Enterprise Data Warehouse for all patients aged 25-50 seen at least once at UHealth primary care clinics between April 2014 and May 2018. We selected each patient’s most current FHH entries within the EHR containing documentation of breast, colorectal, endometrial, and unspecified cancer. Each FHH entry has structured data on the diagnoses, relation, and AOO (if completed) with more detailed information in the comments field. We applied a rule-based AOO identifier built on EasyCIE\(^1\) (a user-friendly clinical NLP tool) to extract AOO from the comments. Next, we instantiated the extracted AOO using the FHIR FamilyMemberHistory resource, which allows representing AOO in one of four data types: numeric, range, period, or string. Two annotators manually reviewed a random sample of 300 positive (i.e., with age of onset) and 300 negative (i.e., without age of onset) cases. We then calculated sensitivity (recall), specificity, and positive predictive value (precision) for each FHIR data type.

Results

The sensitivity, specificity, and PPV achieve between 98% to 100% across all four data types. Of the non-flagged cases, we observed only one range error.

Table 1: Disease age of onset classification by data type. PPV = positive predictive value.

Discussion

The most spurious false-positive errors for age were caused by a missing modifier (“?”” indicating fuzzy range). The only false-negative error was a missed range: “70s I think”. We are enhancing EasyCIE to extract and encode additional FHH information, including family relation, sidedness, and cancer type using FHIR.

The impact of emotion on medication errors: A text mining analysis approach

Akiko Shibuya, RN, PHN, PhD1, Jimpei Misawa, PhD2, Rie Ichikawa, MD, PhD2, Yukihiro Maeda, BH1, Izumi Ikeda, RN, PHN, MSN1, Mihoko Koshida, RN, PHN, PhD1, Teruyoshi Hishiki, MD, PhD3, Yoshiaki Kondo, MD, PhD2

1 Faculty of Nursing, Toyama Prefectural University, Japan; 2Department of Health Care Services Management, Nihon University School of Medicine, Tokyo, Japan; 3Department of Information Sciences, Toho University, Chiba, Japan

Abstract
The initial phase of decision-making before any medical procedure is largely affected by the emotions of healthcare providers. We used a text mining approach to analyze the emotions of healthcare providers during decision-making prior to drug treatment to determine the association between emotions and medication errors. Our approach may reveal how the emotions of physicians affect medication errors, and may have a significant impact on patient safety.

Introduction
Medication errors that occur in hospitals have been a source of concern for decades. There is an increasing number of studies focusing on the analysis of medication errors. Studies suggest that errors in medication dose and usage are common, and that these errors result from the lack of attention, verification, and knowledge of healthcare providers1. However, only a few studies to date have focused on the emotions of healthcare providers and how they affect decision-making prior to any medical procedure. Some studies examined human factors in medical errors2; however, these studies focused on the behavior and experience of healthcare providers, and only a limited number of studies focused on emotions and used text mining approaches to analyze medical errors. In the present study, we focused on the emotions of physicians during the decision-making phase prior to drug treatment and used a text mining approach to analyze these emotions in the decision-making phase.

Methods and results
A total of 973 cases of medical errors were identified from the Japanese national medical error database using the terms “medication” and “physicians” for the search. Text mining was used to analyze emotions extracted from the comments sections that provided a summary for each medical error case. The association between medication error and emotion was subsequently examined. All analyses were performed using SPSS Text Analytics for Surveys 4.0 and SPSS 24.0. There were 764 negative comments and 228 positive comments (including some overlaps, p<0.001).

Figure 1. Emotions in medication errors

Figure 2. Association between medication errors and emotions

Negative emotions included fear, disgust, sadness, surprise, and anger (including some overlaps). Fear was the most common emotion (58.6%), followed by disgust (28.7%) and sadness (9.2%) (p<0.001). Overdosing was the most common error (15.6%), followed by wrong dose (13.1%) and wrong medication (7.4%) (p<0.001). Figure 1 shows the type of emotions for each error. A correspondence analysis was performed to determine the association between the medication errors and physicians' emotions (Figure 2).

Conclusion
We focused on physicians' emotions in the decision-making phase prior to any medical procedure, and used text mining to analyze physicians' emotions in the decision-making phase of drug treatment. The proposed method to determine the association between medication errors and emotions may help improve safety measures for drug treatment.

Predicting Patient Deterioration Using Continuous Monitoring and Concepts from the Field of Sports

Zvika Shinar, PhD¹, Veronica Maidel, PhD¹, Patricia C. Dykes, PhD, RN, FAAN, FACMI², Dalia Argaman, MSc¹, David W. Bates, MD, MSc²
¹EarlySense Ltd, Ramat Gan, Israel; ²Partners HealthCare System, Inc., MA, USA

Abstract
This study employed for the first time, continuous monitoring in non-ICU units, to predict major clinical deterioration. Applying machine learning on features extracted with the help of concepts from the field of professions sports, outperformed the commonly used MEWS score.

Introduction
Clinical deterioration of general ward patients can result in ICU transfer and/or death. Previous studies showed that continuous monitoring may provide a benefit in terms of improved patient outcomes and cost efficiency. The goal of this study was to test whether machine learning models based on features from continuous (contact-free) monitoring data and concepts from the field of sports¹ can improve standard Early Warning Scores (such as MEWS).

Methods
All patients hospitalized in five medical/surgical (non-ICU) units between April 2016 and April 2017 in a community hospital in Massachusetts, were monitored continuously with a contact free system (EarlySense Inc.). Monitoring included heart rate (HR), respiratory rate (RR), motion, and bed presence, every 10 seconds. Age-normalized features (based on maximal HR, calculated as 220-age, and HR range) were calculated and compared against a threshold corresponding to HR zones, as utilized in the field of professional sports (see Fig 1). Similar definitions were used for the first time for respiration. Machine learning classifiers (RFC & SVM) were trained to perform selection of the best features and to derive two predicting models, for expiration and for ICU transfer 24 hours prior to an event. The models were compared in a validation cohort using the area under the receiver operating characteristic curve (AUC).

Results
The study covered 11,737 unique hospital stays, including 138 deaths, and 770 ICU transfers. Validation model AUCs outperformed or were as good as MEWS AUC for the same data set. For ICU, the model’s AUC vs. MEWS’ AUC measures were 0.73 vs. 0.68 respectively. For mortality, MEWS and the model performed equally well, at 0.88.

Conclusion
We believe this work is novel in three ways: (1) we developed an early warning score based on continuous monitoring, (2) applied professional sports terminology to hospital medicine using an individual calibration of HR based on age and resting baseline, and (3) offer an analogy for the calibration of respiratory rate. The results outperform or perform as well as the commonly used MEWS score.

3 Department of Oral Health Sciences, Medical University of South Carolina, Charleston, South Carolina., 29425, USA

Abstract: Methods for extracting relevant biological information from expression profiles mostly rely on individual genetic expressions. Consequently, these methods are suboptimal in detecting small differences within the pathways that in aggregate result in a large multivariate effect. We propose Multivariate Pathway Enrichment Analysis (MPEA). MPEA harnesses the power of multivariate association to identify the subtle associations between genetic pathways and phenotype of choice. A reference is available at https://github.com/alekseyenko/MPEA.

Method: MPEA requires a multivariate expression array of control and test groups as well as reference to the genes involved in each genetic pathway. MPEA algorithm consists of three steps. Firstly, it calculates an enrichment score (ES) for individual pathways using distance correlation [2] of the expression profiles of the pathway between the control and test subjects. Next, it uses a permutation test over the entire expression profile to estimate the significance of the ES score. Finally, it corrects for multiple hypothesis testing to compensate for the multiple studies pathways.

Results: We compared the statistical power of MPEA against GSEA [3] for different effect sizes. Our simulation results show that MPEA has higher sensitivity compared to GSEA for different effect sizes, Figure 1. Next, we applied MPEA on real datasets and observed that MPEA is capable of identifying enrichment in pathways that are dimmed not significant in GSEA model. We bring an instance of the PCA plot of the expression profile of such pathway in Figure 2.

Conclusions: We showed that taking into consideration the interrelationship between the genes in genetic pathways significantly improves the statistical power of pathway enrichment detection.

Automated Information Extraction to Support Response Assessment in Myeloproliferative Neoplasms

Evan Sholle, MS1, Spencer Krichevsky, BS2, Sajjad Abedian, MS1, Prakash Adekkanattu, PhD1, Diana Jaber, BA2, Niamh Savage, BA2, Joseph Scandura, MD, PhD3, Thomas R. Campion Jr, PhD1,4,5

1Information Technologies and Services Department, Weill Cornell Medicine, New York, NY; 2Joint Clinical Trials Office, Weill Cornell Medicine, New York, NY; 3Department of Medicine, Weill Cornell Medicine, New York, NY; 4Department of Healthcare Policy and Research, Weill Cornell Medicine, New York, NY; 5Department of Pediatrics, Weill Cornell Medicine, New York, NY

Introduction

The myeloproliferative neoplasms (MPNs) are a clinically related set of neoplastic malignancies of hematopoietic stem cells, pluripotent cells that give rise to multiple cell lineages in the blood. The primary criteria for effectiveness of MPN treatments is response, which is determined by a structured set of criteria issued by working bodies in the field. These criteria include, among others, myeloblast counts, transfusion dependence, cytogenetics, and mutational status.

The current gold standard for determining response in clinical trials requires manual review of the patient’s electronic health record (EHR) by trained personnel, a time-consuming and difficult task. While some of the data required for the assessment of response exist in a structured fashion, some exist in free text reports, necessitating review by trained staff to extract elements required to assess response. We hypothesized that by leveraging natural language processing (NLP) information extraction techniques, we could obviate the need for manual abstraction of these concepts.

Methods

Utilizing Leo, an open-source NLP platform developed at the Veteran’s Administration on the Apache Unstructured Information Management Architecture (UIMA), we developed an information extraction pipeline designed to extract three principal components from bone marrow biopsy reports: myeloblast counts, cellularity, and fibrosis. After initial pipeline development, trained research personnel annotated a sample of 300 bone marrow biopsies to serve as the gold standard. We then compared the output of the pipeline to manual annotation to assess its performance, calculating precision, recall, and F-score for each of the three components, as well as accuracy for extracted values. All calculations were performed using the R statistical software environment.

Results

The pipeline extracted aspirate myeloblasts with precision of 0.97, recall of 0.79, and F-score of 0.87; biopsy cellularity with 0.84 precision, 0.94 recall, and an F-score of 0.89; and fibrosis scores with precision of 0.91, recall of 0.91, and an F-score of 0.90. Extracted aspirate myeloblast scores were accurate in 95% of extracted cases. Extracted quantitative cellularity values were accurate in 73% of extracted values, and qualitative values were accurate in 56% of extracted values. Fibrosis scores were accurate in 69% of extracted values.

Discussion

While the assessment of response in cancer patients is a notoriously difficult problem, to our knowledge, this is the first documented effort to extract structured data elements from free text reports specifically for the purpose of supporting response assessment. This information extraction pipeline still holds the potential for improvement, especially with regard to extraction of qualitative assessments of cellularity. Future work in this area will revolve around incorporating the results of this pipeline into a larger technique for computational determination of response.

Information Seeking Practice Among Healthcare Professionals in Pakistan: A Review of Current Trends and Needs

Amna A. Siddiqui¹, Syed A. H. Rizvi¹, Jawwad Ahmed¹, Asif A. Syed², MD, MPH, Paul Fontelo³, MD, MPH. ¹Dow University of Health Sciences, Karachi, Pakistan; ²University of Illinois, Chicago, IL, USA; ³National Library of Medicine, Bethesda, MD, USA.

Introduction:
Evidence-Based Medicine (EBM) integrates clinical experience with current information to provide effective healthcare. We wanted to analyze the information requirements, current needs and prevailing trends of practicing doctors and medical students of a lower-middle-income country with only 33% of the population with internet access¹.

Methods:
Data was gathered from 160 participants (physicians and med-students) using convenience sampling by completion of either a paper or online questionnaire, which assessed their clinical background, technology access, need for health-related information, and the preference of resources to obtain information in different scenarios. Results were analyzed using SPSS version 17.0.

Results:
Basic mobile phones (with limited internet connectivity) is the most common device used at home (99.3%) and work (88.1%). Smartphones were available only to 17.5% participants at work. Internet connectivity was available for 96.8% at home but only 73.7% at work. Around 30.6% encountered questions in practice 2–4 times a day, and 50% were very likely to look up a reference. Most common resource for the majority of given clinical scenarios was a senior colleague, while medical websites (Medscape, Up-to-Date, WebMD etc.) were the first choice for non-specific general medical queries (Fig.1). Approximately 68.8% said that they used PubMed in daily practice. The most common reason for not using PubMed mentioned the ease in using other search engines, like Google.

Figure 1: Preferred source of information in given scenarios.

Conclusion:
Limitations of technological access must be considered when designing information resources in lower-middle income countries. As suggested by the participants, open and free internet connectivity, easy access to online resources, and tools with functionality independent of internet may enhance the uptake of EBM in Pakistan.

Preventing inpatient hypoglycemia: A predictive model built from multi-center EHR data

Michael Simonov, MD1, Silvio E. Inzucchi, MD2, Francis P. Wilson, MD, MS1
1Yale Program of Applied Translational Research, New Haven, CT; 2Section of Endocrinology, Yale School of Medicine, New Haven, CT

Introduction
Severe hypoglycemia (blood sugar < 40mg/dL) is an important inpatient adverse event which is associated with increased morbidity, mortality as well as length of stay1,2. Centers for Medicare and Medicaid Services (CMS) is developing a hypoglycemia quality measure suggesting the importance of approaches to reduce such episodes. Current medical practice is heavily reactionary, namely a hypoglycemic episode prompts a subsequent change in medical care. There remains a need for proactive approaches aimed at predicting hypoglycemia before it occurs and prompting appropriate care. As an introductory step to changing such approaches, we set out to build an effective and implementable predictive model using existing health care record data with the ultimate goal of ready EHR implementation.

Methods
Inpatient data was obtained from three distinct hospitals in the Yale New Haven Health System (YNHHS). Data included time invariant data, such as demographics and past medical history, as well as time-updated data including vital signs and laboratory values. Severe hypoglycemia within the next 24 hours was set as the primary goal of the models. Several predictive models were evaluated; a primitive approach using only most recent glucose, a simple decision tree, and a multivariate logistic regression. Logistic regression and tree models were first trained on a subset of the data and then tested on the remaining held out data subset with performance measured by ROC curves.

Results
The final cohort included 203,962 patient encounters patient encounters with a total of 18.8 million individual time points for analysis. There were 2,633 encounters (1.3%) where the patient experienced at least one episode of severe hypoglycemia. Approximately two-thirds of these encounters were in diabetic patients and the remaining were in non-diabetics. Logistic regression was applied to data within the training dataset and the model displayed a performance of AUC 0.79 over the test data. In this logistic model, the most important features, as measured by z-value, were potassium, diabetes, minimum glucose in 72 hours, and bicarbonate. An easily-implementable decision tree model with four decision points displayed similar performance to the logistic regression model with decisions based on minimum 72-hour glucose, most recent glucose, creatinine, and length of stay. The primitive model, which was developed to align with current clinical practice, displayed very poor performance with an AUC of 0.55.

Conclusions
Logistic regression as well as a simple decision tree have good performance at predicting severe hypoglycemia. These models are superior to predicting hypoglycemia based solely on glucose, as is a common current clinical approach. We purposely limited model complexity by including readily-accessible and measurable features to construct parsimonious models which could be built in existing EHR decision support frameworks. The models presented here show promise in the development of a proactive approach for the prevention of severe inpatient hypoglycemia.

Adverse Events Monitoring for Medication Assisted Treatment of Opioid Use Disorder: Using Healthcare Data Interoperability to Inform Practice

Shyamashree Sinha, MD, MBA, MPH1, Robert Lee, MD1, Sarah Mullin, MS1, Jinwei Hu, MD1, Arlen Brickman, MD1, Angie Li, MD1, Peter L Elkin, MD, MACP, FACMI1
1Department of Biomedical Informatics, Jacobs School of Medicine and Biomedical Sciences, University at Buffalo, SUNY

Abstract

The goal of this study is to use electronic healthcare records from clinics and inpatient services to monitor opioid addicted patients who are on Medication Assisted Treatment (MAT), for adverse events including withdrawal, toxicity, and overdose. We also sought to find the treatment outcomes with methadone and buprenorphine in terms of the number of adverse events after the initiation of therapy.

Introduction

Retrospective patient records were collected from encounters occurring between January 2010 and April 2018 for patients with prescription opioid medications for non-cancer pain conditions after obtaining necessary IRB approval.

Method

The outpatient practice included 14,801 unique patients and the county hospital and outpatient clinic had an additional 8,330 unique patients. Electronic data from the different clinical data warehouse sources were collected, merged, de-identified, and then placed on a secure server. Deterministic matching was performed using social security number, date of birth, last name, and the first three letters of the first name. We were able to link 715 patients’ records between the two data sources. We examined the data for evidence of opioid related adverse events. These included withdrawal events, overdose, or other toxicity related events. Opioid related adverse events were defined by ICD-9-CM and ICD-10-CM codes for abuse, adverse events, complications, or poisoning. The outcomes examined did not include patient deaths. We then looked at the patients who had been prescribed an opioid medication, with or without a record of adverse events, who were subsequently placed on methadone or buprenorphine therapy based on National Drug Codes (NDC) of these medications.

Results: A total of 1096 patients on buprenorphine, 338 patients on methadone. 45.5% of patients were female, 87.2% were white, and 3.5% were Hispanic. 796 patients were removed due to a prescription date after diagnosis date. 229 of the buprenorphine group and 250 of the methadone group had an adverse event. The relative risk of having an adverse event while on methadone as compared to buprenorphine was 3.54 (95% CI 3.1040 to 4.0371) with a significance level of P < 0.0001. Number needed to treat (NNT) was 1.884.

Discussion: The findings of this study clearly indicates the advantage of buprenorphine or a combination therapy over methadone in having adverse events. Further longitudinal studies have to be performed to compare different aspects of MAT in the future.

Figure 1: The bar graph shows the number patients taking buprenorphine and methadone therapy. (Series1: Number of patients with adverse events before and after initiation of therapy; Series2: Number of patients with no adverse events reported.)

Duplicate Laboratory Testing in the Context of Patient Care Transitions

Liron D. Sinvani, MD, Kayla Finuf, MS, Michael Qiu, MD, PhD,
Renee Pekmezaris, PhD, Jan Horsky, PhD
Center for Research Informatics and Innovation, Northwell Health, Manhasset, NY

Introduction

Timely and appropriate testing is critical for practicing evidence-based care and following clinical guidelines and best practices. The number of laboratory tests performed in the United States is estimated to be 4–5 billion annually. Over- and under-utilization of tests, however, can lead to lower care quality and higher costs. For example, unnecessary blood draws increase patient discomfort and the potential for infections and also the likelihood of false-positive results that lead to unwarranted interventions with further risks. Care transitions are known sources of patient risk from errors such as medication discrepancy and incomplete records but may also lead to laboratory repeats at intervals that are shorter than recommended. The objective of this descriptive study was to find the frequency of inappropriate repeat testing at a large, integrated healthcare delivery network for five commonly ordered laboratory tests. Specifically, we wanted to estimate the rate of duplicative testing in the context of care transitions between hospital and the community.

Methods

We queried a clinical data repository that aggregates all inpatient and ambulatory information from EHRs to find patients with at least one order during a 3-year period (2016-18) for the following common lab tests: TSH (thyroid stimulating hormone), HbA1c (Hemoglobin A1c), Cholesterol–lipid profile and for Vitamins B12 and D (25-Hydroxy). The collected dataset included order date and setting (hospital vs. community). Orders were marked as “repeat” when the time elapsed since the preceding test was shorter than guideline recommendation; otherwise as “index.” We analyzed testing rates and focused on the frequency of duplicate tests associated with care transitions, defined as scenarios where the index and repeated orders originated in different settings (hospital or community).

Results

There were 81,561 patients with 163,591 TSH orders, out of which 22,116 (14%) were repeats (<60 days), 81,205 patients with 179,706 HbA1c and 26,727 (15%) repeats (<90 days), 76,861 patients with 170,147 Cholesterol and 23,655 (14%) repeats (<90 days), 31,908 patients with 49,569 Vitamin B12 and 14,222 (29%) repeats (<365 days), and 44,629 patients with 90,735 Vitamin D and 33,137 (37%) repeats (<365 days). Repeat tests that followed a care transition totaled 3,168 (14%) for TSH, 6,122 (23%) for HbA1c, 3,993 (17%) for Cholesterol, 1,504 (11%) for Vitamin B12 and 2,488 (8%) for Vitamin D. The repeat rate was higher in the “to hospital” direction, from 1.4 times (B12) to 2.9 times (Cholesterol) than in the “to community” direction (Figure 1).

Figure 1 Tests repeated on care transition

A significant proportion of tests, ranging from 14% for TSH to 37% for Vitamin D, appeared to be duplicates. The high rates are congruent with previous published reports but we also found that duplicate tests were performed at up to 3-times higher rate (Cholesterol) during and after hospital admission than after discharge to the community. We hypothesize that when hospitalists have a problematic, laborious or nonexistent access to outpatient records they order the tests they need even if they may be repeats. EHRs where lab results are “silod” in displays and do not afford effective review of lab order history or when they are distributed over non-integrated systems likely contribute to test overutilization. Summaries of lab results medications that are available in discharge documents perhaps more conveniently aggregate this information for ambulatory clinicians who therefore have a better understanding of recent testing. Importantly, test duplication causes extra discomfort and pain to tens of thousands of patients every year and likely contributes to lower care satisfaction. Electronic alerts to clinicians about duplicate tests during ordering may help alleviate this problem. We plan to expand this study to include EHR interface evaluation and human-computer interaction studies to explore whether better system integration and usability can decrease duplicative testing.

The Cancer Imaging Archive (TCIA), NCI’s Imaging Data Resource

Kirk E. Smith, B.S.¹, Bill Bennett, B.A.¹, Lawrence Tarbox, Ph.D.¹, Tracy Nolan, B.E.¹, Geri Blake, M.Ed.¹, Justin Kirby, B.S.², John Freymann, B.S.², Fred W. Prior, Ph.D.¹
¹Biomedical Informatics, University of Arkansas for Medical Sciences, Little Rock, AR
²Frederick National Laboratory for Cancer Research, Leidos Biomedical Research, Frederick, MD

Introduction
The Cancer Imaging Archive (TCIA) is the National Cancer Institute’s (NCI) repository of publicly accessible cancer images and supporting metadata¹. The data in TCIA are organized into collections by cancer type or research protocol. Collections are treated as data publications, with each one assigned a Digital Object Identifier (DOI) and citation to reference the dataset². Each collection includes a descriptive summary, licensing details, multiple search and download interfaces, citations, version control, and links to supporting data. TCIA also supports submission of third-party analyses of existing collections such as tumor segmentations and radiomic features. A help desk provides email and phone support along with user manuals and FAQs.

Data Acquisition and Curation
A TCIA submissions team consists of a Submissions Manager, a DICOM curator, and a Data Support Specialist who follow a standards-based approach to ensure accurate and timely acquisition and curation of data from submitting sites around the world. The Posda toolkit³ is used to inspect and edit each image for DICOM conformance, linkages to supporting data, PHI within the pixels, and PHI within DICOM elements. Care is taken in removing PHI to retain data that is useful to the researcher. A private tag dictionary is maintained within Posda. Once fully curated the data are moved into TCIA for public consumption.

Data Collections
TCIA supports 92 collections derived from major research initiatives including the Cancer Genome Atlas (TCGA), Clinical Proteomic Tumor Analysis Consortium (CPTAC), Quantitative Imaging Network (QIN), the Cancer Moonshot and clinical trials. TCIA also hosts the Lung Imaging Database Consortium (LIDC) collection, the Reference Image Database for Evaluation of Response (RIDER) collections and a number of NCI internal research programs as well as community initiated datasets.

Utilization Metrics
The success of TCIA may be measured by its number of users and published manuscripts. TCIA typically supports 15,000 active users per month from more than 125 countries that download approximately 75 TB of data. Over 700 publications have referenced TCIA and used its data. TCIA data been used in 14 image analysis challenge competitions⁴.

Conclusion
TCIA is a persistent archive that increases public availability of high quality cancer imaging data, supports NIH data sharing requirements, facilitates reproducibility of research, and creates a culture of open data sharing among collaborators. TCIA provides a number of services to support the submission and hosting of the data, relieving the contributors from the majority of data sharing risks.

Introduction

Sentiment Analysis (SA) methodologies are being investigated with increasing frequency for potential applications in healthcare. One concern is that these methodologies are lacking in the ability to analyze healthcare text because their lexicons were not curated for this purpose and do not include a comprehensive set of health-related terms. The purpose of this observational descriptive study is to perform secondary analysis of previously collected patient illness narratives² to assess the feasibility and face validity of SA methods to characterize the sentiment of the illness narratives and explore how various SA methods and their lexicons impact the results. The patients’ narratives are based on patient interviews conducted by one of the authors (HC) and focus on the psychosocial and spiritual impact of illnesses, written from the perspectives of patients with serious illness.

Methods

We analyzed de-identified two- to four-page narratives (n=10) at various levels of text analysis (document, paragraph, sentence), using four SA approaches: TextBlob Pattern (TB-P), TextBlob Naïve Bayes (TB-NB), NLTK Vader (NV), and SentiWordNet (SWN). We compared the sentiment polarity (a numeric representation of the sentiment between -1 and +1), the terms used for calculating the score, and the inter-rater agreement. We also identified medical-related terms from the narratives using eight medical terminology standards (i.e., RXNORM, SNOMED-CT, LOINC, CPT, ICD9CM, ICD10CM, MESH and NCIT) from the National Center for Biomedical Ontology's BioPortal and compared them with the terms used by the SA methods, with the goal to identifying overlaps and gaps of terms.

Results

At the document level, most of the patient-illness narratives were classified as positive by all the SA approaches. However, we found more variations and disagreements among the SA approaches when polarity was evaluated at the paragraph and sentence level. The average Cohen’s kappa ranged from 0.8 to 1.0 at document level, from 0.06 to 0.49 at paragraph level and from 0.10 to 0.35 at sentence level. The most frequent parts of speech per narrative were verbs (average 18.47%) and nouns (average 17.71%) with fewer adjectives (average 5.36%) and adverbs (average 6.76%). The overall proportion of terms from the ten narratives with polarity zero is 25% for TB-P and 27.5% for SWN. TB-NB and NV do not provide lists of terms used for calculating polarity. The selected BioPortal ontologies identified an average of 27.6 (15.6%) unique terms per document that were not identified by both the TB-P and the SWN. The NCIT ontology identified the most terms from the narratives followed by the SNOMED-CT and the LOINC ontologies with averages of 144.4, 88.8 and 72.7 terms per narrative, respectively.

Discussion

The variation in the results of the four SA approaches indicates that these SA approaches have limitations and are not suited for use with patient-illness narratives. Overall, the SA methods demonstrated a lack of polarity concordance and missed potentially important healthcare terms. SA in healthcare must also consider factors related to the patient’s health status, conditions, diagnosis, and more. Our analysis of the patient-illness narratives at the sentence, paragraph, and document levels to explore the variation in the results confirmed that an assessment of the whole document might obfuscate important and meaningful variations. As we moved from document to paragraph to sentence, the variations in polarity scores increased and agreement between the SA approaches decreased. BioPortal served as a complementary evaluation to non-healthcare related SA approaches.

An Informatics Governance Model for a Shared Electronic Disease Surveillance System in Public Health: Minnesota Perspective

Sarah Solarz, MPH¹, Ann Kayser, MPH¹, Sarah Boneske, MPH¹, Hanna Chakoian, BA¹, Sripriya Rajamani, MBBS, PhD, MPH, FAMIA¹,²,³, Emily Emerson, BS¹

¹Minnesota Department of Health, St. Paul, MN; ²School of Nursing, ³Institute for Health Informatics, University of Minnesota, Minneapolis, MN

Introduction

The Minnesota Electronic Disease Surveillance System (MEDSS)¹ supports infectious disease surveillance at a state level for Minnesota. MEDSS was implemented in 2008 and is used for case management, contact tracing and outbreak investigations. Conditions that are reportable to public health and relevant electronic lab reports are stored in MEDSS. Its scope has expanded to include non-infectious diseases, such as hearing loss and birth defects. It is a person-centric surveillance system with ~1,494,508 events across infectious diseases, lead and community and family health programs. MEDSS has a user base across state programs, local public health agencies and external clinical partners with varying access/roles. The central information technology agency for the state and the system vendor collaborate with the MEDSS informatics team to support the system. Given this matrix of users, technical assistance, funding and priorities, it is essential to have an informatics governance model in place for oversight and ensuring smooth operations.

Methods

A systematic approach was pursued over the past few years to have various MEDSS groups facilitate the process of deciding and approving system improvements and prioritizing the on-boarding of data exchange partners. These groups needed to have broad representation to ensure various stakeholders are included and also to assure that funding requirements and user expectations were met in a timely fashion. The coordination of these groups and overall collaboration across public health and technical professionals is under the purview of the MEDSS informatics team.

Results

The MEDSS informatics team (n=5) leads the overall operations guided by user input and grant objectives. MEDSS Steering Committee (n=17) with MEDSS and ELR user groups (n=85) are integral to identifying system issues, enhancements and priorities. Technical issues are addressed by system admin team (n=5) and messaging team (n=5). MEDSS leadership (n=4) oversees all these groups. They collaborate with MDH Office of Health IT which sets e-Health policy goals, and other internal/external partners.

Conclusions

The current governance model supported by various experts has placed MEDSS in a stronger position to respond to various federal/local initiatives and also to be strategic on decisions given various constraints, including funding. Information systems across public health agencies have varying capabilities, technical support and different governance structures. The proposed model can be adopted/adapted by other programs or in other jurisdictions.

Acknowledgement: The authors thank the numerous experts who participate in various MEDSS governance groups.

Why is Data Harmonization Difficult?
Towards a Taxonomy for Structuring the Mapping of Variables between Data Models

Abstract
To enable high-powered multi-site studies, numerous healthcare organizations are attempting to harmonize their electronic health records (EHRs) with common data models such as PCORnet and ACT. However, the harmonization process is known to be difficult, requiring extensive manual curation by domain experts. Here we report on a case study of harmonizing data from an EHR to PCORNet, which enabled an examination of the complexity involved in data harmonization. The results led to a mapping taxonomy useful for structuring the mapping process, and for the development of scripts to populate databases.

Introduction
Motivated by the need to conduct high-powered and generalizable studies across multiple sites, numerous healthcare organizations have invested in harmonizing patient data in their EHRs with national data standards such as PCORnet and ACT. Unfortunately, EHRs in specific healthcare organizations have been designed with locally-determined conventions for naming (e.g., sex vs. gender), encoding (e.g., Hispanic vs Hispanic-Black), and data entry (e.g., free text vs. structured field). This complexity requires domain experts to manually determine the correct mapping. Here we examine the mappings used by a team of domain experts in harmonizing the data model used by the University of Texas Medical Branch (UTMB) hospital’s EHR, with the PCORnet2 data model, for building a multi-site registry to analyze opioid dependency in trauma patients.

Method
Our method consisted of the following steps: (1) assembled a team of domain experts consisting of 2 physicians, a researcher, and a database expert; (2) identified 3 research questions to analyze the association of patient variables to opioid dependency (e.g., How are trauma characteristics (type, site) associated with opioid dependency (>6 months post-injury)?); (3) identified variable names and their encodings in the UTMB data model; (4) mapped the selected variable names and encodings from the UTMB data model to the PCORnet data model; and (5) identified the types of data mappings used by the team.

Results and Discussion
To address the 3 research questions related to opioid dependency, the team identified 178 variables, of which 6 were specific to trauma (e.g., trauma site), while the remaining 172 were generic (e.g., demographics, and medications). By examining the UTMB and PCORnet data models, the team mapped the above variables to 13 PCORnet-defined domains (the number of UTMB variables in each domain are shown in parentheses): DEMOGRAPHIC (7), VITAL (13), ENCOUNTER (14), CONDITION (26), DIAGNOSIS (13), PROCEDURE (13), LAB_RESULT_CM (28), OBS_CLIN (16), PRESCRIBING (20), DISPENSING (11), MED_ADMIN (8), DEATH (4), DEATH_CAUSE (5). The following 6 PCORnet domains were not relevant to the selected characteristics: PROC_CM, PROVIDER, OBS_GEN, HARVEST, PCORNET_TRIAL, and ENROLLMENT. Furthermore, 37 UTMB variables necessitated an examination of actual patient records to determine their correct semantic mappings, which required IRB approval that is currently pending.

Examination of the above mapping process helped to identify 5 types of mapping: (1) one-to-one (e.g., Patient ID number mapped to PATID); (2) one-to-many (e.g., Drug-Screen containing amount of opiates mapped to multiple LOINC Codes to record different amounts of opiate such as 91052-1, 91043-0, 10369-7); (3) many-to-one (e.g., Operation Date and Operation Time merged into PX_DATE using the DD/MM/YY HH:MM format); (4) one-to-none (e.g., Procedure End Date, and Procedure End Time do not have corresponding variables in PCORnet); (5) derived (e.g., Sequential Organ Failure Assessment (SOFA) Score calculated based on Systolic Blood Pressure, Serum Creatinine, Serum Bilirubin, Serum Glucose, Platelets, PaO2/FiO2 Ratio, Glasgow Coma Scale). Furthermore, the above taxonomy was also useful for categorizing the variable encodings (e.g., Black-Hispanic and Non-Black Hispanics, merged to Hispanics and therefore categorized as many-to-one). We are currently evaluating whether this taxonomy covers the types of mappings required by the ACT model.

The above mapping taxonomy should be useful to help collaborating sites use a consistent nomenclature when mapping each variable, enabling more efficient communication, consensus, and reporting across sites. Furthermore, the above taxonomy enables the use of modular programming for reducing complexity and redundancy when creating extract-transform-load (ETL) scripts at each site, with the goal of more efficiently and accurately populating the registry with actual patient data.

* these authors contributed equally to this work

Overview: In this study, we trained a weighted k-Nearest Neighbor (KNN) on real patient clinical record to prescribe medication that has the lowest predicted HbA1c for each patient visit. Our cohort consists of 6,218 T2DM patients from Partners Biobank with 42 unique T2DM medications. We grouped medications into 8 clinically distinct categories ranging from mono-therapy to combination therapy. We also extracted multiple clinically informative features, including sex, age, HbA1c and BMI measurements. Feature weights were determined for each treatment by regressing post-treatment HbA1c against all features. During the model training, for each patient visit, the algorithm found k most similar patient visits based on weighted Euclidean distance under each treatment regime. Then mean HbA1c of those k patient visits under each treatment regime were calculated and the regime with the lowest mean HbA1C was recommended by the algorithm. The algorithm was also validated in a testing dataset and similar performances were obtained.

Conclusion: Among 41,758 patient visits, the predicted mean post-treatment HbA1c under our prescriptive algorithm was lower than that of standard care by 0.24 ± 0.01% (P < 0.001) (Table1). The patient visits with HbA1c ≥7.5% benefited the most from the predicted treatment plan, where post-treatment HbA1c was 0.37% lower than standard care. All the other subgroups also had significant reduction in predicted post-treatment HbA1c. For patients visits under some form of insulin treatment, our algorithm found that prescribing both insulin and metformin could more effectively reduce HbA1c. Our algorithm also confirmed that for patients under some form of insulin therapy, switching to treatment without insulin on average led to a suboptimal glycemic control. For patients visits without insulin, metformin was predicted to be the most effective in reducing HbA1c.

In Figure1, each cell in the figure represents patients for whom the prescriptive algorithm recommended switching from the regimen on the vertical axis to the regimen on the horizontal axis, labeled with the number of patients who made that switch. (METO: metformin alone; INSO: insulin alone; OTHO: other drug alone; METINSO: metforimin+insulin; MET1: metforimin+other(1); INS1: insulin+other drug(1); METINS1: metforimin+insulin+other drug(1); MULTI: other drugs (>=2))

1Cedars-Sinai Health System, Los Angeles, CA

Introduction

In 2015, the National Institute of Standards and Technology (NIST), in partnership with the Office of National Coordinator (ONC), provided a grant to Cedars-Sinai to use standards-based technologies to pilot the creation and use of federated identities in healthcare to access multiple distinct Health Provider Organization (HPO) Electronic Health Record (EHR) systems. We developed Single Federated Identity Login to EHRs (Single-FILE), which supports an identity ecosystem in healthcare through federated identity broker services. Key attributes are that the federated identity can be pseudonymous (i.e. allow use of a social identity such as Facebook, Google or other identity), provide single sign-on (SSO), support multi-factor authentication (MFA), and include privacy considerations in the architecture from the onset.

Design and Implementation

Single-FILE has a hub and spoke architecture that provides identity, authentication, and authorization broker services. Until EHRs include this functionality, it requires deployment of an identity server (IdS) at each HPO that is delivered as a Docker container. A Single-FILE user selects a social credential (Google or Facebook) or one issued by Single-FILE to be used as a federated identity for SSO. The user provides a partial Social Security Number, zip code, and data of birth that Single-FILE uses to query the EHR system for a match. Once a match has been found, a One-Time Passcode (OTP) is sent to the phone number registered in the EHR. Upon acknowledgment of the OTP the federated identity is bound to the user’s EHR identity. This process is repeated for each EHR. An important component of Single-FILE is a Trust Framework, which is critical to the acceptance of a federated identity. This framework, a legal, multi-party agreement, specifies the required roles, responsibilities, legal requirements, and conformance standards for each participating HPO.

Identity proofing assurance levels (IAL) are essential when using a federated identity. NIST IAL standards1 for non-healthcare specific domains range from IAL-1 (least assuring) to IAL-3 (most assuring). IAL-2 requires resolution, validation, and verification of government issued photo identifications with validation against the issuer’s database. Since this is not feasible in healthcare operations, we proposed the use of historical transaction data through the trusted referee mechanism provided by NIST IAL standards to attain IAL-2 status.

Single-FILE allows users to perform an identity verification step via an OTP to bind a digital identity with an IAL-2 proofed identity from an HPO. This has been deployed at Cedars-Sinai and the California Rehabilitation Institute as a proof-of-concept and will allow patients to access EHR data at both HPOs using a single federated identity.

Conclusion

Single-FILE’s identity ecosystem model allows HPOs to serve as a “trusted referee” to confer IAL-2 status to user digital identities they have created. Another potential benefit is to provide a monitoring system that could help detect fraudulent activity and improve awareness to the patient of potential misuse. During the development of Single-FILE, Apple’s Health App and Epic’s Happy Together were released. These provide partial solutions for patients with multiple HPO accounts, but still lack key features of a true federated identity that can decrease both the maintenance burden and the security/privacy risk for users.

Detection of Opioid Overdose Cases from Electronic Health Records: A Pilot Study using Data Collected from the MIMIC III Database

Alfred Sorbello, DO, MPH\textsuperscript{1}, Rashed Hasan, PhD\textsuperscript{1}, Henry Francis, MD\textsuperscript{1}, Mitra Ahadpour, MD\textsuperscript{1}

\textsuperscript{1}US Food and Drug Administration, Silver Spring, MD, USA

Introduction:
In this pilot study, we assess three traditional approaches to detect opioid overdose cases from information recorded in the Medical Information Mart for Intensive Care III (MIMIC III) electronic health record (EHR) database\textsuperscript{1}.

Methods:
The three methods assessed are: (1) International Classification of Diseases, Ninth Revision (ICD-9) code algorithms, (2) keyword searches of free text narratives using SQL queries, and (3) natural language processing (NLP) using NLTK-python library with clinically relevant keywords/phrases and negation as defined by a clinical expert. Consecutive pre-validation cases were manually assessed by a single reviewer as suspect, probable, or confirmed opioid poisoning cases based on the CDC case definition\textsuperscript{2}.

Results:
As shown in Table 1, the highest numbers of probable or confirmed cases were identified with ICD-9 codes. Keyword searches retrieved numerous pre-validation cases, but with many false positives. NLP and keyword searches detected cases not identified with ICD-9 codes.

\textsuperscript{*}ICD-9 opioid poisoning diagnosis codes (965.00, 965.01, 965.02, 965.09), E codes for accidental poisoning (E8500, E8501, E8502), undetermined intent (E980.0 - E980.5), and self-harm/suicide (E950.0-E950.4). Keyword Facet A - Opioid Drug Facet: heroin, methadone, oxycodone, oxycodin, codeine, suboxone, hydrocodone, MS Contin, hydromorphone, morphine, buprenorphine, dolophine, tramadol, ultram, tval, fentanyl, actiq, duragesic, buprenex, permocet, vicodin, loricit; Facet B - Opioid Term Facet: opiate, opioid, opiates, opioids, opioid pain meds, opioid pain medications, opioid drugs, narcotics, narcotics, pain meds, pain medications; Facet C - Overtone Facet: overdose, overdosed, excess, excessive, too much, intoxication; Facet D - Benzodiazepine Drug Facet: clonidine, klonopin, alprazolam, diazepam, valium, clonazepam, temazepam, ativan, Xanax, zolpidem, benzodiazepines, benzo, benzos, chloridiazepoxide, Librium, chlorazepate, traxene, estazolam, prosom, flurazepam, alprazolam, oxazepam, serax, Restoril, triazolam, halcinon, quazepam, doral; PreV = pre-validation; NLP = natural language processing; NA = not applicable; *other keywords/phrases: alcohol, smoking, depression, history of polysubstance abuse.

Conclusions:
When combined with ICD-9 codes, extracting information from free text in EHRs augments opioid overdose case detection. Future work explores EHR phenotyping using supervised machine learning for case ascertainment.

A structured approach to working with wearable health data: lessons learned from the University of Chicago IBD biosensor study
Philip Sossenheimer, BA; Olivia Yvellez, BA; Anoop Mayampurath, PhD; Samuel Volchenboum, MD, PhD; MS; David T Rubin MD
University of Chicago, Chicago, Illinois

Problem:
In recent years there has been increased interest in the use of commercially-available wearable devices as a means of passive patient monitoring in inflammatory bowel disease (IBD). These devices can collect and store patient data, including steps, heart rate (HR), and sleep metrics that could be useful for passively monitoring patients. Previous studies using wearable devices suggest that patients with IBD have decreased physical activity and poorer sleep quality compared to healthy controls, however data collected from wearable devices have not successfully been leveraged to predict disease status in IBD patients. Here we report preliminary results and lessons learned from our study investigating the utility of wearable health devices in monitoring IBD.

Methods:
Patients in the IBD clinic at the University of Chicago were enrolled in an IRB-approved observational study. Each participant was given a Fitbit (Charge or Alta HR, San Francisco, CA) and installed software to collect the wearable data as well as IBD-related survey questions (Litmus Health, Austin, TX). Clinical and demographic data were captured from patient medical records and stored in a Research Electronic Data Capture (REDCap) database. The predictive ability of biosensor data for disease activity was determined by comparing Fitbit metrics from the week before a disease activity assessment between patients with active or quiescent disease, and calculating the AUC for each metric. Multivariate logistic regression was performed with five-fold cross validation to assess the predictive ability of the biosensor data for disease activity.

Results:
So far 189 patients have been consented and enrolled in the study. Patients tended to be male (n = 100, 52%), white (n = 170, 90%), and young (median age = 37, IQR = 28-47). Compliance with the biosensor was 47.9% (IQR 17.0-88.0%) during the day, and 29.1% (IQR 8.4-60.7%) during the night. Our multivariate model including steps, resting heart rate, and basic clinical characteristics had an AUC of 0.72 for predicting disease activity, with an overall accuracy of 67%.

Research Challenges and Lessons Learned:
One of our main challenges was ensuring good compliance (percent of days with recorded Fitbit data) while wearing the device for an extended period. To improve compliance moving forward, we have updated our application to include a real-time data feed, allowing us to proactively contact patients who are not wearing their device by telephone. Although we have had moderate success in predicting disease activity, we believe our results could be improved by establishing baseline characteristics for individual patients during times of objective disease remission (as established by endoscopy or serum/stool markers) and evaluating how changes from that baseline correlate with changes in disease symptoms.

Conclusions:
Wearable health devices offer significant opportunities for improved patient monitoring. Researchers interested in studying the utility of these technologies should consider ways to ensure study compliance, clearly define study outcomes from the outset, and have a clear strategy for data analysis.
Toward large-scale management of clinical quality dashboard visualizations: The Performance Summary Display Ontology

Cooper Stansbury1, Colin Gross2, Veena Panicker2, BDS, Zach Landis-Lewis, PhD, MLIS2
1University of Michigan Dearborn, Dearborn, MI; 2University of Michigan, Ann Arbor, MI

Introduction

Efforts to create and maintain clinical quality dashboards and reports are often siloed, making it hard to study the general conditions under which a particular visual artifact is useful for improving clinical practice. We propose a Performance Summary Display Ontology (PSDO) as a formal computable model for describing graphical, structural, and theoretical characteristics of information visualization artifacts. We designed and built PSDO as part of a learning health system to study when, where, and how different visual artifacts can aid in quality improvement communication to healthcare professionals and teams. Our representation of visualization artifacts is intended to be broadly generalizable while accounting for the need to represent granular differences between displayed attributes such as color, spacing, and semantic content. We believe that the use of ontology to manage knowledge about information visualizations enables not only closer scrutiny of design choices as they relate to outcomes, but also the ability to facilitate information interoperability between visual artifacts in healthcare organizations.

Methods

Using Basic Formal Ontology (BFO)1 and The Open Biological and Biomedical Ontology (OBO) Foundry best-practices, we developed easily extendable design paradigms to represent information visualization with regard to domain-specific semantics. By building on the high-level representational structures described by Zhang2 and Munzner3, we defined classes representing core components of visual artifacts and their relations. Through iterative content analysis of dashboards and reports; discussion with healthcare professionals, healthcare administrators, visualization designers, and programmers; and application of visualization theories2,3, we identified universals relating to content-type, physical design, display-type, and mutable physical properties.

Results

The representation in PSDO extends OBO Foundry ontologies concerning information artifacts (IAO) and statistical visualization artifacts (STATO) to represent visual artifacts in terms of their qualities, dimensionality, type, and sets of granular components (‘marks’). We represent the qualities and emergent properties of individual marks and mark aggregation in terms of their semantic content: a) performance measures, b) entities ascribed a performance, c) performance, and d) time intervals. Importantly, by representing the semantic content of a display at various levels of granularity, we allow for management and retrieval of artifacts about a particular entity dependent on other query constraints. By representing visualizations with greater generalizability and deeper granularity in an ontology, we enable retrieval of artifacts dependent on a variety of graphical and theoretical conditions. PSDO contains the building blocks for large-scale visual artifact management without sacrificing graphical ‘fitness for use.’

Conclusion

There is a need to manage knowledge about visual artifacts, even within a single healthcare organization, such that the effects on communication of the visual artifacts can be better understood. By strengthening ontological representation of information visualizations, we believe that we can contribute to (1) better access and management of artifacts, subject to constraints at different levels of specificity, and (2) a foundation for learning health systems that enable humans and computers to leverage each other’s respective strengths in order to understand how, why, and when different visualizations are effective.

Patient-Centered Care Team Communication and Coordination Tools in a Pediatric Ambulatory Cancer Care Center

Daniel Stein, MD, PhD, Eugenia Kim, MS, Keri Martin, Jennifer Kim, Aaron Ostrovsy, MPH, You Chung Jr, MSN, RN-BC, CCRN-K, Melissa Zimmermann, MS, BSN, RN-BC, Tham Nguyen, MSN, Eric Schmitz, Christina Ward, MBA, Maritza Rosa, MPH, Gregory Jordan, MaryAnn Connor, MSN, RN-BC, CPIM, Jan, Julianne Ruggiero, MSN, CPNP, Rachel Bright, BSN, RN, CPHON, Jill Ackerman, MBA, Farid Boulad, MD, Peter Stetson, MD, MA
Memorial Sloan Kettering Cancer Center, New York, NY

Introduction

Interest in care coordination has increased steadily over the years both as a means of improving patient outcomes and decreasing costs. Effective communication and coordination of care has been established as one of six National Quality Strategy priorities by HHS, and care coordination initiatives have been estimated to result in $240 billion in savings by the Institute of Medicine.1,2 At Memorial Sloan Kettering (MSK), our Pediatric Ambulatory Care Center (PACC) sees approximately 100 patients/day for outpatient oncology services, and the clinical team consists of over 100 members including physicians, advanced practice providers, nurses, nursing assistants, patient care techs, care coordinators, social workers, pharmacists, and child life therapists. The PACC leadership observed challenges in care coordination in this setting, and therefore sought to improve team member identification and communication efficiency by collaborating with our Informatics teams to implement two new digital tools into the PACC workflow.

Methods

Two new tools were introduced in the PACC: 1) A secure text messaging app for clinician communication accessed via smartphones and computer workstations; 2) A custom-developed tool for care team assignments, which integrates with the electronic health record (EHR), allows staff to view and update members of a patient’s care team, and includes features such as routing messages via the secure text messaging platform. Implementation planning and go-live of these tools were completed in multiple phases. A project team was formed, and an analysis was conducted of the current PACC workflows to assess potential impact and desired integrations, after which a series of development and configuration efforts were performed and tested. Scheduled training sessions followed prior to go-live, which occurred in two phases, the first in October 2018 with the care team tool and the second in December 2018 with the secure texting app. System audit data was collected for two months after implementation to evaluate usage in terms of team assignments made, secure messages sent, and the roles of the individuals taking these actions.

Results

For each of the two months, nearly 2,000 care team assignments on patients with visits in the PACC were made, and approximately 7,000 secure messages were sent among staff associated with the PACC. Data collected from system audits demonstrated that a diverse set of staff consistently used the secure texting app and the care team tool, with nursing showing the highest activity for both tools. The functionality to send secure messages directly from the care team tool was utilized with the highest volume of directed messages being those from nurses to advanced practice providers. Preliminary analysis of user surveys showed the tools were easy to use and useful in coordinating care.

Conclusion

Preliminary feedback from the PACC teams indicate that providing a tool for secure, closed-loop communication and a mechanism to easily identify a patient’s care team members has been beneficial for team coordination, patient flow, and patient care. Further studies involving user surveys and analysis of audit and EHR data are underway to evaluate usage of the tools over time and impact on clinical workflow and patient outcomes.

Use of Information Visualization to Enhance HIV-Related Clinical Interactions

Samantha Stonbraker, PhD, MPH, RN1,5, Carmela Alcántara, PhD2, Silvia Amesty, MD, MPH, MSEc1, Maureen George, PhD, RN, AE-C1, Ana F. Abraído-Lanza, PhD1, Mina Halpern, MPH5, Suzanne Bakken, PhD, RN1, Rebecca Schnall, PhD, MPH, RN-BC1

1School of Nursing, 2School of Social Work, 3Vagelos College of Physicians and Surgeons, Columbia University, New York, NY, 4College of Global Public Health, New York University, New York, NY, 5Clínica de Familia La Romana, Dominican Republic

Introduction

Information visualizations (infographics) can enhance clinical communication related to chronic conditions. The purpose of this study was to assess the feasibility of using infographics during clinic visits to improve communication and subsequently, health outcomes in persons living with Human Immunodeficiency Virus (HIV) (PLWH).

Methods

In preliminary work, content for infographics was established with a rigorous triangulation methodology; then, an iterative participatory design methodology that included PLWH, health care providers, and visualization experts was used to develop infographics.1 For the current study, we are using a pre-test post-test design to explore feasibility of infographic use during clinic visits at a primary care clinic in the Dominican Republic. Initially, two physicians were trained to use laminated, paper-based infographics to convey health information during visits, then we enrolled 50 adult PLWH who receive the intervention at baseline (3-, and 6-month visits). At each visit, primary outcomes of CD4 count and viral load are extracted from participants’ records and participants complete questionnaires at baseline, 3-, 6-, and 9- month visits that include demographics and six secondary outcomes: HIV-related knowledge, engagement with clinician, satisfaction with provider and the clinic, self-efficacy to manage HIV, adherence, and health related quality of life. Outcomes were selected based on the pathways through which communication can improve health outcomes identified by Street et al.2 and measured with scales previously validated in Spanish. Descriptive statistics of demographics were calculated and means/standard deviations established for each measure at each time point. Mean changes between scales were determined for each time point of continuous variables using paired t-tests and Chi-square and Fisher’s exact tests for categorical variables. Alpha for significance was .05 for all tests. Data collection for final follow up visits is planned for August 2019.

Results

Participants (N=50) are predominantly female (56%), with a mean age of 40.4 years (SD ± 10.6) and have been living with HIV for a mean of 6.3 years (SD ± 6.1). For preliminary analysis, mean differences in scores between baseline and 3-month visits were calculated for the 47 participants who completed both visits. The mean CD4 count decreased from baseline (377.2 ± 273.5) to 3-months (372.8 ± 246.8) as did mean viral load from baseline (89,650.8 ± 245,218.4) to 3-months (84,861.3 ± 245,422.5) though neither change in primary outcome was significant. Participants’ HIV-related knowledge statistically significantly increased from baseline (7.9 ± 2.2) to 3-months (10.0 ± 1.4) (95% CI, 1.4 – 2.7). The engagement with provider scale scores statistically significantly decreased (as desired) from baseline (14.9 ± 3.5) to 3-months (13.3 ± 1.0) (95% CI, 0.49 – 2.60). Pain intensity also statistically significantly decreased from baseline (1.3 ± 2.3) to 3-months (0.27 ± 1.2) (95% CI, 0.50 – 1.84). Remaining secondary outcome measures showed improvements in mean scores between time periods, some with statistically significant changes.

Conclusion/Discussion

Information visualization is a key informatics approach. Preliminary data show infographic use during clinic visits is a feasible method to facilitate HIV-related communication and is associated with improvement in patient outcomes.

Applying SNOMED CT Concepts to CPT Codes: Enabling Consistent Queries for Health Services Researchers, and Specialty-specific and Visit-specific Views of Patient Information

Norman E. Stone III MD1, Carol A. Bean PhD, Thomas J. Neal MD MPH1, Karl J. Stiller PharmD, David F. Schmidt MD3, Andrew J. Holdaway MD2, Lauren C. Thompson, PhD1

1 DoD/VA Interagency Program Office, Rosslyn, VA 2 Defense Health Agency, Falls Church, VA 3 Veterans Health Agency, Washington, DC

Introduction & Background
The American Medical Association’s (AMA) Current Procedure Terminology (CPT)1 is the primary standard for categorizing healthcare services, from outpatient office visits and telephone calls, to inpatient rounding and surgery. The Category I CPT section consists of 9,314 5-digit numeric codes and descriptions structured in a flat, 2-level, hierarchy. This structure groups related procedures along one axis of description, typically a base procedure. Although closely-related procedures appear sequentially – e.g. knee replacement procedures – other groupings of procedures are difficult to identify – e.g. all major joint replacement procedures. Some of the most important questions about the operations of health institutions require grouping procedures around these broader dimensions of relationship.

The purpose of this study is to demonstrate the utility of applying descriptive concepts from the Systematized Nomenclature of Medicine Clinical Terminology (SNOMED CT)2 to CPT codes for improved relating of CPT codes along multiple dimensions of relationship. The intent is to (a.) provide a model for improving standardization of queries by health services researchers and health system operations officers, and (b.) to enable specialty-specific and appointment-specific views of patient health data.

Materials & Methods
The 2018 AMA CPT was reviewed and a selection of orthopaedic surgery-related codes was identified. Each CPT code and long description were analyzed and matched to a single SNOMED CT concept3 (Axis 1). The CPT Code’s long description was then segmented into atomic concepts that were each mapped to SNOMED CT concepts (Axis 2). Synonyms were identified and mapped to SNOMED CT concepts (Axis 3). The long description was then reviewed and additional SNOMED CT concepts were applied, including anatomic region (Axis 4), medical specialty involved (Axis 5), location the procedure is performed, implant or graft required, etc. (Axis 6). See Figure 1.

Figure 1: Model

Results
86 CPT codes and long descriptions were analyzed. Figure 2 demonstrates an example for CPT code 27447.

Figure 2: Example

27447

Conclusion
Applying SNOMED CT concepts to CPT codes is feasible and adds useful information for health services researchers. It enables association of related CPT procedures stored in non-adjacent regions of the CPT value set. If extrapolated to other standard terminology sets, this approach can enable specialty-specific and appointment-specific views of patient health data, in turn leading to improved clinical efficiency and safety.

Accelerating Self - Service Analytics and Rapid Data Exploration using a Custom Tableau Web Data Connector (WDC) to REDCap

Olga Strachna, MS1, Alexander J. Tanchoco2, Stuart M. Gardos3, Wazim Narain, PhD1, Peter D. Stetson, MD, MA1
1 Division of Health Informatics, 2 Information Systems; 3 Memorial Sloan Kettering Cancer Center, New York, NY

Introduction/Background
REDCap is becoming widely used within the healthcare domain as a tool to capture structured, abstracted data from the electronic health record for use in clinical research1. As of today, there are over 895K users spread across 3342 institutions working on 653K projects2. Similarly, Tableau analytics software is seeing an adoption increase within healthcare organizations around the world. It offers the ability to seamlessly connect and integrate over 100 native data connectors as well as generic Open Database Connectivity (ODBC) interfaces and custom developed Web Data Connectors (WDC) which utilize Application Programming Interfaces (APIs) to extract data from applications3. As healthcare organizations become more data driven, there’s an increasing need to integrate multiple sources of data to model care pathways, streamline healthcare operations, and simplify the decision-making process. Currently, the analytics cycle from data request to dashboard completion can take approximately 1 to 2 months’ time depending on the project complexity. Our goal was to develop a secure, scalable, self-service analytics framework allowing users to access patient data quickly with the ability to ask questions in a straightforward plain text format. This allows for rapid data exploration by end-users to develop hypotheses without any coding.

Methods
We developed a secure, user-friendly, custom, production ready Tableau WDC to seamlessly connect to REDCap project data with the ability to integrate data from diverse data sources such as our data warehouse, Hadoop clusters or Splunk for real time system audit log data, as examples. In addition, we developed a self-service analytics framework for publication of governed data sources and utilizing them within the Tableau Server 2019.1 new Ask Data feature, shown in Figure 1. The Ask Data feature allows for rapid discovery and hypothesis generation by using simple human friendly question format as the interface to ask a question.

Results
As depicted in Figure 2, the analyst user can seamlessly log-in to REDCap through the WDC using their network credentials via single sign-on. This eliminates the need to manage multiple passwords or the need to look up complex API keys generated by the REDCap system. The analyst user is then allowed to view only their projects and inspect the data fields available for importing. With one click, the service securely loads all the project data into a Tableau Data file where they can further integrate numerous other data sources to create one curated data set for the analysis. This mechanism reduces the manual data entry needed to be done in REDCap systems given that the data is available in structured format elsewhere. Once published to the Tableau server, the clinical or administrative end-user can explore the data visually and rapidly without the need for any coding or backend expertise on data preparation or integration.

Conclusion
With the increase in variety, volume, and variability of data available within the healthcare domain, it’s imperative to allow clinicians and researchers to have the ability to rapidly explore their patient’s data to identify patterns in clinical care operations or patient outcomes over time. Working side by side with data analytics experts during the initial discovery phase is key to formulating a well-structured dataset. Allowing users to have direct access to their requested dataset opens the door for hypothesis development and quick insights into the data. Integrating clinical research databases such as REDCap with structured EHR, operational or administrative databases creates unparalleled opportunities for precision medicine analytics projects, where EHR data is augmented with richer data abstracted into REDCap databases. Lastly but not least, having a data governance framework and working side by side with data experts is key for the success of data driven clinical operations and research projects. Employing a data governance framework, allows for generation of high quality and robust datasets accessible for data driven projects within the clinical domain while maintaining privacy and security compliance as required by HIPAA regulations. This mechanism applies to all types of projects within any clinical domains and specialties that utilize multiple sources of information to analyze data and derive insights.

Initial findings of embedding safety alerts in a psychiatric electronic health record system

Gillian Strudwick, RN PhD\textsuperscript{1,2}, Jane Paterson\textsuperscript{1,2}, John Fernandes\textsuperscript{1}, Kimberly Hunter\textsuperscript{1}, Sheldon Hubert\textsuperscript{1}

\textsuperscript{1}Centre for Addiction and Mental Health, Toronto, Ontario, Country, Canada; \textsuperscript{2}University of Toronto, Toronto, Ontario, Canada

Abstract

Ensuring clinicians are aware of safety risks associated with caring for individuals with a high risk for violence is required by law in some jurisdictions. This is done to allow clinicians the opportunity to prepare and plan for encounters with patients that are safe for all involved. This poster will provide the initial findings of embedding safety alerts in a psychiatric electronic health record system that communicates potential safety risks to clinicians.

Introduction

Ensuring psychiatric clinicians are aware of safety risks associated with caring for individuals with a high risk for violence and aggression is required by law in some jurisdictions. This is done to provide psychiatric clinicians the opportunity to prepare and plan for encounters with patients that are safe for all involved.\textsuperscript{1} One way of communicating potential safety risks to psychiatric clinicians is to embed alerts or ‘pop ups’ into the electronic health record system. In this case, when a clinician opens the record of a patient who has been identified as having a high risk for a safety related incident, an alert is generated for the clinician providing the necessary alert information. The purpose of this poster is to provide the initial findings of embedding safety alerts in a psychiatric electronic health record system. This poster will provide: 1) information related to the nature and number of safety alerts generated during the evaluation period, 2) perspectives of clinicians related to their behavior once viewing a safety alert, and 3) information related to the change in safety related incident reports before and after the implementation of the safety alert system.

Methods

This poster provides an overview of a study conducted at the Centre for Addiction and Mental Health in Toronto, Canada. Ethical approval was obtained. A safety alert system was developed, and embedded in the organization’s electronic health record system. Safety alerts included aggression/violence, sexual aggression, weapons, arson, as well as two non-safety related alerts which were letter of trespass and unauthorized leave of absence risk. A mixed methods evaluation was completed with data obtained from focus groups (n=6), the organization’s incident report system and the organization’s electronic health record system. A thematic analysis was conducted of the focus group transcripts, and descriptive statistics were generated for the information extracted from the organizational systems.

Results

During the 1 year evaluation period, 90 safety alerts were generated. On average, 7.5 safety alerts were initiated each month, with the majority of these being related to aggression/violence. During the same period, 3,381 unique patients were provided care at the organization. Not all clinical areas of the organization used the alerting functionality, however the clinical area with the most alerts initiated 12 over the course of the evaluation period. With regards to clinician perception of the alert functionality, it was reported that when safety alerts were present, clinicians used extra vigilance when interacting with these individuals. It was also reported that since the alerts were used sparingly, no alert fatigue had occurred. With regards to the safety related incidents for those individuals with safety alerts present, there was a decrease in the number of incident reports for most (n= 55, 61%), and an increase in the number of reports for a smaller number (n=25, 28%). Tables and graphs that depict the study results will be present on the poster. A limitation of the study is the use of incident reports, since these are voluntarily initiated.

Conclusion In conclusion, embedding safety alerts in electronic health record systems may be one strategy to support improved levels of safety in psychiatric clinical environments, however more robust and further evaluation is required.

Mapping Unstructured Diagnoses to ICD10 using Natural Language Processing and Web-Scraping
Theresa C. Sudaria, MS, Nam Nguyen, MS
Veradigm, San Francisco, CA

Introduction
Historic problem list data from the Allscripts ambulatory EHR data set has a high volume of free-text, unstructured text. Structuring problem list data into ICD10 codes facilitates downstream analysis. However, manually mapping free-text to ICD10 codes is a labor-intensive and time-consuming process because of the number of ways a concept can be expressed in free text. Natural Language Processing (NLP) techniques have been used with similar mapping problems that need to evaluate text similarity. Web search engines are also a useful tool to map free-text. Here, we develop an automated mapping approach using natural language processing (NLP) techniques and web-scraping of a search engine.

Methods
Problem list data from deidentified Allscripts ambulatory EHR data were used that included a subset of free-text problems that were previously mapped to ICD10. The already-mapped problems were used as a training set (576,898 problems), and subset of unmapped free-handed diagnoses were used as a test set (2000 free-text problems). For preprocessing, each of the words were lowercased, with punctuation removed, and normalized using NLTK’s WordNetLemmatizer. We performed a Bing search using python packages (BeautifulSoup and requests) with the unmapped free-text problem concatenated with the string “ICD10” as the search parameters. Regular expressions were then used to find the last occurrence of ICD10 category within the first 10 web URL strings returned. The 2 most frequent ICD10 categories were retained. Next, the training set was subsetted by ICD10 category. To compare these train set descriptions to the unmapped diagnosis, Sci-kit Learn’s TFIDFVectorizer converted the descriptions into numeric arrays, based on term frequency and rarity of words, and Sci-kit Learn’s cosine similarity returned the similarity between these arrays by measuring the cosine of the angle between them. Lastly, numpy’s argmax function found the result with the highest confidence score. To speed up the process of mapping thousands of descriptions we used a python package (multiprocessing) to use half the cores in the machine.

Results
We obtained 83% accuracy on ICD10 mapping of the test set. For the items that were matched correctly, the mean confidence score was 98.8% with a standard deviation of 4.9%. For the items that were not matched correctly, the mean confidence score was 95.0% with a standard deviation of 12.1%. When we only accept imputed ICD10 codes with confidence scores of 0.9 or higher, we boost our accuracy to over 95% while retaining 86% of our mapped codes. 59% of records with confidence scores lower than 0.9 were actually mapped correctly.

Discussion
By scraping the web for the category codes before using NLP techniques, we solved the problem of finding all variations of medical acronyms and misspellings. For diagnoses that have the same acronym, it returned the most likely, common diagnosis. It also helps us know which words to emphasize. For example, when comparing “humerus fracture, initial encounter” to “humerus fracture” or “scapula fracture, initial encounter”, web scraping knows to emphasize “humerus” instead of the words, “initial encounter”.

Conclusion
This mapping tool can be effective to improve historical data in diagnosis datasets. Currently, the algorithm fails when a provider abbreviates a rare disease that shares the same acronym for a more common disease. For future work we would explore clustering methods which would categorize diagnoses, acronyms, and words commonly used by differing provider specialties to improve precision and accuracy.

IRB Policies Around Initial Contact for Targeted Research Recruitment at Academic Medical Centers: A Preliminary Report

Dawn E. Sugarman, PhD1,2, Alisa B. Busch, MD, MS1,2, Jeanhee A. Chung, MD2,3, P. Pearl O’Rourke, MD2,4  
1McLean Hospital, Belmont, MA; 2Harvard Medical School, Boston, MA; 3Massachusetts General Hospital, Boston, MA; 4Partners Healthcare Systems, Boston, MA

Introduction. The identification of and outreach to patients has become easier as research use of electronic health records (EHR) increases. The potential for high-volume, targeted recruitment requires a re-examination of institutional policies regarding initial contact. The goal of this research was to learn how academic medical centers (AMCs) currently manage initial recruitment contact requests from researchers; specifically, how often a clinician known to the patient had a role in that initial contact and how often a researcher (unknown to the patient) was allowed to directly contact without involving a known clinician.

Method. A brief survey was sent to Institutional Review Board (IRB) chairs at AMCs comprising the top 50% of 2018 NIH funding (N=34). The survey asked respondents to consider the different ways that initial contact with patients with either: (1) asthma or (2) depression, as determined by medical chart review, would be permitted. For respondents who indicated that researchers may contact patients directly, we explored if and how patient permission to be contacted directly was ascertained with follow-up qualitative interviews.

Results. Survey response rate was 68% (N=23; U.S. Region: 35% West, 26% South, 22% Midwest, 17% Northeast). For each scenario, respondents could select more than one response. In both scenarios, 44% (n=10) allowed researchers to contact the patient only after a clinician introduced the study to the patient (Figure 1). 48% (n=11) of the AMCs allowed researchers to contact patients directly with no involvement of a clinician for the asthma scenario; fewer allowed this type of contact for the depression scenario (n=8, 35%).

![Figure 1. Type of contact by scenario (asthma vs. depression, N=23).](image)

The AMCs that allowed direct research contact approached patient permission in a variety of ways (Table 1). Four qualitative interviews were completed with institutions that allow direct contact (36%) and revealed that approval for direct contact was determined on a study-to-study basis by the local IRB.

<table>

<tr>
<td>Patients are contacted directly by default, but can opt out from future direct contact</td>
<td>5 (46%)</td>
<td>4 (50%)</td>
</tr>
<tr>
<td>Patients are contacted directly and may not opt out from future direct contact</td>
<td>4 (36%)</td>
<td>2 (25%)</td>
</tr>
</tbody>
</table>

Table 1. Method of contact for AMCs that allowed direct contact

Conclusion. Although preliminary and limited by low response rate, the results of this study show that nearly half of the AMCs allowed researchers to directly contact patients without the involvement of a treating clinician; however, this number was lower for studies involving sensitive diagnoses. As EHRs make it easier for researchers to identify patients for recruitment and demand rises from the research community to make it easier to reach out to these patients, institutions will need to re-examine their policies that support recruitment efforts, while being sensitive to patient expectations and privacy.
Plausible links from soil nutrients to human diets and obesity

Walton Sumner
University of Missouri, Columbia, MO

Introduction. Malnutrition is a major global public health problem comprising two broad syndromes, undernutrition and obesity. Undernutrition generally involves gross nutrient deficits with obvious clinical manifestations. Overweight and obesity require a surplus of calories, but also often involve subtle deficiencies of other nutrients. Human malnutrition could result from soil chemistry, crop selection, processing, and malabsorption. In fact, trace element deficiencies (e.g. Mg, Zn) have become common in soils and people worldwide. Plant, fungal, and bacterial vitamin synthesis pathways include many enzymes that use trace elements as cofactors. Therefore, soil trace element deficiencies might create predictable vitamin deficiencies in crops, and malnutrition in people.

Scott-Boyer, et al, linked multiple bioinformatics databases to identify relationships between 15 human diseases and 22 enzyme cofactors (13 vitamins and 9 trace elements). Obesity-related vitamins were B2, B3, B5, and C; bipterin; glutathione; and heme. The most strongly related element was Mg: others were Ca, Fe, Fe-S, Mo, and Zn. This study used the same databases to direct crop studies exploring how soil chemical balance might link to obesity.

Methods. KEGG synthetic pathways identified enzymes for steps from non-limiting precursor molecules to obesity-related vitamins. KEGG links to the Brenda enzyme database, which identifies vitamin and metal ion cofactors. Manual review of KEGG and Brenda records permitted tabulation of each vitamin’s typical synthesis steps and cofactor requirements, and, for each distinct element, the number of element-favoring steps (many enzymes favor Mg, but can use alternative divalent cations, like Ni). Separately, amaranth was grown on experimental farm plots managed conventionally (nitrogen fertilizer; moderate Mg deficit) versus with deliberately balanced soil nutrition (including adequate Mg). Seeds were analyzed for trace elements; vitamins B2, B3, and B5; and available calories.

Results. Mg is a favored cofactor in one or more steps in the synthesis of 7 of the 8 obesity-related vitamins (heme synthesis allows either Mg or Zn at one step). Three syntheses require Zn. Vitamin B6 is required for B5 and heme synthesis, but it has no definite dependencies. Amaranth seeds grown on nutrient balanced soils had higher K, Mg, and Mo compared to seeds grown on conventionally managed soil; lower Cu, Mn, Ni, and Zn; and nearly identical caloric density. Trends for higher B2, B3, and B5 synthesis in balanced soil were not statistically significant.

Conclusion. Biosynthetic pathway data suggested that crop content of 7 obesity-related vitamins could follow Mg in soil, and 3 could follow Zn. However, farm soil chemistry affected trace element content of amaranth seeds more than B vitamin content. Trace element deficiencies in farm soils could be causally related to obesity by one or more of at least three mechanisms: (1) Element deficiency (and perhaps related vitamin deficiencies) could impair function of obesity-related gene products; (2) “Hidden hunger” for essential nutrients (elements, vitamins, or essential amino and fatty acids) could drive excess calorie consumption while impairing functions dependent on the deficient nutrient; (3) Increased consumption of one or more alternative cations could have a toxic effect, e.g. Cu or Ni interfering with mitochondrial function. Food processing may further add and subtract nutrients, and increase calories, potentially relieving or exacerbating soil-related imbalances. Similar analyses may suggest soil connections for other diseases and guide the rational design of disease-specific diets and nutrient supplements.

Refinement of Health Technology Tools Through Usability Studies

Teresa Taft, PhD¹, Chuck Norlin, MD², Heidi Kramer, PhD¹, Charlene Weir, RN, PhD¹
¹University of Utah, Salt Lake City, UT; ²University of Utah Health Sciences Center, Salt Lake City, UT

Introduction
Adoption of Health Information technology tools developed to support clinician’s information needs at the point of care is often low.¹ Clinicians caring for chronically ill, complex pediatric patients often have unmet information needs. The Medical Home Portal² (MHP) online pediatric medical home reference guide was created to serve clinician’s information needs, but has experienced limited usage since its deployment in 2008. The goal of this work was to employ usability assessment methods to identify issues and design solutions aimed at increasing adoption of the tool.

Methods
A 3-tiered usability evaluation was conducted: 1) heuristic assessment, 2) user observation; and 3) expert review. First the investigators conducted an evaluation of the MHP based upon Nielsen’s design heuristics.³ Second, investigators observed 6 pediatricians interacting with the MHP using a complex pediatric vignette. Each physician generated 3-5 of their own information needs in caring for the patient. “Think- aloud” protocols were used to record the user’s perspectives as they searched for the information in the MHP. Search tasks and usability issues were identified based on pediatrician comments and heuristic findings were confirmed. Finally, investigators and designers developed technically feasible solutions that were evaluated by 4 pediatrician experts, to focus improvements to the tool.

Results
Studies demonstrated that information pediatricians sought was available in the MHP but was often difficult to locate. A sample of targets, search strategies, issues with completing the task, and design solutions are described in Table 1.

Table 1. Targets, Search Strategies, Issues, and Design Solutions

<table>
<thead>
<tr>
<th>Target</th>
<th>Search Strategies</th>
<th>Issues</th>
<th>Design Solutions</th>
</tr>
</thead>
</table>
| Diagnosis module | - Typing diagnosis in main search bar.  
- Clicking 1st, 2nd, or 3rd header tab. | Some search result labels were misleading | Replace the search tool. |
| Information related to the diagnosis module | - Scrolling & scanning the diagnosis module page.  
- Clicking items in the diagnosis module side menu.  
- Clicking external links.  
- Clicking a tab in main header navigation bar.  
- Typing terms in page search bar. | Navigation tabs disappeared with scrolling.  
Users did not open nested lists.  
Links to some websites were not active.  
Hyperlinks within diagnostic modules sometimes led to information that was not specific to the diagnosis. | Correct the error in code.  
Remove nesting of lists by default.  
Allow user to nest.  
Regularly check for broken links and repair or remove them.  
Remove general links from diagnosis modules. |
| Information for caregivers | - Users searched through most areas of the website in looking for parent/caregiver information. | Search mechanisms varied across pages.  
Half of main header tabs clearly conveyed contents; half did not.  
‘Parent & Family’ pages were lengthy and written at a ‘very high’ reading level. | Adopt a uniform search display and method across all pages of the website  
Refine main header tab labels and content groupings.  
Refine ‘Parent & Family’ pages to reach a 6th – 8th grade reading level. |

Conclusion
Heuristic evaluation, a user study, and expert review were effectively combined to identify issues and design solutions for iterative refinement of the underutilized Medical Home Portal. This process may be useful in optimizing other underutilized medical information tools.

Privacy-preserving and non-intrusive video recognition technique to count the number of patient room visits during patient deterioration: a simulation study

Ahmad P. Tafti, PhD, Edin Cubro, Hongfang Liu, PhD, Brian W. Pickering, MB, BCh, Vitaly Herasevich, MD, PhD
1Division of Digital Health Sciences, Mayo Clinic, MN
2Department of Anesthesiology and Perioperative Medicine, Mayo Clinic, MN

Introduction

Video analytics and image recognition are on the rise outside of clinical practice, in many applications ranging from self-driving cars and remote sensing to robotics and augmented reality. Even as artificial intelligence and video recognition continue to evolve, we still do not see much of these technologies implemented at the bedside in healthcare. Using currently available frameworks for automatic video understanding, our broad objective is to extend computer vision to the clinical practice to shorten the time to and increase the reliability of recognition of deterioration in hospitalized patients. It is anticipated that computer vision applications will contribute data to optimize the performance of predication analytics. In addition data gathered may be used to augment EMR patient data that is intermittent and delayed in that setting. As a first step to construct and evaluate augmented computer systems, we performed a simulated experiment using an overhead door camera combined with a computer vision algorithm to test the hypothesis that this approach could reliably count the number of visits to patient’s room.

Method

Counting frequency of visitation at any given time, can be estimated based on the two major computer vision-based strategies: 1) The line of interest (LOI) where a camera is fixed on a virtual line, thus people crossing this line are counted; 2) The region of interest (ROI), in which people in certain regions are counted. In this contribution and for the sake of flexibility and generalizability to different environmental settings, we used the ROI-based method. The proposed pipeline of the system along with a sample input and output of the system are shown in the figure.

Result

For the experimental setup, we used three types of video cameras simultaneously, Sony RX0 (1080p), Sony Action Cam HDR-AS100V (720p), and Sony Action Cam FDR-X3000 (4Kp). We also captured the video streams on both 60fps and 30fps bases. To validate the robustness of the method, besides illumination changes, we asked our volunteers to provide some sort of challenges (e.g., stay at the gate, move their hands across the gate, etc.). Comparing the ground truth visitation frequency with those estimated by the algorithm, we can summarize the results as: 1) Using the 60fps basis, we achieved accuracy of 91.31% when the room light was on (470Lux) and 86.96% when the room light turned off (145Lux); 2) 4Kp and 1080p versus 720p resolutions did not change the results, where 720p speeds up the process and it needs less storage devices; 3) Using the 30fps video feed, we obtained accuracy of 82.61% when the room light was on and 78.27% when the room light turned off.

Discussion and Outlook

We have shown that it is feasible to implement privacy-preserving (using overhead camera only) and non-intrusive computational strategy (using RGB camera only) to reliably count the number of visitation to a patients room. This work opens research avenues for further qualitative and quantitative analysis to more efficiently identify patterns of visitation frequency to patients’ rooms, with anticipated applications including better healthcare delivery and documentation. As part of our ongoing works, we are utilizing supervised machine learning methods to recognize and classify visitors role by scrubs and clothes.
Implementing a System for Predicting and Notifying When Patients are At-Risk for Acute Physiologic Decompensation

Abdul A. Tariq, PhD¹, Rohit Chaudhry, MS¹, Natalie H. Yip MD², Kui Tang, MS¹, Ryan DeCosmo, BS¹, Ruchi Shah, MS¹, Robert A. Green MD¹, David K. Vawdrey, PhD¹,³

¹Value Institute, NewYork-Presbyterian Hospital, New York, NY, USA; ²Department of Medicine, Columbia University Irving Medical Center, New York, NY, USA; ³Department of Biomedical Informatics, Columbia University Irving Medical Center, New York, NY, USA

Introduction

Unanticipated patient decompensation affects patient outcomes and can prove fatal. In our institution, nearly 15% of all 2018 in-hospital deaths were “unanticipated” i.e. the medical team did not foresee this outcome. Early warning systems, based on patient acuity scores, have been proposed to identify such cases in advance, so that the medical team can intervene and potentially prevent adverse outcomes. In this study, we report on the development and deployment a mobile-phone-based Early Warning System (EWS) across five campuses of the NewYork-Presbyterian Hospital (NYP). Inspired by the RE-AIM framework for making informatics interventions successful, we provide best practices and lessons learned from our deployment (named “NYP EWS”) to guide other hospitals.

Methods

The NYP EWS is based on a measure of acuity from the literature¹. The system is deployed on twenty five medicine units across the enterprise. NYP EWS computes dynamic patient acuity scores based on real-time patient vitals from flowsheets. When the score crosses a critical threshold, the system automatically sends a mobile phone notification to the patient’s care team, enabling them to respond as appropriate. To minimize alert burden, we silence the system for four hours after any alert. As such, the majority of residents and nursing receive fewer than 3 alerts per day (Fig A; B).

Results

Since go-live in October 2018, NYP EWS has issued more than 4000 alerts on nearly 15% of the population of the units on which it is active. A governance committee, comprised of clinical and IT leaders, oversees enhancements to the system based on regular feedback sessions with nursing and physician partners. For example, in response to resident complaints about over-alerting, we discovered that while the alert burden was similar for residents and nurses, the physicians were alerted in clustered bursts versus an even distribution for nurses (Fig C; D; each point reflects alerts/provider per day). Relaying these results back to the physicians qualitatively improved system perception.

Conclusion

We believe that our system is trusted and utilized because we developed it in partnership with stakeholders, tailored the application to minimize burden on the clinical staff, and continuously iterate on the design to incorporate feedback. We believe that these are useful principles to guide such early warning system deployments elsewhere.

Identifying Non-VA Care Encounters using ADT Messages: Early Data from Two VA Medical Centers

Will L. Tarver¹, Omar Bouhaddou,² Nitin Jain,² & Brian E. Dixon¹,³,⁴
¹VA HSR&D Center for Health Information & Communication, Roudebush VA Medical Center, Indianapolis, IN; ²US Department of Veterans Affairs, Washington, DC; ³Indiana University Fairbanks School of Public Health, Department of Epidemiology, Indianapolis, IN; ⁴Regenstrief Institute, Center for Biomedical Informatics, Indianapolis, IN;

Introduction
The Veterans Health Information Exchange (VHIE)¹ enables the exchange of data between the Veterans Administration (VA) and outside healthcare organizations. Within the VA, admission, discharge, transfer (ADT) alerts can be important notifications to support quality improvement as well as care coordination. Using VHIE, non-VA community health partners can notify VA clinicians and staff when Veterans seek care outside the VA.² This can lead to timely and appropriate follow-up after patient discharge.

Methods
In this study, we sought to describe early patterns of non-VA alerts from community partners using data extracted from ADT messages sent via VHIE. A notification protocol within the electronic medical record was configured to notify VA providers of a patient’s non-VA event. Sent within 24-72 hours of a patient’s non-VA event, these alerts include information such patient demographics, visit type (e.g., emergency, inpatient, outpatient), and changes in status (e.g., discharge from or transfer to a facility).³ We examined ADT notifications sent to two VA medical centers located in Salt Lake City, UT and San Diego, CA during the 2017 calendar year. Descriptive analyses were used to examine patterns in the data received from non-VA facilities as well as the incidence of non-VA care.

Results
A majority of Veterans seeking care in non-VA facilities were male (86.8%) and non-Hispanic white (78.6%) followed by black (2.0%). Outpatient visits constituted 64.4% of total non-VA encounters while emergency room and inpatient admissions constituted 22.2% and 13.4%, respectively, in Salt Lake City. Similarly, the San Diego site observed 53.6% of total outpatient visits while emergency room and inpatient admissions constituted 29.3% and 17.1%, respectively. In the outpatient setting, an average of 24 patients in Salt Lake City (60.6%) and 141 patients in San Diego (54.2%) were identified as repeat visitors (2 or more visits) within the same month representing the largest proportion of repeat visits.

Discussion
ADT notifications provide an important opportunity for population health management and improving the health outcomes of Veterans at high risk for hospital readmission. ADT alerts potentially offer several benefits which include identifying patients that are hospitalized or seeking care in other medical facilities, improving health care quality by increasing provider awareness of their patients’ health history, allowing hospitals to track patients and prompt intervention when needed, and supporting care coordination and transition. Lessons learned may provide solutions to challenges faced in population health management such as tracking patients between discrete points of care using HIE.

References
INTRODUCTION – In electronic health record system (EHR) optimization, resources are devoted to continued improvement in EHR user competence\textsuperscript{1,2}. Physician burnout secondary to excess time spent using the EHR is common\textsuperscript{3}. Few EHR optimization processes are described in the peer-reviewed literature. We therefore developed an institutional Epic EHR optimization program for efficient EHR use to decrease physician frustration and burnout.

METHODS - Two-hour small-group sessions led by clinical informaticists and systems analysts on efficient EHR use were offered to all MSHS outpatient practices based on practice characteristics like burnout risk and interest, via e-mail and interpersonal discussion, starting in July 2018. Curriculum elements include efficient chart review strategies and EHR customization tips. Pre- and post-optimization EHR usage data was obtained using the Divurgent reporting interface. Provider satisfaction surveys were administered to assess the effect of optimization on subjective wellness immediately pre- and post-session, and at six weeks post-session.

RESULTS - Between 6/2018 and 5/2019, 363 providers in 98 practices underwent optimization training. Table 1 lists themes that emerged during sessions. Figure 1 shows number of minutes that participating providers spent documenting in the EHR on off duty days, before and after optimization training.

DISCUSSION - Optimized providers show a trend towards less time spent documenting in the EHR on off duty days. Themes reported are informing future optimization efforts at MSHS including training of EHR champions, i.e., advanced users, who can provide long-term local support to peers. Survey results show lasting optimization effects for improved efficiency, confidence, and satisfaction; qualitative comments validate in-session themes and indicate provider desire to troubleshoot and improve specific functions within the EHR.

**Table 1 - Themes Discovered During Optimization Sessions**

- New-hire online EHR training not sufficient for daily practice
- New and current providers benefit from at-the-elbow support on EHR use
- Ongoing dissemination of EHR tips in a structured format at the individual practice level is useful
- Individual practices should have representation at institutional IT workgroups

**REFERENCES**

Introduction
The electronic health record contains a wealth of clinical information as unstructured free text. This information has the potential to enhance clinical decision support systems, define at-risk populations, or provide insight for secondary research. Unfortunately, extracting this data is difficult and time consuming. Many commercial enterprises have developed natural language processing (NLP) systems to solve this problem, however these systems may not have been trained to recognize clinical text and are often expensive. An open source project known as the Apache Clinical Text Analysis and Knowledge Extraction System (cTAKES) was developed as an attempt to fill this gap. However, while cTAKES provides health specific NLP under a free license, the application runs as a single process and analyzing large sets of notes can take months or even years to complete.1 As a result, many institutions only run cTAKES on a small cohort of patients. This can lead to significant underutilization of important clinical data. At Children’s Hospital of Philadelphia (CHOP), we sought to develop a fault-tolerant and scalable cTAKES pipeline capable of processing hundreds of millions of clinical notes in parallel.

Methods
The cTAKES pipeline was developed for use in Arcus, the CHOP Research Institute data strategy. The Arcus database contains over 114,500,000 clinical notes with approximately 50,000 new notes added each day. The data spans a period of 19 years. We chose to focus initially on cTAKES since it is an open source Apache project and a common standard for health-related NLP. To determine the appropriate infrastructure, we evaluated multiple processing frameworks including the Unstructured Information Management Application Asynchronous Scaleout (UIMA AS), Apache Spark, and a public cloud provider’s pipeline execution framework. Each infrastructure was evaluated on its ability to provide a fault-tolerant, distributed, and scalable processing environment. The pipeline was developed in Java to align with cTAKES. Testing was performed on a small subset of the Arcus clinical note data.

Results
We developed a fault-tolerant, distributed, and scalable cTAKES pipeline using the Apache Beam programming model. We chose to use Beam given its well documented Java software development kit as well as its support for a variety of processing backends including a local Java virtual machine, Apache Spark, and a public cloud provider’s pipeline execution framework. The multiple supported backends make it easier for our pipeline to be used by other institutions. Our production pipeline runs on a public cloud provider’s processing backend, which takes advantage of the cloud platform’s network configuration and native auto scaling based on application throughput.

The pipeline was tested on 3,446,233 notes, which took 44 minutes and provided 18,846,466 ontology mappings from the Human Phenotype Ontology. Use of the cloud-based processing backend allowed our job to scale to 503 machines, each with 4 central processing units and 15 gigabytes of random-access memory. Total cost for the job was $57.23. It is estimated that running this volume of data using out-of-the-box cTAKES would take over 21 days. Our research also suggests that both UIMA AS and Apache Spark would increase performance when compared to out-of-the-box cTAKES, but each required existing infrastructure that did not dynamically scale.

Discussion
We developed an NLP pipeline capable of processing large volumes of data using open source technologies to support code reuse across institutions. The pipeline runs daily and auto scales based on application throughput. NLP systems have made great advances in creating structured representations from unstructured clinical text. The derived data can then be used for a variety of purposes including clinical decision support and providing filtering criteria for research cohorts. Unfortunately, due to the time and cost associated with implementing and running NLP systems, only a few institutions have realized the potential of NLP for very large cohorts and clinical data sets. Further development of fault-tolerant and scalable health-related NLP is required.

The More You Know: Displaying Individualized MME Reports During Discharge Order Entry Reduces Opioid Prescribing

Bryan C. Thorne, MD PhD, Jason A. Lyman, MD MS, Rena Morse, BA, Bethany M. Sarosiek, RN, C. Page Muthusubramanian, FNP, Traci Hedrick, MD, David Ling, MD University of Virginia Health System, Charlottesville, VA

Introduction
As part of the University of Virginia Health System's (UVAHS) efforts to address the opioid epidemic, we implemented a non-interruptive decision support tool in a subset of our surgical discharge order sets in an effort to improve opioid prescribing for post-operative patients. Baseline data suggested that opioid prescribing was not being personalized based on the needs of patient, instead relying on default configuration within the order sets. We partnered with our Enhanced Recovery After Surgery (ERAS) team to develop an evidence-based approach to post-operative discharge opioid prescription, and modified our colorectal discharge orders to display recent opioid administrations and the associated Morphine Milligram Equivalence (MME).

Decision Support Tool
The ERAS team conducted a literature review and developed recommendations around post-discharge pill quantity based on the MME amount of oral opioids taken by the patient in the 24 hours prior to discharge (Table 1). Because our EHR does not natively calculate MME for inpatient opioid administration, we developed rule-based logic to calculate a maximum MME for the previous 24 hours. This was calculated by multiplying the highest dose of each opioid given by the number of doses of that opioid, and multiplying by a standard conversion factor to get MME. These rules were developed for the three most commonly used oral opioids on the inpatient formulary at UVAHS. The 24 hour maximum MME was displayed to clinicians in the pain medication section of the ERAS Colorectal discharge order set, along with explanatory text and prescribing recommendations. An order group containing oxycodone orders with the recommended dispense numbers was created to ease adherence to the recommendations.

Results
The discharge opioid prescribing tools were released in August of 2018. We analyzed data from August 2018 – February 2019 in the post-intervention group, and compared with that same time period one year earlier. We excluded patients taking opioids prior to the surgery from our analysis, leaving 145 patients in the pre-intervention group and 196 patients in the post-intervention group. Through February 2019, the percent of patients discharged without a prescription for an opioid increased from 12 % to 21 % (p =.043). For those patients who were discharged with an opioid and for whom the order set was used, the average days supply decreased from 5.4 to 4.4 (p =.011), and the average quantity dispensed decreased from 32 pills to 26 pills (p <.001). We also monitored repeat prescriptions of opioids within 14 days of discharge as a balancing measure and found no significant differences (8% pre-intervention vs. 7% post-intervention, p=.837).

Conclusions
Using a relatively simple intervention consisting of displaying inpatient MME information to providers at the point of ordering, providing a recommendation based on this information, and orders with quantities defaulted matching the recommendation, we were able to achieve a reduction in the number of patients being discharged with opioids and in the quantities of opioids prescribed. We noted strong variation between residents as to their use of the order set and prescribing practices. This pilot was successful at decreasing the amount of opioids prescribed, and our next steps will include standardizing onboarding for the resident coming on service as well as spreading the learnings and standardized discharge prescribing practices to our other ERAS surgical programs.

Biological Network Knowledge in Molecular Tumor Boards

Thorsten Tiede, Dipl.-Inf. (Bioinformatics)\textsuperscript{1,2}, Oliver Kohlbacher, Prof.\textsuperscript{1,2,3,4}

\textsuperscript{1}Applied Bioinformatics, Center for Bioinformatics, University of Tübingen, Tübingen, Germany; \textsuperscript{2}Institute for Bioinformatics and Medical Informatics, University of Tübingen, Tübingen, Germany; \textsuperscript{3}Institute for Translational Bioinformatics, University Medical Center, Tübingen, Germany; \textsuperscript{4}Biomolecular Interactions, Max Planck Institute for Developmental Biology, Tübingen, Germany

Introduction

Molecular Tumor Boards (MTBs) are interdisciplinary meetings with the aim of suggesting optimal, personalized treatment plans for cancer patients based on molecular data (genomics, transcriptomics). The recommendations are based on molecular modes of action rooted in systems medicine and rely on prior knowledge from public databases. Web resources like cBioPortal already offer visual representations of the interaction-network context of potential cancer-driving genes that can be used in MTB discussions. Integrating omics data on the level of biological networks in an interactive (visual analytics) approach can provide additional insights and speed up the discussions in MTBs.

Method

We developed a mapping of biological network data from the Systems Biology Markup Language (SBML) to a neo4j graph database, making them searchable and annotatable via the Cypher Query Language. Based on this mapping and subsequent identifier-based merging strategies, we can easily load and persist arbitrary public biological network resources available in SBML. A RESTful interface gives access to and allows filtering on the networks by interaction type (e.g., extract only phosphorylation events) or node type (e.g., only genes or metabolites). Additionally external scalar or categorical annotations can be mapped to nodes and/or edges (e.g., patient-specific expression values, confidence scores, drug target information) and simple graph algorithms can be executed (e.g., shortest path, breadth-first and depth-first search to extract network contexts, de novo pathway enrichment). After each step a new network-representation is persisted in the database, which can be used in subsequent steps. In this way intermediate results are not lost and can be reused, allowing for easy interactive exploration of the data. Implementation of the W3C Provenance Model makes backtracking of the steps taken to create any network in the service or any element therein possible. Additionally, access to arbitrary database contents can be restricted on a user basis, enabling collaborative work while still enabling data privacy, which is essential for patient-specific data. The created networks can be downloaded in the GraphML-format and may contain an arbitrary number of annotations on the nodes and edges defined by the user. Graph drawing tools like Cytoscape can then be used to visualize the graphs and detect user interaction with the network. Interactive navigation of the graphs is accomplished via subsequent calls to the service.

Results

The unified graph for protein-protein interactions derived from 221 non-metabolic KEGG pathways consists of 4,311 nodes and 73,586 undirected edges capturing interaction events even across traditional pathway-boundaries between genes and gene-products. For network contexts generated from this graph with a reasonable amount of nodes n and relationships r (n \leq 100, r \leq 500), sub-second response times can be achieved, enabling interactive analysis of data within graphical user interfaces for MTBs. A caching middleware allows to precompute time- and resource-intensive analysis steps in a preparation phase making them readily available in a presentation phase. The modular service-oriented design-approach using REST interfaces makes it easy to integrate in any existing clinical infrastructure and thus available to MTB processes. The open source software is available on https://github.com/kohlbacherlab.

Conclusion

We present a service for generating, annotating and analyzing biological networks in a clinical setting to help elucidate patient-specific disease-driving forces. We exemplify the viability of this approach by providing a mechanism to bring personalized network-contexts to Molecular Tumor Boards via the widely adopted GraphML interchange format and a responsive and modular RESTful application.
From User Experience to Digital Health Adoption (UXA): A Synthesized Framework to Guide Nursing Science

Dante Anthony Tolentino, MA, RN, Doctoral Candidate1, Sheila M. Gephart, PhD, RN1
1The University of Arizona College of Nursing, Tucson, AZ

Introduction: Many digital health technologies, including the Electronic Health Record (EHR) originate from a mechanistic isolationist characterization of workflow. The combination of a mechanistic view and the rapid implementation of the EHR yielded unintended consequences (UCs) and negative user experiences (UX) though their description is underdeveloped in nursing. UCs include technology-induced errors, unfavorable workarounds, additional work, and technology overdependence that hamper situational awareness and impact decision-making.

Purpose: To describe the synthesis of concepts from Task-Technology Fit theory and the Technology Acceptance Model to derive a new, synthesized framework that addresses antecedents and outcomes of nurses’ UX.

Method: The User Experience to Adoption (UXA) conceptual framework was formulated using Walker and Avant’s Theory Synthesis method. It builds on empirical evidence from nursing studies on UX from 2008-2018. This framework is a byproduct of the initial evidence from a comprehensive literature review. We pulled together available information about nurses’ UX with the EHR and organized the different concepts and statements to represent user experience and technology adoption.

Results: In the UXA Framework (Figure 1), UX is a precursor to actual system use, which is aligned with the construct of adoption. Nurses’ actual system use is derived from the fit among task, technology, individual, and organizational characteristics. This interplay impacts UX consequences, which are categorized across functional, physical, perceptual, cognitive, psychological, and social dimensions. In this framework, actual system use is mediated by user intention and influenced by UX consequences. Task characteristics include documentation demands, non-functional data entry requirements, task switching, regulatory impact, and information access. Technology characteristics include hardware, software, and environmental design factors. Individual characteristics encompass computer attitudes, skills, literacy, age, clinical experience, training, and previous experience with EHR. Organizational characteristics include users’ input to design, authentic leadership, organizational support and communication, work setting, and work shifts. The model depicts the multi-dimensional outcomes of UX encompassing interruptions, performance, satisfaction, workload, workarounds, documentation time, and communication processes. We will test the framework by using quantitative measures. We will use data mining to describe nurses’ task characteristics as measured by nurses’ EHR navigation patterns. We will also use regression analysis to quantify the relationship between the antecedents and outcomes of user experience. We will measure technology characteristics by the preferences and settings for individual nurses’ roles. We will assess individual characteristics by nurses’ demographic information. We will measure organizational characteristics using the nurses’ hospital site. Finally, only the cognitive dimension will be measured at this time using time spent in the EHR and cognitive workload using NASA-TLX.

Conclusion: The UXA framework can be used in a wide variety of practical applications including describing the antecedents and consequences of UX with the EHR. It can be used to design interventions to prevent unintended consequences and to identify factors for assessing meaningful use and adoption of EHR. The framework may have applicability to other technologies beyond the use of the EHR.

Cross-Organizational Knowledge Sharing in the Department of Veterans Affairs (VA) to Create a Central Gateway to Information About VA Data

Timothy N. Trautman, BSD1,2; Jenifer E. Stelmack, MSW3; Amy D. Caudill, BA4; James R. Peterson, BS4; Rebecca M Gibbs, BS, MS, MBA4; Maria Souden, MSI, PhD3,5

1VA Informatics and Computing Infrastructure, Salt Lake City, UT; 2University of Utah, School of Medicine, Salt Lake City, UT; 3VA Information Resource Center, Hines, IL.; 4National Data Systems, Veterans Health Administration, St. Petersburg, FL; 5University of Illinois, School of Information Sciences: The iSchool at Illinois, Champaign, IL

Abstract

In a complex healthcare environment with a wide range of data resources, understanding how cross-organizational stakeholders can bring together and disseminate information that educates researchers about existing available data is essential to conducting research. This poster presents a real-world example of how cross-organizational stakeholders at the Department of Veterans Affairs (VA) worked together to provide researchers and operational VA data users with a central gateway to information about VA data.

Problem

The Department of Veterans Affairs (VA) maintains nearly two petabytes of data related to Veteran’s health and healthcare, which are collected from over 8,000 sites and organized in multiple databases managed by multiple offices. Understanding the VA data landscape, the content, the structure, utility of available data, and processes for requesting permission to access these data is essential to conducting research in this complex environment. While the VA maintains information about these data, it is spread across multiple locations within the VA network making it challenging for clinical and health services Researchers to determine whether the data they need exists. Thus, it was conceived that an effort was needed to bring all the information into one source – the VHA Data Portal.

Project Purpose

The VHA Data Portal was born from key stakeholders’ interests in consolidating information about vital organizational data resources that support VA data users, including Researchers. A small cross-organizational Portal workgroup was charged with developing an integrated solution that would meet each office’s unique mission, requirements, and customer needs. The workgroup began by surveying information available on the websites of key stakeholders with expertise in VA data and in developing and disseminating data-related resources. The development process involved resolving differences to present information about data resources with a coherent architecture and voice.

Product

The VHA Data Portal is a collaboratively developed VA Intranet site which brought together resources from four VA offices to support a common goal of providing a central knowledgebase about VA data and data access processes. The Portal is organized into seven main categories: data sources, data access request processes, tools and applications, resources (such as data quality and technical reports, user guides, data documentation), training and education, policy and administration, and user support. It now integrates information about VA data from multiple VA offices into a single location and serves as a central gateway to this data knowledge.

Conclusion

A central gateway to data knowledge is essential for educating Researchers and operational data users about available data in a complex healthcare environment with a wide range of data resources. As measured by user feedback, frequency of use, and interest from other program offices seeking to contribute, the VHA Data Portal has had tremendous success in consolidating data information that serves the needs of all data users and supports research that improves Veteran healthcare.

Learning Objective

Our objective was to understand the problems that Researchers and operational data users face in finding, understanding, and using data and how a solution of consolidating data information can save immense time and frustration leaving Researchers more time to conduct research with better outcomes due to a better understanding of available data and its characteristics. Operational data users experience a more streamlined process to gather the data they need to determine more profound performance measures that will lead to greater operational excellence within the VHA.
Addressing the Challenges of Telemedicine Implementation Using a Critical Success Model Approach

Tulu Bengisu¹, Cynthia LeRouge², Nelson King³, Spurthy Dharanikota⁴

¹Worcester Polytechnic Institute, Boston, MA; ²Florida International University, Miami, FL; ³Khalifa University, Abu Dhabi, UAE; ⁴Florida International University, Miami, FL

Introduction and Background

The American Heart Association recommended telestroke, a web-based application of telemedicine for acute stroke, as a low-cost and effective tool to improve access to critical stroke care and quality of care within underserved and rural regions. Understanding what is truly critical to success of telestroke, and emerging health services technology innovations, in general, is vital given competing innovation paths, constrained resources, and pressure to show promising outcomes. Critical Success Factors (CSF) is a persistent construct found in the health information technology (IT) literature that report long lists of “important things to consider” when embarking on digital initiatives. Such published lists seem to have strayed from the empirical roots, meaning, and application of this construct to discern critical knowledge, identify relationships and responsibility, and show a pathway to action. We use a longitudinal case of a telestroke implementation to revisit and rekindle a deeper analysis into the meaning of CSFs. Exploring CSFs for telestroke helps health organizations realize the value that expedited access to care via telemedicine can afford, and guide policy makers away from legislating innovations that hinge upon realizing difficult to achieve factors. We use an empirically rooted critical success factor framework (Figure 1) to explain the success factors in the form of facilitating actions. Engaging in facilitating actions increase the probability of success, and the lack of facilitating actions decrease the probability of success. The interim outcomes resulting from facilitating actions can be described as those outcomes that overcome barriers and address key implementation challenges. Our work specifically addresses: 1) What challenges do these CSFs address? 2) What success factors (key facilitators and interim outcomes) are associated with a telestroke implementation project?

Methods:

Three data collection rounds - Round 1 (prior to go live), Round 2 (go-live) and Round 3 (5-year reflective lookback) occurred during the 7-year longitudinal study in a Midwest telemedicine network with two hub hospital sites. This study used multiple methods including 27 semi-structured interviews, observation, and focus groups. Inductive and deductive coding methods identified a universe of “important factors”, grouped important factors by level, and applied an outcome-driven meaning of criticality to the resultant lists and associated quotes to discern “critical” ones. The questions in Round 3 were framed such that the interviewees revisited the factors identified as critical in the previous interview rounds and their perception about the importance of those factors was recorded. The corroborated findings were then grouped into the final list of key challenges and critical factors. The last step involved revisiting extant literature of the CSF construct to evolve a meaning and labels as well as a process for identifying CSFs that could carry across to other HIT contexts.

Results:

We identified telestroke challenges in our case for each of the areas depicted in Figure 1 – Industry Structure (e.g., limited reimbursement and specialist shortage), Strategic Context (e.g., program sustainability), Environment (e.g., limited mastery of telemedicine), Temporal (tPA guidelines of 3 hours), and Role (buy-in from stakeholders). In working down our model we identified 45 important telemedicine factors (facilitators and interim outcomes): 5 at industry level (e.g., telestroke protocols), 10 at organizational level (e.g., business plan, board of director support), 16 at sub-organization level (e.g., leverage existing infrastructure, community education), and 14 at individual level (e.g., persistent effort). Of these, 17% were determined unique to telemedicine (e.g. tele-personable clinicians).

Conclusion:

We hold that the prevalent long lists of “things to be considered”, popularized as CSFs, are iterations of best practices and perhaps a starting point, but not an end, for deep CSF analysis. The original outcome-driven meaning of CSFs holds insight into the challenges to overcome and should be revised by researchers for use and possibly empirical extension, particularly in the general area of HIT and specifically telemedicine.
Canary Library: a Sharing and Learning Community for NLP Developers

Alexander Turchin, MD, MS¹, Joonghee Kim, MD, MS¹, Sammy Elmariah, MD²,³
¹Brigham and Women's Hospital, ²Massachusetts General Hospital and ³Harvard Medical School; Boston, MA

Introduction
Narrative documents contain a large fraction of clinical data. NLP technology can help extract this information. Nevertheless, widespread adoption of NLP has yet to materialize. This is in part due to dearth of publicly available, portable and user-friendly tools. The result is two important barriers to NLP utilization: a) development of NLP tools typically requires extensive computer science expertise and b) it often involves a significant time commitment.

We sought to create a solution that would help researchers overcome these barriers. The first step was development of Canary, a GUI-based NLP-based information extraction platform that does not require software engineering or computer science expertise. It has been developed for processing narrative electronic documents to support the extraction of clinical concepts via user-defined knowledge discovery criteria and lexicons. This addressed the first barrier to NLP adoption – the need for involvement of an expert computer scientist. In order to address the second barrier – the time it takes to develop NLP tools – we propose to leverage high portability of NLP tools developed for the Canary platform, which can be easily reused on any other Canary installation. Below we describe the Canary NLP Tool Library that creates a forum for researchers to publicly share their NLP tools to allow everyone to build on accomplishments of others.

Software Description
The Canary software allows users to model their target information using lexicons and detection criteria, ranging from simple to complex, via a user-friendly graphical interface. The components forming the NLP pipeline include (1) text normalization & preprocessing; (2) vocabulary definition; (3) information discovery parameter definition; (4) structured value extraction; and (5) data filtering. Unicode support allows it to work with most languages.

To assist with data acquisition, a companion tool called the Canary Data Converter allows the conversion of data from various sources into a Canary-compatible format, with the possibility of adding support for new formats. After processing the input data, Canary produces structured output which can be analyzed to obtain study results ranging from prevalence statistics to longitudinal analysis of patient outcomes. Canary is now available for download at http://canary.bwh.harvard.edu.

Canary NLP Tool Library
Canary website includes a Library section where publicly shared NLP tools are posted. Information about each tool can include the concept(s) that the tool identifies in narrative data, its authors, accuracy and relevant publications. NLP tools can be submitted to the Canary website administrator for screening and posting. Security risks are minimal as an individual Canary NLP tools is a set of text-based configuration files describing the language model for identification of the concept of interest.

At this time Canary NLP Tool Library includes five NLP tools: a) Diagnosis; b) Family History; c) Left Ventricular Ejection Fraction; d) Aortic Valve Area and e) Mean Aortic Gradient. While Diagnosis and Family History tools are built for specific examples (diagnosis of calciphylaxis and family history of breast cancer, respectively), they can be easily adapted to other use cases. Recall and precision of the posted tools are estimated to range from 70-80% (Diagnosis and Family History) to as high as 95-98% (Left Ventricular Ejection Fraction and Aortic Valve Area). While it is likely that the shared tools may require modifications when transferred to another institution, these are expected to be minor, compared to the overall workload of NLP tool development. The goal of the NLP Tool Library is therefore to enable researchers to see farther ahead by standing on the shoulders of the giants – their colleagues.
Text De-Identification Impact on Subsequent Machine Learning Applications

Gary Underwood, MS¹, Andrew Trice, BS¹, Youngjun Kim, PhD², Jean-Karlo Accetta, MS¹, Stephane Meystre, MD, PhD¹,²
¹ Clinacuity, Inc., Charleston, SC; ² Biomedical Informatics Center, Medical University of South Carolina, Charleston, SC

Introduction: The recent adoption of Electronic Health Record systems in the U.S. has resulted in very large quantities of clinical data becoming available in electronic format, with tremendous potential, but also equally growing concern for patient confidentiality breaches. De-identification of clinical data has been proposed as a solution to both facilitate secondary uses of clinical data and protect patient data confidentiality. The majority of clinical data is recorded as text, and efficient de-identification of this data can be based on Natural Language Processing (NLP) methods. Recent advances in NLP methods have been enabled by supervised machine learning and deep learning approaches, both relying on annotated clinical text for development and evaluation, on large quantities of clinical text. To allow use and sharing of this text, collections of clinical text have been de-identified according to the HIPAA Safe Harbor method, detecting all identifiers and replacing them with tags (e.g., “J. Smith” with [**PatientName**]) or with realistic surrogates (e.g., “J. Smith” with “A. Jones”), a process we call “identifier resynthesis.”¹ For NLP efforts focused on automatic text de-identification, the identifier surrogates should be as realistic as possible, maintaining the original morphology (capitalization, punctuation, spacing, etc.), variety, and consistency (e.g., all mentions of a patient name replaced with another same random name). Identifier resynthesis is the only viable option, but how this process possibly affects the accuracy of algorithms trained and tested with such de-identified text has rarely been evaluated, and only for sequence modeling algorithms such as Conditional Random Fields.²

Methods: To assess the potential impact of text de-identification with identifier resynthesis on subsequent use of the de-identified text for NLP-based named entity recognition (NER) using machine learning algorithms, we used an existing corpus of 228 clinical text notes from the Medical University of South Carolina. Notes were of the five most frequent types (e.g., progress note, discharge summary). All notes had been manually annotated for all identifiers defined in the HIPAA Safe Harbor rule³ and the corpus was split in a training subset (178 notes) and a testing subset (50 notes, based on power analysis). For resynthesis of the manually annotated identifiers, we used a component adapted from the BoB text de-identification application,¹ itself adapted from MIST.⁴ Identifier resynthesis breadth, accuracy and consistency were improved. The NER application we tested focused on identifiers and included part of CliniDeID, a complete text de-identification system. It included supervised machine learning algorithms (Conditional random fields, Margin infused relaxed algorithm and Structural support vector machines) but not the deep neural network components. We trained and tested it with various combinations of the original clinical notes (i.e., not de-identified) and the de-identified notes: training and testing with subsets both original or de-identified, or training with one and testing with the other. For accuracy measurement, metrics included recall, precision and the \( F_1 \)-score.

Results: All possible combinations of training or testing with original (“Original”) or de-identified text (“Resynth.”) were compared, and no significant difference was observed (Chi-squared test with \( p \) values between 0.998 and 0.912).

**Title:** One Year After the Big Bang: “Things are going ok”  
**Authors:** Kim M. Unertl, PhD, Joyce Harris, MA, Shilo Anders, PhD, Peggy Cunningham, Laurie Novak, PhD, Taylor Avery, Carrie Reale, Patricia Sengstack, DNP, Nancy Lorenzi, PhD

**Affiliation:** Vanderbilt University Medical Center, Nashville, TN

**Introduction.** Health information technology (IT) implementations may “go live” on a single day, but the transition to effective use and adoption occurs over an extended time as individuals and their organization adapt. After 30+ months of planning, preparation, and training, Vanderbilt University Medical Center applied a “big bang” approach to implement a new health IT infrastructure, called eStar, across the entire clinical enterprise on November 2, 2017, involving 3 hospitals, 800 outpatient clinics, 125 physical locations, and 18,000+ users. Our research team studied the impact of the new Epic-based system on workflow, roles, and communication before, during, and after implementation. This poster reports on the final phase of our yearlong study of the health IT implementation.

**Methods.** Our team applied a systematic, rigorous approach to studying the large-scale health IT implementation. We developed a survey instrument for data collection one-year post-implementation. The research team collaboratively developed potential questions related to workflow and system use. The instrument was pilot-tested with a convenience sample, revised, and used during observation to assist with conversations about the new health IT and its ongoing impact on work and teams. The final survey instrument consisted of four Likert-scale questions (Table 1) and a free-text response question: “One year after eStar implementation started, how do you feel about how things are going?”

**Results.** We collected 171 surveys across 12 clinical areas (inpatient n=57, outpatient n=67, emergency department n=47). Respondents included patient services staff, medical assistants, nurses, advanced practice nurses, clinical leaders, physicians, and other staff. Of our sample, 44 people had prior Epic experience, 122 people did not have prior experience with Epic, and 5 people chose not to answer. Table 1 shows the results for the first four questions.

Answers to the free-text question (n=120) provided positive and negative feedback on individual and team experiences. Positive comments included an inpatient nurse who wrote, “It has been great. It is easy to use, complete tasks, and document.” Negative comments included an inpatient nurse who wrote “There are still a lot of kinks to be worked out. It’s not entirely user-friendly and physicians aren’t able to use it either, which makes our job more difficult.” Continued optimization needs, along with frustration with the optimization process were major themes. One inpatient physician wrote, “Needed improvements are not being implemented.” while an outpatient nurse noted, “The improvement process is tedious and bureaucratic.” Nurses and front desk staff also noted that frequent changes, sometimes without notice, made it difficult to become comfortable using the system. Across all roles and settings, people discussed usability issues, including the clicks required to complete tasks compared to the previous system, difficulty finding information, redundant/duplicated charting, difficulty charting common activities such as education, and scheduling inefficiencies. Another theme was an ongoing need for more training and help with personalization, as one outpatient nurse wrote, “There are so many things that Epic can do but we have had little to no training since initial implementation.” Finally, respondents discussed their expectations moving forward, as one physician wrote, “Seems to be ‘status quo’ at this point. Need to get people back to innovation/improvement mode.”

**Discussion and Conclusion** One-year post-implementation, adaptation to the new health IT infrastructure is still ongoing. While the majority of respondents agreed that they can complete day-to-day tasks efficiently with the new system, there was less agreement that the new system helped deliver high quality patient care. Analysis of free-text responses identified potential areas to focus attention and interventions on moving forward.
Refactoring and Expanding the Informed Consent Ontology (ICO)

Jonathan M. Vajda, MA1, J. Neil Otte, PhD2, Cooper Stansbury, MS3,
Marcelline R. Harris, PhD3, Frank J. Manion, PhD3, Cui Tao, PhD4
1University at Buffalo (SUNY), Buffalo, NY; 2Johns Hopkins University Applied Physics Laboratory, Laurel, MD; 3University of Michigan, Ann Arbor, MI; 4University of Texas Health Science Center at Houston, Houston, TX

The Informed Consent Ontology (ICO) represents the domain of informed consent, including the process of informed consent and related processes (e.g. informing a patient of their rights), the information produced by consent, and the resulting consent powers. Since sensitive materials such as specimens and data change hands across organizations governed by different policies and regulations, tracking the moving parts is critical to consent provenance. Our work addresses the need for ICO to have greater generality and granularity for widespread use as a reference ontology.

To improve this representation, the developers coordinated with the Document Acts Ontology (D-Acts), Ontology for Biobanking (OBIB), the Common Rule Ontology (CRO), and the Data Use Ontology (DUO). D-Acts represents document acts (e.g., signing contracts) and deontic roles (e.g., a role permitting a physician to perform surgery). The Ontology for Biobanking (OBIB) extends the Ontology for Biomedical Investigations (OBI), focusing on annotation terms relevant to biorepositories. CRO represents the Common Rule, DUO represents consent codes to annotate data with usage permissions. We used common refactoring methods applied in software development whereby code is improved through restructuring while preserving functionality while it is expanded and reevaluated. We reviewed every ICO term, marking for revision or deprecation in a spreadsheet. Use cases tested design flaws and maturity. Coordination with other ontologies promoted interoperability and avoided redundancy. We annotated blank consent forms with classes to show coverage of relevant terms.

ICO’s new release is improved for use as a reference ontology. The most general terms were revised in tandem with ontologies being importing in whole (denoted by black arrow in Figure 1) or in part (yellow arrow). Entities too specific for a reference ontology were recast or deprecated. The model of informed consent forms and their parts, e.g., directives, is enhanced. ICO incorporates CRO (purple arrow), enabling better representation of types of regulations across contexts. ICO’s new term ‘stasis of regulation’ is attractive to biobanks interested in tracking inventory over time or in querying when and where regulations are in force. This poster shows hierarchies of ICO and collaborating ontologies, and samples for intended use.

Mind the Gap: Revolutionizing the EHR Downtime Experience with an interoperable Workflow Tool

Patrick van Nieuwenhuizen, MD1, Jacqueline Soegaard Ballester, MD2, C. Priya Joshi, MD2, Subha L. Airan-Javia, MD3

1Hospital of the University of Pennsylvania, Philadelphia, PA  2VAMC, Philadelphia, PA, 3Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA,

Background

During EHR transitions or updates, hospital systems often undergo 8-16 hour EHR downtimes during which there is reduced access to data, documentation, and task management systems1-2. These downtimes have the potential to interrupt patient safety. At hospital systems that we are aware of, there are no alternative electronic platforms to fill the gap during downtimes.

Purpose

We created a web-based tool used for rounding and team-based task management that auto-populates data (labs, vitals, imaging reports), allows multiple users to manage interactive to-do lists and notes simultaneously, and is accessible via computer and phone. Though this tool was not initially intended to address the issue of data availability during downtime, we reviewed data usage during downtime to determine whether workspace tools have the potential to patch the discontinuity that occurred during the downtime.

Description

Six months after we implemented our web-based tool, our institution implemented a new EHR, during which there were a total of 27 hours of downtime across 4 hospitals spread across two days. During this downtime, the old EHR was viewable but did not have updated vitals, imaging, or lab data. In contrast, our tool, in addition to the static data at the time the old EHR became read-only, our tool continued to pull a subset of updated data from feeds directly from source systems including labs, radiology, clinical care plans, and tasks. In addition, while the old EHR was in a “read-only” mode during the downtime, clinicians were able to use our electronic tool to take notes and update tasks. After the new EHR went live, users were able to import this written care planning information into the new EHR. After the EHR transition, we assessed whether there was increased demand for our tool during the downtime. To do this, we measured the total number of different actions undertaken by users within our tool before, during, and after the downtime. These actions included those related to task management (figure 1) and viewing data (figure 2). Figures 1 and 2 illustrate that during the downtime, users accessed our application to view clinical data and manage their tasks more frequently than before or after the downtime. This increased usage suggests that there was demand for an alternative platform during the EHR downtime. Qualitatively, in user interviews, users reported decreased anxiety about the downtime because they were able to access clinical data within our tool. This may have improved patient safety during the transition, although we do not have data to validate that claim.

Conclusions

It is critical to think of how we can preserve safe patient care during EHR downtimes. Our experience suggests a need for alternative platforms for viewing data and managing tasks during EHR downtimes. Best practice may include the availability of alternative platforms for viewing data and managing workflow to stand in while EHRs are unavailable during downtimes.

OMOP Based Data Pipelines for Consistent Results in Cohort Identification Tools

Mahesh Vangala, MS; Yurima Guilarte-Walker, MS; Douglas Buell, BS; Keith Pelletier, BS; Katherine Luzuriaga, MD; Jomol Mathew, PhD.
University of Massachusetts Medical School, Worcester, MA.

Introduction and Background: Electronic Health Records (EHR) are increasingly becoming an integral part of healthcare. Cohort identification, feasibility studies and retrospective insights leveraging EHR data are accessible to researchers via nationally funded open-source solutions such as i2b2 and ACT as well as commercial third-party systems such as TriNetX. However, as a result of the wide variety of EHR systems available in the market and due to the proprietary nature of EHR data mapping, each organization is left with implementing custom Extract-Transform-Load (ETL) processes for loading data into these tools. This type of data loading is resource intensive and is especially cumbersome for healthcare organizations who employ EHRs from multiple vendors. A loading strategy that leverages a centralized and standard data model offers an optimal solution to enable easy data loading and establish consistent results across the systems.

Methods: We developed a dataflow pipeline (Figure 1) based on OMOP – CDM² (Observational Medical Outcomes Partnership – Common Data Model). OMOP was selected over other data models such as PCORnet as it is widely supported by cohort identification tools (TriNetX, i2b2 etc.). Nonetheless, we faced challenges integrating ACT/i2b2 ontologies with OMOP. ETL tools (Pentaho v6.0.0) and SQL scripts were used to map clinical data from the EHR source system (EPIC Clarity 2018) following OMOP – CDM specifications (v5.3). Prior to loading the data into each specific cohort identification tool’s data repository, a de-identification process was performed as per HIPAA guidelines (Section 164.514(a) Deidentification Standard - Safe Harbor Method Sections 164.514(b)(2)). Data mappings were evaluated using common metric counts (such as counts for Diagnoses, Procedures, Medications) between OMOP and the source EHR system – EPIC Clarity. In addition, we performed QA on randomized concept counts across our central research data warehouse, OMOP, TriNetX and i2b2 to confirm the data consistency. The resulting de-identified OMOP CDM Data repository was then used as the common data source for the cohort identification tools – i2b2 (v1.7.09c), ACT-SHRINE (v1.25.4) and TriNetX.

Results: We have successfully mapped the proprietary concepts from the EHR system and translated them into OMOP – CDM standardized concepts, namely, demographics and conditions (SNOMED), medications (RxNorm), labs (LOINC codes) and procedures (CPT4 codes). We then integrated data for a time period of October, 2017 to March, 2019 from 3,024,893 patients from our research data warehouse into the systems. Due to the proprietary nature of EHR system (EPIC – Clarity DB Schema), scripts cannot be shared over public servers. It is for this reason, we would like to share the intellectual material (non-proprietary scripts and/or guidance) in a controlled manner from UMCCTS Data Science Core.

Patient Perceptions of Data Visualizations in Diabetes Self-Management

Jacqueline Vaughn BSN RN1; Allison A. Lewinski PhD, MPH, RN2; Anna Diane BSN RN1; Janee Stevenson BSN, RN3; Ryan J. Shaw PhD RN1

1Duke University School of Nursing, Durham, NC; 2Center of Innovation to Accelerate Discovery and Practice Transformation, Durham VA Health Care System, Durham, NC; 3Winston-Salem State University

Introduction: Mobile Health (mHealth) technologies such as wearables and smart phone applications (apps) help adults with type 2 diabetes engage in consistent, complex diabetes self-management. However, these technologies collect a significant amount of patient-generated health data (e.g., blood glucose, weight, physical activity). This large amount of data can cause data overload and/or fatigue, and loss of important information for both patients and clinicians resulting in poorer health outcomes (Lor, Koleck, & Bakken, 2019). Developing effective, meaningful, and interpretable ways to visualize these data addresses these challenges by providing valuable insight to guide patient decision making and self-management behaviors.

Methods: We conducted a mixed methods exploratory study for 60 patients with type 2 diabetes. Patients used 4 mHealth devices (i.e., wireless glucometer, cellular scale, wearable accelerometer, and smartphone delivered text message surveys) for 6 months to monitor and track their blood glucose, weight, physical activity, and medication adherence. We purposively selected 20 participants based on study engagement to participate in semi-structured interviews. As part of the study the research team developed data visualizations (e.g., charts and graphs) of these data for this subset of 20 study patients (Figure 1). The visualizations were shared with these patients retrospectively after they finished the study. The interviews focused on the patient’s participation in the study and the data visualizations.

Results: We identified two main themes related to the patients’ perceptions of the data visualizations. Patient responses about the usefulness of the visualizations were varied. Most patients (n=12), when looking at the visualization, could verbalize the relationship between the data points and their health actions. The first theme, meaningfulness of the data visualization, described how patients made sense of their healthcare data in relation to their self-management behaviors. We noted two sub-themes: (1) good to see the data—which stated that seeing the data was valuable because the patients could see the trends over time and obtained insight into their health behaviors; and (2) discrepancies—which the patient felt the visualization did not accurately depict their actions. The second theme, construction of the data visualization, described patient perceptions of the design and structure of the data visualization. Patients stated three types of suggestions for the data visualizations: requests for additional information in the visualization, various layout preferences, and access issues.

Conclusion: Effective visualizations can illustrate comparisons, associations, and trends over time in a succinct and easily understood manner. These results are the first step in understanding the differing needs of visualizing data for patients with diabetes and their healthcare providers. Our findings indicate the importance of incorporating patient feedback in the design of the visualization in order to ensure this feedback is actionable and assists the patient.

Time Expression Annotation for Multiple Clinical Specialties

Natalia Viani, PhD¹, Hegler Tissot, PhD², Ariane Bernardino, MS¹, Sumithra Velupillai, PhD¹

¹Institute of Psychiatry, Psychology and Neuroscience, Kings College London, London, UK; ²Institute of Health Informatics, University College London, London, UK

Introduction

When applying natural language processing (NLP) methods to the analysis of clinical notes, temporal information extraction is a crucial yet challenging task. The availability of temporally annotated corpora is an important step towards the development of well-performing and generalizable NLP tools. In the clinical domain, two shared corpora have been created including temporal annotations: the 2012 i2b2 corpus¹ and THYME². In this work, we present a corpus of clinical texts annotated with time expressions. This corpus will be made available to the NLP community.

Methods

We extracted documents from MTSamples (www.mtsamples.com), a collection of Medical Transcription Sample reports for multiple specialties. We selected the following specialties for manual annotation: discharge summaries, psychiatry-psychology, pediatrics, and emergency. These subsets were double-annotated for five types of time expressions (date, time, duration, frequency, and age-related), including their normalized values. As a proof-of-concept for NLP development, we applied SUTime (a rule-based system for time expression extraction) on annotated documents³.

Results

For each clinical specialty, Table 1 reports the number of documents (with total number of tokens), the number of time expressions marked by at least one annotator (merged), and those marked by both annotators (overlap). For the inter-annotator agreement (IAA), we report F1 score for text spans (allowing overlapping annotations) and type accuracy (on overlap annotations). In all document subsets, the most frequent “type disagreement” was duration-date. For SUTime, we report precision (P), recall (R), and F1 score on merged annotations (without system refinement).

Table 1: Time expression annotation and SUTime results per clinical specialty.

<td>0.76 (0.86)</td>
</tr>
<tr>
<td>SUTime P, R, F1</td>
<td>0.85, 0.73, 0.78</td>
<td>0.73, 0.71, 0.72</td>
<td>0.73, 0.84, 0.78</td>
<td>0.79, 0.74, 0.76</td>
</tr>
</tbody>
</table>

Conclusion

We present a corpus of documents annotated for time expressions, considering four clinical specialties. We will use the annotated corpus to: 1) study how temporal information is documented in clinical text, with a focus on disagreements involving durations, and 2) define new ways to capture the most useful information for clinical timeline reconstruction. The SUTime results show that our corpus can be successfully exploited for NLP system development and evaluation.

Enabling Data Democratization - Interactive Graphical Representations of Unplanned Readmissions for Cancer Patients

Cyd Charisse Villalba, MS, RN-BC, PMP, Sara Berger, MBA, Steve Martin, MD, Peter Stetson, MD, MA, Wazim Narain, PhD, MPH, Joery J. Nunez, BA, Tiffanny Newman, PhD, Patrice Schwegman, BS, Rita Reynolds Silverberg, MS, Patrick Samedy, MS, MBA, and Dhruvkumar Patel, MS
Memorial Sloan Kettering Cancer Center, New York, NY

Introduction
Cancer is the second leading cause of death in the United States, with an incidence rate increasing yearly due to an aging population. The Agency for Healthcare Research and Quality (AHRQ) approximates $80.2 billion was spent directly on cancer-related medical costs in 2015, 38% of which was incurred during inpatient hospitalizations. Current non-cancer readmissions metrics focus on 30-day all-cause, disease-specific (AMI, COPD, HF), or post-procedure (vascular, PI) readmissions. The Comprehensive Cancer Center Consortium for Quality Improvement (C4QI) along with the Alliance of Dedicated Cancer Centers (ADCC), which includes Memorial Sloan Kettering Cancer Center (MSKCC), collaborated with the National Quality Forum (NQF) to develop NQF 3188: 30-Day Unplanned Readmissions for Cancer Patients. Approved in 2019’s final ruling, it is now a required claims-based outcome measure for FY 2021. Notwithstanding regulatory compliance, the establishment of a cancer-specific readmissions metric enables a nuanced assessment of the specific factors and interventions that are most meaningful to this cohort. Medicare cancer readmissions are higher than all-cause readmissions within non-cancer institutions, and even within cancer centers, specific surgical treatments and cancers, as with bladder, pancreatic, ovarian and liver cancers, the risk of readmissions are higher (likely due to post-surgical complications, infection and dehydration). Other significant predictors of cancer readmissions include comorbidities, older age, advanced disease, and index length of hospital stay. In light of the hallmark regulation and aligning with MSKCC’s mission, the team established an unplanned cancer readmissions data source enabling intuitive and robust operational and analytical dashboards.

Methods
The in-house development team augmented a pre-existing inpatient readmissions datamart with discharge status, disposition, age, primary payor, and diagnosis, to enable application of measure criteria. Readmission rate was then trended monthly from 2017 to the most recent month with a complete 30-day post-discharge period. In addition to the 30-day metric, 7 and 14-day readmission rates were also displayed to assess whether these are more sensitive readmission markers. Other dimensions such as discharging department, service, attending and unit were also graphically presented to enable drill-down analysis. Moreover, a separate tab outlining comprehensive case details allowed for ad-hoc patient-level analysis. Lastly, the readmissions metric was integrated into high-level operational and performance dashboards, ensuring key stakeholders are aware of trends and patterns.

Figure 1. Cancer-patient readmission rate by primary payor over time.

Results
In addition to providing a baseline in preparation for regulatory compliance, the dashboard highlighted marked variances in readmissions rate and patient volume between discharging departments, services, attendings and units. These findings may aid in outlining the most appropriate benchmarking methods to apply inter- and intra-institution. Also, enabling trended comparisons between Medicare and non-Medicare cohorts for three timed metrics (7, 14, and 30-day) may be useful in providing much-needed insights into the cancer patient population at MSKCC. Further analysis is required to establish correlation, causation and clinical significance between different factors that could impact readmissions.

Conclusion
Aligning a regulatory project deliverable to a broader institutional initiative allowed one data product to fulfill multiple needs, current and future. Next steps include expanding the underlying data source to allow for broader and deeper analyses, as well as tailoring subsequent design and content for specific workgroups and use-cases.

Dynamic Phenotyping to facilitate Accrual for Prospective Clinical studies: A Case Study in Heart Failure

Introduction

The adoption of electronic health records (EHRs) in the United States has generated large datasets that enable observational research. An essential step in utilizing these datasets for research is to identify patients with certain characteristics that match a set of eligibility criteria—a process known as phenotyping or patient cohort identification. We describe a dynamic phenotyping approach to facilitate recruitment for a prospective study on heart failure.

Methods

Dynamic phenotyping consists of multiple computer-assisted screen cycles. At the start of each cycle, the phenotyping algorithm is used to identify eligible patients from the EHR, creating an ordered list such in which those patients most likely to be eligible are listed first. This list is manually screened, and the results are analyzed to improve the phenotyping algorithm for the next cycle. We applied this approach to EHR data at Brigham and Women’s Hospital (BWH) to accrue heart failure patients for an intervention study.

The eligibility criteria for the study included adult patients that had a diagnose of heart failure with reduced ejection fraction, and whose cardiac care was managed primarily by a cardiologist at BWH. We utilized a variety of algorithms for identifying the patients including rules, regular expressions for text processing, and logistic regression on coded data and concepts extracted from clinical notes. For evaluation, in each cycle we measuring the positive screen rate (PSR) using the annotations from the manual screening in the next cycle (Table 1).

Results and Discussion

A total of 1,022 patients were screened in four cycles, with 223 (23%) of patients being found eligible for enrollment into the intervention program. When a single run of computer pre-screening is used, the pool of eligible patients is expected to decline as manual screen progresses, resulting in more false positives and a subsequently downward trend in the positive screen rate (PSR). We used multiple computer pre-screens and improved the computer algorithm for each pre-screen. This process offset the dip in the PSR by providing an enriched cohort in every cycle. Without an iterative approach, the PSR was expected to dip below the 20% measured in the first cycle; however, the cyclical approach increased the cumulative PSR to 23%. Our results demonstrates that dynamic phenotyping can improve recruitment for prospective clinical studies. However, additional case studies are required to establish our finding.

Integrative workflow for lung cancer clinical decision support: needs and opportunities

Jinglu Wang, MSc, Yalini Senathirajah, PhD
1Weill Cornell Graduate School of Medical Sciences, New York, NY, USA; 2University of Pittsburgh, Pittsburgh, PA, USA

Introduction
Incorporation of clinical decision support (CDS) at the point-of-care requires integration of multiple information sources, involvement of system vendors, consideration of population data on which models may be based, and interoperability, as information may be sent outside a health system or vendor product. Currently, there are several lung cancer diagnostic and risk prediction tools online. All require the provider to perform the cognitively loading and time-consuming task of data gathering (from EMR, patient, other providers, external systems, and paper records) and insertion into (usually) online forms-based systems which then return a set of risk predictions and further recommendations. Acting on these usually involves further manual documentation, explanation to patient and other providers, order entry, and communication to other stakeholders.

Interoperability and current technical approaches
As a majority of tools are realized as online forms, the public APIs that are now required in EMRs can be leveraged to gather and send data simultaneously to multiple tools (e.g. Fleischner, Lung-RADS, NCCN) and receive back their recommendations in a common interface, allowing comparison and order entry on the provider-facing side. FHIR as both a data model and a communication standard would permit appropriate visualization and explanatory interfaces such that providers with little or no knowledge of the specific algorithms can progressively view rapid, at-a-glance status, or deeper, more visible explanation, as desired. This ‘white box’ approach would help ensure the ‘five rights’ CDS requirements (Right Information, Person, Intervention format, Channel, and Time in workflow) are met. This approach permits development of models with better AUC (accuracy of 73% for traditional clinical diagnosis vs. 85% with cognitive computing approaches). It would make use of CDS hooks, specialized patient-directed questionnaires, and NLP for other information forms such as faxes and transmitted notes. As the science changes, health information technology needs to leverage a variety of information in order to implement effective LDCT screening at the population level. There is still tremendous variation in the use of guidelines in clinical settings. Radiologist concordance on imaging studies alone vary as much as 62% on part-solid nodules to 85% on solid nodules. While clinical risk calculators are helpful, they are seldom used in the evaluation of patients due to the need for manual data entry. Recent randomized trials such as the PLCO and NLST have shown that current guidelines are suboptimal algorithms for all but the same underlying populations. Several different algorithms exist: 1. NPS-BIMC (Bayesian Inference Malignancy Calculator); 2. Brock University Calculator 3. Solitary Pulmonary Nodule Malignancy Risk (Mayo Clinic model) 4. MSKCC Lung Cancer Screening Decision Tool 5. AHRQ Lung Cancer Screening Tools for Clinicians and Patients

Conclusion
Predictive analytics holds promise but needs to facilitate patient-provider-team interaction. Newer interoperable technology combined with flexible design may allow us to align care and technology to create provider-centered workflows; only when this is done is widespread use likely and achieve the promise of precision oncology.

CLAMP-ATR: A deep learning pipeline for attribute recognition of clinical concepts

Jingqi Wang, MS, Yaoyun Zhang, PhD, Hua Xu, PhD,
School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, Texas, United States

Introduction: Attributes of clinical concepts, such as severity and negation modifiers of clinical problems in clinical text, are vital elements for clinical natural language processing (NLP). A high-performance, easy-to-use toolkit to automatically recognize attribute information of clinical concepts from clinical text is highly desirable. Here we introduce CLAMP-ATR (Attribute), a newly developed comprehensive pipeline for attribute recognition with the CLAMP NLP toolkit.¹ It not only achieved high-performance on attribute recognition across different corpora, but also made customization easier by providing a Docker container for training deep learning models and a GUI interface for building pipelines.

Methods: Currently, CLAMP-ATR recognizes three types of important clinical concepts and their attributes: 1) Problem and modifiers of subject, negation, severity, body location, etc.; 2) Lab test and its value; 3) Medication and signatures of dose, form, rout, frequency, etc. An NER model is first built to recognize primary clinical concepts, including problems, tests, and medications. Then the CLAMP-ATR will use the output of primary concepts as features to recognize their attributes. To achieve the most optimized performance of the attributes, we developed three attribute models separately. Algorithm: We use the deep learning based biLSTM-CRF algorithm for both concept and attribute recognitions. Character embeddings and word embeddings are used as input features. The word embeddings are pretrained on the MIMIC III dataset. For attribute recognition, an additional embedding layer is added to represent the primary entities as features. Evaluation: The problem-modifier model was evaluated on the data of the SemEval 2015 task 14 challenge;² the test-value model was evaluated using 338 annotated discharge summaries from MTSamples; and the medication-signature model performance was evaluated on the N2C2 shared task track 2.

Model customization: We build a Docker container for training deep learning models using local data. It works as an insulated virtual environment with all deep learning libraries and pre-set parameters. The users can run this container on their own corpus with just simple docker commands. In addition, the trainer can use GPUs if they are available in the host machine. It also provides advanced options if the users need to update the pretrained embeddings or adjust model parameters. The final model will be encoded into a single file, which can then be loaded into a CLAMP pipeline, where users can further customize it using the CLAMP interface.

Results and conclusions: The performance on each type of clinical concepts and their attributes is listed in Table 1. Notably, the performances of problem-modifier and medication-signature recognition are comparable to the top ranked in the SemEval 2015² and N2C2 challenges. The performance of test-value recognition is also promising for practical applications. Figure 1 shows the visualization of identified concepts and their attributes in the CLAMP interface. A high-performance, easy-to-use toolkit to automatically recognize concept and attribute information from clinical text will greatly facilitate related clinical and translational research and applications.

Conflicts of Interest: Dr. Xu and The University of Texas Health Science Center at Houston have research-related financial interests in Melax Technologies, Inc

Figure 1. Visualization in CLAMP
Association between Cardiotoxic Chemotherapy and Myocardial Infarction

Liwei Wang, MD, PhD1, Suzette J. Bielinski, PhD1, Paul A. Decker, M.S1, Jill M. Killian, B.S., Nicholas B. Larson, PhD, M.S1, Rui Zhang, PhD2, Hongfang Liu, PhD1
1Mayo Clinic, Rochester, MN, USA; 2University of Minnesota, Minneapolis, MN, USA

Introduction

Cancer treatment-related cardiotoxicity can occur due to direct effects on cardiac myocytes and may include damage to the vascular endothelium, hemodynamic flow alterations, and thrombotic events. Incidence of cardiotoxicity of cancer treatment vary from 7.4% to 13.3%. Assessment of the long-term effects (10–20 years) of chemotherapy on coronary heart disease is lacking. In a population based cohort, we sought to study the effect of exposure to cardiotoxic chemotherapy and subsequent coronary heart disease, defined as acute myocardial infarction (MI).

Methods

We assembled a cohort of 74,470 Olmsted county residents on 1/1/2006 with no prior history of MI using the Rochester Epidemiology Project 1 and followed them through 12/31/2016 for incident MI. To extract cardiotoxic chemotherapy exposure status prior to the index date, a four-step strategy was used. First, ingredients of all drugs these patients were exposed to before 1/1/2006 were extracted using a natural language processing tool, MedXN2. Ingredients were then identified as chemotherapy drugs by mapping to the chemotherapy ingredients provided by a knowledge base (https://hemonc.org/wiki/Main_Page). The ascertained chemotherapies were further linked to potential side effects using the SIDER knowledge base. Finally, the side effects were mapped to the System and Organ Class (SOC) of Medical Dictionary for Regulatory Activities (MedDRA) system and “cardiac disorders” SOC was used to extract cardiotoxic chemotherapies. The association of prior cardiotoxic chemotherapy exposure (ever/never) with risk of MI was assessed using proportional hazards regression, with corresponding hazard ratios (HR) and confidence intervals (CIs) reported.

Results

Of the 74,470 participants in the cohort, 6,587 (9%) were previously exposed to cardiotoxic chemotherapies. The subjects were 51±15 (range: 30-105) years old; 54% were female and 88% were white, reflecting the population of the upper Midwest. Average systolic blood pressure was 124±18 (57-252) mmHg, 22% received hypertension treatment in the previous 2 years, and 8% had a diagnosis of diabetes. Average total and HDL cholesterol was 195±38 and 56±17 mg/dL, respectively. There were 1494 (2%) incident MI during follow-up. There was a significant univariate association of exposure to cardiotoxic chemotherapy and subsequent MI. This association remained with further adjustment for age, sex, race, systolic blood pressure, hypertension treatment, and diabetes (Table 1). Similar results were observed when the analysis was stratified by sex.

Table 1. Results for the association of exposure to cardiotoxic chemotherapy and MI.

Conclusion

Leveraging an existing cohort of 74,470 Olmsted county residents, we identified a significant association between exposure to cardiotoxic chemotherapy and subsequent MI. Future work will expand to investigate the association of chemotherapies and other cardiovascular diseases as well as explore mediating factors such as increased burden of cardiovascular risk factors in cancer survivors.

Design and Evaluation of a Decision Support Risk Calculator for Radiotherapy for Older Women with Early-stage Breast Cancer

Shi-Yi Wang, MD, PhD¹, Suzanne B. Evans, MD², Sarah Mougalian, MD², Brigid K. Killelea, MD¹, Liana Fraenkel, MD, MPH², Cary Gross, MD², Fuad Abujarad, MS, PhD²

¹Yale School of Public Health, New Haven, CT, USA; ²Yale School of Medicine, New Haven, CT, USA

Radiation therapy – or radiotherapy – is typically received by women with breast cancer after a lumpectomy to lower the risk of cancer recurrence in the affected breast.¹ The benefits of radiotherapy largely depend on tumor characteristics, comorbidities, and the patient’s functional status.² In fact, it has been found that radiotherapy can be safely omitted for a majority of older women aged 65 or older with early-stage breast cancer.³ In order to ensure that these women do not receive unnecessary therapy that could potentially cause undue harm, we developed a web-based mobile application for comprehensive risk calculation called “Radiotherapy for Older Women” (ROW). This tool provides individualized estimates of overall survival and local recurrence, accounting for patient age, comorbidity, functional status, and tumor characteristics. These estimates are presented in a readily interpretable manner, which patients and providers can use to discuss whether the patient should pursue or forgo radiotherapy.

ROW was developed using a User-Centered Design (UCD) approach. We first estimated individualized risks of breast cancer recurrence, breast cancer mortality, and all-cause mortality using simulation modeling. The simulation model integrated two existing prediction models, the Early Breast Cancer Trialist Collaboration Group prediction model for breast cancer specific outcomes and ePrognosis for life expectancy. We then convened an advisory committee comprised of breast cancer survivors, patient advocates, oncology clinicians, and researchers to receive feedback on the tool’s functionality. We also used expert interviews and stakeholders group meetings to develop a set of functional and technical patient-centered requirements. We incorporated users’ needs and limitations at each stage of the design process per the UCD approach and conducted User Experience (UX) evaluations as well to ultimately produce a usable and acceptable software that delivers a more satisfying user experience. To demonstrate feasibility, we have been testing the use of ROW with two groups of older women subjects: healthy volunteers and breast cancer patients. We have been gathering performance and satisfaction data to evaluate the extent to which the user interface function matches the user requirements in design specification, which will ensure that user needs have been met. It is possible that our tool could integrate with the EMR in the future. Currently, we are validating the tool without integration to ensure its feasibility.

To date, we have recruited 20 healthy volunteers and 5 breast cancer patients for the feasibility evaluation. Our initial analyses suggest that women are very satisfied with the tool and that 96% of women would recommend the use of this tool to others. The majority of women have stated that they liked the tool and that it was easy to use, and most thought that the functions in the tool were well integrated. A majority of women have also reported high confidence in their ability to navigate the tool on their own and have stated that it is easy to learn. At this stage, we feel it is important for the patient to use the tool under the supervision of the provider. These results suggest that ROW is feasible and satisfactory for older women with breast cancer, and there is potential for the tool to reduce barriers to decision support implementation and improve patient-provider communication. The study is currently ongoing to further validate this tool.

Trajectories of Functional Status of Cognitively-impaired Patients in EHRs

Yanshan Wang, PhD, Sunghwan Sohn, PhD
Division of Digital Health Sciences, Mayo Clinic, Rochester, MN

Introduction
The aging population has led to an increase in cognitive impairment (CI) resulting in significant costs to society. In general, CI is diagnosed by clinicians through assessment. However, it is not routinely performed, causing a delay in timely diagnosis. Currently, little is known about temporal trends of patient health functions (i.e., activity of daily living [ADL]) in electronic health records (EHRs) and how these trends are associated with the onset of CI in elderly patients. We investigated the use of EHRs to better understand early signals of elderly patient CI by examining ADL trajectories.

Materials and Methods
The study data consists of physician-diagnosed CI patients (n=1,435) and cognitively unimpaired (CU) patients (n=1,435) matched by age and sex from patients 65 years of age or older in the Mayo Clinic Biobank. The physician-diagnosed CI patients were determined based on diagnosis under the diagnosis section in clinical notes. The ADL was collected from the current visit information (questionnaires) and specific sections in clinical notes, such as instructions for continuing care, ongoing care orders, and system review. The clinical notes were processed by the MedTaggerIE (https://github.com/medtagger/MedTagger), a clinical NLP pipeline developed by Mayo Clinic, to extract ADL related concepts. We use the ADL categories as follows: basic ADL - bathing, dressing, transferring, toileting, and feeding; instrumental ADL - transportation, preparing food, housekeeping, and responsibility for own medications. The trajectories of ADL between CI and CU patients were compared in every 6 months for 5 years before the first physician-diagnosed CI and the latest visit for CI and CU patients, respectively. The ratio and trends of deteriorated ADL and/or patients were analyzed.

Results
CI patients had more deteriorated ADL than CU patients for all ADL categories. Fig 1 shows the ratio of deteriorated ADL for each category, 1 year before CI diagnosis for the CI group and the latest visit for the CU group. The most deteriorated ADL in 1 year prior was transferring (13% for CI and 10% for CU patients) in basic ADL and housekeeping (10% for CI and 7% for CU patients) in instrumental ADL. The instrumental ADL (a right half in Fig 1) was more deteriorated than basic ALD (a left half in Fig 1). The difference between the two groups is relatively small for feeding and transferring. The trajectory for responsibility for own medication was the steepest among ADL categories. Fig 2 depicts the deteriorated ratio of responsibility for own medication for the past 5 years (the dotted line denotes linear trend). As can be seen in Fig 2, CI patients have a much steeper slope when approach to the CI diagnosis than CU patients, which is notable much before the actual CI diagnosis.

Discussion
We have observed notable differences in trajectories of ADL mined from EHRs between CI and CU patients, approximately 1 to 1.5 year(s) earlier than actual physician-diagnosis CI. The trajectories of certain individual ADL (e.g., responsibility of own medication) were closely associated with the CI development and might have a potential to surrogate costly assessment, facilitating a routine practice (i.e., EHR data) in clinical care and research.
Clinical Use of an Information Retrieval Framework for Cohort Discovery from Electronic Health Records

Yanshan Wang, PhD1, Andrew Wen, MS1, Sijia Liu, PhD1, Jennifer St. Sauver, PhD1, Adil E. Bharucha, MD2,3, Chunhua Weng, PhD4, Hongfang Liu, PhD1
1Department of Health Sciences Research, Mayo Clinic, Rochester, MN, USA; 2Department of Internal Medicine, Mayo Clinic, Rochester, MN, USA; 3Center for Clinical and Translational Science, Mayo Clinic, Rochester, MN, USA; 4Department of Biomedical Informatics, Columbia University, New York, NY, USA

Background

The widespread adoption of Electronic Health Records (EHRs) has enabled secondary use of EHR data for clinical research and healthcare delivery. Many institutions have established clinical data warehouses (CDWs) in conjunction with cohort discovery tools, a majority of which are based on relational databases, such as i2b2, to enable investigators to use EHRs for cohort discovery in clinical research. As a significant portion of clinically relevant patient information is embedded in clinical narratives, cohort discovery using only structured data such as diagnosis codes or procedure codes will display limited retrieval performance. To compensate for this, substantial efforts have been made to use clinical narratives for cohort discovery; one major approach is the usage of natural language processing (NLP) to encode concepts from unstructured EHR data for cohort retrieval. However, existing NLP methods for concept encoding are either optimized for a single information extraction task or have imperfect generalized performance. This problem is magnified when the extracted NLP artifacts are utilized in downstream applications, such as concept matching for cohort criteria. Information retrieval (IR) is a field that is concerned with the structure, analysis, organization, storage, searching, and retrieval of relevant information. While IR has established its success in providing easy access to the vast amount of information available on the Web, IR has not been widely utilized in cohort discovery due to its lack of ability to handle complex EHR data and cohort criteria.

Method

A novel IR framework empowered by NLP is currently under-development at Mayo Clinic that will be able to store and index EHR data, and retrieve and rank patients for cohort discovery tasks using not only structured EHR data, but also unstructured clinical text. The IR framework is a toolkit independent of the data to be indexed, and thus it is generalizable and portable. Due to these innovations, the IR framework has an advantage over traditional cohort discovery tools for querying unstructured EHR data as well as an advantage over text-based search engines for querying both structured and unstructured EHR data given complex cohort criteria with contextual constraints. However, the challenge we have been facing are: 1) what would be the ideal clinical use cases of the IR framework, and 2) how to evaluate the framework.

This study aims to identify the clinical use cases for utilizing and evaluating our cohort discovery tool based on an information retrieval (IR) framework. Two practical clinical applications have been found: identifying patient cohorts for retrospective clinical studies, and recruiting patients for clinical trials. Retrospective cohort studies, one of the research areas that mostly rely on EHR data, have been used to evaluate population health and identify risk factors. Enabled by the Rochester Epidemiology Project (REP), many cohorts have been created with EHR data. Another clinical use case is clinical trial recruitment, which is fundamental to the success of randomized clinical trials since it remains the biggest barrier to clinical and translational research. Mayo Clinic ranks No. 1 among 51 academic institutions in terms of both number of clinical trials and number of results reported. The data of a number of completed clinical trials and recruited patients are available at Mayo Clinic to evaluate the approach.

Results

20 cohorts were identified from REP studies based on disease areas and study time. These cohorts covered different diseases, such as zoster, heart disease, and fracture. Another 20 completed clinical trials at Mayo Clinic were identified, for which the EHRs of these recruited patients were available at Mayo Clinic.

Conclusion

This study identified 40 cohorts from two clinical use cases, including identifying patient cohorts for clinical studies and recruiting patients for clinical trials, that could be potentially used to utilize and evaluate our IR framework.
Analysis and Resolution of Medication Terminology Errors to Achieve Semantic Interoperability between the Department of Veterans Affairs and Department of Defense

Pradnya P. Warnekar, MSHI1, Jaqui Parker, RPh1, Carol A. Bean, Ph.D1, Daniel Territo, MS1, Lauren C. Thompson, Ph.D1
1 VA-DoD Interagency Program Office, Rosslyn, VA

Introduction

The Clinical Data Repository/Health Data Repository (CHDR)1 is a health information exchange framework between the Department of Veterans Affairs (VA) and Department of Defense (DoD), used to transmit, in real-time, allergy and medication profiles for patients registered for care in both Departments by using national terminology standards. VA and DoD have their own processes to map local medication names to RxNorm2. The RxNorm name and RxNorm Concept Unique Identifier (RxCUI) are transmitted to the recipient Agency in a HL7 message. The receiving Agency translates the RxCUI back to an equivalent local code that participates in its existing clinical decision support systems. If the receiving Agency cannot translate the RxCUI, a terminology error is recorded, and the medication is not stored in the patient’s medical record. This results in exchange of an incomplete patient medication profile and physicians must spend time collecting and documenting the missing information. Most of the terminology errors are resolved "naturally" when the subsequent versions of mapping files are deployed in production, but interoperability suffers in the meantime and comparable errors recur in the new files. This paper analyzes the causes and rates of medication terminology errors in CHDR over the calendar year 2018 and suggests ways to resolve errors in a shorter time frame.

Materials and Methods

For the current analysis, CHDR production audit logs from January 01, 2018 to December 31, 2018 were queried for all medication terminology errors. All the RxCUIs that each Agency received and could not map back to one of its local codes were collected. A list of all unique RxCUIs with their frequencies was compiled for VA and DoD. Both lists were compared to the next versions of mapping files from both Agencies and RxNorm February 2019. The comparison allowed identification of errors that would be resolved by the next content updates at both Agencies. The errors that would not be resolved by the next content updates were divided into three groups: (1) Errors due to mapping rules differences (2) Erroneous mappings (3) Formulary differences between the two Agencies.

Results

In 2018, the total number of translations attempted at VA and DoD were 59,440,924 and 27,397,326 respectively. The number of failed translations at VA and DoD were 3,335,496 (1327 unique RxCUIs) and 1,159,114 (612 unique RxCUIs) respectively. When the latest mapping files are deployed in production, two types of content updates will occur: (1) retired RxCUIs will be replaced by active RxCUIs, and (2) the latest VA and DoD medication names, with their corresponding RxCUIs, will be available for exchange. These updates will resolve approximately 86% of DoD errors and 67% of VA errors. Of the unresolved errors, mapping rules differences and mapping errors account for 64% of VA and 78% of DoD errors. Differences between the two Agencies’ formularies cause 36% of VA and 22% of DoD errors. For example, VA carries the tablet form of Ibrutinib 140 MG while DoD carries the capsule.

Conclusion

To achieve and maintain a successful mediation terminology-based interoperability effort, common mapping rules, frequent, coordinated content updates, error monitoring and resolution, and open, regular communications are needed.

Scalable Process to Generate Aggregated Patient Data for Analysis

Nich Wattanasin, MS¹, Taowei David Wang, PhD¹, Vivian Gainer, MS¹
Shawn N. Murphy, MD, PhD¹,²
¹Partners Healthcare, Boston, MA; ²Massachusetts General Hospital, Boston, MA

Abstract
The Informatics for Integrating Biology and the Bedside (i2b2) platform is a framework enabling clinical research and data analysis at participating sites of the Accrual to Clinical Trials (ACT) network. At Partners Healthcare, we have developed a scalable and self-service approach for generating aggregated patient data to support the patient recruitment process for ACT.

Introduction
The goal of the National Clinical and Translation Science Award (NCATS) Accrual to Clinical Trials (ACT) project is to create a federated network made up of sites from the Clinical and Translation Science Award (CTSA) Consortium to accelerate participant accrual to the nation’s highest priority clinical trials. The network for cohort discovery utilizes the Shared Health Research Information Network (SHRINE) platform to connect CTSA hubs comprised of Information for Integrating Biology and the Bedside (i2b2) clinical data warehouses for research.

One of the aims of ACT is to enable the identification of potential research subjects for clinical trials among the ACT participants across the CTSA consortium. While initial cohort discovery and feasibility studies are made by obtaining aggregate patient counts from sites in the network, the in-depth work to select potential research subjects for recruitment is performed at each local site using informatics tools that we have developed.

Methods & Results
At Partners Healthcare, we have developed an i2b2 plugin that enables the viewing and exporting of aggregated patient data—one patient per row—from an i2b2 data warehouse. The plugin makes use of a new scalable processing engine that we developed called ai2b2 which assists with constructing the output file from the i2b2 Patient Data Object (PDO) in a multi-threaded and shared worker pool approach. This enables the ability for local investigators to review and retrieve aggregated patient data files from i2b2 in a reliable, efficient, and self-service way.

The investigator first picks a query in i2b2 that represents the desired patient population for the output file, chooses health-related criteria—such as demographics, diagnoses, medications, or labs—to define the columns of the file, and finally, selects the desired aggregations to generate. This workflow produces a “job file” which the ai2b2 engine utilizes to start spawning workers in the background to create the file (Figure 1). The result of this plugin is a comma separated value (CSV) file constructed from many “blocks” created by each worker communicating with i2b2—completely in the background and detached from the user’s browser session.

![Workflow Diagram](image)

**Figure 1.** Workflow after an investigator starts the file creation process from the plugin

Conclusion
The scalable process to be able to generate high-quality and relevant data sets from the i2b2 data warehouse has many applications. Existing i2b2 data warehouses already support the capability to serve patient data beyond the aggregate count. However, this plugin helps to unlock, organize, and present that data to an investigator in a managed way. For the ACT project, this plugin supports the patient identification workflow by producing aggregated data sets which investigators can use to help find potential clinical trial participants.
Great expectations: patient response to portal invitations to contribute to their electronic medical records

Emily C. Webber, MD1,2,3; Courtney Hines2; Leiza Schmoll2; Danyelle Binko, MHA2; Jason T. Schaffer, MD2,3; and Seung Park, MD2
1Riley Children’s Health, Indianapolis, IN; 2Indiana University Health, Indianapolis, IN; 3Regenstrief Institute, Indianapolis, Indiana

Introduction Patient interest and ability to use a portal to their EHR can be variable, despite widespread use1 and aligning patient and clinician needs with technical functionality is critical to success.2 In this project, we report a project to deploy patient contribution forms across several hundred clinics, allowing to patients to contribute data to their EHR through their portal, employing continuous improvement to sustain high levels of responses.

Methods Content for “Clipboards” was selected for widespread value to clinicians and patients, including analysis of clinical data and questions routinely gathered on paper forms. The primary components included: medical history (diagnoses or problems), procedural history, allergies, and a review of systems. The type of visit most likely to collect this data were included, and mapped to an appointment type. The “Clipboards” were distributed via portal to patients with the upcoming appointments, and the patients received an email alerting them to a new form in their portal and reminding them of their upcoming appointment. After completion and being submitted by the patient, the data was reviewed during the visit by the clinical team for inclusion or rejection from the EHR. There were two changes during our study: the first was an update to the “Clipboard” content which removed the review of system and reduced the overall number of Clipboards (based on patient and clinician input). In the second change, patients did not receive e-mail notifications of a waiting Clipboard.

Results Patient response rate in the first month increased to around 28% consistently. The review of systems was noted to be ‘too technical’ by patients leaving comments on the portal itself. Initial feedback from specialists was that the included components were not always addressed, particularly the review of systems section. After removing some appointment types and replacing the review of systems with a free text field for “concerns this visit”, patients continued to complete the Clipboards around 28% of the time, with a smaller group of appointments included. After the removal of the email notification reminders, patient response remained consistent.

Discussion Patient portal efficacy has been described as a means for niche populations or disease specific efforts to improve engagement; however, in this effort we describe a systematic effort to leverage the portal to for common elements of medical history. Response rates by patients have remained stable at 28%. We anticipate that with additional content that is widely appealing – including the medication list – will increase this response rate and establish new expectations for a ‘normal’ rate of patient engagement with this particular element.

Introduction: Prescription opioid use has more than tripled since the early 2000s and accounts for approximately 24 percent of all opioid misuse-related overdose deaths in the United States in 2017. Previous studies have relied on structured data (International Classification of Diseases - ICD codes) to estimate the prevalence of opioid-related utilization. Concerningly, without including unstructured clinical data these studies may have underestimated the true prevalence of opioid-related utilization. The purpose of this study is to compare prevalence estimates of opioid-related emergency department (ED) encounters using only structured data to a combination of structured and unstructured data using a natural language processing (NLP) approach.

Methods: Our sample included ED encounters from two hospital systems in Indiana from 2012-2017. Patient demographic and encounter data, 30-day prescription history, and unstructured clinical notes were drawn from a statewide health information exchange. We estimated the prevalence of opioid-related ED encounters to analyze trends in encounters using structured data, unstructured data, and a combination of both. To extract narrative clinical text, we developed a dictionary of opioid-related terms appropriate for the ED setting and comparable to past research. A rule-based NLP approach was used to identify encounters that included an opioid term (e.g. “heroin”, “oxycodeone”) in combination with a problem use term (e.g., “abuse”, “misuse”) from unstructured clinical text. We conducted a preliminary computer-assisted chart review of the NLP search strategy on a sample of each cohort (ICD, NLP, NLP/ICD). Kappa coefficients were produced to assess agreement between two abstractors among the three identification approaches. Lastly, we estimated a logistic regression model to identify patient, encounter, community, and prescription history associated with being ‘miscoded.’ We considered an encounter to be miscoded if NLP identified an encounter as opioid-related but there were no opioid misuse-related ICD codes identified in that encounter.

Results: A total of 13,352 patient encounters were identified as having been opioid related using only structured data, with significant increases from 2012 to 2017 (Figure 1). The rate of ICD code-identified encounters was 57.4 per 10,000 in 2017. When we included encounters identified using NLP, the rate of overall opioid encounters increased to 132.6 per 10,000 prior to validating the NLP approach. Inter-rater reliability between two abstractors was notably high for ICD-identified encounters (κ=0.87, and 91% agreement), NLP-identified encounters (κ=0.89, and 98% agreement), and a combination of NLP- and ICD-identified encounters (κ=0.90, and 100% agreement). Although agreement between abstractors was high, the NLP algorithm misidentified opioid misuse 48% of the time in the preliminary review. We expect the true prevalence rate of NLP-identified opioid misuse encounters to be approximately 95 per 10,000 given the false positive rate of the NLP algorithm. Regression results indicate that daytime encounters (OR: 1.213, p<0.003) and Medicaid beneficiaries (OR: 1.024, p<0.001) have greater odds of a miscoded opioid-related encounter.

Conclusions: This research reveals a gross underestimation of the prevalence of opioid misuse encounters in the ED. Natural language processing methods may provide better prevalence estimates of opioid misuse encounters when combined with structured data; however, reassessing predetermined rules may yield more accurate estimates. Encounter and patient characteristics also indicate whether an encounter is miscoded using NLP methods versus ICD codes, which may further inform the need to retest NLP rules. Additionally, future research will utilize comparisons of machine learning based lexical identification methods.

Exploration of the Dental Informatics Working Group in the American Medical Informatics Association

Karmen S. Williams, DrPH, MBA¹, Neel Shimpi, BDS, MM, PhD²
¹Indiana University Fairbanks School of Public Health & Regenstrief Institute, Indianapolis, IN, USA; ²Center for Oral and Systemic Health, Marshfield Clinic Research Institute, Marshfield, WI, USA

Abstract

Dental informatics, as a potential core discipline, is yet in its infancy. American Medical Informatics Association’s (AMIA) Dental Informatics Working Group is comprised of various interdisciplinary practice, academic, and researcher leaders. To understand the insight of practitioners and researchers in the field, an 8-question survey was sent to the membership of the Dental Informatics Working Group. The perspectives of this survey were used to develop goals and objectives and to build action plans for implementing a positive change and active participation in the working group.

Introduction

New and still emerging field within informatics, dental informatics has the potential to bridge the gap between clinical care coordination in dental and medical settings. As an even newer working group within AMIA, dental informatics seeks to serve, collaborate, and share information within and outside AMIA communities. The mission of the Dental Informatics Working Group (DI-WG) is: to serve individuals and organizations with interest or involvement in health informatics with an emphasis on dental informatics; to collaborate with other health care specialties to improve healthcare applications; and to share expertise and experiences in the use of dental information systems, computer technology, and communications to improve patient care, research, and education. The objective of this project was to gain perspective of the DI-WG membership and the impact of DI-WG on the field of dentistry, dental informatics, and dental research.

Methods

A voluntary and anonymous, 8-question online survey of multiple choice and open text questions, was sent to the members of the DIWG for a duration of 4 weeks prior to the 2018 AMIA Annual Meeting. The questions included an assessment of years involved in dental informatics, research interest areas related to applying informatics to dentistry, challenges and opportunities in dental informatics, inciting the next generation, potential presentation topics, interest in presenting topic, and additional comments on increasing DI-WG presence in AMIA.

Results

A response rate of 19% (10/52) was achieved. Based on the summary of 52 members, 33 members represent academic organizations, 12 hospitals and industry, and 7 research institutions. Approximately 30% of respondents were been involved in dental informatics for 2-5 years, and 10 percent with over 20 years of experience. While one person was not involved in research, clinical decision support systems and tools, quality improvement, and dental and medical data integration was the most commonly mentioned research interest. Multiple challenges were indicated including linkage of dental records to rich physical health data, removing siloes and working together with meaningful collaboration among dental informatics professionals, and training and awareness of informatics in dentistry. Targeted educational curriculum, research opportunities being made available to students, and systematic outreach and recruitment strategy were among the responses for inciting the next generation.

Conclusions

Dental informatics is a building field within health informatics with an exciting outlook on growth for the future. Collaboration among dental informaticians and health care was a reoccurring theme. The DI-WG has a commitment to serve, collaborate, and share with all health specialties for the ultimate goal of true patient-centered care.
Automated Discovery of Common Data Elements in HIV Clinical Trials
Using an Interaction Network
Nick D. Williams, Ph.D, Craig S. Mayer, MS, Sigfried Gold, MFA, MA,
Vojtech Huser, MD, PhD, Kin Wah Fung, MD
1Lister Hill Center at the National Library of Medicine, Bethesda, MD, USA

Introduction
HIV clinical trials represent an untapped data re-use opportunity in a crucial research area. Reusing HIV clinical trial data variables in secondary analysis sourced from multiple studies requires the discovery of common data elements (CDE) across HIV studies. Ideally, clinical trials should re-use CDEs right from the beginning when the case report forms are designed. But in reality, most trials invent their own data elements and finding commonality across trials is only an afterthought. Very often, the burden of finding CDEs falls on the data analysts who re-use the data.

Methods
We collected clinical trial variable descriptions from 15 HIV clinical trial data dictionaries. Trial dictionaries were sourced from several harmonization schemes including dbGaP, Veterans Affairs, BioLINCC, IeDEA and NIDA DataShare. Extracted variable descriptions were mapped to UMLS concepts through MetaMap. Eleven semantic types (e.g., birds and plants) were excluded empirically; as they returned no relevant UMLS concepts. Variable description-UMLS concept pairs were processed in Cytoscape into a UMLS concept (node) to variable description (node) interaction network. The network was clustered using Mcode; which was tuned to produce the largest number of clusters; not the most UMLS concept specific. All identified clusters were reviewed manually.

Results
A total of 4,867 variables mapped to 4,282 unique UMLS concepts. The network contained 9,149 nodes and 29,450 edges. Altogether, 251 clusters encompassing 1,758 variables were identified with Mcode. Manual review confirmed 55% of the clustered variables were true positives (TP) i.e., the variables were the same or closely related to their UMLS concepts. Many of the false positive variables (FP) were cases in which variables which should form two or three clusters were mingled (Table 1). If an algorithm could be trained to correctly detect the cluster boundary in the bi-centered and tri-centered clusters, the overall true positive rate would become 88.8%. We found 566 TP variables (in 77 correct clusters) that originated from two or more distinct studies. These would be the likely variables which could become CDEs across studies.

Table 1. Variable Description True and False Positives in Result Clusters

<table>
<thead>
<tr>
<th></th>
<th>Variable TP</th>
<th>Variable FP</th>
<th>% of TP clustered variables</th>
</tr>
</thead>
<tbody>

Discovery of Nurse-Patient Assignment in Medication Dispensing Data
Dana M. Womack, PhD, RN, Michelle R. Hribar, PhD, Paul N. Gorman, MD
Oregon Health & Science University, Portland, OR, USA

Introduction
Clinician burnout is an important workplace concern that is attributable to multiple causes. In particular, excessive workload is a predictor of nurses’ intention to leave their organization and profession, and it is a contributor to missed nursing care. In applied informatics research, the nurse-patient assignment is an important unit of analysis because it reflects nurse workload. Digital availability of nurse-patient assignment is often lacking, as assignment data is often recorded on paper in hospitals that utilize electronic health records. To support research in hospitals that lack electronic assignment data, there is a need for automated derivation of nurse-patient assignment data from available electronic data sources. Medication dispensing data includes information about the nurse, patient, and medication administered, making it a potential source for the nurse-patient assignment.

Purpose
The purpose of this study is to develop and validate a method for automated discovery of nurse-patient pairs using data produced by medication dispensing cabinets.

Methods
The Cross-Industry Standard Process for Data Mining was employed to develop an understanding of patient assignment practices and data sources, prepare a data set, define a method, and evaluate method accuracy. Data were extracted from an Omnicell® automated medication dispensing cabinet. The nurse who dispensed the greatest number of medications for a patient during a work shift was identified as the patient’s assigned nurse. Method accuracy was assessed through comparison of derived and paper-based pairs for a 1-month time period. Discrepancies were reviewed by a Technical Expert Panel which provided recommendations for interpretation of observed differences.

Results
A total of 1,400 nurse-patient pairs were derived through application of the method to data from a 1-year time period. In the 1-month test period, paper sheets contained 10 nurse-patient pairs not present in the derived set, and the derived set produced 18 pairs that were not present on paper. Derived nurse-patient pairs matched paper-based pairs in 393 of 450 test cases (87% accuracy) using exact match criteria.

Discussion & Limitations
Medication dispensing data contains information that can determine nurse-patient assignments with reasonable accuracy compared to paper records of nurse-patient assignments. Paper assignment sheets were not a complete record since some patients who received medications during a shift did not appear on the assignment sheet. The technical expert panel advised that missing patients likely represent new admissions, and suggested that derived data may more accurately represent historical data. With that assumption, accuracy of derived assignments increases to 91% as compared to paper assignment sheets that were 96% complete. A limitation of this method is that it works for historical data only. If used in real-time, accurate assignments would not be available until nurses have administered a majority of scheduled medications during a shift. In addition, patients who do not receive medications are not observable.

Conclusion
Retrospective derivation of nurse-patient assignment data is feasible in hospitals lacking electronic assignment data. The defined method produces high accuracy and serves as a facilitator for research at the nurse assignment level.

Recommendations for a Medical Device Knowledge Base

Melinda Wong, BS Pharm, RPh,1 Karen M. Bavuso, RN, MSN,1
Emily Man Wai Chan, PharmD, RPh,1 Martin Schotel,1 Saverio Maviglia MD, MS,1,2,3
Roberto A. Rocha, MD, PhD1,2,3
1Semedy, Inc., Waltham, MA; 2Brigham and Women’s Hospital, Boston, MA;
3Harvard Medical School, Boston, MA

Introduction
Medical devices are essential for the diagnosis, management, treatment, or prevention of disease or condition. Over the past few years, there has been significant global legislative and regulatory changes in the medical device industry in an effort to establish standardization and tracking of medical devices for safety and performance. However, there is a lack of knowledge base with clinical device information which can enhance quality of care and improve clinical outcomes (e.g. find medical devices manufactured with latex).1 We provide recommendations for types of information to include in a medical device knowledge base to support clinical decision support systems.

Methods
We reviewed publications and other online sources to identify potential information gaps pertaining to the representation of medical devices and creation of an integrated knowledge base.1,2 We assessed adverse events associated with medical devices from a published case report.3 In addition, we reviewed event descriptions of a subset of class II and III devices (i.e. categorized as moderate to high risk to patients and/or users) from the adverse event database managed by the “Food Drug Administration” (FDA), known as the “Manufacturer and User Facility Device Experience” (MAUDE).4 There were limitations in reviewing these sources since the narrative descriptions were based on observations reported and not systematically collected using a predefined protocol. However, for the purpose of knowledge representation, these sources provided general understanding and opportunities for developing a medical device knowledge base.5

Results
We successfully identified several properties that should be included in a medical device knowledge base: (a) product identifiers and descriptors (e.g. device identifier, model number, catalog number, serial number, expiration date); (b) use materials that can cause hypersensitivity reactions (e.g. natural rubber latex, cobalt alloy); (c) possible device interactions including device-device and device-human tissue (e.g. wearable defibrillator and ventricular pacemaker; surgical stapler and human tissue); (d) storage and handling requirements (e.g. specific temperature and humidity levels); (e) requirements prior to use (e.g. sterilization requirements); (f) warnings, precautions, and adverse events; (g) maintenance requirements (e.g. calibration and testing); and also (h) indications for use.

Conclusion
A medical device knowledge base can provide a valuable resource to health care providers, while also aiding in the decision-making processes. We confirmed that adverse events from medical devices and survey responses from health care specialists can provide insights on the type of information that must be included in a medical device knowledge base, contributing to patient safety and outcomes.

Title: Identifying documented medical non-adherence from clinical notes using natural language processing

Joy Tzung-yu Wu, MD MPH\(^1\), David William Grant, MD\(^2\), Shrey Lakhotia, BDS\(^3\), Patrick D Tyler, MD\(^4\), Daniel F Gruhl, PhD\(^5\), Chaitanya Shivade, PhD\(^6\), Sebastian Gehrmann, PhD\(^7\), Leo A Celi MD, MS MPH\(^8\)

Paulson School Of Engineering And Applied Sciences, Harvard University, Cambridge, MA

Introduction

Patient non-adherence (NA), which is estimated to cost around $100 billion annually to the United States healthcare system is an example of clinical information that is only recorded in unstructured clinical notes\(^1\). NA is a behavior when patients do not follow important medical advice. It is thought that NA increases the risk of undiagnosed and poorly-treated illnesses, with consequences ranging from worse patient-centered outcomes to biasing results of clinical drug trials if the effect was not properly controlled.

Our contribution is twofold. Firstly, we present an experts-in-the-loop distantly-supervised NLP pipeline to extract NA. Note that this is documented non-adherence, which results from clinicians choosing to make a note. Such decisions may be shaded by clinician bias but this analysis of this is out of scope. The NLP pipeline was developed without spending significant clinical resources on annotation (<30 hours). We show a comparison of the estimated clinical resource if we had tried to develop a fully supervised NLP algorithm to extract the NA feature. Our second contribution is a quantitative characterisation of patients exhibiting “documented non-adherence”. To the best of our knowledge, this has not been done before in the clinical literature. The patient population in our case came from a tertiary academic hospital in the United States. However, the approach presented should be replicable to extract the NA feature and understand characteristics of other patient populations.

Methods

NLP pipeline - Clinicians used an unsupervised “salient terms” proposal and curation NLP tool\(^2\), which has a user-friendly interface, to efficiently expand the vocabularies indicative of NA if mentioned in clinical notes. We also clinically grouped these documented NA terms into 5 subtypes, which include: 1) medication NA, 2) appointment NA, 3) refusal against medical advice, 4) dietary NA, and 5) NA, not otherwise specified. Subsequently, a rule-based NLP pipeline was developed to extract the NA features from notes. First we detect whether a NA term was mentioned by a note. If no mention, the note is negative for NA. If mentioned, we used NLTK to tokenize sentences in the note, and Negex to detect negation at sentence levels. If NA was not negated in most sentences in a note, then the note is deemed to contain evidence of documented NA. To improve recall, medication and dietary NA were broken down to their conceptual components (medication, diet, and non-adherence) to be captured separately if they occur in the same sentence (e.g. patient [missed] several doses of her [warfarin]). Subsequently, any hospital admission that includes any note with evidence of documented NA as per our NLP pipeline was predicted to have NA.

Test dataset for agreement - Two clinicians (DWG, SL) independently annotated 300 notes (50 notes randomly sampled from notes that just mention terms for each predicted NA subtype plus 50 notes that do not mention any NA terms) to evaluate the NLP pipeline.

Clinical analysis - An open source intensive care unit (ICU) database (MIMIC-III\(^9\)) is used for this study. We included all patients aged between 10 and 90 at their first hospital and ICU admission, and performed a quantitative analysis of their demographic, comorbidities, ICU severity, readmissions and mortality outcomes as grouped by the presence or absence of NA and its subtypes.

Results: Table 1 shows the inter-annotator and agreement with the NLP results on NA overall and for each specific NA subtype.

<table>
<thead>
<tr>
<th></th>
<th>NA overall</th>
<th>Medication</th>
<th>Appointment</th>
<th>Dietary</th>
<th>Refusal AMA</th>
<th>NA, NOS</th>
<th>No evidence of NA</th>
</tr>
</thead>
<tbody>
<tr>

<td>0.88</td>
<td>0.84</td>
<td>0.76</td>
<td>0.94</td>
<td>0.88</td>
<td>0.74</td>
<td>0.92</td>
</tr>
<tr>
<td>Average NLP % agreement</td>
<td>0.87</td>
<td>0.84</td>
<td>0.74</td>
<td>0.89</td>
<td>0.80</td>
<td>0.79</td>
<td>0.96</td>
</tr>
</tbody>
</table>

Conclusion

We curated lexicons of terms indicating five different different types of documented NA behaviors in notes. Using these lexicons we built a rule-based NLP pipeline to identify NA patients. An evaluation of the pipeline using gold standard curated by clinicians resulted in a performance of 87% accuracy. A comparison of NA across different dimensions in the EHR shows interesting trends.

Development of a Consult Management Tool to Streamline Consult Scheduling Process and Improve Staff Satisfaction

Jianji J. Yang, PHD, Jonathan Sun, MS, Mika Asher, BS, Jerry Kohler
VA Portland Healthcare System, Portland, Oregon

Introduction

Electronic Consult is a common feature in EHR systems, such as Computerized Patient Record System (CPRS). In CPRS, a consult is used as a two-way communication on behalf of a patient consisting of a provider (sender) request seeking expertise from another provider (receiver) regarding evaluation or management of a specific problem. Upon receiving the consult, the receiving service will schedule a visit with the patient to evaluate the issue before providing expert advice to the sender.

In 2016, Veterans Health Administration (VHA) issued a Directive to update and standardize consult business rules, processes and procedures, clearly defining oversight responsibilities. It outlines the requirements and timelines for each steps of the consult processes in details, e.g. submission, unit level management, tracking and closure.

Problem Statement

The Directive requires action taken within 3 days after a consult is submitted and multiple scheduling attempts (phone calls and letters) over a period of 2 weeks prior to discontinuing a consult if no response from the veteran. There was no system to track the consult lifecycle, and no good ways for staff to check where they were and where they had left off. Because of the asynchronous nature of scheduling, schedulers relied on a labor-intensive manual approach involving daily printing of lists for review in CPRS to determine action needed for each consult. The process resulted in duplication of work, delays in timely contacts and consult discontinuation, as well as low staff satisfaction. The aim of this project was to explore an informatics approach to improve efficiency of the proces, and as a result, improve staff satisfaction and veterans timely access to care.

Informatics Tool Development

The VAPORHCS informatics team developed a web-based Consult Tracker application to support timely scheduling activities. The development utilized human-centered user-interface design, agile development process and usability evaluation to inform enhancements. The application leverages data from VA’s Corporate Data Warehouse and employs a service-oriented architecture with multi-layer reusable modules and data services. Its user-interface provides a clear situation awareness for all consults in scheduling phase, as well as day-to-day action filters e.g. 1. Displays all actions due today, 2. Allows filtering by consult priority, 3. Provides high visibility of STAT consults.

Current Status

After piloting in three specialty services and additional usability enhancements from pilot feedback, the Consult Tracker is currently used in all medical and surgical services. Services reported improved staff satisfaction, more timely contacts and discontinuation of consults, and reduction of STAT consult pending time. It helps to streamline consult scheduling process, improves workflow consistency across services, and eventually might have a positive impact on veteran access to care. Scheduling is the first step of the consult process; additional informatics support is needed for other stages of this complex asynchronous communication feature to work efficiently and reduce delay.

Discussions

VAPORHCS developed a web-based application to support the scheduling effort for consult management. It helps to improve efficiency and meet the VHA Directive. There are much informatic efforts to assist clinicians in their care of patients, schedulers and other support staff are integral and essential components of healthcare delivery. Supporting their workflow with informatics tool in turn improves efficiency of healthcare system, patient access and outcome.
Do People with Diabetes Receive Balanced Diabetes Self-Management Education? An Analysis of Clinic Notes against AADE7™ Principles
Qing Ye, MS¹,², Richa Patel, MD³, Uzma Khan, MD³, Suzanne A. Boren, PhD, MHA¹,², Min Soon Kim, PhD¹,²
¹Informatics Institute; ²Department of Health Management and Informatics; ³Department of Medicine, University of Missouri, Columbia, MO

Introduction
Diabetes self-management education and support (DSME/S) delivered by medical providers has been shown to improve patient engagement in self-care. However, the time providers spend with their patients is limited, and may limit the delivery of DSME/S efficiently. The American Association of Diabetes Educators Self-Care Behaviors™ (AADE7™) provides structured and validated diabetes self-management guidelines to help providers deliver the seven key principles of DSME/S. The objective of this study was to use AADE7™ guidelines to identify gaps in the knowledge presented by physicians during clinic visits. The research question was “Do the clinic notes address the seven principles of AADE7™?”

Methods
We used PowerInsight®, a clinical reporting platform for electronic health records, to identify people with type 1 or type 2 diabetes, only listing those who were 18 years or older and who visited the Diabetes and Endocrinology Center at the University of Missouri Health Care between January 1, 2017 and January 1, 2018. We applied exclusion criteria, such as pregnancy, incarceration, chronic liver or kidney disease, or HIV to create a patient list of 100 patients. For each patient, we extracted History of Present Illness (HPI) and Impression and Plan (I&P) sections from two clinic notes per patient. In these two sections, providers record patients’ daily self-management behaviors and provide recommendations for their patients. We developed a codebook by consulting the AADE7™ guidelines for the education items on Healthy Eating (HE), Being Active (BA), Monitoring (M), Taking Medication (TM), Problem Solving (PS), Reducing Risks (RR), and Healthy Coping (HC). We employed a multi-step coding process over a 10-week period along with bi-weekly group reviews. Ye and Patel coded the clinic notes based on the codebook. An interdisciplinary team (Khan, Boren, Kim) randomly selected and reviewed 10% of the clinic notes to ensure accuracy of coding. Using deductive thematic analysis, we first evaluated if the particular AADE7™ principle was addressed and then counted how many times it was addressed in each patient’s two clinic notes. We used the Generalized Linear Mixed Model (GLMM) to predict the most likely outcome for each of the seven principles of the AADE7™ for each patient. For each of the seven principles, we used the Mann-Whitney tests to understand whether the count of codes differed based on sex and age.

Results
The codebook included HE (12 codes), BA (13 codes), M (17 codes), TM (13 codes), PS (6 codes), RR (9 codes), and HC (8 codes). Out of 1,317 patients, 100 patients were selected, resulting in 200 notes with 400 note sections for coding. There were 68 patients aged 18-64 years and 32 patients aged 65 years and older. There were 52 males and 48 females. The count of codes for each principle were divided by the number of clinic notes. In HPI section, the most common principles were M (mean=2.610, median=2.500) and TM (mean=1.570, median=1.500). The least common principles were BA (mean=0.245, median=0) and HC (mean=0.270, median=0). In I&P section, the most common principles were M (mean=6.430, median=6.750) and TM (mean=1.830, median=2.000). The least common principles were HC (mean=0.105, median=0) and BA (mean=0.320, median=0). The odds of appearance were defined as the ratio probability of appearance over the probability of no appearance. In HPI section, the GLMM showed that the odds of the M appearance divided by the odds of the BA appearance was 27.315. In I&P section, the GLMM showed that the odds of the M appearance divided by the odds of the HC appearance was 72.257. That is to say M had a higher probability of appearance in both HPI and I&P sections. Mann-Whitney tests indicated that there were no statistical differences in the count of codes in the different sex groups and age groups in each of the seven principles.

Conclusion
This study showed clinic notes did not address each of the AADE7™ principles equally, which suggests that patients may not receive balanced DSME during their visits. This unbalanced approach by providers has implications for long-term diabetes management. One of the reasons why information about Monitoring occurred most in the clinic notes may be because of the health insurance requirement. For example, current Medicare requires that providers should document information about blood glucose data and HbA1c to have glucose testing equipment and supplies covered for their patients. Lack of discussion about Being Active and Healthy Coping therefore may have long-term implications because obesity and depression are common comorbid conditions in people with diabetes. Further studies are needed to identify the other underlying reasons for the imbalance.
Visualizer for Evaluating Adherence to Evidence-Based Guidelines

Jingzhi Yu, BA¹, Farhad Ghamsari, BS, MS¹, Samuel Ross, BA¹, Vesna Mitrovic, MS¹, Abel Kho, MD, MS¹²

¹Center for Health Information Partnerships, Feinberg School of Medicine, Chicago, IL; ²Department of Medicine, Northwestern Memorial Hospital, Chicago, IL

Abstract

For many small providers, integrating and visualizing information from multiple sources within their EHR could be difficult given limited training and financial resources. We have created a desktop-based patient history visualizer that takes in patient C-CDA files and easily produces a visualizer for measuring adherence to evidence-based guidelines on co-morbid diabetes and hypertension. This visualizer will be piloted within a group of eligible small providers and the usage and effectiveness of this tool will be evaluated.

Introduction

With the HITECH Act of 2009, Medicare and Medicaid providers were incentivized to adopt and achieve “meaningful use” of Certified Electronic Health Record Technology (CEHRT) through implementation of key functionality and the capture and reporting of core clinical information. This effort was carried forward under MACRA in 2015, with an increased focus on improved outcomes at the lowest cost¹². In order to succeed in rapidly advancing value-based payment models, providers need tools that organize troves of data relevant to quality of care, which can be a complex and time consuming process. Currently available tools providing such functions are more text-based than intuitive visual-based, for physicians and patients alike³. Evaluating adherence to evidence-based guidelines is one type of complex process that requires integrating different sources within CEHRT. Electronic clinical quality measure (eCQM) reports offer performance scores and lists of at-risk patients but do not link to actionable decision support for closing gaps in treatment protocols. During the process of assisting providers with implementing evidence-based care plans, the need for a more convenient and customizable tool became evident.

Methods & Results

We are designing a patient history visualizer that is desktop based, EHR-independent, and easy to use. End users only have to “drag and drop” their desired patient C-CDA files (extracted from CEHRT) to a designated folder in order to produce visualizations of adherence to evidence-based guidelines with the click of a button. C-CDA files are parsed using the glob and lxml package in Python. Patient encounters, procedures, medication and other types of clinically relevant information are extracted from the human readable table section of the C-CDA file.

Given the overwhelming volume of data and user interfaces experienced in navigating CEHRT, organizing a narrow set of information relevant to condition-specific goals is resource intensive. In order to develop a tool that addresses provider needs without manual chart abstraction, we are interviewing care teams focused on patients with co-morbid diabetes and hypertension. These chronic conditions were chosen due to their prevalence in the general population and priority as targets for quality measurement in value-based payment programs. Efforts to produce a visual evaluation of adherence to evidence-based recommendations in this population will serve as the blueprint for supporting the implementation of care plans in other use cases. Finally, we will document physician’s use of the tool and its impact on their performance on quality measures supported by value-based payment programs.

Conclusion

The results of this study could demonstrate proof of concept and benefits of our tool. This study draws attention to designing tools for providers that focus on ease-of-use and decision support with adherence to evidence-based protocols. In addition, more analytical tools should originate from the provider’s need, featuring customizable visualizations representing quality of care. This will not only allow the physicians to maximize the utility of CEHRT but also empower patients to realize the value of the data generated in the course of their care.

Participatory Design of a Web-Based Intervention for Parents to Improve Sleep in Young Children with Arthritis

Weichao Yuwen, PhD RN1, Uba Backonja, PhD MS RN1,2, Maggie H. Bromberg, PhD1, Natalie Donahue, BS RN2,3, Michelle M. Garrison, PhD MPH2,3, Sarah Ringold, MD MS2,3, Teresa M. Ward, PhD RN FAAN2

1University of Washington Tacoma, Tacoma, WA, USA; 2Universtiy of Washington, Seattle, WA; 3Seattle Children’s Hospital, Seattle, WA; 4Seattle Pediatric Psychology, Seattle, WA

Introduction

An estimated 25-40% of young children (2-5 years) in the United States have behavioral sleep problems (e.g., frequent night awakenings, requiring parental presence at bedtime). Sleep problems are even more prevalent among children with chronic health conditions such as juvenile idiopathic arthritis (JIA). Sleep problems in early childhood persist into middle childhood, and predict later development of emotional and behavioral problems, poorer quality of life, and increased health care needs. Face-to-face interventions have been developed to promote sleep health in healthy infants and young children. However, there are numerous barriers to access, including a shortage of trained pediatric providers in managing sleep problems, long waiting lists, transportation constraints, and costs. Additionally, children with chronic conditions are already frequently engaged with the healthcare system so may particularly benefit from distance-based interventions that do not require additional clinic visits. The use of technology to reduce these barriers and support families of children with chronic conditions who struggle with sleep is in its infancy. The purpose of this study was to use participatory design (PD) to engage parents and healthcare providers to elicit JIA-specific issues and needs that impact children’s sleep and in the adaption of an existing healthy sleep intervention to a technology-based format to meet the needs of this clinical population.

Methods

We recruited nine parents of young children with JIA and five healthcare providers from a pediatric rheumatology clinic at a children’s hospital in the northwest. We conducted two in-person PD sessions, one 2-hour session with five parents and one 1-hour session with five providers, respectively. Four parents who were unable to attend an in-person session (e.g., geographic constraints) were mailed a design packet and craft materials. The packet included prompts and the series of activities done in the in-person session. Parents then mailed back the completed packet. Example questions include: “What are things that you and your child do in order to get your child to bed on time? What are the challenges you and your child run into during the hour before bedtime?” Materials and audio recordings from the PD sessions were transcribed and analyzed using directed content analysis.

Results

Six parents and three providers were female, and 57% of the participants were non-Hispanic White. PD data was categorized into three domains: intervention content, features and functions, and other aspects. For content, participants shared common barriers to good sleep in children, sleep hygiene practices, and JIA-specific concerns and needs. Participants suggested many features and functions of a web-based intervention, such as aesthetic and minimalist design, symptoms tracking and data visualization, reminders, and peer connection. Healthcare providers also shared thoughts on how to design the intervention to be easily incorporated into the child’s clinical visits.

Conclusion

Engaging with the stakeholders and the end-users early in the development process through PD sessions and packets yielded valuable information that will be incorporated into our web-based intervention and empirically tested.

Plugin for importing Spreadsheets into Informatics for Integrating Biology and the Bedside platform

Akshay Zagade BE\(^1\), Vishal P. Vernekar BE\(^1\), Shek-Wayne Chan\(^4\), Kavishwar B. Waghoolikar MBBS PhD\(^2,3,4\), Rupendra Chulyadyo \(^3\), Yuri Ostrovsky PhD\(^1\), Alyssa P. Goodson \(^4\), Ameet Pathak MS\(^1\), Corey Glynn MS\(^3\), Christopher Herrick\(^4\), Shawn N. Murphy MD PhD\(^2,3,4\)

\(^1\) Persistent Systems, Pune, India and Santa Clara, CA; \(^2\) Harvard Medical School, Boston, MA; \(^3\) Massachusetts General Hospital, Boston, MA; \(^4\) Partners Healthcare Boston, MA; \(^5\) Brigham and Women’s Hospital, Boston, MA;

Introduction

The Informatics for Integrating Biology and the Bedside (i2b2) platform has been extensively deployed as a data warehouse to facilitate researchers in identifying patient cohorts for conducting research. However, the platform can be useful for individual researchers to query study/project-specific datasets. This is because study specific datasets can often be very large running into millions of rows, and hence cumbersome to query using spreadsheet software. The i2b2 web-client can readily provide the querying functionality for such datasets and assist non-expert users without knowledge of SQL or spreadsheet software to perform queries. To enable such a use case, we have developed a server-side plugin for i2b2, that will allow non-experts to easily import data from spreadsheets into i2b2.

Methods

The plugin is a daemon process that scans a file system folder for a ZIP file. This ZIP file contains a CSV (comma-separated values) file wherein each patient and that patient’s data are represented on a single row. On finding the CSV file, the plugin parses the first three rows for metadata, generates the i2b2 ontology, and then pivots the sheet to generate facts for insertion into the i2b2-fact observation table. The i2b2 ontology is created by inserting rows into concept dimension and metadata tables, such that the ontology is available for querying in the i2b2 web-client.

<table>
<thead>
<tr>
<th>Patient ID</th>
<th>Date</th>
<th>Age</th>
<th>Zip Code</th>
<th>LDL</th>
<th>LDL Unit</th>
<th>LDL Date</th>
</tr>
</thead>
<tbody>
<tr>

<td>56</td>
<td>01863</td>
<td>194</td>
<td>mg/dl</td>
<td>01/01/2019</td>
</tr>
</tbody>
</table>

The logic implemented for generation of the ontology from the first three rows is as follows (see Table 1): The first row contains a list of the column names. The second row contains the canonical concept paths for each item in the first row. The third row optionally contains the corresponding concept codes. Second row must contain a column with value ‘src_patient_id’ indicating that the column contains the patient id in the source system. Second row could optionally contain a column ‘row_datetime’, which is the time used for each fact generated for that row. If this column is absent the file modification date is taken as the start_date for each fact. Second row could optionally contain @date in the concept path, to indicate date modifier for the fact. Second row could also optionally have suffix of @unit will be stored as the unit for the fact. We benchmarked the plugin performance (Table 2), on 8 CPU machine (2.13GHz) with 32 GB RAM for the plugin, and 12 CPU machine (2.6 GHz) with 26 GB RAM for i2b2 containers.

A natural language processing system to extract rich genetic and phenotypic information from Chinese clinical narratives

Xiaohui Zhang, MD, Yaoyun Zhang, PhD, Qin Zhang, PhD, Yuankai Ren, MS, Jianhui Ma, MB, Qi Sun, MD

1Peking Union Medical College Hospital, Beijing, China
2Digital China Health Technologies Co. Ltd, Beijing, China
3National Cancer Center, Chinese Academy of Medical Sciences, Beijing, China

Introduction

The prevalence and deaths of cancer cases in China stand at 21.8% and 27.1%, respectively, in consistency with those worldwide.[1] Notably, breast cancer ranks first among female, urging a rapid promotion of precision medicine. Fortunately, unstructured text in clinical notes of the electronic health records (EHRs) systems contain the richest phenotypic and genotypic test information, which can be extracted automatically by natural language processing (NLP) methods. Many efforts have been taken to extract such information in the US.[2] Despite that China has a large scale of EHR data from a representative population, the development of NLP-based tools and its applications for precision medicine is at its infant stage. This study takes the initiative to build NLP systems to facilitate the precision medicine of breast cancer.

Method

First, an information model was designed by domain experts, which contains a rich set of fine-granular genotypic and phenotypic information. In total, 58 entities (i.e., clinical concepts and their attributes) and 59 relations between them were defined (Ref. Table 1). Next, 100 encounter notes, pathology reports and procedural notes were manually annotated. The overall inter-annotator agreement was 0.81 for entities and 0.89 for relations. Then the current state-of-the-art BERT language model[3] pre-trained on a 3 Giga byte dataset of clinical text was fine-tuned, to develop the IE models for named entity recognition and relation extraction. Specifically, the named entity recognition was represented as a sequence labeling task and the relation extraction was represented as a binary-class classification task to determine whether two entities have a specific type of relation or not. The default settings of parameters as recommended in BERT were used for model training. [2]

Results & Discussion

Ten-fold cross validation was conducted for experimental evaluation. Overall, the IE system achieved a F-measure of 93.53% (68.97%~100%) for entity recognition and a F-measure of 91.4% for relation recognition (52.60%~100%). Given that a rich set of multiple types of entities (58) and relations (59) were recognized, the experimental performance was really encouraging and promising. Some entities and relations have low frequencies in the dataset (<10) and got the lowest performance. More data will be annotated in the future to increase the training set. Heuristic patterns and domain knowledge will also be used in the future to further improve the system performance.

Conclusions

Experimental results demonstrated the feasibility of using clinical NLP tools to extract rich genetic and phenotypic information from Chinese clinical narratives automatically. Typical use cases of precision medicine for breast cancer will be examined in the future leveraging information extracted from a larger scale of clinical data.

Challenges and Opportunities of Data Quality Improvement in Healthcare Organizations

Yili Zhang PhD, Urmita Banerjee, B'Tech, and Güneş Koru, PhD
University of Maryland, Baltimore County, Baltimore, MD

Introduction
With an increasingly volume of health data maintained in healthcare information systems, there are tremendous potentials to improve decision making and healthcare operations toward better care and health. Unfortunately, problems of data quality, which indicates whether data conforms the quality to serve the needs for specific goals, are wide spread in healthcare organizations. Therefore, systematically improving the quality of healthcare data in a continuous fashion is vital in healthcare organizations. Although there are a few research studies about data quality, how to improve data quality in a systematic and collaborative fashion in large healthcare organizations has not been explored yet. As the first step, this study contributes to the body knowledge by developing a comprehensive understanding of the challenges and opportunities toward collaborative and continuous data quality improvement in healthcare organizations.

Methods
Qualitative methods were adopted due to a need to conduct a deep investigation into this research in real-life settings of healthcare organizations. Upon being contacted by a State Health Department which expressed a need to understand the issues around data quality improvement, our study identified this department as the research context based on the resources made available for the project by the organization. Twelve semi-structured interviews were conducted to collect rich contextual data from the healthcare administration officials, who maintain and utilize of Medicaid data as their daily work. Established systems analysis strategies guided the formation of open-ended research questions. Expert sampling and convenience sampling were adopted to select participants who are in the position of data management in healthcare organizations and interact with Medicaid data in their daily work. The interviews were conducted over the phone, recorded, and transcribed verbatim to ensure accuracy. The data analysis of interview adopted Framework method, which is appropriate for interview transcripts in a systematic and flexible way. Respondent validation and member-checks are also taken to obtain accurate and reliable results. Data collection from interviews stopped when there is no new code found in data. Finally, a thematic framework to classify and organize data was generated.

Results
Three main themes identified as the challenges of data quality improvement are: (i) a lack of communication among healthcare professionals to develop a common understanding about data standards used in various systems, a participant mentioned: “You know I commonly ask for reports that I believe are clear but when I get the data it doesn’t answer my question”; (ii) the legacy system that manages Medicaid data without data validation features: “So if we can not completely upgrade the system, and the current system cannot take the improvement”; (iii) and a lack of documentation about data, which helps to understand the meaning, usage, correlation, and validation of each data item, as one said “If we don’t have good documentation, we may end up denying someone falsely”. The opportunities of data quality improvement are: (i) developing a data dictionary to describe features, standards, and uses of data items: “And I wish there would be a more prompt thing like how would this file be used and what do you want the end product to look like...”; and (ii) availability of automated tools to check for validity of data from different resources and groups: “... they receive updates from us once a week. Sometimes it will more beneficial if they can receive it everyday, but you know there are a lot of patients, sort of like that”. Participants realized problems in data quality when they claim a reimbursement, look at a specific record, or interact with external people such as providers. Their current solutions to improve data quality includes manual checks, various ad-hoc approaches, and using paper-based request forms.

Conclusion
The lack of data quality is considerably affecting the daily operations in the healthcare organization. However, currently employed practices fall short in effectively and efficiently improving the quality of data, and there is no systematic process yet in the organization to improve data quality according to participants. In the future, health organizations are likely to benefit from IT supported collaborative workflows that continuously improve data quality.

A Survey of Clinicians’ Perception of Pharmacogenomics Testing for Antidepressants

Yiye Zhang, PhD, MS1, Yonaka Harris2, George S. Alexopoulos, MD1; Adam Stracher, MD1; M. Elizabeth Ross, MD, PhD1, Rainu Kaulash, MD, MPH1, Jyotishman Pathak, PhD1
1Weill Cornell Medicine, New York, NY; 2New York City College of Technology, New York, NY

Introduction
Depression was identified by the WHO in 1990 as the fourth most disabling medical condition, and by the year 2020 it is predicted to be the second most disabling condition worldwide. (1) The current standard of care for depression is based on “trial-and-error” of a multitude of medications, including antidepressants. One way to reduce trial-and-error strategy is to use pharmacogenomics (PGx) testing to guide medication treatment and increase the likelihood of response by reducing the number of ineffective medication trials. While the scientific understanding of PGx is accelerating, its translation to routine clinical practice has progressed slowly. In an effort to investigate the barriers and opportunities in the adoption of PGx testing, we conducted a survey of clinicians’ current knowledge of and experience with PGx testing and their perception of its utility in routine clinical care.

Methods
A 41-question survey was created using Qualtrics (Qualtrics, Provo, UT). We distributed the survey electronically to 394 clinicians in Psychiatry, Internal Medicine, and Neurology at Weill Cornell Medicine (WCM) between October to November 2018. Participants were offered a $25 gift card as incentives to participate. All responses were anonymized and kept confidential. This study was approved by the WCM internal review board (IRB).

Results
As of March 2019, 69 surveys were started and 67 were completed (18% response rate). Results show that more young clinicians (under the age of 30, 31-40 and 41-50) had placed at least one order for PGx testing than physicians above age 50 (25% vs. 9%, Figure 1 left). Conversely, older physicians felt more well-informed about PGx testing for antidepressant than younger physicians (67% vs. 29% agree). Across specialty, 19 out of the 27 (70%) psychiatry providers felt well-informed about PGx testing for choosing antidepressant, whereas 3 out of the 21 (14%) internal medicine providers felt the same way (Figure 1 right). Furthermore, while a majority of the clinicians responded that they would prefer non-genetic testing over PGx testing for their patients in general (52%), internal medicine clinicians were the most likely to not order a PGx test for antidepressants (73% never ordered in the last year).

![Figure 1. Age vs. number of prescriptions, and specialty vs. feeling well-informed about PGx for antidepressant](image)

Conclusion
Findings from the survey suggest that while clinicians have knowledge of the PGx testing and understand the benefits, there still remain significant concerns and barriers in the adoption of PGx testing in routine clinical care.

Contextualizing Consumer Health Information Seeking

Zhan Zhang, PhD1, Caleb Wilson2, Zhe He, PhD2
1Pace University, New York, NY, USA; 2Florida State University, Tallahassee, FL, USA

Introduction

There is an ongoing trend for people turning to online resources, such as social Q&A sites and health forums, to seek personalized healthcare information. People are increasingly doing so in part due to many online health communities allowing them to ask full questions in natural language (as opposed to search terms) and to include key contextual health information with these questions. Prior work has highlighted the significant impact of contextual factors (e.g., people’s goals and motivations) on the result of information searching [1]. However, little attention has been paid to examining how patients formulated their questions to fulfill their information needs. Built upon our prior work [2], this study set out to examine the correlation between the types of information people provided and the types of support people were seeking by analyzing questions that people posted in a major social Q&A site.

Methods

Details on data collection and analysis has been published previously [2]. Briefly, two researchers independently performed content analysis on 967 randomly sampled posts containing laboratory test results pertaining to diabetes (e.g., HbA1c, glucose), collected from Yahoo! Answers between 2009 and 2014. The data analysis process consists of codebook development, group discussions, inter-rater reliability testing, and qualitative coding. This analysis helped us identify the types of information that people needed and provided. In this study, we further analyzed the posts identified through our previous work, and focused on the correlation between the types of information people provided and the types of support people sought. Figure 1 shows frequently observed correlations. The number represents the frequency where a particular type of information need and information provided co-occur in the posts.

Results

We found that people tended to provide different types of personal health information in a post, including demographic and medical information, to explain their current conditions to the community members to elicit relevant answers. We also found that specific types of information provided coincide with certain information needs. For example, when people sought help understanding the results of lab test, they often provided more details about the context of lab test they took (e.g., lab procedure, what they eat or drink) in addition to the results (e.g., “I drank sweet tea at 8:30 am and had my blood drawn at 12:30 pm”). Therefore, consumer-facing informatics tools should be designed, at both algorithm and interface levels, to present lab test results within patients’ contexts (e.g., age, medical history). Even though some contextual elements may not necessarily affect the accuracy of test results, the systems should provide explicit, consumer-friendly explanations to address any concerns or assumptions that patients may have. It is also worth noting that people would express their emotions when they asked for help. This observation suggests that informatics tools should be designed more emotion-responsive by providing means for patients to seek emotional support, i.e., through a social network in online communities to connect with peers who have similar conditions.

Finally, we want to note that many of the findings are generalizable to other chronic conditions even though the work was done in the context of diabetes. The results could have implications for the design of context-based consumer informatics tools, including EMR, to provide more personalized information that better meets patients’ needs.

Deep Learning Using Electronic Health Records and Genetic Data to Predict Cardiovascular Diseases

Juan Zhao, PhD1; QiPing Feng, PhD2; Patrick Wu, BS1; Joshua C. Denny, MD, MS1,3, Wei-Qi Wei, MD, PhD1

1Department of Biomedical Informatics, 2Division of Clinical Pharmacology, 3Department of Medicine, Vanderbilt University Medical Center, Nashville, TN, USA

Introduction
Cardiovascular diseases (CVD) is a complex disease, which involves genetic, environmental, and lifestyle causes. Despite well-known prediction tools, such as the Framingham studies that identified several conventional risk factors (e.g. age, smoking and hypertension), CVD remains the leading causes of deaths and major global burden. Thus, early prediction for CVD is essential. Previous studies have identified genetic variants associated with CVD.1 Polygenic scores have been used to summarize genetic contributions for individuals’ traits, however; how to combine genetic variants with other biological and lifestyle factors remains a challenge. Deep learning models such as convolutional neural networks (CNN) and LSTM can explore temporal patterns on electronic health records (EHR) data to enhance disease prediction.2,3 In this study, we utilized a concatenating framework of CNN to combine temporal EHR data and genetic features for prediction. We compared the predictability of this approach with models using only EHR data.

Method
Data Description: The study used Vanderbilt University Medical Center’s (VUMC) de-identified EHRs and BioVU, the largest single-site biobank in the U.S. All individuals had 10-year follow up from 01/01/2007 to 12/31/2016. We extracted 7-year EHR records prior to 01/01/2007. We defined cases as individuals with ≥1 CVD diagnosis codes (ICD-9-CM: 411; * or 433; *) from 01/01/2007 to 12/31/2016; controls are individuals without any CVD diagnosis codes. We divided the observation period into one-year slice window to extract the temporal features. The study was limited to European and African ancestry adults.

Features: We extracted demographic data (i.e., age, gender, and race), lifestyle factors (i.e., smoking, BMI), lab and measurements such as systolic/diastolic blood pressures, total cholesterol, high-density lipoprotein, and preselected diagnosis and medication codes. We chose 204 single nucleotide polymorphisms (SNPs) associated with CVD, and used 0, 1 or 2 as the count of minor alleles for each SNP.

Deep learning models: To enlarge the statistic power, we pretrained a 1-D CNN on EHR dataset (removing the testing test) to learn representations of longitudinal EHR (Figure 1). We concatenated the pretrained CNN with an input layer with 204 SNPs and linked to a deep neural network with one hidden layer (dense_1). We used the genotyped individuals to train and validate the concatenated model.

Results
We identified 109,490 individuals, including 9,824 cases and 99,666 controls (mean [SD] age 47.4 [14.7] years; 64.5% female and 86.3% European) that met our inclusion criteria. Of them, 10,162 individuals were genotyped. We performed 10-fold cross-validations. Results showed the Area under the Receiver Operating Curve (AUROC) that using only EHR features is 0.704 (+/- 0.008), and the proposed model combing genetic features is 0.716 (+/- 0.006).

Conclusions
In this study, we proposed a concatenating framework of CNN to fuse heterogeneous features. Adding genetic features offered small but significant benefits to clinical features, which underline the importance of genetic data.

Summarization of Patient Education Material for New Media Platform

Yiqing Zhao, PhD¹, Yanshan Wang, PhD¹, Paul R. Kingsbury, PhD¹, Michael A. Panzer², Richard T. Van Ert², Hongfang Liu, PhD¹

¹ Division of Digital Health Sciences, Department of Health Sciences Research, Mayo Clinic, Rochester, MN.
² Division of Content Management and Delivery, Department of Global Business Solutions, Mayo Clinic, Rochester, MN.

Background
Printed or Internet-based patient education materials frequently consist of detailed information of disease conditions and procedures. However, they were usually designed for a general audience and sometimes fail to address the unique needs, interests, and concerns of different individuals. With the advent and dissemination of as interact new media platforms such as Amazon Alexa, our ability to understand audiences’ information needs has significantly increased. Also, considering the over-estimated health literacy among general population¹, we need to provide more brief and relevant information while still keep easy-to-understand explanation of some medical terms.

Methods
In this study, we used TextRank² to algorithm to summarize patient education documents. We tested on a subset of patient education documents focused on diseases and procedures. We first identified sections within each document and apply the algorithm on each section separately. We applied summarization ratio of 0.7 (percentage kept) on each section. We compared a sample our summarization results (20 documents on diseases and procedures respectively) against manually summarized documents. Summarization performance was evaluated using ROUGE-N metric³.

Results
We collected 3,286 patient education documents from Mayo Clinic Department of Global Business Solutions, which is also accessible from Mayo Clinic homepage (https://www.mayo Clinic.org). Among which 876 documents are Questions and Answers, 862 are Health Articles, 1,109 are about Disease Conditions, 22 are about First Aid tips, 88 are about Symptoms, and 329 are about Test Procedures. Sections for Disease Conditions include: Overview, Symptoms, Causes, Complications, Diagnosis, Treatment, Lifestyle and home remedies, Alternative medicine, Preparing for an appointment, Risk factors, Coping and support, and Prevention. Sections for Test Procedures include: Overview, Risks, Why it's done, What you can expect, How you prepare, and Results. Evaluation result is listed in Table 1. For Disease Condition documents, Diagnosis, Causes and Overview sections have relatively high F-score while for Test Procedures documents, Overview section has significantly higher F-score than other sections. Differences in performance might be due to difference in information needs for each sections.

Automatically Identifying Intimate Partner Violence from Clinical Narratives for Emergency Department

Vivienne J Zhu, MD, MS,1 Christine Carr, MD,2 Kit Simpson, Ph.D,3 Roberta Dawson, RN, MBA,2 Alyssa Rheingold, Ph.D.,4 Leslie A Lenert, MD, MS1

1Biomedical Informatics Center, 2Department of Emergency Medicine, 3Department of Healthcare Leadership and Management, and 4Department of Psychiatry and Behavioral Sciences at Medical University of South Carolina, Charleston, South Carolina

Abstract: We developed and evaluated a natural language processing (NLP) approach for identifying intimate partner violence (IPV) from clinical narratives. 191,728 clinical notes from 12,276 adult female patients with emergency department visits were used as a training dataset to iteratively develop a lexicon of IPV, customized negations, and NLP algorithms. Through manual review of clinical notes for 312 NLP identified IPV patients (2.5%) in the training dataset, our NLP pipelines yielded 93.3% precision.

Background: Intimate partner violence (IPV) is a significant public health and criminal justice problem that negatively affects millions of victims yearly in the United States, primarily women (85%) of reported incidents. Although healthcare management associations recommend accurate documentation and coding of IPV incidents, accurate coding of IPV in medical records is still uncommon. In clinical practice, however, providers record clinical findings as narratives for each patient encounter, including symptoms, health histories, and results of physical exams. From these clinical narratives, NLP can identify and extract evidence of IPV-related suspected injuries and mentions of abuse.

Method: We used data from the Medical University of South Carolinas (MUSC) Research Data Warehouse. Female patients who were 18 years-of-age or older and had an Emergency Department (ED) visit at MUSC between 01-01-2017 and 12-31-2017 were eligible for this study. NLP pipelines identifying IPV were developed via extraction of clinical notes relevant to each patient’s ED visit. A de-identified subject-ID was used to link source documents and data across each patient’s records. Of 16,359 eligible patients, we randomly sampled 12,276 (75%) patients to create a training dataset. We used commercial NLP software (Linguamatics I2E version 5.3, Cambridge, United Kingdom) licensed to MUSC to index, parse, and query each research criterion. A set of NLP queries was used to capture semantic and syntactic representations of IPV. The following criteria were used to identify IPV mentions: 1) intimate partner violence (e.g., “domestic violence/abuse,” “intimate partner violence/abuse,” or ”abuse of partner”); 2) the combination of perpetrator (e.g., “husband,” “ex-husband,” “boyfriend,” “baby’s father,” “fiancé”) and abusive behavior (e.g., “hit,” “non-accidental injury,” “assault,” ”attack,” “threaten,” “verbally abuse,” “pull out hair”); and 3) social services (e.g., “My Sister’s House,” “Adult Protective Services,” “Verizon Hope”). Clinical negations were used to exclude false mentions of IPV, such as “no history of” and “denied”, or to exclude a family member as the IPV victim. Herein we report preliminary data for our NLP pipeline development and evaluation.

Results: Altogether, 191,728 clinical notes from 12,276 patients were used to develop the NLP pipelines. Without negation, 326 patients (2.6%) had IPV mention(s) detected from 948 clinical notes. With negation, 312 (2.5%) had IPV mention(s) detected from 907 clinical notes. The common type of providers who documented IPV incidents were physician, social worker, resident, registered nurse, and nurse practitioner. Among 307 terms (with morphologic variations) relevant to IPV, the most prevalent were “domestic violence,” “intimate partner violence,” “domestic abuse,” “Adult Protective Services,” and “assaulted by boyfriend”. Manual review identified 22 false positive IPV patients. The NLP pipeline demonstrated 93.3% precision in the training dataset. Example reasons of false positives included the term “Adult Protective Services” were suggested for other vulnerable patients (e.g., schizophrenia patient), as well as the following features: insufficient post negation for an IPV incident, and patients did not confirm providers’ suspicious or concern about IPV.

Conclusions: The results suggest that NLP can identify and extract evidence of intimate partner violence from clinical narratives obtained during and after ED visits, with high precision for female patients.

Bootstrapping a Mobility Dictionary from a Seed Set

Ayah Zirikly, PhD1, Denis Newman-Griffis, MS1,2, Julia Porcino, MS1, Pei-Shu Ho, PhD1, Jonathan Camacho Maldonado, MD1, Maryanne Sacco, MA1, Alex Marr, BA1
1National Institutes of Health Clinical Center, Bethesda, MD; 2The Ohio State University

Introduction

Limitations in ambulation and mobility are the top disability types that affect individuals1. In order to detect and monitor these limitations, it is essential that information about whole-person mobility is reported consistently. The International Classification of Functioning, Disability and Health (ICF), developed by the World Health Organization2, includes coding standards for mobility. However, low adoption of ICF coding in clinical notes makes automated identification of information about individuals’ function challenging and expensive, especially compared to the ready availability International Classification of Diseases (ICD) codes for diseases. New terminologies can ease the identification and extraction of mobility information. In this work, we expand a manually-extracted seed dictionary to capture terms that are linked to ICF concepts about mobility, such as walking, carrying, and transferring body positions.

Methods

We start with a dataset of 450 physical therapy notes (∼260k words) collected from the NIH Clinical Center (BTRIS), in which mobility concepts have been manually annotated with ICF codes. We extract a seed set containing the high-frequency mobility terms (keywords) from these data, and introduce two methods to expand this seed set. Our first expansion methodology uses VerbNet3, a lexicon that clusters verbs that show semantic coherence into classes. However, this method suffers from multiple limitations: the expansion only considers unigrams in isolation, and because all VerbNet class members have equal weight, they cannot be ranked and filtered as expansion terms. Therefore, we propose another expansion method that overcomes these limitations. We use word vectors trained from PubMed data with FastText4, and sum-vector for multi-words terms. Then, we retrieve the ten nearest neighbors (NN) to the original keyword, based on the cosine similarity between the vectors for original keyword and a candidate term. This allows words to be compared on their semantic properties in context rather than form alone.

Results

We test the recall of the expanded dictionary resulting from the two approaches using exact and partial match metrics. Partial match evaluation is done at the token level, where an overlap of one token between the human-annotated mobility term and the dictionary entry will yield a match. In exact match, all the tokens need to be identical. Our combined dictionary yields a recall of 60.35% for exact match, where the VerbNet-based approach has a recall of 16.39%, and the semantically-aware approach yields 50.7%. The partial match results are significantly higher with recall 95.66% for the combined dictionary, in contrast to 32.07% and 87.96% for VerbNet and NN approaches respectively. Results analysis in the exact match evaluation indicates that non-matches are mainly due to: i) Specific punctuation sequences that are hard to match, for instance bed to w/c where w/c is wheelchair; ii) Prepositions in the multi-term expressions (e.g. sit to stand vs. sit-stand). These cases convey the need to improve preprocessing on the seed set and postprocessing on the expansion terms. In addition, a “new” exact-match evaluation can be introduced that does not require full overlap, but rather ignores cases of punctuations and prepositions.

Conclusion & Future Work

We find that a combination of lexicon- and context-based expansion methodologies yield high recall on mobility terms, and a nearest neighbor approach based on word embeddings significantly outperforms lexicon-based expansion. In current work, the expansion terms inherit the ICF code of the original term. In future work, we will expand to methods that infer the correct ICF code from all the other semantically-close terms in the seed set. Additionally, we will investigate aligning our mobility dictionary with SNOMED concepts for further expansion. We will also develop post-processing functions to handle misspellings that are not handled by our expansion methodologies.

Authoring and Integrating Interoperable Clinical Decision Support: CDS Connect Open Source Tools

Shafa Al-Showk, MPH¹, Chris Moesel², Sharon Sebastian, MS, RN-BC², Ginny Meadows, MSHI, RN-BC², Steven Bernstein¹, Mary Nix, MS, PMP¹, Edwin A. Lomotan, MD¹
¹Agency for Healthcare Research and Quality, Rockville, MD; ²The MITRE Corporation, Bedford, MA

Background

In its 2017 special publication, Optimizing Strategies for Clinical Decision Support, the National Academy of Medicine identified several barriers to realizing the full benefits of clinical decision support (CDS), including the high cost of developing reliable, shareable CDS expressions and the absence of systematic means to validate CDS content. The Agency for Healthcare Research and Quality (AHRQ) has been creating prototype infrastructure to ease the authoring and testing of interoperable, standards-based CDS expressions that can be ultimately shared through a national CDS repository called CDS Connect. The aims of CDS Connect, together with other ongoing AHRQ CDS initiatives, are to advance evidence into practice through CDS and to make CDS more shareable, standards-based, and publicly-available.

Description of Demonstration

AHRQ, through the CDS Connect project, has been constructing open source tools to reduce the burden of developing accurate, trustworthy interoperable CDS expressions that can be integrated with health information technology (IT) systems to support evidence-based decision making. The tools include 1) the CDS authoring tool, which provides a user-friendly interface that lowers the barrier to creating standards-based CDS expressions and 2) Clinical Quality Language (CQL) Services, which facilitates integration of the CDS developed using the authoring tool with a health IT system.

The CDS authoring tool empowers non-software engineers to design interoperable CDS logic according to the CQL standard. A key feature of the authoring tool is its ability to interact with the National Library of Medicine’s Value Set Authority Center (VSAC). The CDS authoring tool allows users to build CQL by stringing together value sets, operators, and other connectors to define the logic that can drive CDS. It also supports user-testing of authored artifacts using test data that can be created manually or by exporting synthetic patients using the Synthea project. In addition, users can download their tested CQL logic using the HL7 FHIR DSTU2 model or the STU3 model.

CQL Services is prototype software that allows CQL execution to be externalized via RESTful web services. A health IT system can invoke CQL-based CDS logic by sending web requests to CQL Services, which returns the calculated results back in JavaScript Object Notation (JSON) format. The health IT system can then display the results via their native user interface. CQL Services exposes two application programming interfaces (APIs); a simple custom API for exchanging data and results using the JSON format, and a standards-based API that conforms to the CDS Hooks standard for interacting with external CDS services.

In 2019, AHRQ and its partners, b.well Connected Health and the MITRE Corporation, are developing and testing CDS to support preventive health care. As a use case, this demonstration will highlight how the CDS authoring tool can be used to create and test CDS such as this, and how CQL Services can be used to integrate the validated CDS in a health IT system for clinical testing and implementation.

During this presentation we plan to demonstrate: How to build CQL-based clinical decision support artifacts using the CDS Connect Authoring Tool; how authors can incorporate value sets from the National Library of Medicine’s Value Set Authority Center into their own CQL-based clinical decision support; how the developed CQL-based clinical decision support can be tested against a synthetic dataset; how the CQL Services prototype tool can integrate CDS logic with a health IT system using CDS Hooks standards.

Author Statement

CDS Connect was launched in spring 2017. The CDS authoring tool and CQL Services prototype tools are freely available, open source, and accessible at https://cds.ahrq.gov/cdsconnect/authoring and https://github.com/AHRQ-CDS/AHRQ-CDS-Connect-CQL-SERVICES. Information about the AHRQ initiative, including access to CDS Connect, can be found at http://cds.ahrq.gov.
Background. The National Committee for Quality Assurance (NCQA) recently announced Population Health Management (PHM) as a new standards category to shift focus from single disease to complex case management and wellness by promoting strategies that help coordinate patient care between providers and practices more efficiently. The new standards support and emphasize using data analytics to target resources to the right individuals, but methods for standardizing data analytics and population-based patient care workflows have not yet been specified. Most market-leading EHR vendors provide PHM tools, but solutions are proprietary, difficult to share, and therefore not optimally scalable. Standards-based PHM methods and tools are needed to scale beyond single vendor solutions and to reduce the implementation barriers related to reproducing complex case logic and analytics.

Through a research grant funded by the Informatics Technology for Cancer Research (ITCR) program of the US National Cancer Institute (NCI), we have devised and implemented a PHM platform that adapts a synchronous and individual-level clinical decision support (CDS) standard (the HL7 CDS Hooks standard in conjunction with HL7 FHIR) to an asynchronous population-level CDS via Web services. The primary methods added to the existing standards to support population-level CDS were bulk operations. Rather than creating one CDS Hooks request at-a-time for each patient, CDS Hooks requests were composed in bulk from population-based queries. Bulk CDS Hooks requests and responses were then composed, sent and received by the CDS engine in large batches to reduce network request/response times. Preliminary performance measures have demonstrated these simple batch operations reduce the processing time required by two orders of magnitude.

Use Case. We will demonstrate an application of the PHM platform, which screens and identifies patients who meet National Comprehensive Cancer Network (NCCN) criteria for genetic evaluation of familial cancer risk based on their family history in the EHR. The application uses both structured data and natural language processing of free-text data. Patients identified by the standards-based PHM platform are imported into an EHR's PHM dashboard (e.g., Epic's Healthy Planet) where genetic counseling staff can review individual cases, select, and send bulk outreach messages to patients suggesting they setup genetic counseling appointments. Additionally, the PHM communicates care decisions with the patient's primary care provider to ensure care is coordinated.

A pilot implementation of the PHM platform has been live in the University of Utah Health system and Genetic Counseling Service at the Huntsman Cancer Institute since October of 2018. An NCI-funded, multi-site randomized controlled trial testing two alternate patient outreach approaches is underway. The CDS Hooks services that implement the NCCN familial cancer risk detection algorithms are available to the community as open source software.

The speakers, who are national leaders in standards-based CDS innovations, will describe (i) the PHM workflow; (ii) the family history-based criteria and algorithm logic; (iii) performance optimizations that were made to make population analysis using CDS Hooks viable; (iv) preliminary results of the pilot study; (v) ongoing efforts to integrate the PHM platform with Epic at New York University (NYU) and Cerner at Intermountain Healthcare; and (vi) a discussion of challenges and opportunities for future research leveraging the PHM platform.

Acknowledgement. This project is supported by grant U24CA204800-01 from the Informatics Technology for Cancer Research (ITCR) program of the National Cancer Institute.
ROAD2H: Learning Decision Support System for Low- and Middle-Income Countries

Kristijonas Čyras, PhD¹, Jesus Dominguez, PhD², Amin Karamlou, MSc¹, Denys Prociuk, MSc¹, Vasa Curcin, PhD², Brendan Delaney, MD¹, Francesca Toni, PhD¹, Kalipso Chalkidou, MD PHD¹, Ara Darzi, MD¹
¹Imperial College London, London, UK, ²King’s College London, London, UK

Description

Learning Health Systems offer great potential for Low- and Middle-Income Countries to develop better application of evidence-based practice, whilst at the same time being able to learn about and adapt, rather than simply import evidence and guidelines from more advanced economies. Opportunity is provided for both patient-facing decision support and health-system facing views, the latter being particularly important for enabling planning and resource allocation. In addition, decision support systems should enable transparency of decision making to users and allow for support in prioritization and resolving conflicts between guidelines and individual patient status. ROAD2H (Resource Optimisation, Argumentation, Decision support and Knowledge Transfer to create Value via Learning Health Systems) is a UK EPSRC Global Health Project working in partnership with China and Serbia to provide both individual patient decision support for clinicians and a health system dashboard in the following areas:

- In Belgrade, Serbia, supporting both clinical pathways for the admission and treatment of Chronic Obstructive Pulmonary Disease (COPD) patients with acute exacerbations, and transition of care for community-based patients with COPD between specialist and primary care.
- In W. China (Wushan and Ninquiang), supporting transition of care for COPD between township clinics and county hospitals.
- In Beijing, supporting efficient use of high-cost drugs for Non Small Cell Lung Cancer (NSCLC).

The system takes a combination of local, regional, national and international guidelines, represents them using a logical model (Transition-based Medical Recommendations, TMR¹) and adds an additional argumentation-based reasoning layer² to aid in resolving conflicts among patient-tailored guideline recommendations, while taking into account multiple goals with differing priorities and respecting the patient’s preferences³. Cost effectiveness and willingness to pay for proposed interventions are optimized using a stochastic discrete-event simulation model programmed in R, parameterised using both local clinical and insurance data, and incorporated as an ‘expected’ outcome for health policy. Data is gathered via the EHR system locally and used to drive a dashboard, and potential changes to policy that result in changes to individual clinical recommendations.

Having worked extensively with users on use-cases and data modeling, we have developed an end-to-end exemplar in community-based COPD in the TMR combined with argumentation. We aim to demonstrate a use-case with patient EHR passed through a decision support system operating with interacting COPD guideline recommendations (via TMR) and resolving their interactions (via argumentation) in accordance to the patient’s context, their preferences and/or priorities over goals.

Introduction

Although randomised controlled trials (RCTs) are the most reliable approach to produce high quality medical evidence, protocols for RCTs are slow to produce and often imprecisely specified, resulting in inefficient recruitment and execution. This situation is exacerbated when managing multiple configurations across clinical sites, as required to run trials in a primary care setting. We offer a digital clinical trial platform, or study system (SS), which integrates clinical research and patient care workflows through Electronic Health Records (EHR) systems, taking advantage of initiatives such as CDISC, which provides standards for computational clinical trial definitions, and advances made in data exchange between EHRs and electronic Case Report Form (eCRF) components enabling semantic inter-operability across vendors and automated pre-population of eCRFs from EHR data.

System Design and Features

First, the study protocol is formalised following an extension of CDISC operational data model (ODM) where we have incorporated EHR queries by means of openEHR archetypes for the identification of particular clinical elements (e.g., diagnosis tags, clinical codes, demographics, medication) used as flags to capture potentially eligible candidates. Other extensions include identifiers for retrieval of EHR-neutral, patient-specific data for eCRF pre-population, and attributes to convert item definitions into HTML5 form elements when requested by data node connectors (DNC) deployed at medical practices. The RCT database (DB) is then populated with CDISC representations of the study’s life cycle and eCRFs extracted from the formalised protocol. This is then used by the SS to coordinate study execution across distributed medical sites. Additionally, data-filled eCRFs are also stored in the DB, preserving patient anonymity by means of encryption. eCRFs are grouped by type and the SS acts upon them depending on the specifics of the trial, e.g., a participant’s email address is retrieved from any form of type Contact Details. Similarly, participant randomisation is supported by retrieving randomisation arguments from a submitted form and returning the outcome to the clinician via another form. A third (internal) form provides relevant parameters for the randomisation algorithm to be trial-specific, additionally generating a username and password for participants to access the dedicated web app. Identification and notification of trial-specific events such as form completion reminders are also managed by the SS using text messaging and/or email address. The web app is designed to support patient data collection via form templates. It is accessible to both participants and study members in a study-specific manner with login details stored in an LDAP server. The DNC mediates the relationship between a vendor’s EHR and the centralised SS, adapting to distinct EHRs by means of a vendor-specific plug-in and downloading trial-specific forms when the timing is appropriate. Downloaded eCRFs are pre-populated with patient-specific data and integrated in the EHR when submitted. An embedded Chromium web browser displays eCRFs independent of local browser configuration, providing HTML5- and CSS3-compliant elements while taking advantage of HTML5 constraint attributes and types to validate data.

Current Use and Deployment

The SS is currently being deployed at clinical sites across UK to support a two-year study on whether Ciprofloxacin drops or delayed oral Amoxicillin are non-inferior to current standard practice for children with acute otitis media with discharge (https://doi.org/10.1186/ISRCTN12873692).

Conclusion

We described modeling aspects of the implementation of a study system that addresses the integration of clinical trials into routine clinical practice, reducing both the cost and complexity of the task whilst increasing accuracy and safety by liaising directly with the EHR system. This is achieved by making a functional eCRF semantically interoperable with the EHR system in order to enable patient identification and pre-population of eCRFs with available clinical data.
Using trial2rev to support timely and efficient systematic review updates

Adam G. Dunn, PhD1,2, Paige Martin, BE1, Florence T. Bourgeois, MD MPH2,3
1Centre for Health Informatics, Macquarie University, Sydney, NSW, Australia;
2Computational Health Informatics Program, Boston Children’s Hospital, Boston, MA;
3Departments of Pediatrics & Emergency Medicine, Harvard Medical School, Boston, MA

Abstract
Systematic reviews are time-consuming and often do not target the most relevant medical questions, leading to slow uptake of new trial results and many potentially redundant reviews. We developed the web-based platform trial2rev to connect published systematic reviews to emerging results in clinical trial registries, with the aim of supporting decisions around when a systematic review update should be undertaken. Major use cases include the proactive monitoring of emerging trial results to signal when a review update is warranted and using the database of systematic reviews linked to trial registrations to support evaluation of new methods for automatic screening of trials.

Demonstration
Even for a well-studied area like type 2 diabetes, where as many as 23 new systematic reviews on drug interventions are published each year, it takes a median of 1.5 years for the results of a newly-published drug trial to be included in a systematic review.1 We developed the trial2rev platform in 2018 to help systematic reviewers monitor the accumulation of relevant trial data as a way of quickly determining when a systematic review update is warranted.2 Trial2rev (https://surveillance-chi.mq.edu.au) is a web-based platform and database maintaining structured information on trial-based systematic reviews. It links reviews to the registrations and publications of trials included in the review and provides lists of other similar systematic reviews with overlapping sets of trials. Trial2rev uses PubMed, CrossRef, and ClinicalTrials.gov to identify new systematic reviews and trials. Multiple software agents using machine learning methods are triggered to recommend trials,3 as users interact with the system. While machine learning methods are used to help screen published articles,4 this functionality has not yet been extended to support the use of trial registrations. The trial2rev system enables proactive surveillance of clinical trial registrations to support decisions about when to update a systematic review, a paradigm shift from the traditional workflow of deciding to undertake a systematic review and then reactively screening for relevant trial publications. Trial2rev has not yet been evaluated against manual processes that are currently used to decide when to update a review.

The first use case for the platform is to support systematic reviewers deciding if a systematic review update is warranted. Users start by identifying a systematic review, verify information about the trials that were included, and examine the registrations of ongoing and completed trials that have been recommended as relevant by software agents or human users. Users can flag reviews of interest to receive alerts about the statuses of relevant trials.

The second use case supports the clinical research informatics community with the data and infrastructure needed to test and deploy methods for automated screening of trials for inclusion in systematic review updates. Registered users gain access to the large database of linked systematic reviews and trial registrations to train and test new methods for identifying trials for systematic reviews; and may deploy new methods and software agents in trial2rev.

The source code for trials2rev is available on GitHub and its functionality is updated periodically. The platform currently includes partial structured information for 13,477 systematic reviews and 14,733 linked trials, and new data are made available daily. The research was supported by the Agency for Healthcare Research & Quality (R03HS024798) and the National Library of Medicine (1R01LM012976-01).

Demonstrating the Collection and Integration of Standardized Patient-reported Outcome Data Using a SMART on FHIR® Application

Chun-Ju Hsiao, PhD1, Joseph Blumenthal, BA2, Deliya Wesley, PhD3

1Agency for Healthcare Research and Quality, Rockville, MD; 2MedStar Health National Center for Human Factors in Healthcare, Washington, DC; 3MedStar Health Research Institute, Hyattsville, MD

Background

The effective use of patient-reported outcomes (PROs) can play a critical role in improving health care delivery and patient experience with care. While various efforts promote the use of PROs, their uptake is far from universal. Some electronic health records (EHRs) are able to capture structured PRO data, but this information is not commonly collected at the point of care. In addition, standards have not previously existed to guide and inform the collection and integration of PRO data into health information technology (IT) systems, thereby limiting the ability to easily share these data across health systems. To fill this gap, the Agency for Healthcare Research and Quality (AHRQ) is working with partners to support the development and implementation of electronic applications that can enable the collection and sharing of standardized PRO data across health providers.

Description of Demonstration

In 2018, the Office of the National Coordinator for Health Information Technology created a Health Level 7 International (HL7®) Fast Healthcare Interoperability Resources (FHIR®) PRO Implementation Guide (IG) to address the previously mentioned challenge regarding lack of standards. Together with its partners (MedStar Health and Outcomes Based Electronic Research Database (OBERD)), AHRQ modified an existing mobile application that incorporated the FHIR® PRO IG to enable the collection and integration of standardized PRO physical function data. The modified application can administer Computer Adaptive Tests (CAT) to collect data on patient’s physical function using the state of the art PROMIS® measures. The modified application has been used with three different EHR systems, and demonstrates the interoperable, scalable, and replicable nature of this solution. MedStar leveraged the same technology and processes as those used in most EHR’s data views to surface the PRO data collected from the application. Thus, the PRO data can be included as part of a release-of-information request in the EHR so that PRO information can be used in future medical decision-making.

The architecture of the PRO data collection and visualization ecosystem features a decentralized, scalable, and replicable model. The architecture enables EHR agnostic data ingestion, patient matching, and visualization of these data. This demonstration will include a live walkthrough of the data flow as it begins with the patient accessing a mobile application that administers the CAT by connecting with a SMART on FHIR® external assessment center. The audience will observe how the application is used to collect PROMIS® measures, connects to a secure FHIR® endpoint, and sends these data for storage and subsequent retrieval. The demonstration will also include a customized data visualization of the PROMIS® scores and survey responses that healthcare providers would see in the EHR. In addition, the demonstration will show the “data on demand” feature that expedites site-specific implementation by eliminating the need to create data feeds through proprietary interface engineering.

This demonstration will highlight the unique architecture and how it leverages the power of SMART on FHIR® and the FHIR® PRO IG to create an extensible, light-weight, and portable solution.

Author Statement

The PRO project was launched in Spring 2018. The modified application pilot test plan was finalized in Fall 2018 and the application redesign took place in Winter 2018. Application implementation at nine primary and specialty care practices began in February 2019 and is expected to be completed by June 2019. Evaluation of application usage and users’ feedback will occur in Summer 2019. All authors listed above contributed to the application’s development and implementation. Chun-Ju Hsiao and Joseph Blumenthal will conduct the demonstration.
Evidence-Based Care Made Easy: University of Utah’s SMART on FHIR Platform for Chronic Disease Management and Health Maintenance

Kensaku Kawamoto, MD, PhD, MHS1, Douglas K. Martin, MD,1 Claude Nanjo, MAAS, MPH1

1Department of Biomedical Informatics, University of Utah, Salt Lake City, UT

Problems addressed: crises in care quality and clinician burnout. The U.S. faces a care quality crisis, with U.S. adults receiving only about 55% of recommended care.1 The U.S. also faces a crisis in clinician burnout, and a significant reason is that for every hour of clinical work, clinicians spend 2 hours on clerical work or EHR-related tasks in the ambulatory setting.2 These two issues are likely related, as EHRs generally provide only limited support for delivering evidence-based care efficiently and effectively, contributing to both clinician frustration and suboptimal compliance with evidence-based care standards.

University of Utah ReImagine EHR initiative. In 2016, the University of Utah launched the ReImagine EHR initiative to improve patient care and the provider experience through standards-based, interoperable extensions to the EHR. Supported through operational investments and over $27 million in grants and contracts, this initiative has developed numerous informatics solutions that leverage the HL7 SMART on FHIR and CDS Hooks interoperability standards. Systems developed and deployed into production in the health system’s Epic EHR environment include a neonatal bilirubin management application, a population health management system for individuals at risk of early onset familial cancers, a surgical referral dashboard, a procedure capacity management application, a lung cancer screening shared decision making app, a diabetes treatment outcome prediction app developed in collaboration with Hitachi, opioid-related decision support tools developed with CDC and ONC support, and EHR-integrated medical calculators developed in collaboration with MDCalc. Several of these solutions have been integrated with multiple EHR platforms. The ReImagine EHR team includes seven members certified to develop new FHIR interfaces into the Epic EHR. One of these apps (the bilirubin management app) has won several provider user experience awards.4

SMART on FHIR Disease Management Platform. Building on the expertise gained from the efforts above, the ReImagine EHR initiative identified evidence-based chronic disease management and health maintenance as a key need for improving care quality and the provider EHR experience. To address this need, the Disease Management Platform was developed. This system is fully integrated with the EHR, and it provides care guidance via individual chronic disease modules as well as a unified module that encompasses all relevant modules for chronic diseases and health maintenance. The initial disease module supported by the platform is chronic obstructive pulmonary disease (COPD), and additional modules are in process such as for hypertension, diabetes, general health maintenance, congestive heart failure, and chronic kidney disease. The system is available in the production Epic environment. In order to maximize potential impact, a commercial approach to disseminating the system is being explored.

Key Innovative Features. As one key innovative feature, the Disease Management Platform integrates advanced, guideline-based decision support with commercial EHR technology. Second, the system is able to utilize practically any data available in the EHR, regardless of whether it is currently supported by the base FHIR interface provided by the EHR vendor. This is made possible by additional FHIR interfaces developed by the ReImagine EHR team, and which can be deployed at other healthcare systems. Third, the system pulls in and intuitively organizes relevant data, so that there is no need to hunt for the relevant data across the various modules in the EHR. Fourth, the system provides a unified summary of the patient’s status on guideline-based care standards, as well as actionable recommendations on next steps. Fifth, recommendations can be followed easily, such as through 1-click ordering of needed interventions. Finally, the system facilitates required clinical documentation.

Session Content and Demonstration. The presenters will start by briefly describing the problems addressed, the University of Utah ReImagine EHR initiative, and the approach taken to design and implement the Disease Management Platform. The presenters will then use sample patients to demonstrate how the Disease Management Platform makes it easy – and perhaps even enjoyable – to provide evidence-based care to every patient, every time. The presenters will conclude with a brief summary of evaluations to date, lessons learned, and future directions.

A Molecular Research and Discovery Platform for Placental Research: the Placental Atlas Tool (PAT)

Michael Keller, Ph.D.¹, John Ilekis, Ph.D.², Alexandra Shlionskaya, M.S.¹, Christopher H. Ferguson, Ph.D.¹, Archana Mohale, M.S.²

¹Booz Allen Hamilton, Inc. McLean, Virginia, USA; ²Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, Maryland, USA

Introduction

The Placental Atlas Tool (PAT) (https://pat.nichd.nih.gov/) has been developed to create, maintain, and update a shared research analytics platform designed to serve as an important resource for the placental research community. PAT leverages existing resources to identify knowledge gaps, develop new hypotheses to address those gaps, and identify potential therapeutic targets and biomarkers. PAT addresses a need for scalable and agile systems integration, supporting NICHD’s organizational goals and their user community, and maximizing research investment through data discoverability and reuse.

PAT Technical Implementation

The PAT system employs a microservice architecture methodology to be scalable, extensible, and data-driven to adapt to changing scientific and business needs of the placental research community. PAT was designed to be metadata-driven and built around standardized terminologies of concepts relevant to placental research which were used to identify and annotate all datasets, images, and publications available in the system. Molecular datasets are preprocessed and loaded into the PAT database to be easily discovered and analyzed by users with embedded web-based analytical tools.

PAT User Experience

PAT is based on user-centric design principles and places emphasis on a flexible, data-driven experience that enables discovery from multiple user perspectives. The PAT Homepage provides access to the various explorers as well as education and information resources. The Terminology Browser contains the terminologies that form the basis of the metadata-driven content experience. The Image Explorer allows users to search and sort through placental images enriched with metadata. The Dataset Explorer provides users with access to over 500 placental datasets. The dataset analytics workflow makes bioinformatic analysis of large molecular datasets accessible to all users, regardless of bioinformatic experience and provides common bioinformatic outputs. Users are able to save content entities of interest to their personalized Workspace. Figure 1 provides snapshots of the PAT functionalities listed above.

Figure 1. PAT Functionalities

Conclusion

PAT is poised to maximize the investment NICHD and the broader research community has made in placental research by reinforcing open scientific inquiry, expediting formation of new insights by combining data sources, promoting the testing of new or alternative hypotheses and analytic methods, and facilitating education of new researchers. PAT accomplishes this by coupling cutting-edge data-driven, flexible development principles with rigorous content curation practices, ultimately creating a fluid, accessible, and robust investigational resource.
NIAID Tuberculosis Data Exploration Portal: A Public Analytics Platform

Alyssa R. Long1, Alexander J. Glogowski, MBA1

1Office of Cyber Infrastructure and Computational Biology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland, USA

Introduction

Tuberculosis (TB) is the leading cause of death from infectious disease worldwide, causing over 1.5 million deaths in 20171. Drug-resistant forms of TB present a rising public health crisis, because they are difficult to treat with lengthy and more expensive multi-drug regimens. Diagnosis and treatment for drug-resistant TB often requires a full clinical picture with radiological and pathogen genomic information, yet there was a lack of public data repositories that contained this information as a resource. Responding to this need, the National Institute of Allergy and Infectious Diseases (NIAID) started to collaborate with physicians, researchers, radiologists, and IT specialists in countries with a high burden of drug-resistant TB, forming the framework of the TB Portals Program2. Collecting, validating, analyzing, and annotating a wide range of TB data, we built an open-access repository and developed a user-friendly and powerful advanced analytics resource, TB Data Exploration Portal (TB DEPOT). TB DEPOT facilitates the visualization and analysis of multidimensional TB Portals Program data, which enables researchers to move from data to knowledge to action in the fight against TB.

Tuberculosis Data Exploration Portal

TB DEPOT integrates deidentified clinical, socioeconomic, genomic, and imaging data and allows for user-driven, repeatable, and reproducible statistical analyses. It provides a web-based analytics platform that makes unique, inaccessible drug-resistant TB data available to the research community, and enables the reusability of data, in conformity with the NIH’s Findable, Accessible, Interoperable, and Reusable (FAIR) principles. TB DEPOT provides a self-service capability for users to create, compare, and analyze patient cohorts to generate and test their hypotheses, going from thought to analysis in under a minute. The cloud-based tool is hosted on AWS, designed with an extensible, scalable infrastructure using .NET webforms, Highcharts, R, PLINK, custom algorithms, and provides APIs for data and cohort sharing, all of which can be replicated for other infectious or chronic diseases.

Figure 1.

TB DEPOT, deployed in Production in 2016 and publicly available at: https://depot.tbportals.niaid.nih.gov.

Conclusion

TB DEPOT is the first tool of its kind to facilitate open-access cohort creation, comparison, and analysis through the integration of clinical, socioeconomic, genomic, and imaging data on a web-based platform in a reusable way.

Interoperable Consumer Decision Support: CDS Connect and b.well

Chris Moesel1, Kristen Valdes2, Ginny Meadows, MSHI, RN-BC1, Shafa Al-Showk, MPH3, Quyen Ngo-Metzger, MD, MPH3, Sharon Sebastian, RN-BC, MS1, Edwin Lomotan, MD3

1The MITRE Corporation, Bedford, MA; 2 b.well Connected Health, Inc., Baltimore, MD; 3Agency for Healthcare Research and Quality, Rockville, MD

Background
Since 2016, the Agency for Healthcare Research and Quality (AHRQ) has been developing prototype infrastructure for developing and sharing interoperable clinical decision support (CDS). The infrastructure, called CDS Connect, includes a repository of publicly-available CDS knowledge artifacts and open source software. To demonstrate use of the infrastructure and tools, CDS Connect develops, implements, and shares CDS through use cases in specific clinical domains. In 2019, CDS Connect, in collaboration with the MITRE Corporation and b.well, developed interoperable decision support focused on preventive care. Recommendations were delivered directly to consumers through a comprehensive, patient-facing mobile platform.

Description of Demonstration
The U.S. Preventive Services Task Force (USPSTF) is an independent, volunteer panel of national experts that works to improve the health of all Americans by making evidence-based recommendations about clinical preventive services. The USPSTF works with stakeholders in the delivery of primary care to help communicate and implement its recommendations, which span a range of topics. CDS Connect worked with b.well to transform a subset of USPSTF grade A and B recommendations to CDS expressions for delivery through b.well’s consumer-facing platform.

b.well is a consumer health management platform that connects consumers with a single digital experience to manage all aspects of their health. The platform allows consumers to access their own medical records electronically, receive personalized services and recommendations based on their health needs, view insurance and financial information, and be incentivized to engage in their own health journey. The platform pulls data from electronic health records, health insurers, prescriptions, lab systems, health devices (e.g., fitness trackers), and more while considering patient preferences. The b.well platform organizes a consumer’s experience as a health journey in which they can play games that encourage healthy choices and behaviors, earn rewards for meeting personalized health goals, and receive reminders and incentives for preventive screenings and other ways to manage health for themselves and their family.

The CDS for USPSTF recommendations was developed by translating recommendation statements into fully specified, standards-based representations. Logic statements were encoded in HL7 Clinical Quality Language (CQL) and include value sets – groupings of codes from standard terminologies such as SNOMED-CT, LOINC, and RxNorm – to define clinical concepts. The CDS data model was defined in terms of the HL7 Fast Healthcare Interoperability Resources (FHIR) Draft Standard for Trial Use (DSTU) 2 standard for health data exchange. CQL Services, an open source prototype tool developed by CDS Connect, exposed the CQL-based CDS over a HL7 CDS Hooks API, allowing b.well to invoke the CDS to receive appropriate USPSTF recommendations for each consumer.

The CDS presented through b.well is consumer specific, i.e., tailored to their personal health information and health history. The platform recommends appropriate screenings identified through data such as age, gender, various risk factors, insurance claims, and other aggregated data. Consumers are notified that they are due for a screening via their preferred communication method. The b.well platform uses gamification and behavioral science to educate consumers about the screening and to provide appropriate actions, such as scheduling an appointment with their doctor. Consumers earn points for each task completed through the platform and can then use those points to redeem healthy rewards. Attendees will experience this health journey from the perspective of a consumer presented with USPSTF recommendations and will learn how to access the publicly-available, interoperable CDS artifacts on CDS Connect.

Author Statement
CDS Connect has been operational and widely available since 2017. USPSTF recommendations will be pilot-tested and implemented via the b.well platform in spring/summer 2019. All CDS knowledge artifacts, including the CQL code, results of the pilot, and a detailed implementation guide, will be publicly-available on CDS Connect by September 2019. Information about the AHRQ initiative, including access to CDS Connect, can be found at http://cds.ahrq.gov. All authors listed above contributed to the system’s development. Chris Moesel and Kristen Valdes will conduct the demonstration.
MSK-EXTRACT’s Shopping Cart: Integrating Ontology with REDCap

John Philip¹, MS, Rimma Belenkaya¹, MS, and Peter Stetson¹, MD, MA
¹Memorial Sloan Kettering Cancer Center, New York, NY

Introduction

Memorial Sloan Kettering uses an EHR with clinical notes that is comprised of free text. Despite the advances in natural language processing and other types of machine learning, much of structured clinical data at MSK is a result of manual abstraction, often stored in spreadsheets. This approach is problematic since spreadsheets are often lost, don’t use standard terminology and are not used in a multi-user fashion. REDCap is a PHI friendly, multi-user alternative to spreadsheets. Many institutions try to make REDCap more approachable by teaching classes and using data analysts to help people build their projects. However there remains a steep learning curve in starting a data curation project in REDCap vs spreadsheet. At MSK, the MSK EXTRACT initiative is implementing a three-tier approach to lure people away from spreadsheets to REDCap: a “shopping cart” application to build the REDCap database, dynamic data pull from a data warehouse and an ETL script that sends the abstracted data back to the data warehouse for reuse and analytics. Here we present the “shopping cart” application that enables the use of standard terminology in REDCap databases.

Shopping Cart Application

The Shopping Cart is a web application that helps researchers build REDCap databases built on data elements that have been mapped to ontologies by our terminology team.

Features:

• Add and delete fields. Add and delete permissible values for the fields.
• Fields can be public or private. Public fields are available for Dynamic Data Pull but only the labels are editable. They can also be added to new projects.
• Suggest new fields for terminologists to vet and add to Standard Library of terms after being mapped to ConceptIDs. Such fields are always public.
• Help user organize fields into REDCap screens (aka instruments).
• Use REDCap APIs to update database with changes.
• Use of existing projects as templates to build ones own project.

Conclusion

The key innovations in the shopping cart are: 1. Allowing a crowdsourcing approach to building a standard library. 2. Standard term labels are still customizable unlike most other terminology approaches that lock down terms. 3. The conceptIDs are hidden from the users, keeping people oblivious to the mechanism of standardization while still getting the benefits. 4. Standard terms can be added from the standard library or from other REDCap projects.

Current Deployment Status

As of current writing, the software is in beta. Custom APIs were built to allow communication to TopBraid and to a custom database (EXTRACT DB) stored in DB2. The shopping cart uses the REDCap APIs to update the REDCap database. The application is written in Python, using REACT for front end and Tornado for web framework. In the next few months, we plan to add: 1. a caching database for the standard library to avoid constantly querying TopBraid, 2. chat functionality on a field and project level to allow easy communication between user and the terminologist, 3. Additional search function beyond text search to rapidly find the desired term in the standard library. Recent UI exploration suggests a navigation with a tree structure might work very well.

Killing Cancer With Data: Solving Cancer Data “Interoperability” With Portability Through The Patient

Anil Sethi
Founder and CEO
Ciitizen Corporation
Palo Alto, California, U.S.A.

Reducing cancer-related morbidity and mortality requires greater access to data. But today, across the globe valuable health data is trapped in silos. Institutional data holders are often reluctant to share data, either due to regulatory concerns, competitive concerns (often masked as regulatory concerns), or lack of sufficient incentives or resources to share. It is difficult and costly to find patients to enroll in cancer clinical trials and even existing cancer data initiatives suffer from critical information gaps.

Cancer has a data problem; let patients help solve it.

Ciitizen is developing a patient-controlled cancer data ecosystem that will enable patients to fill these data gaps. Patients already have the right to all of their health information under the Health Insurance Portability and Accountability Act (HIPAA) and other privacy laws. Leveraging this right of access, on behalf of the patient Ciitizen collects comprehensive health information from every place where the patient has received care, from pre-cancer diagnosis forward, including images, notes, pathology reports, genomic/genetic data, and other data not yet available through patient portals. Ciitizen then normalizes and standardizes this data into actionable information (with data provenance) that patients, their caregivers, and clinicians can efficiently and effectively use to seek treatment recommendations or to determine eligibility for clinical trials. Patients also have the option to share their rich cancer histories (both the normalized and standardized information, as well as the raw underlying data) to advance the science of cancer. In essence, Ciitizen democratizes cancer care and research by putting data ownership and control in the hands of patients (and caregivers acting on their behalf) – the stakeholders most highly motivated to collect it, use, and share it liberally to save their own lives and the lives of others just like them.

Ciitizen provides its patient users with sole control over whether and to what extent they share the information in their Ciitizen accounts, both identifiable and de-identified. Ciitizen users will also share in any monetization of their data. In an era of decreasing trust in digital data initiatives, we believe empowering patients with decisions regarding their data is critical to helping assure that data generated from care is robustly available for research and other population health initiatives.

As of the date of submission of this proposal, Ciitizen is in beta and supporting active cancer patients on the Ciitizen platform. Ciitizen is also engaged with multiple partners, including a) supporting an observational study in non-small cell lung cancer for a large multinational life sciences partner, b) partnering with a leading advocacy organization on a rarer cancer to build a clinically validated registry, and c) working with a major health system in the Midwest to drive better clinical trial enrollment with their patient population. By the time of the AMIA annual symposium, we will have scaled up the number of patients on the platform and be able to discuss the early results of these partnerships.
Development, Design and Security Features of a REDCap -Tableau Web Data Connector (WDC) to Facilitate Operational and Clinical Self-Service Analytics
Alexander J. Tanchoco1, Olga Strachna, MS2, Stuart M. Gardos1, Jonathan Wills1, Cynthia Chu1, Joseph M. Lengfellner3, Andrew Zarski3, Ilya Sher1, Mike E. Piscitelli1, Peter D. Stetson, MD, MA2
1 Information Systems, 2 Division of Health Informatics, 3 Research and Technology Management; Memorial Sloan Kettering Cancer Center, New York, NY

Rationale, Motivation and Objectives
With growing interest for translational research in the clinical community, it’s imperative to integrate disparate sources of patient data that are captured in the electronic health record system (EHR) and augmented by data captured during the research phase1. REDCap is a popular tool within the clinical research informatics community that’s commonly used to capture clinical research study data2. While there is an existing mechanism to enable extraction of REDCap data via the REDCap repository of external modules, Tableau developers are required to request, understand the Application Programming Interface (API) mechanism and utilize the API key to authenticate to the system3. We strived to develop a human friendly mechanism for authenticating and connecting to and extracting the REDCap project data by using LDAP/AD credentials which users utilize to access enterprise Memorial Sloan Kettering (MSK) systems. The log in is linked to Datapedia, our internal MediaWiki page for collaborative sharing of knowledge about data, systems, and operational procedures. This mechanism is facilitated through a Tableau dashboard menu that shows the projects the user has access to. The user simply selects the project and does not have to remember or have a separate note of their tokens. The REDCap token is passed on to Tableau and kept in the password of the connection. This ensures that Tableau encrypts this token, just like all the embedded passwords for all other connections. Without a Web Data Connector, Tableau users who want to visualize REDCap data have to export data through CSV files which are stored on their local machines or through the network. Having the data connector facilitates improved security by eliminating data which is stored in file systems and not centrally managed. The MSK Tableau WDC also helps improve productivity and security by eliminating the tedious manual exporting and refreshing Tableau dashboards and data sources by allowing publishers to schedule the refresh automatically or by granting specific permissions for individual users to be able to perform the refreshes without having to share the credentials for connection to REDCap. This system is currently live and approved for development in production Tableau systems.

System Design Features Summary

<table>
<thead>
<tr>
<th>Requirement</th>
<th>Description</th>
<th>Rationale</th>
</tr>
</thead>
<tbody>
<tr>
<td>General / Base</td>
<td>Enable self-service</td>
<td>Enhanced productivity and efficiency</td>
</tr>
<tr>
<td>Functionality</td>
<td>Provide a menu of authorized projects</td>
<td>For self-service, users should only have to remember their ID and password.</td>
</tr>
<tr>
<td></td>
<td>Integration with Tableau Server with the Ability to refresh data on scheduled basis when published to the Tableau Server.</td>
<td>This eliminates the manual updating of the data from REDCap enabling greater productivity by eliminating additional manual processes.</td>
</tr>
<tr>
<td>Security Requirements</td>
<td>Retain and abide by existing REDCap and Tableau Security Processes</td>
<td>Both systems are well designed and their security implementation should not be circumvented.</td>
</tr>
<tr>
<td></td>
<td>Prevent users from having to manually enter their granted API tokens.</td>
<td>Think of the REDCap API token as a user ID but without a password! It is a long string that no normal human cannot remember and they will therefore have to keep it at a place to cut and paste from. If these tokens are compromised, since REDCap is accessible on the internet, it can wreak havoc to that project.</td>
</tr>
<tr>
<td>Reporting Requirements</td>
<td>Eliminate the use of embedded passwords by using the Token as the password</td>
<td>Since the use of the token is required for the REDCap API, and because user ID is not encrypted but passwords are encrypted in Tableau, it made sense to encrypt the token which is then used to pass on to REDCap during connection. No need to keep a separate ID.</td>
</tr>
<tr>
<td></td>
<td>Integration with Active Directory</td>
<td>Provides a single user id and password for all systems.</td>
</tr>
<tr>
<td>Usability Requirements</td>
<td>Self-Service with robust documentation and integration with data definitions</td>
<td>People who are tasked with using REDCap and Tableau are likely to be highly educated and quick learners. They do need to have reference materials available. The use of Datapedia for documentation with live links to the connector allows documentation to be readily updated and tied to the rich data definitions available in Datapedia while being able to take action from within the documentation with integrated AD security.</td>
</tr>
<tr>
<td>Audit Requirements</td>
<td>Utilize both REDCap and Tableau’s security and auditing features.</td>

System Purpose

LOINC® is a freely available international standard for identifying measurements, observations, and documents. Presently, LOINC has more than 80,000 users from 175 countries and has become ubiquitous in health data systems worldwide. Since its inception, Regenstrief has distributed LOINC in custom table formats and with no cost tools for linking local terms to LOINC terms. Such tools are important, but are unique to LOINC. Deploying LOINC content via a standardized application programming interface (API) could enable greater computability, facilitate use in diverse applications, and simplify access to the terminological content needed for biomedical informatics applications. The widely adopted Fast Healthcare Interoperability Resources (FHIR) specification from Health Level 7 provides a standard set of resource descriptions for health data, including terminology content. We have deployed a standardized API for LOINC that implements FHIR terminology services specifications.

System Features

FHIR defines key resources and operations in its Terminology Module, including CodeSystem, ValueSet, and ConceptMap. The CodeSystem resource specifies a set of codes drawn from one or more code systems. With input from the FHIR community, we created a canonical definition of how to represent LOINC as a CodeSystem in FHIR that extends its simple base representation to include LOINC-specific properties of each term. The LOINC CodeSystem defines several kinds of identifiers, including LOINC Codes, LOINC Parts, LOINC Answer Lists, and LOINC Answers. The ValueSet resource specifies a set of codes drawn from one or more code systems. We implemented value sets for key collections of LOINC terms, LOINC Answer Lists, and the new a LOINC Groups. The ConceptMap resource defines a mapping from a set of concepts defined in a code system to one or more concepts defined in other code systems. We implemented several sets of mappings, including from LOINC terms to IEEE device codes, LOINC terms to RadLex Playbook Procedure Codes, LOINC Parts to RadLex clinical terms, LOINC Parts to SNOMED CT terms, and more. We worked with Simpatico Intelligent Systems on extensive updates to the HAPI open source FHIR library that enabled support for these terminology resources with LOINC content, including direct import of many LOINC release artifacts and the features of the canonical definition of LOINC as a FHIR CodeSystem.

Current Use and Deployment

In September 2018, we deployed a publicly available server (accessible via free LOINC user account) powered by HAPI on Amazon Web Services. The service base URL is https://fhir.loinc.org and a detailed feature description is available at https://loinc.org/fhir. Since its launch, this service has processed an average of about 350,000 monthly requests with an average processing time of 163ms per request. We updated the terminology content with the December 2018 and June 2019 LOINC releases, and plan to do so with each upcoming LOINC release.

Conclusion

We have deployed a standardized API for LOINC content based on FHIR that provides programmatic access to current release content in a uniform and well documented format using open source software.

Introduction  An essential prelude to precision medicine is the stratification of patients into subpopulations for increased diagnostic and treatment efficacy. By efficiently matching patients to the right care management programs, improved outcomes can be obtained at less costs and in shorter time. However, electronic health records (EHR) functionality to assist clinical decision-making is restricted due to bias in health records and the difficulty in synthesizing meaningful concepts from the records. This can be resolved by using phenotyping approaches that integrate diverse data modalities. However, phenotyping methods are largely unused for driving clinical care processes, although they have been used to characterize cohorts for epidemiological studies.

Specific purpose of the system The objective of this project is to develop processes and tooling to stratify patient populations for targeted clinical care. The approach is to integrate libraries for machine learning (ML) with workflows for creating clinical annotations to train ML. The expected outcome is to identify patients for selected therapeutic pathways, which will facilitate efficiency and scalability of care delivery to the patient population.

We have developed and implemented a patient stratification process outlined in Figure 1, which incorporates feedback from ancillary clinical staff for enabling rapid development of phenotyping pipeline for identifying patients eligible for selected therapeutic pathways. The process involves (a) creation of ontologies that are geared for determining eligibility of patient for a therapy, (b) use of advanced phenotyping techniques including those driven by ML, and (c) assignment of clinical annotations for training ML algorithms.

Deployment Having deployed the process in the clinical setting for over a year, we are working on scaling the stratification process by using i2b2 plugins that we have developed. Specifically, we have developed plugins to implement key steps the patient stratification process including creation of ontologies to model and compute concepts needed at point-of-care, and incorporation of annotations from the clinical staff to provide inputs for improving the phenotyping algorithms. In this session, we will demonstrate the process for a real-world use case but using simulated patient data and demonstrate the developed i2b2 plugins.1

ESTABLISHING AN ADAPTIVE SUSTAINABLE ENTERPRISE-LEVEL BIOMEDICAL DATA SHARING PLATFORM

Susan Tenney, Ph.D., Alexandra Shlionskaya, M.S., Michael Keller, Ph.D., Alexandra Dawson, M.S., Alissa Fujimoto, M.S., Andrijana Dabic, B.S., Rajni Samavedam, M.P.H.  
Booz Allen Hamilton, Inc.

Introduction
The scientific value of data sharing can only be fully realized if research investigators can readily access and utilize analyzable clinical and other biomedical data. Many research organizations lack the infrastructure and governance at the enterprise level to archive diverse data types, and the ability to distribute this data in accordance with patient privacy, security, and other government regulations. To address these challenges, Booz Allen Hamilton designed a data sharing platform which provides a sustainable infrastructure and streamlined mechanism for researchers to share and discover biomedical data. The platform balances the needs of researchers and their studies with the requirements mandated by institutional and federal policies which govern the sustainment and reuse of shared data.

Conceptual Data Sharing Platform Architecture
The platform utilizes scalable and secure cloud environment, flexible microservice architecture, data-driven design, and user-friendly, accessible front-end to deliver state of the art, policy-compliant, data sharing solution that is agnostic to research areas, data types, sources of the shared data. These design principles enable the secure centralization of complex and heterogenous data types generated from clinical research, in a manner that promotes FAIR (Findable, Accessible, Interoperable and Reusable) data sharing principles. To achieve consistent data representation across studies, the platform uses a harmonized metadata model to represent diverse data types in a unified, structured, and extensible way. This metadata driven approach leverages biomedical terminologies and standards to provide meaningful representation of stored data for streamlined data discovery, access, and retrieval.

Conclusion
The functionality and technical solution of this data sharing platform was designed to accommodate the growing needs of the scientific research community. The policies and governance set in place take into consideration the multi-stakeholder landscape of clinical data sharing, to ensure a transparent and streamlined data sharing process while mitigating the risks of sharing individual participant data. Collectively, this platform would serve as a valuable data sharing resource to maximize the value of existing research data by facilitating broader reuse and secondary analysis.
