2019 AMIA Board of Directors

Officers

Peter J. Embi, MD, MS, FACMI
Regenstrief Institute
Chair

Patricia C. Dykes, PhD, RN, FAAN, FACMI
Brigham and Women’s Hospital
Chair-elect

Titus K. Schleyer, DMD, PhD, FACMI
Regenstrief Institute/Indiana University School of Medicine
Treasurer

Theresa A. Cullen, MD
Regenstrief Institute
Secretary

Directors

Tiffany J. Bright, PhD
Washington University School of Medicine in St. Louis

Wendy W. Chapman, PhD, FACMI
University of Utah

James J. Cimino, MD
University of Alabama at Birmingham Informatics Institute School of Medicine

David Dorr, MD, MS, FACMI
Oregon Health & Science University

Paul Fu, Jr., MD, MPH, FAAP
City of Hope/Los Angeles County Harbor-UCLA Medical Center/University of California, Los Angeles

Wanda Pratt, PhD, FACMI
University of Washington

Gretchen Purcell Jackson, MD, PhD
IBM Watson Health/Vanderbilt University Medical Center

S. Trent Rosenbloom, MD, MPH, FACMI
Vanderbilt University Medical Center

Sarah (Collins) Rossetti, RN, PhD
Partners Healthcare System/Brigham and Women’s Hospital/Harvard Medical School

Neil Sarkar, PhD, FACMI
Brown University

Jessica Tenenbaum, PhD
Duke Translational Medicine Institute

Adam Wright, PhD
Vanderbilt University Medical Center

**Ex-Officio Board Members**

William M. Tierney, MD, FACMI
American College of Medical Informatics President
University of Texas at Austin

Douglas B. Fridsma, MD, PhD, FACP, FACMI
President and Chief Executive Officer
AMIA

Stephen Johnson, PhD, FACMI
Academic Forum Executive Committee Chair
Weill Cornell Medicine

Albert M. Lai, PhD
Working Group Steering Committee Representative
Washington University

Shauna M. Overgaard, MHI, PhD Candidate
Student Working Group Representative
University of Minnesota

Frank Naeymi-Rad, PhD, MBA, FACMI
Informatics Partnership Council Chair
Intelligent Medical Objects
AMIA 2019 Annual Symposium Scientific Program Committee

Chair
Elmer V. Bernstsam, MD, FACMI
University of Texas Health Science Center

Vice Chairs
Dina Demner-Fushman, MD, FACMI
National Library of Medicine

S. Trent Rosenbloom, MD, MPH, FACMI
Vanderbilt University Medical Center

Laura K. Wiley, PhD
University of Colorado

Adam Wright, PhD, FACMI
Vanderbilt University Medical Center

Members
Joanna Abraham, PhD
Institute for Informatics at Washington University in St. Louis, School of Medicine

Alexander V. Alekseyenko, PhD
Medical University of South Carolina

Allison Beck McCoy, PhD
Vanderbilt University Medical Center

Jiang Bian, PhD
University of Florida

Mary Regina Boland, PhD
University of Pennsylvania

Jonathan P. Bona, PhD
University of Arkansas for Medical Sciences

Suzanne A. Boren, PhD
University of Missouri

Andrew D. Boyd, MD
University of Illinois at Chicago
Juliana Brixey, PhD, MPH, RN
University of Texas Health Science Center

Brian Thomas Bucher, MD
University of Utah/Primary Children's Hospital

Thomas R. Campion, PhD
Weill Cornell Medical College

Pamela Charney, RD, PhD
University of North Georgia

You Chen, PhD
Vanderbilt University

Catherine Craven, PhD
Icahn School of Medicine at Mount Sinai

Robert Cronin, MD
Vanderbilt University Medical Center

Berry de Bruijn, PhD
National Research Council, Digital Technologies Research Centre

Judith W. Dexheimer, PhD
Cincinnati Children’s Hospital

Hossein Estiri, PhD
Harvard Medical School

Jungwei Fan, PhD
Mayo Clinic

Susan H. Fenton, PhD
UT School of Biomedical Informatics

Adela Grando, PhD
Arizona State University

Robert A. Jenders, MD, FACP, FACMI
Charles Drew University/UCLA

Thomas Kannampallil, PhD
Washington University School of Medicine
Ramakanth Kavuluru, PhD
University of Kentucky, College of Medicine

Shameer Khader, PhD
AstraZeneca

Saif Khairat, PhD
University of North Carolina

Eric Kirkendall, MD, MBI
Wake Forest Baptist Medical Center

Mei Liu, PhD
University of Kansas Medical Center

Hongfang Liu, PhD
Mayo Clinic

Yuan Luo, PhD
Northwestern University

Bradley A. Malin, PhD
Vanderbilt University Medical Center

Ruth M. Masterson Creber, PhD, MSc, RN
Weill Cornell Medicine

Stephane M. Meystre, MD, PhD
Medical University of South Carolina

Jason M. Mitchell, MD, MS
Cerner Corporation

Stuart J. Nelson, MD, FACP, FACMI
University of New Mexico School of Medicine

Aurelie Neveol, PhD
LIMSI – CNRS

Omolola I. Ogunyemi, PhD
Charles Drew University of Medicine and Science

Carolyn Petersen, MS, MBI
Mayo Clinic

**Andrew B. Phillips**, PhD, RN  
MGH Institute of Health Professions, Massachusetts General Hospital

**Ronald J. Piscotty**, PhD, RN-BC  
University of Maryland

**Lee Pyles**, MD  
West Virginia University

**Luke Rasmussen**  
Northwestern University

**Janise Richards**, MS, MPH, PhD  
Centers for Disease Control & Prevention

**Satya S. Sahoo**, PhD  
Case Western Reserve University

**Hojjat Salmasian**, MD, MPH, PhD  
Brigham and Women's Hospital

**David F. Schneider**, MD  
University of Wisconsin

**Murat Sincan**, MD  
Sanford Health

**Neil R. Smalheiser**, MD  
University of Illinois at Chicago

**Sandeep Soman**, MD  
Henry Ford Health System

**Joshua H. Tamayo-Sarver**, MD, PhD  
CEP America

**Ozlem Uzuner**, PhD  
George Mason University

**Theresa Walunas**, PhD  
Northwestern University
Amy Y. Wang, MD, MBI, FAAFP
University of Alabama at Birmingham Informatics Institute School of Medicine

Keith F. Woeltje, MD, PhD
BJC HealthCare

Po-Yin Yen, PhD, RN
Washington University in St Louis

Kai Zheng, PhD
University of California, Irvine

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publishers of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they are not responsible for any errors or omissions or for the results obtained from use of such information. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this book is accurate and that changes have not been made in recommended dose or in the contraindication for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
Advancing Common Approaches to Working with EHR Log Data

Julia Adler-Milstein, PhD¹, You Chen, PhD², Michelle Hribar, PhD³, Jen Popovic, DVM, MA⁴, J. Marc Overhage, MD, PhD⁵

¹University of California San Francisco, San Francisco, CA; ²Vanderbilt University Medical Center, Nashville, TN; ³Oregon Health & Science University, Portland, OR; ⁴RTI International, Waltham, MA; ⁵Cerner Corporation, Kansas City, MO

Abstract

EHR systems generate log data, which can be productively employed to improve the efficiency, quality, and safety of healthcare. There is a growing number of studies that use EHR log data but, as with any new set of data and associated methods, there is little consistency in approach and there are substantial inefficiencies from researchers replicating foundational work. Following a highly successful AMIA panel in 2018 that introduced log data and its potential uses, we convened 3 workgroups to develop measurement and methods guidance for working with log data. Our panel will present results from each workgroup and illustrate how the products could be used to support a range of research topics. The panel will also engage in a discussant-led conversation about the opportunities, limitations, and methodological challenges of common approaches, and where additional efforts may be needed. The learning objectives for this panel include: increasing awareness of the value of EHR log data for answering various clinical informatics and clinical research questions, understanding new methodological guidance for how to use these data in a research setting, and understanding the remaining domains in which community-led work could improve the quality and efficiency of EHR log data research.

Panel Description

An EHR system generates log data by recording and time stamping events and actions occurring within the system. Traditionally utilized to detect security and compliance issues, EHR log data are increasingly used to address varied clinical informatics and clinical research questions, particularly in the domains of workflow, efficiency, and patient safety¹, ². Because these data are not entered by humans and instead are an automatic byproduct of EHR use, there are fewer challenges with data quality and integrity. However, there are also unique but pervasive challenges in working with log data in a research context.

In early 2018, a community-based effort launched the National Research Network (NRN) for EHR Log Data. The network serves as a forum to connect researchers across the country working with log data and to facilitate sharing research projects, best practices, methodologies, etc (via monthly webinars). As the network rapidly grew to more than 80 participants, it became clear that there was substantial heterogeneity in approaches to tackling similar issues and many examples emerged of different researchers and sites replicating the same foundational work. In response, the network convened 3 workgroups – each taking on a different domain in which developing common methods and measures along with methodological guidance would be valuable. The first workgroup is developing a framework to characterize frontline user task types that are measurable in log data. The second workgroup is developing definitions for prevalent log data measures, such as the start and end time of an encounter. The third workgroup is facilitating an assessment of comparability of log data across sites by developing standards to capture a single, highly-specified workflow.

During the panel, the workgroup leads will present the goals and products of their workgroups as well as give examples of their application to varied research questions. The presentation of results will be followed by a discussant-led conversation, intended to stimulate thought about the strengths and limitations of the workgroup outputs, extensions
of the workgroup efforts that could increase their value, and future needs of researchers working with EHR log data. The panelists represent different institutions (VUMC, OHSU and RTI) and have diverse background and training. Specifically:

**Julia Adler-Milstein, PhD** (moderator and organizer) will kick-off the panel by introducing the panelists and the topic. Dr. Adler-Milstein will also describe the rationale and motivation for bringing this panel together and the efforts of the broader National Research Network that she leads.

**You Chen, PhD** (panelist) will present the results from the first workgroup “Developing a framework to characterize task types”. This workgroup has 19 members coming from 14 different institutions including academic and industrial medical centers, universities and EHR vendors. The goal of the workgroup is to create a framework of task types that capture common clinical activities. Audit logs record a care provider’s activities - such as “accessing a treatment plan” (view), “signing a clinical note” (modify) or “printing an operating room report” (export) - and an EHR system’s activities - such as “a quick note was automatically sent in response to an e-consult” (system). Informed by a literature review to identify commonly reported task categories, the workgroup is collecting access actions generated by different EHR vendors (e.g., Epic and Cerner), and conducting a comparative analysis to build a catalog of task types including administrative, billing and coding, chart review, documentation (notes), orders (medications, labs), patient email, etc. For each task type, the goal is to generate a definition and a list of corresponding access actions that are commonly available in log data. We will discuss limitations and challenges to creating common definitions and associated measures (e.g., differences in granularity of log data entries) as well as provide recommendations for future work that address these challenges.

**Michelle Hribar, PhD** (panelist) will present the results from the second workgroup “Developing measures relevant to audit log work”. This workgroup is comprised of 20 members from 17 different institutions including universities, healthcare centers, government, and industry, and is addressing the lack of common approaches to measure activity timing derived from audit logs. The goal of this workgroup is to produce a catalog of measures with definitions, validations, and applications across different medical settings, EHR vendors and EHR implementations. High-priority measures include those that are frequently reported in EHR log data research, such as “provider documentation time” and “exam start time”. Work on newer measures such as “shift start” and “shift end” times will also be presented along with the methodology for defining and validating these measures across settings, institutions, and EHR vendors. Limitations and challenges for defining these measures will be discussed as well as recommendations for improving their accuracy and reproducibility.

**Jen Popovic, DVM, MA** (panelist) will present the results from the third workgroup “Developing standards to support use of audit log data to characterize specific use cases”. This workgroup is comprised of a dozen members from 11 different institutions, including universities, industry, government and healthcare centers. The goal of this workgroup is to identify and leverage existing/emerging models, such as FHIR resources, to support log data standards-development around a use-case. The selected use-case is, “Characterizing patterns of EHR use across clinical departments and/or types of staff”. The panelist will discuss the resources needed to address this use-case (e.g., Audit Events, Tasks, Practitioners), describe the metrics used with those resources (e.g., Login/Logout), present differences discovered in log data capture and meaning across systems (e.g., whether timestamps associated with Login/Logout represent the same event, such as a user-submit or an authentication), and propose the standards to address the use-case. She will describe limitations and challenges to developing standards across these resources and events, as well as future work needed to scale and extend them to additional use-cases.

**J. Marc Overhage, MD, PhD** (discussant). Dr. Overhage will leverage his substantial experience with EHR log data to facilitate a participatory discussion with the panel and audience to address the challenges and opportunities regarding uses of workgroup outputs. Questions to be considered include:

- What are the primary barriers to uptake and effective use of common approaches to task categorization, time-based measures, and use cases? How can these barriers be overcome?
• How can we be confident that findings from EHR log file analyses supporting workgroup efforts reflect actual user activities?
• How can we consider EHR end-user (e.g., clinical staff) perspectives about log data use/misuse, particularly to the extent that the data may or may not accurately reflect actual user activities?
• How important is comparability of findings from EHR log file analysis with results obtained using other methods to support credibility of workgroup efforts?
• What additional work would enable more rigorous or more efficient approaches to log data analysis across institutions?

Topic Rationale
EHR log data are a potentially powerful input for clinical informatics research. To date, usage of these data demonstrates their applicability to answering a range of important clinical informatics and clinical research questions. However, methodological inconsistency threatens both the rigor and the efficiency of the burgeoning work in this area. The AMIA community is poised to be a leader in sharing guidance that helps the entire community use EHR log files to advance this promising area. It is therefore critical to share current community-led efforts to ensure broad awareness and solicit feedback about how ongoing work can be improved and extended for greater impact. The anticipated audience for this panel will be clinical informaticists at a broad range of institutions including universities, industry (in particular, EHR vendors), government, and healthcare delivery organizations, who are building EHR log data infrastructure or using EHR audit log data to answer clinical and operational research questions.

Statement of Agreement to Participate
All panelists have approved of this submission and agreed to participate.

Panel Participant Details
Julia Adler-Milstein, PhD. Director, Center for Clinical Informatics & Improvement Research. Associate Professor, Department of Medicine, University of California San Francisco
You Chen, PhD. Assistant Professor, Department of Biomedical Informatics, Vanderbilt University Medical Center
Michelle Hribar, PhD. Assistant Professor, Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University
Jen Popovic, DVM, MA. Senior Director, Center for Health Data Analytics, RTI International
Marc Overhage MD, PhD. Chief Medical Informatics Officer and VP Intelligence Strategy, Cerner Corporation

Quantifying Efficiencies Gained Through Shareable Clinical Decision Support Resources

Shafa Al-Showk, MPH, CHES¹, Edwin A. Lomotan, M.D.¹, Kristen Miller, DrPH, CPPS², A. Zach Hettinger, MD, MS²; Jeremy Michel, MD, MHS³,

Abstract

Clinical decision support (CDS) is the process of bringing evidence into practice by providing the right information, to the right audience, using the right channel and format, at the right time (known as the “Five Rights” of CDS). Health care systems have traditionally developed CDS in siloes, which is a sign of redundancy and inefficiency of an overall ecosystem where CDS knowledge might be shared. MedStar, through contract with AHRQ, studied potential efficiencies gained by health care systems using shared, interoperable CDS available through CDS Connect, AHRQ’s web-based platform for sharing CDS artifacts. This panel describes how researchers worked with four health care systems to quantify differences in process, time, and resources between CDS developed entirely internally versus CDS developed with shared CDS artifacts. At the end, participants will be able to translate this knowledge into a business case for health care systems. Participants will be able to access CDS Connect and review its collection of shareable, interoperable clinical decision support. Participants will be able to compare and contrast processes for developing CDS in siloes vs. developing CDS using shared CDS artifacts. Participants will be able to identify measures that quantify potential efficiencies, including time and resources, towards developing CDS.

Introduction

One way to potentially accelerate the movement of research evidence into practice is through computerized clinical decision support (CDS). The process includes translating evidence-based knowledge such as clinical practice guidelines into computable form and then implementing the guidance into an electronic health record (EHR) or other technology as CDS. The design, development, and deployment of CDS is time consuming and resource-intensive. These three major components are essential in the CDS lifecycle (Figure 1). Health care systems currently develop CDS in siloes, which has been estimated at a collective cost of $25 billion, if the process is repeated across all currently recommended care within each health care system in the U.S.¹. This cost may be lowered if the process were more systematic and replicable across settings and if the process were supported by shareable, interoperable, standards-based tools and resources. These include tools for authoring CDS, structured representations of guidelines that are machine-readable, standards-based logic specifications, and implementation guidance. Health care systems would essentially not have to “start from scratch” when faced with CDS development and implementation. CDS Connect, a web-based platform developed by the MITRE Corporation under contract with AHRQ, has provided many of these tools since its inception in 2016. Health system leaders need to know how these tools may affect their current CDS processes, and in particular, whether such tools can improve the efficiency by which CDS can be developed and implemented.
Panel Description

This didactic panel will feature the leads of CDS Connect and researchers investigating potential efficiencies gained by using shareable, interoperable CDS. Panelists will focus on sharing their experience of CDS built in an isolated compared to a sharable state while discussing preliminary findings and lessons learned.

**Shafa Al-Showk, MPH, CHES**, serves as a health scientist and program official in the Division of Health IT in the Center for Evidence and Practice Improvement at AHRQ. She will provide background for the project and how it relates to AHRQ’s overall CDS initiative. Shafa will also moderate the panel.

**Edwin Lomotan, M.D.,** serves as Chief of Clinical Informatics for the Division of Health IT in the Center for Evidence and Practice Improvement at AHRQ. He will describe the CDS Connect platform, including its purpose, history, and content of interoperable CDS tools and resources. As a discussant on the panel, Dr. Lomotan will also provide reactions to results of the Medstar study, including describing potential implications for how health care systems may share CDS in the future and the role of CDS repositories.

**Kristen Miller, DrPH, CPPS,** is Scientific Director of the National Center for Human Factors in Healthcare at MedStar Health and an Associate Professor at the Georgetown University School of Medicine. Dr. Miller is co-principal investigator on the AHRQ contract to quantify efficiencies gained through shareable, interoperable CDS such as that provided through CDS Connect. She will describe analyses and findings to define and quantify efficiencies gained by health care systems to build a business case that could be used to promote the use of shared CDS within organizations (see Figure 1). The research team composed of health information technology experts, human factors experts, and a combination of clinical and non-clinical backgrounds, compiled a list of potential metrics that could be used to quantify and evaluate efficiencies of the CDS lifecycle. These metrics were used in evaluations that included stakeholder discussions and participatory data collection for CDS team members at four healthcare systems in a cross-sectional evaluation of CDS builds with and without the use of CDS Connect. The study design allows for comparisons of processes to evaluate team makeup, reduction of redundant work, and availability of resources. Dr. Miller will share qualitative and quantitative comparisons of the processes. Preliminary findings suggest shareable resources could fill the gap, which requires healthcare systems to independently develop, deploy, and manage CDS. The use of shareable CDS resources most significantly impacts the design process, reducing time and manpower required to retrieve evidence and extract content.

**A. Zachary Hettinger, MD, MS,** serves as the Director of Cognitive Informatics and Medical Director for the Human Factors Center, providing medical and informatics expertise and direction on grants and contracts while practicing clinically and working to improve clinical informatics operations across MedStar Health. Dr. Hettinger is co-principal investigator on the AHRQ contract to quantify efficiencies gained through shareable, interoperable CDS such as that provided through CDS Connect. He will describe MedStar’s experience as an academic nonprofit healthcare system that uses Cerner, going through the CDS lifecycle (see Figure 1) of the isolated CDS build versus the shareable CDS build with specific attention paid to the role of EHR vendor sponsored CDS tools.
Jeremy Michel, MD, MHS, is an assistant professor at the University of Pennsylvania and attending physician at the Children’s Hospital of Philadelphia (CHOP). Dr. Michel will relate the experience of CHOP as a pediatric health care system that uses Epic by comparing and contrasting the development of an isolated CDS build versus a shareable CDS build. He will describe his experiences using the CDS Connect platform to disseminate shareable CDS including and benefits and barriers identified while supporting external site implementations of shareable CDS.

Relevance to Annual Symposium Theme and Importance of the Topic

Our proposed panel fits directly into the theme of the AMIA 2019 Annual Symposium, “Clinical Informatics: Findings related to the design, development, and implementation and maintenance of state-of-the-art clinical systems, including electronic health records, standards and interoperability, clinical decision support, and effects on clinical quality, safety, and patient outcomes.” Health care systems spend considerable resources developing CDS but could take advantage of others’ experiences, including re-using knowledge “artifacts” generated by translating scientific evidence into computable form. Experience is growing in the use of health IT standards that support interoperable CDS and in the use of public infrastructure that supports sharing of CDS knowledge artifacts and tools.

Discussion Questions for Audience Participation

We anticipate the panel will generate discussion in a wide range of areas including business case model and process for CDS development. The panel will also explore with the audience how CDS Connect may serve organizations and patients. Discussions questions may include:

- What are some of the challenges health care systems faced while developing CDS in isolation?
- Does the form of CDS (e.g. semi-structured vs. computer-interpretable structured representation) influence the efficiencies gained by the health care system?
- How might the artifacts and the authoring tool enable you to develop CDS more efficiently?
- How can the CDS build in the isolated state differ from the CDS build in the shareable state?
- How would your health care system approach the option of using CDS artifacts developed elsewhere but available for sharing?

Author statement

All authors have agreed to take part in the panel.

Translating, Implementing, Deploying, and Evaluating Clinical Interventions Using Machine Learning Based Predictive Models: Illustrative Case Studies

Yin Aphinyanaphongs, MD/PhD₁, Jonathan Wilt², Corey Chivers, PhD³, Mark Sendak, MD⁴

₁NYU Langone, New York, NY; ²Oschner Health System, Jefferson Parish, LA
³Penn Medicine, Philadelphia, PA, ⁴Duke Institute for Health Innovation, Durham, NC,

Abstract

Significant barriers to the translation of machine learning based predictive models in clinical care continue to exist. The barriers are both technical and social and successful deployments require significant effort. This panel will provide targeted case studies of machine learning based predictive models through model evaluation, deployment, and adoption. The panel will demonstrate end to end examples of machine learning based predictive models and the issues and processes leading to their successful deployment. In some case studies, model evaluation results demonstrate improvements in quality of care and reductions in cost of care.

Learning Objectives

After participating in this session, attendants should be able to:

- Demonstrate examples of machine learning based predictive models deployed and adopted in clinical practice.
- Describe challenges in successful deployment and adoption of machine learning based predictive models.
- Describe operational principles supporting the deployment of machine learning based predictive models.
- Describe methods for evaluating the clinical impact of these machine learning based predictive models.
- Describe interventions and measurement tools at the point of care.
- Describe how organizational and engineering structure contribute to model translation.

General Description

Precision medicine (1) and precision delivery (2) are two emerging approaches to healthcare delivery. Both efforts propose to target care delivery to those who can most benefit from an intervention. At its core, this targeting task is what every healthcare provider does when a patient walks into our offices. We gather patient data and allocate our resources (medicines, diagnostics, etc) to uncover and address underlying pathology. Precision medicine and precision delivery propose to expand this paradigm with omics and clinical data respectively.

Over many decades, researchers published papers and models with excellent discriminatory performance on multiple clinical problems. In the clinical domain, these models have typically been described as calculators. For example, PORT (3) and Reynolds (4) are two clinical calculators. Some models have been widely adopted such as SIRS (5). However, far more that are published do not. Multiple barriers may account for the limited adoption. One particular barrier was the difficulty in entering data into these calculators. Simple calculators that do not require many predictors are simple to use though they may lack discriminatory power due to their simplicity. Calculators that may require significant numbers of predictors are non-starters for practical clinical use. With the advent of electronic health records and digital recording devices, this barrier is lower and it is now possible to build larger models and potentially more performant models. However, the quality of data stored in the EHR and difficulty extracting and normalizing data to a common data model introduces new challenges to effectively scaling machine learning applications across settings. In addition, the cost to validate and integrate an analytics application is not trivial (6). Concurrently with the digitization of health data, gains in pattern recognition and machine learning have enabled significant improvements in model performance. We are once again at a crossroads with many models being published and few being deployed.

Our premise is that barriers for pragmatic model implementation still exist between the academic research that demonstrates excellent discriminatory performance for multiple clinical problems and the translation of these machine learning based predictive models into routine practice. Naively it would seem easy to believe that
Translating a published model into practice is as easy as deploying a model on a server and feeding it variables and reporting the outcome. In practice, the challenges to deployment and adoption of models are not trivial.

This panel will highlight the lifecycle of a machine learning based predictive model through the experiences of panelists implementing, deploying, and evaluating models at their respective institution. Through case studies, we will each highlight issues and challenges associated with deployment and adoption of machine learning based predictive models.

**Description**

The panel will be organized as follows:

<table>
<thead>
<tr>
<th>Time</th>
<th>Speaker</th>
<th>Topic</th>
</tr>
</thead>
<tbody>
<tr>
<td>8 minutes</td>
<td>Aphinyanaphongs</td>
<td>Predictive analytics in medicine and the predictive model pipeline.</td>
</tr>
<tr>
<td>12 minutes</td>
<td>Aphinyanaphongs</td>
<td>Implementation, deployment, and integration of a 2 month mortality model in clinical practice.</td>
</tr>
<tr>
<td>15 minutes</td>
<td>Chivers</td>
<td>Application of a 6 month mortality risk model to direct inpatient palliative care resources.</td>
</tr>
<tr>
<td>15 minutes</td>
<td>Wilt</td>
<td>Integrating a real-time patient deterioration predictive model directly into clinical workflows.</td>
</tr>
<tr>
<td>15 minutes</td>
<td>Sendak</td>
<td>Translating sepsis machine learning model into practice.</td>
</tr>
<tr>
<td>25 minutes</td>
<td>Aphinyanaphongs</td>
<td>Panel Discussion with Audience.</td>
</tr>
</tbody>
</table>

Each panelist will anchor their content with a case study of a predictive model that they have built, deployed, or evaluated at their institution.

**Aphinyanaphongs:** Dr. Aphinyanaphongs is the Director of Clinical Predictive Analytics at NYU Langone Medical Center. His job is to build, deploy, monitor, and evaluate machine learning based models for optimizing clinical operations and care. His team includes data scientists and software engineers that build sustainable infrastructure to translate clinical needs and research findings into hospital solutions. Dr. Aphinyanaphongs will moderate the session and discuss the overall lifecycle of a predictive model. He will discuss NYU’s experience in deploying a 2 month mortality prediction model at the point of care.

**Chivers:** Dr. Chivers is a Senior Data Scientist at Penn Medicine where he works with clinicians to take predictive healthcare solutions from the idea and experimentation phases all the way to scaled, production implementations. His background is in computational biology and applied statistical modeling with a focus on the management of complex systems and decision making under uncertainty. Dr. Chivers will discuss a current Penn Medicine project using a 6 month mortality risk model to direct inpatient palliative care resources with specific attention to issues surrounding the observability/ measurability of joint prediction-intervention systems in a health care setting.

**Wilt:** Mr. Wilt is the Chief Technology Officer of innovation at Ochsner, an innovation lab and accelerator founded by Ochsner Health System in 2015 to reimagine and revolutionize the experience and delivery of healthcare. He leads the product development and is responsible for the overall technology strategy, advanced analytics and AI, and data integration. He will discuss the successes and challenges of implementing a real-time inpatient deterioration predictive model directly into clinical workflows in Epic.

**Sendak:** Dr. Sendak is the Population Health & Data Science Lead at the Duke Institute for Health Innovation, where he leads interdisciplinary teams of data scientists, clinicians, and machine learning experts to build technologies that solve real clinical problems within DukeHealth. He leads a medical student innovation scholarship and data science internships to train the workforce required to bring medicine into a new digital age. He will discuss
the successful implementation of an inpatient sepsis prediction model.

Significance of panel topic and intended audience

Data science and predictive analytics are taking increasingly large roles in health care. A plethora of research has demonstrated that machine learning based predictive models can identify patients for care prioritization and potentially reduce costs (7). Translating these findings into actual practice is essential to realize their potential gains. Healthcare organizations have recognized this potential and are making investments in building infrastructure and teams. Thus, this panel topic is timely and needed. Our intended audience include machine learning researchers who want to translate their papers into practice, data scientists within healthcare organizations, healthcare executives who want to assess infrastructure and conceptual concerns in making investments in predictive analytics, change managers and behavioral economists who can address the challenges of model adoption, user interface designers who build the end users experiences, medical educators who train future health care providers, and clinicians who will design and implement the interventions based on the model recommendations.

Discussion Questions

- What technical challenges did you overcome?
- How did you communicate with the clinical team to drive change?
- What tools and systems support successful predictive model translation?
- What resourcing (in people, software, and hardware) is necessary for successful translation?
- What skillsets are necessary for translational clinical predictive analytics teams.
- What mechanisms are possible to pool our collective knowledge and experiences in deployments to identify best practices?

Participation Statement

All proposed panelists have agreed to participate in the panel if the proposal is accepted.

References

Abstract

This panel will introduce the Informatics Technology for Cancer Research (ITCR) program, an NCI initiative to support investigator-initiated informatics technology driven by critical needs in cancer research. Investigators supported by ITCR will share their perspective on the importance and challenges in developing and disseminating informatics technology stemming from an academic setting, using their own projects as case studies, and will discuss how programs like ITCR can benefit these efforts. Panelists will also describe how their tools are benefiting the scientific goals of the targeted cancer research communities and how interactions with end users have shaped the development of their tool. In addition, the panel will discuss ways in which the cancer informatics community of practice that is evolving through ITCR is promoting collaboration and interoperability within and beyond program participants. The NCI ITCR program coordinator will moderate the discussion and will also provide a brief overview of NCI’s goals for supporting informatics technology development.

A general description of the panel and issues that will be examined

Remarkable progress in biomedical informatics supporting cancer research has been made in recent years. The emerging use of cloud computing to support big data analysis; innovative computational methods for variant calling and driver mutation detection; the application of machine learning and other artificial intelligence methods to image analysis; and the application of natural language processing to clinical information, for example, have all had fundamental impacts on cancer research. However, the use of informatics in everyday research remains a challenge for a number of reasons including the low availability of user-focused tools; lack of sufficient support for existing tools; the need for training materials; lack of interoperable tools; and the lack of tools to meet specific scientific needs. These critical needs are recognized by NCI and formed the basis of the NCI Informatics Technology for Cancer Research (ITCR) Program whose scope serves informatics needs that span the cancer research continuum.

In this panel, four ITCR investigators will describe their informatics development projects and how involvement in the ITCR community has impacted their efforts. These projects represent a range of cancer informatics activities, including cancer genome visualization, network-based treatment decision support, medical image analysis, and electronic health record (EHR) data exploration. Each investigator will outline the scientific goals and impact of their technology and discuss their perspective on informatics technology development in an academic setting, including how programs like ITCR can support their efforts. Topics for consideration will include user outreach, engagement, and support; resource sustainability; interoperability; security; and scalability. The ITCR program coordinator will moderate the panel and will also provide perspective on the NCI’s investments in informatics technology development and future goals for this program.

An explanation why the topic of this panel is timely

Cancer research is a data intensive science and accelerating progress in this field demands information technology to support the collection, management, integration, and analysis of cancer research data, especially as cancer research is entering a “big data” era. For technology to truly support and impact science, it must be driven and guided by research priorities. In addition, successful tools will also be user friendly, stable, secure, and interoperable with other tools in the research workflow. This panel is aimed at addressing the important goals and challenges with developing informatics technology that can have the broadest impact on cancer research.
Panelist’s perspective

Simina Boca, Ph.D. will discuss the CDGnet tool, which provides therapy recommendations for precision oncology using biological networks. For many cancer types, it is becoming increasingly common to check for specific molecular features in order to decide on a targeted treatment plan. Our objective is to expand the range of targeted therapy options for cancer patients who undergo molecular profiling by developing a user-friendly, evidence-based approach that accounts for the cross-talk within cancer pathways and is personalized for the individual patient. CDGnet fulfills this goal by incorporating a variety of publicly-available resources and combining them into biological networks.

David Hanauer, M.D. will discuss EMERSE (project-emersere.org), which is a free text search engine for clinical concepts in the EHR. EMERSE has been used for a wide variety of cancer research tasks ranging from cohort identification to data abstraction. ITCR support has been instrumental to build the infrastructure necessary for widespread dissemination, allowing the team to focus on security, documentation, training, and outreach. Ongoing ITCR-supported efforts also include developing new functionality for efficiently querying clinical notes, and securely networking the instances for cross-institutional cohort discovery.

Ian Holmes, Ph.D. will discuss JBrowse (jbrowse.org), a fast JavaScript/HTML5 genome browser that can be deployed as a static site with very low infrastructural overhead. JBrowse has been used to visualize genomic variants in cancer, for example by the UK Cancer Genome Project project. With ITCR support, the project is building cancer informatics features into JBrowse, including a circular viewer for analyzing the distribution of structural variants, a richly integrated human dataset, and modern web tooling to facilitate the construction of bioinformatics web dashboards.

Despina Kontos, Ph.D. will discuss the cancer imaging phenomics toolkit (CaPTk), a dynamically growing software platform for analysis of radiographic images of cancer. CaPTk integrates advanced tools leveraging machine learning and medical image analysis algorithms that have been developed in the context of active cancer imaging studies to derive phenotypic imaging signatures of diagnostic and predictive value. With emphasis given on being a very lightweight and efficient image viewer and eliminating the prerequisite for a substantial computational background, CaPTk thus aims to facilitate the swift translation of advanced computational algorithms into routine clinical quantification, analysis, decision making, and reporting workflow. Results from clinical studies in brain, breast, and lung cancer will be demonstrated.

Juli Klemm, Ph.D. will provide a brief overview of the program and NCI’s goals for funding investigator-initiated informatics technology development. She will moderate the panel and focus discussions on challenges and best practices for successful informatics technology development for cancer research.

Discussion questions to enhance audience participation

1. How do you engage the user community to ensure your tool is usable by and useful to the target audience?
2. What are the challenges for taking software from a research project to something that is hardened, generalizable, and usable across a wide variety of settings?
3. What are the common challenges that software projects encounter that ITCR funding helps to overcome?
4. What roadblocks to tool adoption and dissemination have you experienced?
5. What are key features for a software to succeed in an impactful clinical translation?
6. What are the barriers to incorporating emerging software tools in cancer clinical trials?

Agreement to participate

All speakers have agreed to attend AMIA 2019 Annual Symposium and participate on this panel.

Toward Patient-facing Clinical Decision Support: Critical Issues and Near-term Opportunities

Aziz Boxwala MD, PhD; Janet Desroche, Blackford Middleton, MD, MPH, MSc; Joshua E. Richardson PhD, MS, MLIS; Julie A. Scherer, PhD
1Elimu Informatics, Inc. Richmond, CA; 2MEDITECH, Westwood, MA; 3Apervita, Inc. Chicago, IL; 4RTI International Chicago, IL; 5Motive Medical Intelligence, San Francisco, CA

Abstract
A confluence of factors is changing patient-facing clinical decision support (CDS) from a possibility to a reality. Recent product advances, the growing adoption of wearable consumer technologies, and policy updates are but some of the many factors to open CDS beyond hospital and clinic EHRs to consumers wherever they go. How is patient-facing CDS to best support patients and how will any resulting data from patients inform clinicians’ decision-making or support learning health systems? This panel is comprised of both pioneers in the field as well as current implementers and will consider critical issues as to how the marketplace is addressing CDS for patients in light of rapidly changing interoperability standards, rapid shifts in the healthcare and consumer markets, and game-changing policies such as the 21st Century Cures Act and the Office of the National Coordinator’s Notice of Proposed Rulemaking. Through field experiences and clinical scenarios, the audience will come to understand the challenges and opportunities for patient-facing CDS and learn new approaches to developing and implementing such as the AHRQ-funded Patient-Centered CDS Learning Network’s efforts to pilot a patient-facing CDS demonstration application and candidate reference architecture.

Significance
Clinical decision support (CDS) has historically been the realm of clinicians in healthcare settings where knowledge is delivered at the “right” opportunities to alert, remind, or deliver current evidence about a patient and/or population. Yet importantly, CDS is rapidly moving from the domain of electronic health records (EHRs) into tools (e.g. smartphones, home computers, voice assistants, etc.) that interact directly with patients and even their caregivers. This shift from EHR-based CDS to potentially ubiquitous CDS presents game-changing implications on ways that informaticians, policy-makers, and vendors address the challenges (and opportunities) that “patient-facing CDS” poses.

The Patient-Centered CDS Learning Network defines patient-facing CDS as, “CDS that involves direct participation by individual patients in their health-related decisions and actions by leveraging reliable and timely evidence from patient-centered outcomes research findings and/or patient-specific information (e.g. patient-generated health data).” There are multiple technological and standards-related challenges for effectively integrating patient-facing CDS into care pathways. Recent policy announcements and programs highlight the timeliness – if not urgency – of the topic. The National Institutes of Health’s 21st Century Cures Act, the Office of the National Coordinator’s Notice of Proposed Rulemaking (NPRM), and the Food and Drug Administration’s Software as a Medical Device (SaMD) are just some of many recent policy efforts that have implications for patient-facing CDS. Furthermore, technology is rapidly advancing to the point that wearable trackers and devices are attaining research- and medical-grade levels of validity and reliability. It will soon be feasible – maybe even common - for patient-directed CDS tools to be made available. How are clinicians to incorporate these data into workflows and use these data to inform their own decision-making and communications with patients?

It is key for audiences to understand the ways that current (and rapidly evolving) policies, standards, and technologies will soon be changing the ways that next generation products, services, and research will need to incorporate patient-
facing CDS. This panel includes presenters with multiple perspectives – including developer, EHR vendor, content provider, and research – as to how current the next generation of tools and services will address these systematic changes.

Description of the Panel

The panel will be organized as follows:

<table>
<thead>
<tr>
<th>Time</th>
<th>Speaker</th>
<th>Topic</th>
</tr>
</thead>
<tbody>
<tr>
<td>5’</td>
<td>Richardson</td>
<td>Moderator – Introduction of the panelists</td>
</tr>
<tr>
<td>15’</td>
<td>Boxwala</td>
<td>Review of patient-facing CDS and considerations related to interoperability including the HL7 SMART-on-FHIR architecture</td>
</tr>
<tr>
<td>15’</td>
<td>Scherer</td>
<td>Considerations (including security and privacy) for delivering CDS content to consumers</td>
</tr>
<tr>
<td>15’</td>
<td>Desroche</td>
<td>Considerations for integrating patient-generated health data and patient-facing CDS into EHRs</td>
</tr>
<tr>
<td>15’</td>
<td>Middleton</td>
<td>Considerations of policies and technologies for maintaining trust in patient-facing CDS</td>
</tr>
<tr>
<td>25’</td>
<td>All</td>
<td>Discussion, Q&amp;A with audience</td>
</tr>
</tbody>
</table>

Learning Objectives

1. Understand the major barriers, and opportunities, to wider use of patient-facing CDS in practice
2. Learn about new approaches to implementing and delivering patient-facing CDS
3. Learn about standards for CDS and progress of the Learning Network Patient-facing CDS Work Group

Individual Speaker Contributions

**Joshua Richardson, PhD, MS, MLIS** – Dr. Richardson will serve as the panel moderator and introduce the panel participants as well as frame the discussion. Later in the program, Dr. Richardson will summarize the takeaways from the panelists and lead the audience Q&A.

**Aziz Boxwala, MD, PhD** – Dr. Boxwala will briefly review the history of personal health records and clinical decision support and then describe how these areas are merging into one area: patient-facing clinical decision support. He will provide insights into how the HL7 SMART-on-FHIR and other CDS standards can enable patient-facing CDS.

**Julie Scherer, PhD** – Patient-facing CDS at scale requires longitudinal patient data, computable clinical knowledge, and sophisticated knowledge execution services. Dr. Scherer will discuss design, development, and implementation requirements for patient-facing CDS; explore the issues associated with achieving scale while ensuring privacy; and examine available patient-facing CDS solutions.

**Janet Desroche** – Patient-facing CDS poses multiple challenges and opportunities to EHR platforms such as ways any clinician may “prescribe” CDS for patients via smartphones, and conversely, incorporate the patient-reported outcomes that result. As an EHR vendor executive, Ms. Desroche will discuss how EHR designs and implementations will increasingly account for patient-facing CDS and solutions for supporting shared decision-making between patients and providers. She will draw examples from her experience as a member of the College of Healthcare Information Management Executives (CHIME) Opioid Task Force.

**Blackford Middleton, MD, MPH, MSc** – Dr. Middleton will briefly review recent policy and technology developments driving patient-facing CDS and describe work from the Patient-Centered CDS Learning Network on maintaining Trust in decision support artifacts. He will offer suggestions for how these principles translate into practice for various forms of knowledge repositories.
Expected Discussion and Discussion Questions
Interest in patient-facing CDS and in implementing provider-facing CDS continues to grow. However, the adoption of provider-facing CDS is increasing slowly at best and may be eclipsed by the adoption of consumer-facing CDS at scale in the near term. We expect the audience will want to engage the panelists in discussions on approaches for effective implementation of patient-facing CDS, approaches to standards-based approaches to patient-facing CDS systems. The discussion questions include:

1. How are informatics standards evolving to meet the requirements of patient-facing CDS in research and healthcare more broadly?
2. In what ways are content providers addressing patient needs for reliable and actionable CDS?
3. In what ways are EHR vendors adapting to support patient-facing CDS and consumption of patient-generated health data?
4. How will current CDS approaches (people, processes, and technology) need to evolve to promote adoption within the culture of medical care?

Intended Audience
- **CMIOs and CNIOs:** responsible for implementing clinical decision support in healthcare organizations, and considering patient-facing CDS
- **CMO/CQO/CNO:** responsible for achieving high quality care, reduced unwarranted clinical variation, reduced patient harm, patient engagement strategies
- **EHR Implementers:** implementation staff responsible for implementation and effective use of EHR tools, and system optimization, including patient-facing tools
- **CDS Systems Developers:** development staff building clinical decision support tools and services for providers and their patients
- **Knowledge vendors** supplying content for CDS services
- **Policy authors:** those setting healthcare policies and creating clinical practice guidelines

Attestation
The panel moderator has assurances from all participants that they will be available to participate at AMIA 2019.

The National Patient-Centered Clinical Research Network (PCORnet):
From Conception to Execution

Tom Carton, PhD, MS1, Maryan Zirkle, MD MS MA2, Shayna Barbash2, Betsy Shenkman, PhD, MSN3, Abel Kho, MD4, Adrian Hernandez, MD, MHS5
1Louisiana Public Health Institute, New Orleans, LA; 2Patient Centered Outcomes Research Institute, Washington, DC; 3University of Florida, Gainesville, FL; 4Northwestern Feinberg School of Medicine, Chicago, IL.; 5Duke Clinical Research Institute, Durham, NC

Abstract
The Patient-Centered Outcomes Research Institute (PCORI) funded the National Patient-Centered Clinical Research Network, PCORnet. PCORnet leverages the power of electronic health data in a national distributed research network (DRN) to conduct patient-centered research. From late 2013 to present, PCORnet has built, refined and expanded its infrastructure to connect various stakeholders in productive research partnerships that leverage the power of large volumes of high-quality health data maintained by partner networks. This panel will focus on the unique attributes and lessons learned in the areas of governance, research capabilities, and sustainability during PCORnet’s evolution toward a cohesive self-governing Network.

This panel will describe PCORnet’s advancement across governance, research infrastructure and overall network sustainability.

Learning Objectives:
At the conclusion of this panel, participants will be able:
1. To describe the PCORnet infrastructure and how it has changed over time.
2. To discuss the lessons learned conducting research in PCORnet.
3. To describe the process for accessing PCORnet resources and the long-term business model for leveraging and sustaining PCORnet’s innovative infrastructure.

Panel breakdown

Moderator: Maryan Zirkle

The goal of this panel is to present information on PCORnet’s evolution toward a sustainable Network that conducts high-quality Patient-Centered Research (PCR). The panel will include four panelists each describing unique attributes and lessons learned from the Network’s infrastructure development and implementation.

I. PCORnet Overview (Panelist: Tom Carton)

The panelist will provide information on the building blocks of PCORnet. The presentation will serve as a foundation for understanding the Network’s distributed infrastructure and operations.

II. PCORnet Governance and Partnerships (Panelist: Betsy Shenkman)

Over the years, PCORnet has evolved into a cohesive, self-governing Network that connects various stakeholders through efficient governance. The presentation will highlight PCORnet’s unique decision-making processes and describe how various partners work in collaboration to support sustainability.

III. PCORnet Research Capabilities (Panelist: Abel Kho)
PCORnet has been utilized in dozens of research studies. The presentation will provide information on significant results from specific research studies utilizing PCORnet and infrastructure refinements in the following domains: data quality, operational techniques/processes, and stakeholder engagement.

IV. PCORnet Sustainability: Front Door and Business Development (Panelist: Adrian Hernandez)

The final portion of the panel will focus on PCORnet’s shift to a new business model in support of sustainability from various funders and organizations. The presentation will describe the process for accessing PCORnet resources as well as the overall business development process.

Discussion Questions:

1. What are some of the components of a clinical research network that have proven to be integral in a network’s successful and long-term sustainability?
2. What business models have demonstrated to be successful in national networks?
3. Are there additional research capabilities that should be considered within PCORnet?
4. What areas of governance should be further strengthened within the Network?
5. What additional partnerships should be considered within the Network?

Impact and Targeted Audience:

The current clinical research ecosystem faces several challenges in conducting research, including engagement of key stakeholders and generation of timely evidence that answers questions that matter most to patients and their doctors. PCORnet helps to overcome these challenges through using an infrastructure, tools and policies that support efficient clinical research, utilizing multiple data sources, and enabling people and systems to work collaboratively. This panel provides an overview of the opportunities to collaborate and engage with PCORnet partners, and showcases a unique governance structure that underlies a Network that has and will continue to make a significant impact on the health care ecosystem.

This panel will be targeted at clinicians, researchers, educators, healthcare leaders, policy makers, and Health IT professionals who have had little or no contact with PCORnet.

There are no prerequisites for this panel, but a basic understanding of data modeling or distributed research networks would be helpful.

Statement on panel participation:

All panelists included in this panel have agreed to participate on the panel.
ONC’s Leading Edge Acceleration Projects (LEAP) Advance an Application Programming Interface-based Ecosystem with Real World Use Cases for Population Health and Patient Care

Kevin Chaney, MGS\(^1\), Teresa Zayas-Cabán, PhD\(^1\), Kenneth D. Mandl, MD, MPH\(^2\), Kristen Miller, DrPH, CPPS\(^3\)

\(^1\)Office of the National Coordinator for Health Information Technology, Washington, DC; \(^2\)Computational Health Informatics Program, Boston Children’s Hospital, Boston MA; \(^3\)National Center for Human Factors in Healthcare, MedStar Health, Washington, DC

Abstract

It is critical the field of health IT innovate far quicker to optimize real-time solutions in areas ripe for momentum. The 21st Century Cures Act requires health IT to have application programming interfaces (APIs) which enable access to all of a patient’s data with no special effort. The Office of the National Coordinator for Health Information Technology (ONC) published a proposed rule to implement these APIs, both for bulk data access and for one at a time patient access. In anticipation of a new generation of health IT, ONC created the Leading Edge Acceleration Projects (LEAP) in Health IT funding opportunity, informing the development, implementation and use, and/or advancement of well designed, interoperable, and scalable health IT. Two projects under LEAP in health IT, will be showcased on this panel. Dr. Mandl will discuss and demonstrate a provider-payor use case employing the emerging SMART/HL-7 bulk-data API, which defines a Fast Healthcare Interoperability Resources (FHIR®) “Flat FHIR” format. Dr. Miller will present on work advancing clinical knowledge at the point of care via risk calculator implemented as a SMART on FHIR app into an active surveillance tool clinicians can use in electronic health records (EHRs) to integrate and improve patient care.

Introduction

The Office of the National Coordinator for Health Information Technology (ONC) drives the administration’s efforts to increase the adoption of health IT and promote nationwide interoperability of health information to improve health care\(^1\). In 2010, through the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009\(^2\), ONC created the Strategic Health Information Technology Advanced Research Projects (SHARP) cooperative agreement program\(^3\) to close the gap between the promise of health IT and its realized benefits. Substitutable Medical Applications, Reusable Technologies (SMART) Health IT\(^4\), a standards-based technology platform that enables innovators to create apps that seamlessly and securely run across the healthcare system, is hailed as a major achievement from the SHARP program, gaining national prominence\(^5-6\).

Since then, the health care ecosystem and technology supporting it have rapidly progressed. More providers than ever have implemented electronic health record (EHR) systems and sophisticated health IT tools and applications have come to market. As the electronic exchange of health information (EHI) has matured, the amount and types of health data available has expanded too. Data standards such as Health Level 7 International’s (HL7®) Fast Healthcare Interoperability Resources (FHIR®) and application programming interfaces (APIs) are making it easier for the sharing of health data. Yet, there is still much to learn about delivering and presenting emergent data to providers and between clinical and non-clinical settings in support of care and research – especially in ways that are unobtrusive and seamless. While working to implement the 21st Century Cures Act\(^7\) provisions, ONC identified gaps with respect to leveraging EHR data to support population-level analyses and services as well as integrating clinical knowledge into routine clinical practice. The reasons for these gaps range from lack of data standards and interoperability to digitization, integration, and presentation of new evidence into clinical workflows in safe, useful, and useable ways. Without strong anticipatory research and development, these challenges could compound as we move into an era of exponential data growth.

Leading Edge Acceleration Projects (LEAP) in Health IT
In 2018, ONC published the Leading Edge Acceleration Projects (LEAP) in Health IT funding opportunity to further a new generation of health IT development and inform the innovative implementation and refinement of standards, methods, and techniques for overcoming major barriers and challenges in the field. This panel presents in detail the focus of LEAP and the ongoing work of the first two funded projects. Key aspects of both projects focus on reduction provider and health system burden of utilizing health IT, while incorporating data access and use via an API for innovative purposes. Each panelist will leave time for discussion around the development, implementation, and use of their respective solution, as well as early legal and policy implications. This panel aims to stimulate a highly interactive discussion and strengthen the community’s knowledge of innovative uses of health IT, barriers and solutions for use, and areas ripe for future work.

Panel Objectives and Presenters

The aim of this panel is to provide an overview of how ONC’s LEAP in Health IT program is preparing the U.S. for an interoperable, modular, health IT ecosystem. Panelists will discuss current and emerging challenges facing the field, demonstrate prototypes of canonical use cases, and outline priorities for next steps.

Mr. Kevin Chaney (moderator and organizer), is a Senior Program Manager at ONC and co-leads ONC’s the LEAP in Health IT program. He will introduce the session, provide an overview of ONC’s relevant portfolio of work, and describe the goals of the LEAP in Health IT program. He will also moderate the session.

Dr. Teresa Zayas-Cabán (presenter), is the Chief Scientist at ONC and her division leads ONC’s scientific and evaluation efforts including LEAP in Health IT, patient-centered outcomes research, and precision medicine programs. She will provide an update of ONC’s priorities and activities, how those align with LEAP in Health IT priorities, and emerging challenges for further exploration.

Dr. Kenneth D Mandl (presenter), directs the Computational Health Informatics Program at Boston Children’s where he leads the transformative SMART Health IT initiative and is Principal Investigator of an ONC LEAP in Health IT project. He will provide an overview of a population health use case for the FLAT FHIR Bulk API, which can drive change for populations, payers, providers, and patients at scale. Mandl is developing and testing at production scale, an open source, reference population health app for use between payers and hospitals. The project relies on the emerging SMART/HL7 bulk data export standard, which has already been implemented in EHRs through the Argonaut process, and is currently being balloted through HL7. The Centers for Medicare and Medicaid, Google and Microsoft are already using the standard. For measurement of value and performance, providers and payors can share a well-defined view into a live shared dataset in “flat FHIR” format.

Dr. Kristen Miller (presenter), is the Scientific Director of the National Center for Human Factors in Healthcare at MedStar Health, an Associate Professor of Emergency Medicine at Georgetown University School of Medicine, and Associate Faculty at the Innovation Center for Biomedical Informatics at Georgetown Medical Center. She is the Principal Investigator of an ONC LEAP in Health IT project. She will provide an overview of MedStar Health’s work transforming a stand-alone Million Hearts Risk Calculator into an interactive surveillance tool, as a SMART on FHIR app, and will discuss lessons learned in the technical design and integration, legal and policy implications, and opportunities for future enhancements. Clinical decision support is often limited by its proprietary nature specific to vendors and it is rarely integrated into clinical workflows, largely limited to a “pop-up” functionality that is largely ignored by the clinician. The innovations of the Mobilizing Million Hearts tool reimagine decision support to advance knowledge at the point of care, optimize care coordination, engage patients as partners in their care, and provide feedback regarding value-based care and risk-based accountable care organization success metrics.

Panel Discussion Questions

- Does ONC see any current or emerging areas ripe for future LEAP in Health IT?
- Are there disruptive technologies the field should be prepared for?
- What technical and policy needs or gaps, have been identified through your work limiting the usage of these FHIR-based APIs?
- Are there anticipated health IT infrastructure and/or standards barriers impeding the utilization of these solutions?
- How easily can these solutions be applied to other similar aspects in the field (eg, other risk calculators, or other bulk data types)?
Panel Learning Objectives

- Participants will have a strong understanding of ONC’s scientific efforts, with a strong focus on the LEAP in Health IT Program, and the newest focal areas of interest.
- Participants will learn about the technical development and utilization of each LEAP project to date.
- Participants will learn what challenges and barriers each LEAP project experienced and how those could impact broader uptake by the field.
- Participants will learn what gaps currently exist providing bulk data sharing and integration into real time decision making.

Conclusion

There is a growing anticipation that advances in interoperability and innovative health IT solutions will transform health care in a myriad of ways. However, as with the use of any innovative technology, emerging technical challenges and policy barriers could hobble progress. Understanding these impediments and their root causes, while grappling these issues head on through innovative approaches, LEAP can demonstrate creative ways to leverage and modernize health IT to improve health care. This panel aims to stimulate a rich discussion and gather participant input that will inform and strengthen the innovative work being explored.

Statement of Participation

Each of the panelists and the moderator have confirmed that they will participate if this submission is accepted, at the assigned timeslot during the Annual Symposium.

Challenges of deploying Computable Biomedical Knowledge in real-world applications
Derek Corrigan, PhD\textsuperscript{1}, Vasa Curcin, PhD\textsuperscript{2}, Jean-Francois Ethier, MD CM PhD\textsuperscript{3}, Allen Flynn, PhD\textsuperscript{4}, Davide Sottara, PhD\textsuperscript{5}
\textsuperscript{1} Royal College of Surgeons in Ireland, Dublin, Ireland. \textsuperscript{2} King’s College London, London, United Kingdom. \textsuperscript{3} Université de Sherbrooke, Quebec, Canada. \textsuperscript{4} University of Michigan, Ann Arbor, MI, USA. \textsuperscript{5} Arizona State University, Phoenix, AZ, USA

Abstract
The popularity of health data science and persistent problems with avoidable medical errors combine to put a bright spotlight on the growing need for as much actionable health knowledge as possible to be expressed in standardised, computable forms that can be shared, reused, validated, traced as it evolves across time (provenance) and extended by other researchers. Recognizing this need, several major computable biomedical knowledge organizing initiatives are underway around the globe - Research Objects, MCBK, TRANSFoRm, CodeOcean, Knowledge Grid. This panel shall deliver on four key learning objectives. Attendees will come to: (1) Understand major (a) research, (b) clinical, (c) population health, and (d) educational use cases for actionable Computable Biomedical Knowledge (CBK); (2) Recognize common barriers to the widespread adoption and use of CBK to improve health; including the need to position CBK artifacts in relation to existing standards, such as FHIR, BPMN, DMN, PMML, PFA, RDF/OWL, etc. and be able to discuss strategies for achieving large-scale CBK artifact implementation in concrete scenarios, including the routine use of CBK created outside an organisation with possibly different technologies; (3) Understand a series of key design considerations that come into play when creating CBKs. (4) Learn the challenges of managing large numbers of routinely evolving CBK artifacts in ways that span research, clinical, health operations, and educational environments and be aware of emerging software tooling used to address CBK management at scale; (5) With the idea that all knowledge is relational by nature\textsuperscript{[1,2]} in mind, envision the most critical relationships amongst CBK artifacts and how these relationships can be used to improve the findability, accessibility, interoperability, and reusability (FAIRness) of CBK artifacts, collections of CBK artifacts, and related CBK-enabled IT services.

The panel shall look into the key challenges of deploying CBK artifacts in the real world context, organised into four sessions:

Session 1: Challenges Designing Highly-functional CBKs (Flynn)

Making CBKs Findable, Accessible, Interoperable, Reusable (FAIR). From the perspective of good library practices, emerging solutions for making CBK artifacts findable, accessible, interoperable, and re-usable will be presented and remaining gaps exposed for attendees to learn from\textsuperscript{[3]}

Principles for Determining Scope of CBKs. The presentation will share a set of principles for assessing and deciding on an appropriate scope for individual CBKs and for collections of CBKs. These principles will address state and statelessness, pure functions vs. functions with side effects, and metadata to indicate the scope of CBKs and how it was determined.

Mutability and Versioning of CBKs. A series of design decisions related to managing change for CBKs will be surfaced and discussed. The topics of semantic versioning, versioning strategies, and publishing immutable snapshots of CBKs will be covered. The costs of managing CBKs and collections of CBK will be highlighted in this context.

Multiple Representations and Using CBKs in Combination. Some CBKs are better expressed using a combination of programming and/or knowledge representation languages. This poses a challenge at the integration level when the CBKs are deployed. Examples of combining multiple CBKs for effect will be shown.

Session 2: Managing CBKs (Sottara/Curcin)

Lifecycle of a CBK. The lifecycle of CBK artifacts used for Clinical Decision Support and other purposes needs to be better understood. Discrete stages of development and deployment of Clinical Prediction Rules - derivation/validation/impact analysis/dissemination - each have their associated methodologies, actors, outputs and metrics \textsuperscript{[4]}, which can be generalised to apply to CBKs as well.
Management of CBKs at scale. Deploying large quantities of CBKs (ultra-complex models; models of models; large or massive collections) is a challenge. Two components are present here: 1) the "management" at rest: how to track what all the CBKs are, how they relate and where/when are they used; 2) the "in motion" component: how do multiple CBKs deployed in the same environment interact: are all and only the ones that matter deployed, do they work in parallel/empower/conflict with each other? If they need to interact, should it be by orchestration or choreography?

Persistence and replay. To support ongoing learning in learning health systems, there are scientific and legal needs to persist CBK and to be able to "re-run" or recreate scenarios using CBK on demand. This raises issues of digital preservation, provenance/pedigree, versioning, logging/auditing, access, and technical support, among other things.

Session 3: Using CBKs (Corrigan / Ethier)

Tooling. Guideline Producing Organizations (GPOs), such as UK’s NICE, and other professional organizations are used to producing human-readable forms of content such as spreadsheets, PDFs, journal articles, white papers, etc. New tools are needed by these organizations if they are to transition successfully to producing and publishing CBK artifacts.

Interoperability. One challenge is to recognize that interoperability is a matter of degrees. Two things are interoperable according to the degree to which they function jointly to achieve a goal. Significant unresolved issues pertain to CBK interoperability, including data-level integration (for standardized, structured I/O) but also deployment-level integration (can I execute the CBK in an artifact with the tools that I have; containerization, etc.) and protocol integration (can I formulate requests and responses in a standard way - FHIR, REST-ful web services, SOAP etc.)

Session 4: Evaluating CBKs (Flynn / Ethier)

Safety and Effectiveness: As the complexity of computable biomedical knowledge (CBK) increases beyond the simple rules and formulas we use today, what must we do to ensure that it is safe and effective? How should CBK be tested? How should biases in CBK be denoted and communicated? What data about CBK must we routinely collect to study its safety and effectiveness in practice? What usage guidelines and alert mechanisms are needed to safely use CBK in practice to shape health decisions? How to measure the impact of CBK / What scenarios are more amenable to the introduction of CBK?

Applicability: In what context is this CBK intended (not) to be used? What is the purpose of a CBK module? Is it safe/possible, and if so how, to port a CBK from an environment in which it has been proven to a new one? Can/Should the information produced by a CBK be used for a different purpose?

Discussion questions

Following the panelists’ presentation of the topics above, we will invite the audience to speak about:

- Their experiences of CBKs in practice: phenotype portals, analytic script libraries, vendor repositories
- Strategies for validation of CBKs across research groups
- Lessons learned so far in unpublished work, so that the community can learn from one another.
- Reflections on the issues raised in the presentations

Panelists

The panel members are:

Derek Corrigan, PhD is an IT professional who moved into academic research with 15 years of industry experience as both a software developer and management consultant. He joined the HRB Centre for Primary Care Research working on a collaborative European Union funded research project developing infrastructure to support a Learning Health System (www.transformproject.eu). His research primary research interests include knowledge representation using ontologies and semantic web technologies, the development of computable representations of clinical evidence, service based decision support systems for primary care. Other research interests include development of OpenEHR archetypes and the implications for research of software as a medical device.
Vasa Curcin PhD (moderator) is a Senior Lecturer (Associate Professor) in Health Informatics at King’s College London. A computer scientist by training, his research focuses on reproducible informatics methods for analytics, and clinical trials and decision support embedded in Electronic Health Records, with special interest in Learning Health Systems. He is leading the Biomedical Informatics Group at the School of Population Health and Environmental Sciences.

Jean-Francois Ethier, MD CM, PhD is a clinician-scientist and associate professor in the Department of Medicine of the Université de Sherbrooke and the Sherbrooke University Health Center. His research focuses on methods to support learning health systems (LHS) to support integrated research, knowledge transfer and care delivery. More specifically, his projects target semantic interoperability between health and research infrastructures, temporal data operations to support complex health data queries as well as formal models (ontologies).

Allen Flynn PhD. Following his graduation as a Doctor of Pharmacy from the University of Michigan, Allen studied Computer Science. After working as a network analyst, he returned to pharmacy practice as a hospital pharmacist. He then became involved with several major health IT projects and developed expertise in Electronic Health Records and medication system safety. This real-world experience inspired Allen to dedicate the rest of his professional career to improving the knowledge-delivery capabilities of health IT. He went back to school and earned his doctorate at the University of Michigan School of Information. Presently, Allen is an Assistant Professor and he studies knowledge infrastructure for health while serving as the technology lead for the Knowledge Grid team of the Department of Learning Health Sciences at the University of Michigan Medical School.

Davide Sottara PhD is Principal Knowledge Engineer at Mayo Clinic and is affiliated with Arizona State University. His work focuses on research, design and development of standards-compliant, knowledge-based and model-driven clinical architectures and applications.

All of the panelists have agreed to take part in this panel and have contributed to its conceptualization and the development of this abstract.

Envisaged audience:

It is expected that the audience will be made up both of individuals who understand the need for computable representations of biomedical knowledge, and those who are new to the field - researchers, informaticians, and guideline designers.

Complexities of a patient-powered data era: BYO (bring your own) genomics and wearables

Erin L. Crowgey, PhD\textsuperscript{1}, Matthew K. Breitenstein, PhD\textsuperscript{2}, Theresa Walunas, PhD\textsuperscript{3}, and Samuel L. Volchenboum, MD, PhD\textsuperscript{4}

\textsuperscript{1}Nemours Alfred I. duPont Hospital for Children, Wilmington, DE; \textsuperscript{2}University of Pennsylvania, Philadelphia, PA; \textsuperscript{3}Northwestern University, Chicago, IL; \textsuperscript{4}University of Chicago, Chicago, IL

Abstract
Genomic testing has lead to a paradigm shift in our understanding and treatment of disease, with particularly noteworthy accomplishments in oncology. Recent advances in consumer genomics services such as 23andMe have empowered the patient to sequence their genome independent of their healthcare provider. In parallel, personal wearables [e.g. Garmin, FitBit] have become inexpensive and ubiquitous, providing information for personal health maintenance and activity monitoring. While patients are increasingly empowered with new information about their health, genome, and healthcare risks, there are also growing concerns about how people will access these services, how they will interpret and use the data, and how data will be protected from nefarious uses. As these products and services expand, it is critical that informaticians be amongst the most informed in the healthcare ecosystem. The learning objectives for this discussion are: 1) understand risks and benefits to patients and providers for the different approaches for generating personalized genomics data, 2) learn about strategies for engaging patients and consumers in research and return of results in a patient-driven genomic era, and 3) learn data governance, privacy, and data standards required for these large-scale projects.

Introduction
Medicine is rapidly expanding to include new and exciting ways to measure and monitor health and disease. Increasingly, information about a patient’s health is being collected outside of the traditional patient-provider interactions. New and exciting ways are emerging for patients to monitor their health and wellness and to predict the onset of disease. Traditionally, patients would have to approach their healthcare provider to obtain genomic testing, usually performed in a CLIA-certified lab. Over the past few years, the emergence of relatively-inexpensive and easily-accessible personalized genomics services has empowered people to seek and obtain their own genomic testing, outside of the traditional confines of a clinic or hospital interaction. As the costs have fallen and availability of these tests has improved, the technology continues to mature, giving patients ever-increasing access to information about their genomic information and consequent predictions about health and wellness.

In addition to personalized genomics services like 23andMe, consumers are able to collect myriad of other data related to their health. Consumer wearables and sensors provide further insights for patients about their activity and fitness. Patients often see this new wealth of information as a positive influence on their health. Many have used these tools to make positive changes to their lifestyle, for instance, modifying behavior as a result of a genomic report. Yet, the widespread availability of these data sources present challenges to both patients and providers. It is now common for patients to bring to their providers data that they have collected, either through a wearable or sensor or from a personalized genomics service. Sometimes, patients are concerned about findings and want to get their provider’s input on their risk assessment. Too often, providers are ill-equipped to field patient concerns, because these data are often poorly documented or described or the relevance to the patient’s current status is unclear. There are many opportunities now to help patients leverage these data. Under the right circumstances, this information can be a powerful way to empower patients to be invested in their own health. This panel will explore several important areas related to this new patient-driven genomics era.
Instructors

Dr. Matthew K. Breitenstein, PhD (panel moderator), is an Instructor of Informatics at the University of Pennsylvania, Perelman School of Medicine. Dr. Breitenstein is an expert in translational bioinformatics and deploys ‘flipped science’ in a full-spectrum of translational research projects (from clinic-based populations to molecular hypotheses). Dr. Breitenstein is recognized as an expert in pharmacogenomics and was recently awarded the prestigious 2019 Marco Ramoni Distinguished Paper Award for Translational Bioinformatics by the American Medical Informatics Association. The Breitenstein Lab’s methodologic research sets the stage for multi-omic data to inform ‘personalized’ or ‘N of 1’ therapeutic prescribing recommendations in hematologic and oncologic care settings.

Dr. Erin L. Crowgey, PhD, is the Associate Director of the Biomedical Research Informatics Center at Nemours Alfred I. duPont Hospital for Children. Dr. Crowgey has expertise in molecular biology and bioinformatics and is the chair of AMIA’s Genomic and Translational Bioinformatics working group. Dr. Crowgey’s primary research focus is developing and applying computational pipelines for analyzing clinical genomic data from rare Mendelian diseases and pediatric cancers. She has analyzed over >1000s of NGS libraries across multiple different assays. She will present on the history of genomic technologies, with a focus on next generation sequencing, and applications in the medical field.

Dr. Theresa Walunas, PhD, is an Assistant Professor of Medicine and Associate Director of the Center for Health Information Partnerships at Northwestern University. Dr. Walunas is an immunologist and medical informaticist who seeks to bridge clinical data, genomics and real-world data to improve outcomes using patient centered strategies. She will discuss the intersection of genomic technologies with clinical and other forms of real world data to impact outcomes and strategies for involving consumers and patients in project design and the return of results.

Samuel L. Volchenboum, PhD, MD, is an Associate Professor of Pediatrics and the Director of the Center for Research Informatics (CRI) at the University of Chicago. Dr. Volchenboum will discuss patient-driven data collection, including wearables and sensors and personalized genomics services. He will discuss the data governance, privacy, and security considerations for how these data are handled by companies and consumers. He will also discuss methods by which consumers can best leverage these data to promote their own health and wellness.

Relevance

There are different approaches for generating large scale genomic resources. The panelists will explore the similarities and differences between commercial entities such as 23AndMe, and NIH funded models including All of Us, eMERGE, and TOPmed, and foundation medicine. These different models present different risks and benefits to the consumer, and the complexities of high-throughput genomics data adds yet another level of dimensionality. This topic is relevant for patients, providers, and clinical researchers.

The panelists will also discuss the evolution of how genomics data are used for both research and business perspective purposes. In reality no data are “free,” and consumers are either paying for a service or having their data leveraged or commercialized. Interpreting genomics data is heavily dependent on analyzing an n=1 in context with pedigrees and population frequencies and demands a large-scale publicly available resource. Currently, there are several publicly-available resources, such as dbSNP, dbGap, and ClinVar, that provide a wealth of data and have enabled the identification of numerous disease associated mutations. Understanding the integration across all of these projects will be extremely valuable to the clinical research community.

Collectively, the panelists will review real-world experiences within the topics outlined. The panel consists of a multidisciplinary team with diverse expertise. Dr. Volchenboum, MD, PhD, will be able to interact with audience from a physician point of view, and also as leader in data standards and governance. Dr. Walunas intersects with the bench research and translational research worlds and will reflect on the intersection of data across these spaces as well as strategies for engaging consumers in research. Dr. Crowgey has extensive background in molecular biology, bioinformatics and genomics, and will provide expertise to the discussion in regards to data analysis and difficulties with genomic data interpretation and application, and complexities associated with returning results outside of a traditional patient-doctor interaction.
Discussion Questions

1. How are social determinants influencing this new era? Certainly, not everyone can pay for fitbits and 23AndMe? How easy should it be for patients to have their external data used as part of their routine healthcare?

2. Is the patient-centered data era a public science experiment? Where are the places in the research endeavor that patients and consumers can and should play a key role?

3. How do insurance companies play a role in the new patient-driven genomic era? How should the legal system protect patients’ privacy?

4. How does it influence a consumer when they receive genomic results without the support of a trained medical staff team? There are numerous positive examples, but it is important to also recognize the risks.

5. What are the impacts of predictive versus prognostic data, and variants of unknown significance? The differences in the application of these markers complicates the interpretation and application. Are patients and providers prepared?

Declaration

Submitting author, Erin L. Crowgey, confirms that the panelists agree to attend the Symposium in November if this abstract is accepted for presentation.

Acknowledgements

ELC would like to thank the National Institute of General Medical Sciences of the National Institutes of Health grant number U54-GM104941 and the Nemours Biomedical Research Department for support.
Modernizing Health IT in Indian Country: Promoting a Patient-Centric Community Health Model

Theresa A. Cullen, MD, MS1,2, Maia Z. Laing, MBA3, Carolyn Crowder (Inupiat)4, Paul G. Biondich, MD, MS1,2, Howard Hays, MD, MSPH5

1Global Health Informatics, Regenstrief Institute, Indianapolis, IN; 2Indiana University School of Medicine, 3Office of the Chief Technology Officer, Immediate Office of the Secretary, U.S. Department of Health and Human Services, Washington, DC; Indianapolis, IN; 4Crown Consulting & Management Services, Anchorage, AK; 5Hays Health Informatics Consulting, LLC, Tucson, AZ

Abstract

The Indian Health Service (IHS) has enjoyed a 50-year history of successful, innovative and open source development of health information technology (IT). Due to multiple factors, the IHS is currently engaged in evaluating options for health IT system modernization. The Office of the Chief Technology Officer (OCTO) at the Department of Health and Human Services (HHS) collaborated with IHS and the Office of the National Coordinator (ONC) to design and conduct a multi-faceted, expert-driven and research-based approach to evaluate alternatives for health IT modernization. This panel will describe the drivers for IHS health IT modernization, the design and execution of the HHS/IHS Health IT Modernization Research Project, and methods used to ensure community engagement in modernization efforts. The panel will focus on sharing lessons learned and rubrics developed for HIT modernization applicable to other healthcare organizations.

Introduction and Background

The IHS is the principal healthcare provider for American Indian and Alaska Native (AI/AN) people in 37 states. The agency is unique among federal government healthcare systems, providing cradle-to-grave care to a defined population — members of 573 federally recognized tribes — not as a statutory mandate but as a treaty obligation. AI/AN people inhabit some of the most isolated, rural, and spectacularly beautiful parts of the United States. This population has some of the highest disease burdens and the lowest life expectancy of any ethnic group in America. The IHS has a mission encompassing personal, population and public health, and is required to report on the status of this mission to the Administration and to Congress1,2,3.

As health care and health care delivery has changed, healthcare organizations have faced the dilemma of whether, when and how to modernize the systems supporting their operations4. The breadth of Indian Health Service mission, combined with the geopolitical diversity of Indian country, creates unique challenges for health IT design and delivery1,5,6,7. These unique challenges are faced by other resource-constrained health care systems who are focused on helping their members achieve health equity by leveraging HIT solutions. This presentation discusses a comprehensive approach to modernization decision making: the development of a comprehensive qualitative, quantitative and research-based platform to identify and evaluate approaches to modernization, with a reliance on human centered design processes. The evaluation of HIT modernization for the Indian Health Service included researchers, cutting-edge technology innovators, veterans of healthcare in Indian country, and icons of health IT leadership in the U.S.- brought together to help answer how to approach health IT modernization in the IHS. Frameworks developed, lessons learned, and alternative analyses applicable to multiple organizations will be presented during this session.
Panel Description

Executing the Project – Theresa Cullen -- Presenter

Dr. Cullen will discuss the IHS Health IT Modernization Research Project in detail, describing the multiple concurrent work streams (site visits, data calls, literature research and evaluation, Human Centered Design methodology, legacy system assessment, Community of Practice modeling, and analysis of alternatives), the expertise brought to the project, and the collaboration among the project teams and stakeholders, including government agencies, tribal representatives, and community members. She will review the outcomes and recommendations of the project, including reusable frameworks developed, lessons learned and opportunities for further research. She will then introduce the panelists. At the conclusion of the panelists’ presentations, Dr. Cullen will summarize the findings of the project and how HHS and IHS are expected to proceed with subsequent phases of a multi-year modernization effort.

The HHS Perspective of the Project – Maia Laing

Ms. Laing will provide background on the IHS Health IT Modernization Research Project from the perspective of HHS, in particular that of the Office of the Chief Technology Officer. She will discuss how the project was conceived in collaboration with IHS and ONC leadership, and describe the expectations and deliverables.

History of Health IT in the IHS – Howard Hays

Dr. Hays will briefly review the 50-year history of health IT in the IHS, describing its origins on the Tohono O’odham Reservation in southern Arizona and its evolution to a comprehensive suite of over 100 applications supporting the full range of clinical and business processes at facilities serving AI/AN people across the country. He will discuss the current technical and enterprise architecture of health IT deployment in Indian country, outlining the many factors that are driving the need for modernization. This presentation will articulate the timeliness and criticality of a thoughtful evaluation of IHS options for health IT modernization\(^8,9,10\).

Tribes, Tribal Self-Determination, and Health IT – Carolyn Crowder

Ms. Crowder will orient the audience to the uniqueness and complexities of the government-to-government relationship between Indian tribes and the U.S. government. She will describe the prerogatives of Indian self-determination and how the exercise of those prerogatives by the tribes impacts programs, functions, services and activities offered to Indian people. Finally, she will offer a uniquely personal perspective as both a tribal member and tribal healthcare executive on the impact of health IT in Indian country and the importance of tribal engagement in the health IT modernization process.

Regenstrief Institute’s Take on the Problem – Paul Biondich

Dr. Biondich will discuss how Regenstrief Institute’s expertise in global health informatics was leveraged to design the approach to the IHS Health IT Modernization Research Project. He will discuss the establishment and utilization of a Technical Advisory Commission (TAC) of leading health IT academicians and executives, and the approach to evaluate and assess modernization options.

Why is this Important?

The IHS and Tribal health delivery systems have always focused on community and public health with a unique focus on holistic wellness and patient-directed clinical decision-making. IHS health IT evolved to support the same. Health IT modernization at the IHS has been driven by the increasing complexity and costs of maintaining legacy systems, an ever-changing regulatory environment, and the impact of plans by the VA to transition away from support for certain components on which IHS health IT is dependent\(^11\).

The effort to modernize the IHS health IT system seeks to harness emerging technologies to design robust, adaptable solutions that support evolving models of care. These care platforms must be designed to support patient and community engagement in a continuing effort to reverse decades of health and health care disparity faced by AI/AN people. These circumstances have provided an opportunity to evaluate IT system design and modernization options for the largest rural health network in the US. The panelists will present the approach and the rubrics developed to support the current HIT modernization evaluation. Attendees with interests in underserved and under-resourced populations, as well as those focused on modernization and future-proofing of health IT, will find this to be a compelling conversation.
Discussion Questions
1. What can be learned from the current and envisioned HIT model in Indian country which might influence future health IT development decisions for other health systems?
2. How might emerging technologies over the next decade impact the recommendations about HIT modernization?
3. How were Human Centered Design principles integrated into this project?
4. What scientific method was used to ensure that community engagement and site visits reflected an accurate perspective of the issues, gaps and requirements of users and facilities in the field?
5. How might national health policies redefine health IT system solutions to effectively address population health in the future?

Panel Organizer Statement: All participants have agreed to take part in the panel and discuss the topics as outlined above.

Using Social Media to Study Mental Health Conditions - Challenges and Opportunities

Vasa Curcin, PhD¹, Jyotishman Pathak, PhD², Elizabeth Ford, PhD³, Goran Nenadic, PhD⁴,⁵

¹ School of Population Health and Environmental Sciences, King’s College London, London, United Kingdom. ² Weill Cornell Medicine, Cornell University, New York, USA. ³ Brighton and Sussex Medical School, Brighton, United Kingdom. ⁴ University of Manchester, Manchester, United Kingdom. ⁵ The Alan Turing Institute, London, United Kingdom

Abstract

Social networks are increasingly seen as a promising source of data for mental health research. The resulting applications are manifold, from improving diagnostics and monitoring patient activity, to developing digital interventions and targeted advertising of mental health services. This panel will deliver on some key learning objectives in the area: (1) Understand the ethics and governance frameworks; (2) Understand recommended technology for collecting data from popular social networks (Twitter, Facebook, Reddit); (3) Discuss approaches to complex concept definitions needed for working in the mental health domain; and (4) Learn about current state-of-the-art NLP and machine learning techniques for processing social network data, their capabilities, and what the future may hold for this field.

Introduction

According to World Health Organization (WHO), the total number of people with depression globally was estimated to exceed 300 million in 2015. It is further estimated that approximately 16% of residents in the United Kingdom experience depression at some point in their lives. Likewise, in the US, approximately 16 million adults, equaling 6.7% of all adults in the country, have experienced a major depressive episode in the past year. Mental health problems are also predicted to cost 16.3 trillion USD between 2011 and 2030, through services, treatments, and a decline in productivity at work.

Collecting reliable data on mental health disorders and treatment outcomes, however, is a challenging task. For their disorder to be correctly ascertained, patients need to recall how they felt and what happened to them in the previous time period, which helps clinicians obtain comprehensive background information. However, this method is time-consuming and error-prone as sometimes patients may not be able to correctly recall their experiences. Additionally, voluntary recruitment into research studies may systematically bias the results, with those who are experiencing the most severe symptoms least likely to participate in research.

With massive volumes of data being generated on social media platforms, researchers are increasingly studying how these data relate to user behaviour, their mood and symptoms related to mental health condition. Studies have found that by focusing on user-generated messages, it is possible to screen for users with depression. This alternative method of detecting mental illness from produced content can supplement the traditional diagnostics based on recollection data, and can offer deeper insights into users past activities, experiences, behaviours, and feelings.

The panel will share recent work, challenges and opportunities that lie ahead in this area of investigation by focusing the discussions across four complementary themes:

Ethics, governance and people’s attitudes (Ford)

The key ethical issue to be determined when designing a research study using social media, is whether social media users are “participants” in the research, or whether their content is public data which stands alone. Purely observational research (no participant contact) of publicly available data (no log-in or permission needed to view), which is used for research for public benefit, and does not involve vulnerable groups, could theoretically be conducted without ethics approval or individual consent. However, it is important not to lose public trust in the endeavours of research, given
than in an age of scandals such as Cambridge Analytica, public distrust is running high. We will present the general ethical consensus around use of social media data along with guidelines for new studies.

**Data collection from social media (Curcin)**

Designing instruments to perform data capture from social networks, such as Twitter, Facebook and Reddit, is a non-trivial task. In addition to getting relevant ethics approvals where necessary and developing tools within the constraints of each platform’s API, care has to be given to the internal privacy and security rules, and these have to be followed through the lifecycle of the study to ensure that changes in regulations do not adversely affect the data collection instrument. We shall illustrate this point with a Facebook app designed to capture mental health data through CES questionnaires presented to users, and through a Twitter harvesting tool which uses hashtags to identify relevant posters and extracts their full post histories.

**Concept definitions (Nenadic / Ford)**

Identifying mental health conditions and outcomes can be challenging from user generated text. An exemplar case study will be presented to initiate discussion; this focuses on defining patient non-adherence to depression medications, reported in patient discussion forums. While named entities such as anti-depressants are straightforward to identify, determining the indication for the medication (the underlying disorder) may be much harder, as it is less frequently explicitly mentioned. Non-adherence to medication is a complex concept for which the definition needs the logical combination of several pieces of information. These issues may result in very complex annotation schema, poor inter-annotator agreement, and consequently limited accuracy in NLP algorithms.

**Techniques to analyze social media data (Pathak)**

Analysing information about mental health from social media offers some of the most challenging problems to the developers of natural language processing (NLP) and machine learning (ML) algorithms. Some evidence suggests ML algorithms may outperform rule-based NLP algorithms in this rapidly evolving environment, but they are less transparent and may exhibit hidden bias. Furthermore, in addition to textual data, many social media sites offer users the ability to post multimedia content, e.g. emojis, pictures, videos and URL links. All of these sources may communicate relevant information about the user’s state of mind. Building models from multimodal data is an important research challenge to address in improving our ability to use social media data for mental health research.

**Discussion Topics:**

Following four presentations detailing the discussion themes above, and using a range of exemplar case studies which illustrate the key issues, we will invite the audience to participate in discussions on:

- Their experiences in using social networks to collect research data
- The impact of changing governance regulations on study progress and governance approaches in different jurisdictions
- How NLP and machine learning techniques for social media data will evolve and which avenues look most promising
- Anecdotal and systematic evidence on attitudes to data mining social networks for health research
- Lessons learned so far in unpublished work, so that the community can learn from one another.

**Panelists:**

The panel members are:

- Vasa Curcin PhD (moderator) is a Senior Lecturer in Health Informatics at King’s College London. His research focuses on reproducible informatics methods for analytics, clinical trials and decision support embedded in Electronic Health Records, with special interest in Learning Health Systems.
- Elizabeth Ford PhD is a Senior Lecturer in Primary Care Research at Brighton and Sussex Medical School in Brighton, UK. Her research focuses on analytical methods, ethical issues and public engagement for
using NHS patient data and social media data for research, particularly focusing on mental health and
dementia.

- Goran Nenadic, PhD, is Professor of Computer Science at the University of Manchester and Fellow of the
Alan Turing Institute. His research focuses on natural language processing for healthcare applications. He
leads the UK healthcare text analytics network (Healtex).

- Jyotishman Pathak, PhD is the Frances and John L. Loeb Professor of Medical Informatics and Chief of the
Division of Health Informatics, Department of Healthcare Policy & Research at Weill Cornell Medicine.
His research focuses on developing and applying informatics methods for data mining and phenotype
extraction from electronic health records, and their applications in pharmacogenomics, comparative
effectiveness research, and population health research, particularly focusing on major depressive disorders.

All of the panelists have agreed to take part in this panel and have contributed to its conceptualization and the
development of this abstract.

**Intended Audience**

This panel session will appeal to all researchers interested in, or already using, social media data for mental health
research. Using a range of interesting exemplar research cases, it will introduce novice participants to key ethical
and logistical concepts for designing and executing social media studies. It will also allow more experienced
researchers to share current challenges and to discuss future directions for the research field as a whole.

  - Location: Atlanta, GA
  - Email: dil8@cdc.gov

- Presenter 3:
  - Name: Charlie Ishikawa
  - Academic Degree: MSPH
  - Affiliation: Kahuina Consulting
  - Location: Boston, MA
  - Email: charlie.ishikawa@kahuina.com

- Presenter 4:
  - Name: Denise Chrysler
  - Academic Degree: JD
  - Affiliation: Network for Public Health Law, Mid-States Region
  - Location: Ann Arbor, MI
  - Email: dchrysler@networkforphl.org

Abstract

The goal of IZ Gateway project is to simplify the process for a multistate provider organization to submit immunization information to the appropriate immunization information system (IIS) without requiring the provider organization to create individual point-to-point connections with each IIS in the regions they operate in. This will reduce the cost for multistate provider organizations to send immunizations to the appropriate IISs and will improve the completeness of information in IIS.

The project team conducted an environmental scan to inform the development of clear technical requirements necessary to support simplified provider reporting to immunization registries across jurisdictional boundaries (without the need to make multiple connections). Organizations such as large multistate public and private provider organizations, hospital groups, adult focused care groups, large and independent pharmacy chains, and other entities involved in sending and receiving immunization data across jurisdictional boundaries were interviewed to inform this project.

Panel Description

Healthcare organizations providing immunizations to patients in multiple states are challenged to participate in modernized immunization information system (IIS) exchange, because the burden of
establishing and maintaining connections with the many IIS jurisdictions where they immunize patients is too great. Reducing this barrier and increasing multi-state provider reporting will tremendously benefit patient care, everyday public health and the effectiveness of interventions during emergencies and disasters.

The Immunization (IZ) Gateway is a Centers for Disease Control and Prevention and Health and Human Services Office of the Chief Technology Officer project to improve IIS information completeness by reducing the cost of immunization data exchange with multiple IISs for multi-state provider organizations; e.g., regional health care systems, retail pharmacies, and health service units of the Veterans Administration and Department of Defense. The project began in late-2018 with an environmental scan. Covering topics ranging from technical barriers and solutions to legal and policy challenges, the scan found issues that concern centralized onboarding, interstate immunization information sharing, and architectural and business requirements for a nationwide IZ Gateway service.

During this panel, participants will have an opportunity to learn about the IZ Gateway use cases and environmental scan findings, and discuss solutions for key technical and policy barriers. By the end of the workshop, participants will be able to...

1. describe the benefits of an Immunization Gateway service to providers, patients and public health,
2. define the legal, policy and regulatory issues involved in developing a centralized hub to share data between multi-jurisdictional providers and IIS or among IIS,
3. describe efforts that have informed the Immunization Gateway approach
4. constructively critique immunization gateway service requirements based on present IIS capabilities,
5. devise potential solutions to address legal, policy and regulatory barriers, and
6. identify an action that they can take within 3 months to advance the gateway initiative
7. leverage findings from the Immunization Gateway to apply lessons learned to other health data exchange initiatives.

**Discussion Questions:**

1. What value do stakeholders perceive in the services that an Immunization Gateway (IZ Gateway) could provide?
2. What technical solutions or architectures might ease policy barriers to multijurisdictional exchange of IIS data?
3. How do data security concerns and requirements impact the feasibility of an IZ Gateway service?
4. For an IZ Gateway-like service to be useful on a nationwide, what should be an acceptable level of tolerance for idiosyncratic IIS business practices (e.g., on-boarding and data quality monitoring)?
5. What existing information services, systems, or standards could be leveraged to accelerate multijurisdictional exchange of IIS data?
6. What other use cases might an IZ Gateway service be extended?
7. What are the scalability issues inherent to the IZ Gateway, and how might they be addressed?
8. What do you envision as the first milestone marker or indicator of success in demonstrating the IZ Gateway concept?
9. What additional benefits may the centralized hub bring beyond those discussed for immunization information systems that may be leveraged for different data exchange opportunities?
Citizen Science: Using Informatics to Engage Vulnerable Populations in Scientific Research

George Demiris PhD, FACMI1; Anne Turner MD, FACMI2; Sarah Iribarren RN, PhD2; Katherine Sward PhD, RN3

1University of Pennsylvania, Philadelphia, PA; 2University of Washington, Seattle, WA; 3University of Utah, Salt Lake City, UT

Abstract

Citizen science refers to the collection and analysis of data by various population groups in real-world settings as part of a collaboration with scientists. Citizen science aims to respect and facilitate contributions from community members to scientific inquiry, build capacity, facilitate community-driven questions and promote dissemination. The advancement of wearable and passive monitoring technologies and direct-to-consumer genetic test kits and the continued diffusion of social media have led to an increase in citizen science projects in health care. Informatics tools introduce opportunities for large cohort research studies to understand disease and drug response and the role of environmental parameters. Vulnerable populations, namely communities with limited access to resources or at a higher risk to experience discrimination, are less likely to engage in citizen science. Informatics tools for communication, data collection and engagement can address some of the challenges that vulnerable populations experience in engaging in citizen science. This panel will provide examples from ongoing research studies demonstrating the potential for informatics to target access barriers. We will discuss innovative approaches to participant recruitment, data collection, participant engagement and communication platforms. Case studies include participants from diverse groups (across the life-span, in urban and rural settings, within the US and abroad).

Panel Description

Citizen science refers to the collection and analysis of data by various population groups in real-world settings as part of a collaboration with scientists characterized by reciprocity and mutual respect. Citizen science aims to respect and facilitate contributions from community members to scientific inquiry, build capacity, facilitate community-driven questions and research design and promote dissemination to maximize impact and uptake. The advancement of wearable and passive monitoring technologies and direct-to-consumer genetic test kits and the continued diffusion of social media have led to an increase in citizen science projects in health care. The use of platforms like Quantified Self or DIYgenomics enable individuals to participate in larger studies or engage in self-experimentation. Informatics tools that facilitate patient generated health data introduce opportunities for large cohort research studies to understand disease and drug response and the role of environmental parameters (such as living conditions, air and water quality, the built environment and available community resources) outside of clinical settings or formal organizational parameters. Citizen science and crowd-sourced health research studies are considered a potential valuable extension to traditional health and biomedical research.

The ability for individual citizens to participate in these meaningful opportunities is impacted by inequities in existing health systems. Vulnerable populations, namely communities with limited access to resources or at a higher risk to experience bias or discrimination, are less likely to engage in health related citizen science initiatives. Examples of vulnerable populations in this context include individuals and communities with limited access to digital tools that are often necessary for communication and data collection in citizen science projects, those with lack of trust in formal systems of care and academic research, or likely to experience bias, individuals with limited English proficiency or health literacy.

Informatics tools and strategies have the potential to address some of the challenges that various vulnerable populations experience in engaging in citizen science projects. This panel will provide examples from ongoing research studies demonstrating the potential for informatics systems to target access barriers. We will discuss innovative approaches to a) participant recruitment (such as crowdsourcing to understand priorities and preferences for older adults experiencing transitions in their care settings and needs); b) data collection (such as sensor-based, integrated health monitoring systems for measuring environmental, physiological, and behavioral factors in...
epidemiological studies of pediatric asthma); c) participant engagement (such as mhealth tools to interact with study participants in real time and validate behavioral choices); and d) communication platforms (such as tools to reach out to study participants in challenging circumstances like end of life care settings). The panel presentations describe case studies and examples that cover participants from diverse population groups (across the life-span, in urban and rural settings and within the US and abroad) who may be experiencing barriers to accessing health resources including accessibility, distance and bias. Furthermore, these presentations describe different technologies and study design approaches. The intended audience includes among others, informatics researchers in the areas of citizen science, and health disparities, with an emphasis on participatory research, as well as system designers and policy makers.

Participants and audience will discuss crucial questions such as:
- How can informatics tools incorporate features in their design that address digital divide and data literacy?
- What are the ethical concerns of citizen science projects for vulnerable populations?
- How can inclusive design inform the creation of citizen science tools?
- What are the opportunities and practical challenges in utilizing tools such as momentary time sampling, crowdsourcing or sensor based environmental assessment to facilitate data generated by participants in diverse settings?

The four panelists will cover the following areas:

Use of informatics tools to engage caregivers in end of life care settings (Demiris)

Family caregivers play an essential role in the delivery of care for a patient with advanced illness, especially in hospice and palliative care settings. During that time, caregivers face many physical and emotional challenges and have to coordinate many tasks and responsibilities, often with limited or no time for self-care. While interventions to support family caregivers are greatly needed, participating in research studies during that time can be very challenging. There are barriers to conducting research in the context of palliative and hospice care, and these are exacerbated for rural populations. We describe efforts to use informatics platforms to tailor recruitment and engagement of hospice caregivers within an NIH-funded randomized clinical trial (Grant Nr. R01NR012213) examining the role of technology in supporting problem solving for hospice caregivers. We discuss ethical and practical challenges in recruiting and retaining study participants in a study that is co-designed by family caregivers, and highlight strategies to maximize participant engagement and tailoring intervention material to improve acceptance and utility. We also discuss dissemination strategies to promote research opportunities for a domain that is less explored in the context of research, namely end of life care, in rural communities.

Innovative approaches for engaging difficult to reach populations in informatics research and technology design (Turner)

Involvement of users in the development and design of health information tools is a tenant of health informatics. Older adults make up a substantial portion of the US population and an even larger portion of health care expenditure and activates. While it is important to get the perspectives of a diverse group of older adults, recruitment may be difficult because of physical and social isolation and limited mobility. The challenge of limited participation and inclusion of older adults in research studies is well documented. We will discuss current efforts underway at the University of Washington to recruit and retaining older adults from a variety of settings to participate in research studies. In particular we will discuss the strengths and limitations of crowdsourcing platforms, social media and community organizational networks for recruiting difficult to reach populations. Experiences gained through several federally funded research projects such as, SOARing, SHARE-NW and Enhanced Fitness to recruit participants from rural, low income, cognitively impaired and culturally diverse populations will be shared and discussed.

Use of informatics tools to support individuals self-managing treatment (Iribarren)

Tuberculosis (TB) is an urgent global health threat and the world’s deadliest infectious disease despite it being largely curable. Poor medication adherence to TB regimens, along with challenges in monitoring patients and returning them to treatment, are important contributing factors to poor outcomes and the development of drug resistance. Individuals with TB face multiple barriers to good treatment adherence such as medication side effects, stigma, and lack of understanding about the disease and its treatment. Populations in resource limited settings with limited health literacy may experience additional challenges both in engaging in health interventions and also have access to participate in research studies. With advances in, and proliferation of, mobile technologies, there is substantial interest in the possible use of mobile interventions to address these challenges. We describe efforts to develop and refine TB treatment support tools, which link an app developed using user-centered design principles and a paper-based drug metabolite urine test strip modified for home use, to improve treatment outcomes (K23NR017210). We discuss...
interacting with study participants in real time and validating behavioral choices. We also discuss challenges for data gathering and research participant engagement in an international population in Argentina where self-management of treatment is the usual care and for a disease historically heaviest felt by marginalized populations.

Measuring environmental, physiological, and behavioral factors in epidemiological studies (Sward)
Lifestyle/behavior and environmental exposures are primary influences on disease state or wellness, particularly for adults and children with chronic conditions. Various factors such as literacy, health literacy and barriers to accessing care services may affect the ability of individuals and families to engage in extensive research studies that examine multiple factors such as the environment and the community in addition to information captured within a clinical setting. The NIH/NIBIB-funded Pediatric Research using Integrated Sensor Monitoring Systems (PRISMS) informatics center at Utah (1U54EB021973), with pediatric asthma as the exemplar condition, aims to develop and implement an informatics ecosystem to support integrated health monitoring systems for measuring environmental, physiological, and behavioral factors in epidemiological studies, using passive and wearable sensors. High-resolution sensor data need to be integrated with clinical, research-specific, and self-report data. We discuss the high-engagement participatory design process used to understand family and researcher priorities and preferences; concerns and actions to protect privacy and data security; and family’s interactions as part of the research process. Citizen science was evidenced in part by a nearly universal tendency to self-experiment, when provided real-time ability to see the data from sensors.

Participants (All panelists have agreed to participate)

George Demiris, PhD, FACMI, is a Penn Integrates Knowledge University Professor in the School of Nursing and Department of Biostatistics, Epidemiology and Informatics in the Perelman School of Medicine, University of Pennsylvania. His research focuses on the design and evaluation of patient and family centered tools to support aging in place and improve the quality of home and hospice care. He is co-founder of the Hospice Caregiving Research Network and a Fellow of the Gerontological Society of America.

Anne M. Turner, MD, MLIS, MPH, FACMI, is Professor in the Department of Health Services, School of Public Health, and Department of Biomedical Informatics and Medical Education, School of Medicine, University of Washington. Her research focuses on the application of information technology and human centered design to address public health issues involving health inequities resulting from language incongruence, aging and those living in rural environments. Dr. Turner is Associate Director of the Health Promotion Research Center at the University of Washington.

Sarah Iribarren, RN, PhD, is an Assistant Professor in Biobehavioral Nursing and Health Informatics at the University of Washington, School of Nursing. Her research focuses on the design and evaluation of patient centered innovative mobile solutions which may be key to a fairer distribution of scarce healthcare resources and a method to extend the reach of nurses and nursing to vulnerable people who may be isolated from information and healthcare services either by geography or by social or economic status.

Katherine Sward, RN, PhD, FAAN, is an Associate Professor in the University of Utah College of Nursing, and adjunct Associate Professor in the Department of Biomedical Informatics. Her research focuses on clinical and translational research informatics and decision support. She leads informatics efforts for the NICHD-funded Collaborative Pediatric Critical Care Research Network (CPCCRN) data coordinating center, and for the NCATS-funded Trial Innovation Network (TIN). She and her PRISMS collaborators are leading efforts in environmental informatics (exposure health informatics) at the University of Utah.
Reducing Burden: Evidence-based Solutions for Improving Clinicians’ EHR Experiences

Chris Dymek, EdD¹, Thomas H. Payne, MD², Genevieve B. Melton, MD, PhD³, & Hardeep Singh, MD, MPH⁴

¹Agency for Healthcare Research and Quality, Rockville, MD; ²University of Washington, Seattle, WA; ³University of Minnesota, Minneapolis, MN; ⁴Michael E. DeBakey Veterans Affairs Medical Center and Baylor College of Medicine, Houston, TX

Abstract

Electronic Health Record (EHR) use has been increasingly associated with clinician burnout. Up to 49% of a clinician’s time is spent working on EHR and other administrative activities. Given competing pressures of being clinically productive and trying to maximize face-to-face time with patients using imperfect and sub-optimized EHR systems, there is a tremendous need to fundamentally transform these systems and improve clinicians’ experiences. This panel will feature findings and implications from important health information technology (IT) research projects aimed to improve clinicians’ EHR experiences. Specifically, presentations and discussions will revolve around evidence-based solutions to improve three of the highest contributors to EHR burden: (1) documentation, (2) chart review, and (3) inbox tasks. The panel will conclude by moderating an in-depth discussion with the panel members and audience about health IT research priorities to further build the evidence-base for alleviating EHR-related clinician burden. The learning objectives for this panel include: increasing awareness of new health IT research aimed to reduce clinician EHR burden; understanding the potential for leveraging these health IT tools and applications into various healthcare settings; and understanding future health IT research directions aimed to improve the clinician EHR experience.

Panel Description

More than half of clinicians and healthcare workers in the United States experience burnout symptoms. Despite the potential benefits of EHRs, one factor consistently associated with burnout is the increasing amount of time and effort clinicians spend on EHRs. Heavy EHR usage has been associated with increased clinician burden that normally leads to losses in productivity, job dissatisfaction, increased health care costs, and even increased rates of suicide. A recent study in four different specialty practices found that 27% of a clinician’s time was spent in clinical face-to-face time while 49% was spent using the EHR and addressing other deskwork.

In order to address the EHR burden issue in a meaningful way, it is useful to understand specific areas of greatest burden. Arndt et al developed a taxonomy to help specify the percentages of time spent by clinicians in key EHR functions. The three main areas needing attention from a time perspective were documentation, chart review, and inbox tasks. In this panel, we discuss the nature of these burden areas; present current evidence for proposed solutions; and discuss promising health IT research directions. Panelists will share three use cases aimed to improve the usability and functionality of EHR systems and reduce clinician burden. The presentation of use cases will be followed by a discussant-led conversation, intended to stimulate thoughts and suggestions on future health IT research needed to build the evidence-base that will enhance clinicians’ EHR experiences. Clinical practice and policy implications will also be noted where applicable. The panelists’ work has been supported by the Agency for Healthcare Research and Quality (AHRQ), and they were selected based on the diversity of their studies related to EHR burden areas. The
The panelists represent different institutions and have specific, relevant expertise given their diverse background and training.

**Chris Dymek, EdD** (moderator and organizer) will kick off the panel by introducing the panelists and the topic including its greater significance and context in today’s healthcare landscape. Dr. Dymek will also describe the rationale and motivation for bringing this panel together.

**Thomas Payne, MD** (panelist) will present the panel’s first use case. Many clinicians are frustrated due to increased documentation requirements and EHR usability issues that result in exceedingly long timeframes to document. Recent evidence indicates that some clinicians might benefit from voice recognition software that helps create text from voice commands. Dr. Payne will present findings and implications from a research project that developed a voice-generated enhanced electronic note system (VGEENS) aimed to address problems associated with electronic progress note documentation. VGEENS has been integrated with commercial EHRs and Dr. Payne will provide insights on how this tool might provide an alternative for clinicians who prefer voice to typing to create notes.

**Genevieve Melton, MD, PhD** (panelist) will present the panel’s second use case. Chart review has always been a time-consuming task. Reviewing redundant information increases cognitive burden and causes increased risk of errors in diagnosis and treatment. Dr. Melton will present an innovative research study that applied probabilistic language modeling methods and improved automated methods to detect and visualize new, non-redundant information in patient note and reduce chart review burden. She will also present findings around in-chart reading/retrieval styles based on clinicians’ preferences and workflow demands. Differences in reviewing styles compared to the traditional ‘S-O-A-P’ format shows potential for improved EHR clinical note interfaces that need to be more aligned with clinicians’ mental models, task needs, and workflow demands.

**Hardeep Singh, MD, MPH** (panelist) will present findings and implications from a portfolio of research studies. Handling inbox tasks is an emerging burden for clinicians due to increases in new EHR-based notification types. Dr. Singh will present findings from a portfolio of research studies focused on defining, measuring and reducing clinician inbox notifications. These studies include feedback from practicing end-user clinicians and provide robust evidence needed to improve EHR inbox content and design as well as organizational workflows and policies. In addition to discussing current sociotechnical challenges related to addressing the burden of EHR inbox notifications, he will also discuss strategies to help filter messages relevant to high-quality care, EHR design examples that support team-based care, and staffing model frameworks that can assist clinicians in managing this influx of information.

**Chris Dymek, EdD** (discussant). Following presentations of the above-mentioned use cases, Dr. Dymek will lead the panel (and the audience) in a conversation about research opportunities regarding EHR burden, with a particular focus on emerging research areas of interest such as artificial intelligence (AI) including new paradigms around automation and ‘autonomation’ of clinical tasks. Questions to be considered include:

- What type of EHR-burden-related research will be most useful for clinicians and other healthcare staff? Discussion themes will address priorities as well as methods and study designs.

- What are some short- and long-term practice and policy directions to stimulate health IT research and implementation activities to both measure as well as reduce EHR-burden?

- How can EHR vendors, healthcare system leaders, and policy makers play a shared role in helping organizations make evidence-based tools/applications available and easy to use?
**Topic Rationale:**

Based on provisions in the 21st Century Cures Act, federal policy for burden reduction related to the use of EHRs and other health IT has progressed considerably. However, there remains a lack of robust evidence to inform progress in both scientific and practice transformation needed to reduce EHR and health IT burden and improve clinician experiences. This timely panel presentation will highlight three use cases and a discussion around evidence-based EHR tools and applications aimed at reducing clinician burden.

**Participation Statement:**

All proposed panelists are aware of this panel submission, and have agreed to participate in the panel if the proposal is accepted.

**Panel Participant Details:**

- **Chris Dymek, EdD.** Director, Health IT Division, Center for Evidence and Practice Improvement, Agency for Healthcare Research and Quality
- **Thomas Payne, MD.** Professor, Departments of Health Services and Biomedical Informatics & Medical Education / Medical Director, Information Technology Services, University of Washington Medicine
- **Genevieve Melton, MD, PhD.** Professor, Department of Surgery, University of Minnesota Medical Center / Chief Data and Health Informatics Officer, Fairview Health Systems
- **Hardeep Singh, MD, MPH.** Professor, Department of Medicine, Baylor College of Medicine / Chief, Health Policy, Quality & Informatics Program, Center for Innovations in Quality, Effectiveness and Safety, Michael E. DeBakey VA Medical Center
QDM to QUICK – Mapping the Future

Floyd Eisenberg, MD, MPH¹, Claude Nanjo, MPH², Juliet Rubini, RN-BC, MSN, MSIS³, Joe Kunisch, PhD, RN-BC⁴, Moderator: Kathy Lesh, PhD, RN-BC, CPHQ⁵
¹ESAC, Inc., Rockville, MD, ²University of Utah, Salt Lake City, UT, ³Mathematica, Richboro, PA, ⁴Memorial-Hermann Healthcare System, Houston, TX, ⁵Battelle, Arlington, VA.

Abstract

The panel will discuss how existing efforts to express electronic clinical quality measures (eCQMs) have been mapped to new, evolving standards to enable and encourage continuity with emerging health information technology (IT) efforts without disrupting existing efforts to evaluate clinical care in current healthcare settings. The work is based on efforts to harmonize standards for quality measurement and clinical decision support (CDS) using the Health Level Seven International (HL7) logical representation, Quality Improvement Clinical Knowledge (QUICK) data model, and HL7 Fast Healthcare Interoperability Resources (FHIR) Clinical Reasoning resources as the structural components and HL7 Clinical Quality Language (CQL) as the expression language. By the end of the presentations the attendees will:

☐ Understand the issues in defining data models and traversing concepts between data models.

☐ Learn challenges aligning requirements for retrospective performance measurement with existing methods by which data are captured during routine care delivery using clinical software.

☐ Learn the process for translating measurement concepts in published eCQMs to newly emerging CDS standards to provide consistent information retrieval, improve workflow, reduce burden, and increase performance rates.

☐ Describe current challenges with mapping existing eCQM data elements to existing EHR data elements to accurately capture the quality of care being delivered.

General Description of the panel and the issue(s) that will be examined and brief description of each panelist’s presentation.

The panel will discuss how existing efforts to express electronic clinical quality measures (eCQMs) have been mapped to new, evolving standards to enable and encourage continuity with emerging health information technology (IT) efforts without disrupting existing efforts to evaluate clinical care in current healthcare settings. The work is based on efforts to harmonize standards for quality measurement and clinical decision support (CDS) using the Health Level Seven International (HL7) logical representation, Quality Improvement Clinical Knowledge (QUICK) data model, and HL7 Fast Healthcare Interoperability Resources (FHIR) Clinical Reasoning resources as the structural components and HL7 Clinical Quality Language (CQL) as the expression language.

Kathy Lesh will introduce the panel and provide a high-level introduction of eCQM standards. She will also facilitate the questions and discussion.

Floyd Eisenberg will provide an overview of the Quality Data Model (QDM), a conceptual data model used to express eCQMs and discuss its evolution to align with FHIR.

Claude Nanjo will present the QUICK model, how its structure correlates to the QDM, supporting eCQM developers who might be transitioning from QDM to FHIR. He will also discuss the value proposition behind QUICK and how it enables the authoring of FHIR version-agnostic knowledge artifacts.

Juliet Rubini will discuss how measure developers have been engaged in the development and use of QUICK, showing examples of QDM-based eCQMs using QUICK and the current status of testing.

Joe Kunisch will discuss how the QUICK model aligns with existing data capture and availability within clinical settings and why alignment of the models helps to reduce clinical documentation burden. He will also discuss implementation challenges and possible mitigation strategies.

Several Centers for Medicare & Medicaid Services (CMS) quality reporting and value-based purchasing programs include eCQMs. eCQM development uses the QDM, a conceptual data model, for the core concepts that eCQM developers use to define data elements when authoring their measures by taking into consideration clinical workflow and information that should be expected within existing electronic health records (EHRs). Efforts by HL7, standards development organization, to harmonize data models for clinical quality measurement (CQM) and CDS developed QUICK, a logical data model. QUICK was developed to enable eCQMs to reference required information while allowing local implementation sites latitude to use HL7’s FHIR version(s) they have available without requiring different versions of an eCQM. QUICK, is an implementation guide (IG) to help eCQM and CDS artifact developers create and test measure expressions for data they should be able to expect in existing software implementations using FHIR for eCQMs and CDS. FHIR’s core maturity model requires evidence of data
availability in 80% of existing clinical software. Thus, QUICK represents a surrogate method to evaluate clinical information without disrupting existing clinical workflow and data capture while allowing each implementation site to use the version of FHIR in their existing software. This current effort to translate QDM to QUICK enables transformation of eCQM queries to consistently retrieve information, improve workflow, reduce burden, increase performance rates, and share logic with CDS rules, thereby enhancing clinical quality prospectively.

Figure 1 details efforts in HL7 to evolve standards for eCQMs over time defining the structure, the data model, and the expression language.

The QDM version for eCQM reporting in 2021 (version 5.5) specifically addresses concepts as they are specified in the HL7 FHIR IG known as QUICK. QUICK is a logical model with an IG for using FHIR to author quality measures and CDS artifacts with the FHIR Clinical Reasoning resource (e.g., measure, measure report, Event-Condition-Action-Rules). The relationship between QDM version 5.5 and FHIR is significant as the maturity model for the base FHIR resources requires that they are available in 80% of existing EHRs; hence, the newest versions of QDM should represent concepts present in current clinical information systems. Subsequent QDM versions (version 5.5 planned for measure reporting in 2021) will also be mapped to QUICK. Some existing eCQMs expressed in QDM have been converted to FHIR consistent with the QUICK IG using fabricated data in the HL7 FHIR Connectathons. CDS artifacts have been created based on a few eCQMs and tested as well. Floyd Eisenberg will discuss some of the challenges mapping information required for defining concepts (i.e., the QDM) with existing FHIR resources, and how those challenges have been mitigated through the harmonization effort. Joe Kunisch will discuss how the use of a logical data model can facilitate coordinated eCQM and CDS development and implementation.

The QUICK Update (version 3.0.2), published February 2019, includes mapping of QDM categories of information and attributes to the QUICK concepts and metadata. The anticipated September 2019 HL7 balloted version of QUICK will be FHIR version neutral such that users can specify the FHIR version implemented at each site to retrieve information for eCQMs or clinical decision support (CDS) CQL expressions. The QDM to QUICK mapping is significant because QDM has evolved over the past seven to eight years to a much more expressive and detailed conceptual data model that benefits eCQM development. The mapping to QUICK allows CDS developers to more directly translate eCQM concepts to CDS artifacts to improve the capture and use of data in an EHR that supports and represents the quality of care being delivered to a patient. QUICK is predominantly based on FHIR resources with some extensions to express metadata not present in basic FHIR resources. Most of the QDM concepts map directly to FHIR resources and extensions represented in QUICK. The mapping tables provide bidirectional mapping, i.e., QUICK concepts to corresponding QDM datatype(s) and attributes, and QDM datatype and attribute mappings to QUICK resources and metadata. In some cases, multiple QDM datatype and attribute mappings to QUICK resources and metadata. In some cases, multiple QDM datatypes map to a single QUICK resource as indicated in the QUICK mapping tables. Some areas did not map well, leading to recommendations to base FHIR resources for clarification, or modifications to the QDM conceptual model. Table 1 shows some examples of the mapping exercise. Floyd Eisenberg will provide more details during the presentation. In some cases, the base FHIR resources were purposely non-specific, leading to conflicts as subsequent FHIR versions added granularity. For example, until subsequently
defined by the HL7 Workgroup managing the resource, blood pressure could be specified as two observations, a systolic and a diastolic reading, or as a single observation with two components: blood pressure, systolic component, and diastolic component (the latter was the more recent decision).

All panelists will discuss their role in the process employed to complete the mapping effort, comments received during the ballot process, and resolution prepared for a September 2018 HL7 ballot to align the CMS QDM effort with QUICK, allowing direct translation of existing measures to FHIR, and enabling translation of existing measures to clinical decision support artifacts using FHIR as well.

An explanation why the topic of this panel is timely, urgent, needed, or attention grabbing is required with a discussion of anticipated audience.

eCQMs continue to use the QDM and, beginning with the 2019 reporting/performance period, use CQL as the expression language. The expression of eCQMs using QDM as the logic expression presented many challenges for EHR vendors and healthcare organizations to construct and deploy CDS and eCQMs due to the logic and constraints of the QDM. This created significant barriers for healthcare organizations in adopting and successfully implementing eCQMs that captured an accurate portrayal of the quality of care provided to a patient. Using CQL as the logic expression language has alleviated many of those barriers. Currently, many organizations and vendors are evaluating HL7 FHIR and developing clinical decision support processes to improve quality in real-time. The CDS and eCQM efforts can best align if mapping exists to translate the eCQM content to information required to manage CDS. Broad-based programs will not quickly change to new, emerging standards and consideration of such change will require evidence that the health IT industry has tested and is using the new standards routinely. Therefore, a map from the existing eCQM data model to the new and emerging standard, QUICK, provides a mechanism to work with existing and innovative approaches to improving quality with health IT. Tooling to automate the mapping may become available to enable direct translation of a QDM-based eCQM to QUICK/FHIR-based measurement and CDS.

Discussion questions to enhance audience participation.

- What challenges might you expect if quality measures are defined using different descriptions of data than those used to capture information during routine clinical care?
- How will the ability to translate information in clinical quality measures to match the way information exists in clinical software impact you?
- What is the benefit of clear, unambiguous definitions in determining a clinician’s level of performance with respect to a clinical guideline?
- What is the likelihood of reducing clinical documentation burden by assuring that clinical quality measures and clinical decision support efforts define information the same way?

All participants have agreed to take part on the panel.
Learning Across a Healthcare Data Network to Improve Model Robustness and Evidence Reliability

Noémie Elhadad, PhD¹, Jenna Reps, PhD², Alison Callahan, PhD³, Iñigo Urteaga, PhD¹, Patrick Ryan, PhD²
¹Columbia University, New York, NY; ²Janssen Research and Development, Titusville, NJ; ³Stanford University, Stanford, CA;

Abstract
Recent work in machine learning and modeling from healthcare data has shown much promise in leveraging large datasets to infer signal and predict outcomes of interest. With increasing numbers of such data sources available via collaborative efforts such as those created by the Observational Health Data Science and Informatics (OHDSI) network, it is now possible conduct clinical studies at an unprecedented scale. In this didactic panel, we will focus on another contribution of such data networks beyond the increased power of larger sample size, namely learning across multiple data sources as a way to improve the robustness of the learned models and increase the reliability of derived evidence. Our panel participants are junior and mid-career researchers in the field of machine learning for healthcare. We will (1) review the OHDSI network as one example of such a data network, (2) describe use cases in predictive analytics and an on-demand informatics consult service to distill clinical evidence from such data networks, where increased reliability is achieved through learning across different types of observational data, (3) describe current efforts in facilitating external model validation in OHDSI, and (4) illustrate current efforts in machine learning and specifically transfer learning to increase model robustness.

Learning Objectives
- Understand the landscape of healthcare data sources available to informatics and data science researchers, along with the OHDSI common data model across such data sources;
- Appreciate the need for model robustness and increased evidence reliability;
- Enumerate current efforts in increasing reliability of evidence through external validation across the OHDSI network;
- Learn about current efforts in machine learning for improving robustness and reliability of learned models across different datasets;

Panel Participants
Noémie Elhadad, PhD, FACMI is an Associate Professor of Biomedical Informatics at Columbia University. She is affiliated with the Columbia Computer Science Department and the Columbia Data Science Institute. Her research is in machine learning and natural language processing applied to clinical and patient-generated datasets.

Jenna Reps, PhD is a Senior Epidemiology Informaticist at Janssen research and Development. Her work is on novel solutions to personalize risk prediction and is an active contributor in the OHDSI tool suite. She has applied her work on a variety of healthcare prediction problems.

Alison Callahan, PhD is a Research Scientist at the Center for Biomedical Informatics at Stanford University. Her work involves research and development of informatics methods for the analysis of biomedical and clinical data, to derive insights and inform medical decision making.

Iñigo Urteaga, PhD is an Associate Research Scientist in Applied Physics and Applied Mathematics at Columbia University and is affiliated with the Columbia Data Science Institute. His work is in machine learning and signal processing in unsupervised and supervised settings. He has applied his work to clinical and patient-generated datasets.
**Patrick Ryan**, PhD is Senior Director of Epidemiology and the Head of Epidemiology Analytics at Janssen Research and Development, where he is leading efforts to develop and apply analysis methods to better understand the real-world effects of medical products. He is an active collaborator in OHDSI. He served as a principal investigator of the Observational Medical Outcomes Partnership (OMOP), which led to OHDSI.

**Timeliness of Panel**

The fields of machine learning and data science for healthcare are witnessing a drastic increase in interest, at the same time that the amount of and access to healthcare data is rising. In clinical research, for a statistical model to be used effectively it is fundamental that there is extensive understanding of the circumstances where it is reliable. The performance of a model on a single dataset is often insufficient to assess its broad applicability, and external validation is required to generate evidence supporting the model’s performance in similar or different patient populations. Reviews have shown there is a lack of external validation in clinical research [1,2] and this is likely because replicating a model in new data is a challenging task. Large healthcare data networks present an unprecedented opportunity to externally validate statistical models learned on one source by evaluating it against other sources. This capability makes it possible of testing the transportability of models across a data network. The lack of reliable evidence is also problematic at the point of care. Most medical decisions are made without the support of rigorous evidence [3,4]. When treatment guidelines do exist, they often do not apply to complex patients commonly seen in the clinic. As a result, clinicians must often rely exclusively on their own experiences and that of their colleagues when making treatment decisions for the patient in front of them. In contrast, the availability of data and effective methods to analyze it have been transformative in other disciplines, from information technology to law. There is an unprecedented opportunity to realize this same transformation in healthcare [4]. The concepts and ideas discussed in this panel—augmenting data networks with principled approaches to model learning and novel efforts in transfer learning—can make this opportunity a reality.

**Panel Description**

Dr. Elhadad will be the moderator of the panel. She will motivate the need for this didactic panel, and present on the Observational Health Data Sciences and Informatics (OHDSI) multi-stakeholder, interdisciplinary collaborative to create open-source solutions that bring out the value of observational health data through large-scale analytics as an example of a health data network [5]. She will then present a use case for increased model reliability when learning across data sources in the context of predictive analytics. Specifically, she will show how models that learn from claims data increase the power of study and can be leveraged and validated against electronic health record (EHR) datasets to create early detection of disease decision support modules.

Dr. Repps will present on the power of external validation across the OHDSI health data network. She will present tools and methods currently deployed in the OHDSI tool suite to facilitate the external validation of predictive models. She will showcase how the OHDSI standardizations have made sharing models between sites very easy and quick. This capability creates the possible of testing the transportability of models across a data network [5].

Dr. Callahan will present on methods developed for and learnings from offering an informatics consult service [6] to Stanford Health Care clinicians, to rapidly distill evidence from EHR data to inform clinical decisions. She will describe the consult service, including strategies to leverage multiple sources of clinical evidence, and the consult team’s experience using the service as a test bed to evaluate the robustness and reliability of statistical methods developed for analyzing observational health data.

Dr. Urteaga will present machine learning methods for domain adaptation, and how they can be applied to EHR data networks. Transfer learning has become a popular area of machine learning whereby knowledge gained from one source can be integrated with knowledge gained from another source to derive a 'repurposed' composite model that exhibits optimal operating characteristics. This technique opens interesting opportunities if applied across an EHR data network. Dr. Urteaga will present recent work on high-throughput joint unsupervised learning of phenotypes across different EHRs and different clinical settings (e.g., acute care, intensive care, and outpatient care).

Dr. Ryan will present work on improving confidence in causal inference through network analysis. Observational studies are challenged in their ability to produce reliable population-level effect estimation by threats of bias due to confounding, selection bias, and measurement error. Bradford-Hill’s causal viewpoints identify multiple dimensions
beyond strength of association, which can be used to augment the argument of causal effect. This includes 'consistency', which can be operationalized by replication of observed effects across multiple disparate data sources. His presentation will highlight the incremental value of study replication across a data network to increase the confidence in the causal assessment of exposures and outcomes.

**Target Audience**

There are several audience members who might find this panel of relevance: (1) clinical researchers interested in deriving reliable knowledge from large healthcare datasets; (2) data scientists and practitioners who experiment with statistical learning models; (3) informatics and data science trainees interested in learning more about current efforts in statistical methods and machine learning for healthcare.

**Statement of Participation**

All panel participants have agreed to participate in the panel and have contributed to this proposal.

Sync for Genes: Integrating Genetic Information at the Point of Care

Stephanie Garcia, MPH¹, Robert R. Freimuth, PhD², David E. Jones, PhD³, Bob Milius, PhD⁴

¹Office of the National Coordinator for Health Information Technology, Washington, DC; ²Mayo Clinic, Rochester, MN; ³Utah Department of Health, Salt Lake City, UT; ⁴National Marrow Donor Program, Minneapolis, MN

Abstract

Genomic data sharing is critical to the Precision Medicine Initiative (PMI) and the next impetus of genetic research. Launched in 2016, Sync for Genes aims to standardize the sharing of genomic information between laboratories, providers, patients, and researchers. Two phases of this project have culminated, both resulting in the advancement of the Health Level 7 International (HL7®) Fast Healthcare Interoperability Resources (FHIR®) Clinical Genomic profile. During the course of this project, several important gaps were identified in the emerging standard that must be filled to set a firm foundation for the use of genomic data in the provision of tailored medicine and research. This panel will share results and findings from the Sync for Genes project, review the semantic data model work conducted to date, and discuss with the audience priorities for future work. The discussion will explore roadblocks that may be hindering widespread adoption of FHIR for genomics and weigh alternatives that may be in use to support the exchange of genomic data for use at the point of care and for research.

Introduction

Precision medicine is an innovative approach for disease treatment and prevention that takes into account individual variability in lifestyle, environment, and biological makeup. It acknowledges that each person is unique and that the interaction of these factors greatly impacts our health. Delivering on the promise of precision medicine will require a variety of data types to conduct precision medicine research and generate evidence for more effective prevention, diagnosis, and treatment. This information must also be available for the effective delivery of tailored treatment.

While work on collecting and integrating lifestyle and environment data is still emerging, the amount of genetic information available has greatly increased, in part due to the reduced costs of genetic testing and increased understanding of the role genetics plays in our lives. This is particularly true in pharmacogenetics and oncology. Effective use of these results requires that they be shared between laboratories, providers, and with patients. Today, most genetic test results are shared in human-readable, but not machine-readable form. In addition, the organization, content, and formatting of results from different testing laboratories are often inconsistent, making it difficult to integrate genetic test results into electronic health record systems and utilize them effectively at the point of care.

More recently, the All of Us Research program under the Precision Medicine Initiative will collect an unprecedented number of biosamples and other relevant health data (including genetic information when available) to enable precision medicine research. This creates a sense of urgency for ensuring genetic test results can be shared in standardized forms both for conducting the research and sharing genetic sequencing results with participants.

Sync for Genes

In 2016, the Office of the National Coordinator for Health Information Technology (ONC) launched the Sync for Genes project in collaboration with the National Institutes of Health (NIH) with the goal of standardizing the sharing of genomic information between laboratories, providers, patients, and researchers. For the first phase of this project, ONC partnered with the Food and Drug Administration (FDA) and leading private sector organizations to take the first step toward integrating clinical genomics into the clinical point of care by expediting the use of standards, such as Health Level 7 International (HL7®) Fast Healthcare Interoperability Resources (FHIR®). The first phase focused on testing and validation of FHIR resources and included use cases from five pilot sites. Those results have been compiled into a final report published in 2018 and helped inform the development of FHIR genomics STU3.

The second phase of Sync for Genes, launched in 2018, took the next step from use cases (explored in Phase 1) to actual implementation. Four pilot sites expanded the profile work to demonstrate proof-of-concepts that demonstrated the exchange of genomic data in different clinical workflows. The goals of the pilot projects for Phase 2 included:
1. Utah Department of Health Newborn Screening: Share data with providers in real-time for the care of at-risk and vulnerable newborns
2. Lehigh Valley Health Network (LVHN): Pharmacogenomics: Leverage genomic content for diagnosis, care management, & pharmacogenomics to support their advanced cardiology program
3. National Marrow Donor Program (NMDP): Patient/Donor Matching: Convert existing Next Generation Sequencing (NGS)-based human leukocyte antigen HLA genotyping information to FHIR without losing completeness of the data
4. Weill Cornell Medicine: Cancer Genomic Decision Support: Convert discrete genomic results to FHIR and pair data with a clinician-facing app that provides supplemental knowledge of variant results

The Phase 2 pilot sites successfully demonstrated the exchange of a pilot site-specific FHIR message containing genomic data using a server preconfigured with FHIR STU3 resources and profiles. The initial findings from this project, have been shared with the HL7 Clinical Genomics and Orders & Observations work groups to continue to inform the development of the corresponding FHIR specifications. The Phase 2 pilot sites also uncovered challenges with genomic diagnostic reports in general and issues that have industry-wide implications (Table 1). While some of these challenges are outside the scope of this project, they have implications for both research and clinical care. A full report of the outcomes from the Sync for Genes Phase 2 project will be released in summer 2019.

Table 1. Challenges and Gaps

<table>
<thead>
<tr>
<th>Genomic Testing Reports</th>
<th>Industry-Wide Factors</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Do not always contain the same information (variability in data content and granularity)</td>
<td>• Data modeling and semantics</td>
</tr>
<tr>
<td>• Different use cases have unique data needs (variability in data elements)</td>
<td>• Data provenance</td>
</tr>
<tr>
<td>• Research use cases require the exchange of data files such as variant cell format (VCF) in addition to the clinical report</td>
<td>• Privacy and security of sensitive data</td>
</tr>
</tbody>
</table>

Given the findings of the first two phases, Sync for Genes has shifted its focus to the development of robust data models to guide implementers by providing information regarding the semantics of data elements. This will include the definition, structure, conditions or constraints under which data are collected, and relevant value sets, as well as how those data elements are related to one another. This will facilitate implementation, enable both more effective sharing of genetic information, and assist with transition from one version of FHIR to the next.

Panel Objectives and Presenters

The aim of this panel is to share the results and findings from the Sync for Genes project, discuss semantic data model work conducted to date, and discuss with the audience priorities for future work. The panel brings together the informatics and research experts leading this work at ONC, Mayo Clinic, Utah Department of Health, and the National Marrow Donor Program.

Stephanie Garcia, MPH (moderator and organizer) oversees the Sync for Genes project as well as the ONC PCOR portfolio, which is a suite of projects that invests in the health information technology infrastructure that supports the health research enterprise. She has collaborated with public and private stakeholders, successfully executing projects that advance the effective use of health information technology to improve the nation’s health. Ms. Garcia’s will introduce the session, provide an overview of the Sync for Genes project, and moderate the session.

Dr. Robert Freimuth leads a variety of research studies and standards development activities focusing on genomics, including Sync for Genes, HL7, and the Global Alliance for Genomics and Health (GA4GH). He will discuss overall Sync for Genes phase 2 project findings and will present an overview of the semantic data model work that is being done within HL7 Clinical Genomics.

Dr. David Jones is a Senior Health Informaticist at the Utah Newborn Screening Program. He will discuss his team’s experience in exploring the use of FHIR genomics to facilitate the exchange of genomic data within the field of newborn screening. His perspective will also touch upon considerations particular to state organizations and working with data sharing partners.
Dr. Bob Milius is a Principal Research Scientist at the National Marrow Donor Program (NMDP). He will discuss his team’s experience with using FHIR genomics to facilitate the exchange of genomic data by converting existing next generation sequencing (NGS) based human leukocyte antigen HLA genotyping information to FHIR without losing completeness of the data. His perspective will also touch upon his experience with implementing genomics for other use cases relevant to NMDP and working with a standards development organization to advance the technology for the exchange of genomic data.

Panel Discussion Questions

- What is the current status of the HL7 FHIR Genomics implementation guide?
- What were the biggest challenges pilot sites faced when implementing FHIR genomics?
- What are some of the steps that your organization took to address those challenges and what would you recommend to others implementing FHIR genomics?
- How will the data modeling work inform the development of genomics standards?
- What additional informatics work is needed to enable effective integration of genomic information at the point of care?
- What issues has the audience faced when trying to implement FHIR genomics or exchange genomic data?
- What are the highest priorities for future work?

Panel Learning Objectives

1. Participants will have a better understanding of the goals of the Sync for Genes project and findings to date.
2. Participants will learn about the testing conducted by Sync for Genes pilot sites and the implications for standardized sharing of genomic information.
3. Participants will learn about key gaps that exist in the current specification and how they are being addressed.

Conclusion

Delivering precision medicine in the era of genetic testing and sequencing will require effective and efficient sharing of genetic information. Sync for Genes is enabling the sharing of standardized genomic information between laboratories, providers, patients, and researchers as the first path in making genetic data available at the point of care. This panel will share results from this project and gather participant input to inform future work at ONC and NIH.

Statement of Agreement to Participate

All panelists have approved of this submission and agreed to participate.

Promise, challenges, and risks of digital data in mental health research and care

Sharath C. Guntuku, PhD¹, Lauren Southwick, MPH¹, Ian Barnett, PhD¹, Ipsit Vahia, MD², Stevie Chancellor, PhD³

¹University of Pennsylvania, Philadelphia, PA, USA  
²Harvard Medical School, Boston, MA, USA  
³Northwestern University, Evanston, IL, USA

Abstract

Digital data available from social media and passive sensing offer a new window into individual health, with the potential to uncover a nuanced understanding of an individual’s lived experiences, both expressed and unexpressed. Harvesting health insights from digital data is significant yet understudied with implications to advance efforts that capitalize on objective digital data and evidence to improve health forecasting and interventions. In this panel, we will explore how digital data can be used to characterize, forecast mental health conditions, and potentially use it in clinical settings. In the first talk, we discuss how digital data may impact the process of care, specifically the doctor-patient relationship. The second talk explores the potential of real-time detection of behavioral anomalies using passive sensing to forecast schizophrenia. In the third talk, we show how social media can be used to better understand the naturalistic manifestations and consequences of loneliness based on a cohort of Twitter users. The fourth talk examines emergent ethical and methods challenges of utilizing novel digital data sources in mental health research and care. Together, this panel demonstrates the potential for social media and wearable sensors to uncover insight into psychological health and well-being. This panel is designed to explain a new generation of innovative and targeted digital decision support tools, and launch large-scale trials exploring the acceptability, efficacy, and ethical as well as clinical implications of incorporating these tools into clinical care.

Introduction

When individuals post to social media, or use wearable devices, digital data generated through these everyday interactions with technology reveal a great deal about individuals’ behaviors in ways that were previously not observable. Prior work offers particular promise in being able to identify early signals from digital data about individuals’ emotions and mental health (1,2).

The speed with which data is generated creates potential for earlier signal about disease development or exacerbation. The regular production of data also allows for tracking of health in real time or over time, using insights not available from traditional surveys or insurance claims (3). Digital platforms not only can provide markers of health but also serve as platforms that can be used for direct intervention (4).

In this panel, we discuss the promise, challenges and risk (5) associated with the utilization of digital data in health forecasting and interventions. The first talk will focus on the current state of clinical practice using data from two clinician surveys, with the goal of capturing current clinician practices, eliciting preferences and concerns related to including data from electronic media in patient care. The second talk examines the potential of passive sensing data for personalized forecasting of psychotic relapse hospitalizations. The third talk will examine the shows how social media can be used to better understand the naturalistic manifestations and consequences of loneliness based on a cohort of Twitter users. The fourth talk will discuss emergent ethical and methodological challenges of tapping into digital data traces to understand and measure individuals health.

Incorporation of Electronic Media into Clinical Care (Vahia)

This study will discuss how digital data may impact the process of care, specifically the doctor-patient relationship. We present data from two clinician studies that capture physician attitudes and current practices in the US and India. Obtaining collateral information from a patient is an essential component of providing effective psychiatric and
psychotherapeutic care. Research indicates that patients' social and electronic media contains information relevant to their psychotherapy and clinical care. However, it remains unclear to what degree this content is being actively utilized by clinicians as a part of diagnosis or therapy. Moreover, clinicians’ attitudes around this practice have not been well characterized.

An online survey was sent to outpatient psychotherapists aimed at identifying what extent and with which patients they utilized this practice, as well as their reasons for or against doing so. Of the 115 total respondents, 62% indicated that they had viewed at least one patient’s social or electronic media as part of psychotherapy and 65 of those 71 (92%) endorsed being able to provide more effective treatment as a result of this information. Moreover, analysis of survey responses found patterns of use associated with clinicians’ years of experience and patient demographics, including age and primary diagnosis. This study will also present findings from a similar but smaller survey conducted with psychiatrists in India in February 2019.

**Forecasting Schizophrenia Relapse using Passive Sensing (Barnett)**

Among individuals diagnosed, hospitalized, and treated for schizophrenia, up to 40% of those discharged may relapse within 1 year even with appropriate treatment. Passively collected smartphone behavioral data present a scalable and at present underutilized opportunity to monitor patients in order to identify possible warning signs of relapse. Seventeen patients with schizophrenia in active treatment at a state mental health clinic in Boston used the BeeWe app on their personal smartphone for up to 3 months. By testing for changes in mobility patterns and social behavior over time as measured through smartphone use, we were able to identify statistically significant anomalies in patient behavior in the days prior to relapse. We found that the rate of behavioral anomalies detected in the 2 weeks prior to relapse was 71% higher than the rate of anomalies during other time periods.

Our findings show how passive smartphone data, data collected in the background during regular phone use without active input from the subjects, can provide an unprecedented and detailed view into patient behavior outside the clinic (6). Real-time detection of behavioral anomalies could signal the need for an intervention before an escalation of symptoms and relapse occur, therefore reducing patient suffering and reducing the cost of care.

**Measuring and Characterizing Loneliness using Social Media (Guntuku)**

Loneliness affects approximately 30% of individuals in the United States, and is associated with mental health conditions and high morbidity. We characterized the (online) lives of people who express being lonely and correlate their posts with predictors of mental health. We collected more than 400 million tweets posted by 506,216 users in Pennsylvania, USA, from 2012 to 2015. We identified users who had at least five posts containing the words ‘lonely’ or ‘alone’ (lonely group) and compared them to a control group matched by age, gender, and period of posting. Compared to the control group, users in the lonely group contained more posts about difficult interpersonal relationships, psychosomatic symptoms, substance use, wanting change, unhealthy eating, having troubles with sleep, and in general posted more at night. These posts were also associated with linguistic markers of anger, depression, and anxiety. A random forest model predicted expressions of loneliness online with an accuracy of 77% (AUC .86). Our approach can inform online surveillance for high-risk individuals experiencing loneliness and interventions focused on addressing morbidity in this condition.

**Ethical Tensions, Challenges, and Potential Solutions for Predicting Mental Health Status from Social Media (Chancellor)**

Powered by machine learning techniques, social media has been successfully employed to predict mental health states of individuals such as depression, eating disorders, and the risk of suicide. These algorithmic inferences hold great potential in supporting early detection and treatment of mental disorders and in the design of interventions. At the same time, the outcomes of this research can pose great risks to individuals, such as issues of incorrect, opaque algorithmic predictions, the involvement of bad or unaccountable actors, and potential biases from intentional or inadvertent misuse of insights.

In the panel, Chancellor will briefly discuss her findings with her work on this topic area. She will discuss the emergent ethical challenges of conducting this work. This work poses key questions around topics such as equity and fairness, privacy and engagement with stakeholders, issues of validity of methods, and potential for intervention (7), such as: How do you gain meaningful consent to conduct social media research for mental health, if consent is necessary at all? How do you unite findings from psychology and psychiatry to precisely identify behaviors in social
media? What are the changing roles for stakeholders in this process, such as clinical partners and social media users whose data is used to generate these predictions? She will also discuss new findings about these tensions from a literature survey of research conducted in this field. This literature survey draws from 55 papers across health informatics, human computer interaction, and machine learning, that predicts the status of mental health using social media data. These challenges span both methods areas in computer science as well as topical areas for ethics, privacy, clinical psychiatry, and human-centered design. She will also discuss recommendations for to begin to solve these pressing ethical challenges.

An explanation why the topic of this panel is timely, urgent, needed, or attention grabbing is required with a discussion of anticipated audience.

As digital data becomes more ubiquitous and incorporated into decision making for health, it is imperative we discuss the benefits and risks of incorporating this data into practice. Additionally, we believe this panel is well-suited and timely for AMIA given the interdisciplinary audience of the conference as well as the impact such discussions can have on establishing standards of practice within this space. Within the last several months, several articles in journals, such as Nature, New England Journal of Medicine, JAMA, and AMIA were published on this topic, some of which include works by co-authors on this panel. We believe this panel complements AMIA’s conference mission and advances multi-disciplinary discussions around a complex and evolving topic of mental health research and care.

Discussion questions to enhance audience participation

1/ Which of the following modalities of electronic communication was identified by clinicians to be most frequently accessed as part of therapy? a) Facebook; b) Text Messaging; c) Email; d) Instagram

2/ Under the EU General Data Protection Regulation (GDPR), what might be patients and providers’ view on incorporating digital data in health care?

3/ Could digital data’s incorporation in health care further health disparities among marginalized populations?

4/ Considering the role of mental health apps, how will they shape predicting, detecting, and intervening within the healthcare system?

5/ What are the challenges in ethical applications of your research to these topic areas?

Variability of Nursing Workforce Characteristics: Impact on Outcomes

Ellen M. Harper, DNP, RN, MBA, FAAN; Amy Garcia, DNP, RN, CENP; John M. Welton, PhD, RN, FAAN; Lisa A. Moon, PhD, RN, CCMC, LNC

1University of Kansas, Kansas City, KS; 2University of Colorado, Denver, CO; 3University of Minnesota, Minneapolis, MN.

Abstract

Examining variation in clinical practice is an important step to measuring efficiency and effectiveness in care delivery. The study of practice variation by an individual nurse and patient characteristics can indicate potential opportunities to reduce costs and improve the value of healthcare delivery.

This didactic panel will describe the overall approach taken to examine the clinical practice of nurses linked to patients at a single pediatric hospital. This exemplary of emerging data science uses data from multiple electronic data sources, including clinical, administrative, human resources, staffing, and financial systems to identify outcomes with a new level of precision. Examples include nurse-sensitive outcomes throughout each shift, length of stay, and traditional discharge measures. Administrative outcomes include calculations of the direct cost of nursing care by nursing unit and diagnosis. Attendees will become familiar with the Nursing Value Data Model and methodology for working with big data. They will examine variation in nursing clinical practice and discuss their findings, including how it can be better supported for clinical and translational research applications.

Key words: Nurse Value, data science, healthcare quality, practice variation, interoperability, standards

A general description of the panel and issues that will be examined

Examining variation in clinical practice is an important step to measuring efficiency and effectiveness in care delivery. The study of individual nurses, nursing practice, and various patient characteristics can indicate potential opportunities to reduce costs and improve the value of healthcare delivery. Nurse-sensitive outcomes measured in the National Database of Nurse Quality Indicators (NDNQI) represent the concentration of nursing knowledge at the unit level, making it difficult to visualize an individual nurse’s contribution to patient outcomes. Measuring outcomes at the unit or organizational level, (e.g., nursing care hours per day), is not granular enough to reveal the structures and processes that occur within the nurse-patient dyad.

Significant progress has been made in creating terminological and structural standards for representing general clinical data. Yet, standards and interoperability solutions for nurse-sensitive clinical data have not yet achieved the same level of maturity. Standardization of data presents challenges including the lack of structured data elements in the source data systems, poor data governance practices, and a disconnect between clinical practice and research.

This didactic panel will describe the overall approach and results from a retrospective observational research study used to examine the clinical practice variation of nurses linked to patients at a single pediatric hospital. This exemplary of emerging data science uses data from multiple electronic data sources, including clinical, administrative, human resources, staffing, and financial systems to identify outcomes with a new level of precision. Clinical outcomes include progress or deterioration (acuity score) toward nurse-sensitive outcomes (Nursing Outcomes Classification (NOC) scores) throughout each shift, and length of stay (LOS) measures. Administrative outcomes include calculations of the direct cost of nursing care by nursing unit and APR-DRG diagnosis.

Importance of the panel topic

This didactic panel builds on the current national efforts of the Nursing Value Data Model (NVDM) structured methodology, organized through the Nursing Big Data to Knowledge initiative hosted at the University of Minnesota School of Nursing. The NVDM is a standardized, feasible, valid, and relevant data and technology infrastructure used to routinely collect and aggregate nursing-centric data from disparate electronic systems, including electronic health records (EHR), staffing, human resources information systems (HRIS), staff education, and financial systems. Each data element is further defined for clarity and uses definitions from established taxonomies, including the Centers for Medicare/Medicaid Services (CMS), the Nursing Management Minimum Data Set (NMMDS), and the NDNQI.

The panel will include presentations on the following four topic areas:
1. Describe the background and history of the Nursing Value Data Model (NVDM) and introduce the pilot study and how the data dictionary data collection methods used to demonstrate the relationships across disparate electronic data using primary keys (relationships), including data sources, sample, setting and time frame, and nursing care. The broad research questions examined in the study are: 1) Do the characteristics (certification, education, tenure) of nurses assigned to care for a patient significantly impact patient outcomes? 2) What was the variability of the Discomfort Level NOC scores following surgery and total LOS? Do the characteristics of the nurses assigned impact the NOC scores? 3) What are the nursing financial outcomes (e.g., labor costs), and are these influenced by patient, nurse, or unit characteristics?

2. Methods - Models for micro-costing and patient outcomes were developed from data extracted, de-identified and encrypted before secure transfer to HIPAA compliant research repository. Components are illustrated in Figure 1. Sources include data from the EHR, registered nurse (RN) - patient assignments, patient acuity, NOC scores, and characteristics of the nurse from HR and employee data.

![Figure 1](image1.png)

Figure 2
After initial data set up and cleaning, new variables were created e.g. direct nursing costs. The final dataset allows researchers to link each nurse to patients assigned and examine changes in patient’s acuity multiple times during the shift. The approach directly and identifies both patient and nurse-level data (e.g., direct costs of care for each nurse can be calculated using actual hours of care and wage). The approach provides a level of granularity about the moment-to-moment clinical trajectory of patients that have been difficult to capture to date.

3. Sample and Results. This IRB-approved study uses a descriptive, retrospective analysis of 43,936 children admitted to a pediatric hospital over a three-year period (2014 – 2016), with 1,728 nurses assigned to care for them. Qualitative analysis of repeated measures of acuity by unit type is represented in Figure 2. Using inferential analysis of all nurses’ assignments and wage we were able to total the overall RN costs per patient/shift by unit type (Figure 3).

![Figure 2](image2.png)

![Figure 3](image3.png)

Note: these are actual direct costs adjusted for wage, shift differential, and holiday. Does not include indirect costs, e.g. vacation/sick time, benefits.
4. Future directions. Data sensitive to nurses’ are underrepresented in large clinical trials and national clinical research networks. Some national networks e.g. Patient-Centered Outcomes Research Institute use a distributed data model to harness the power of data from multiple sources while taking advantage of partnerships between patients, clinicians, and health systems. The structured methodology presented provides a model for usable and actionable information that can be the basis to improve the quality and efficiency of nursing care delivery systems. Such information provides an understanding of how to optimize nurse staffing and assignment patterns that will improve outcomes by aligning individual nurse’s characteristics (experience, education, certification) to individual patient’s needs.

Discussion questions:
1. How can information in the NVDM be used to quantify and measure nursing value?
2. What nursing activity and operational aspects and efficiencies can be visualized to measure nursing value?
3. Are there better ways to staff nurses? (e.g., put the more experienced nurse on first day post-op)?
4. Is it possible to extend the NVDM methodology to increase the reliability of nurse-sensitive data sharing by creating the foundational elements required for interoperability amongst disparate healthcare systems?

Learning Objectives
1. Attendees will learn about the Nurse Value Data Model and methodology for implementation.
2. Attendees will learn that working with large data sets is challenging but can provide valuable information about nursing care costs, quality, performance, effectiveness, and outcomes.
3. Attendees can engage with panelists on practice variation that is supported for clinical and translational research applications.

Introduction of the panelists
The panel members have a long-standing collaboration in clinical research informatics and the development of the Nurse Value methodology. Each has decades of interest and research dedicated to building a framework to better understand how nursing care is expended for each person/patient and measure the variation in clinical practice specific to defined outcomes. When key nursing data is gathered in a standardized, interoperable manner, it makes it possible to use the information to identify patterns and trends within nurses, units, facilities, and populations.

Working Group Affiliation: Endorsement of this panel presentation is provided by the Nursing Informatics Working Group (NIWG).

Acknowledgment: The study used in this panel discussion was supported by grants from the Agency for Healthcare Research and Quality (AHRQ) 1R03 HS025495-01 and the University of Colorado School of Medicine Data to Value (D2V) project and The University of Kansas School of Nursing Faculty grant.

All participants have agreed to take part in the panel.

Advancing the Collection and Integration of Patient-reported Outcome Data Implementation Architectures Using FHIR® Technical Specifications

Chun-Ju Hsiao, PhD1, Stephanie Garcia, MPH2, Daniella Meeker, PhD3, Joseph Blumenthal, BA4, Keith Marsolo, PhD5

1Agency for Healthcare Research and Quality, Rockville, MD; 2Office of the National Coordinator for Health Information Technology, Washington, DC; 3University of Southern California, Los Angeles, CA; 4MedStar Health National Center for Human Factors in Healthcare, Washington, DC; 5Duke University, Durham, NC

Abstract

The electronic collection of patient-reported outcomes (PROs) supports patient-centered outcomes research by offering a complementary perspective to clinician assessments, and may provide greater insights into health status, symptom burden, adherence, and quality of life. However, PRO data are not routinely available electronically for clinical care or research due to various challenges including the lack of standards and easy-to-use data collection applications. This session will present findings from a project jointly led by the Agency for Healthcare Research and Quality and the Office of the National Coordinator for Health Information Technology that tested the use of the Health Level 7 International (HL7®) Fast Healthcare Interoperability Resources (FHIR®) technical specifications to collect and integrate standardized PRO physical function data in ambulatory care settings. The panel will engage in a discussion regarding the advantages and disadvantages of the different implementation approaches and architectures that were used in the project’s pilot tests as well as opportunities for the scale and spread of these implementation models to other use cases. The learning objectives include: (1) understanding different technical approaches for PRO implementation using FHIR® in settings with different characteristics and resources, and (2) learning about the required capabilities and resources for standardized PRO implementation.

Panel Description

The patient’s perspective is central to healthcare decisions affecting prevention, diagnosis, treatment, and long-term care. As the healthcare industry moves to provide tailored healthcare through initiatives such as precision medicine, patient-centered outcomes research (PCOR) becomes a critical piece of the larger ecosystem, producing new scientific evidence that can help patients, families, and their healthcare providers make informed healthcare decisions. The effective use of patient-reported outcomes (PROs) can play a critical role in improving health care delivery and patient experience with care1-3. Use of PROs for guiding and improving care is especially important for patients with multiple chronic conditions, older adults, and people with disabilities as PROs can reflect outcomes of care for multiple conditions, treated by multiple providers, across multiple settings of care.

While various efforts promote the use of PROs4-5, the uptake is far from universal. Some electronic health record (EHR) systems are able to capture some structured PRO data, but this information is not typically collected at the point of care. Data element and data capture standards could allow for PRO assessments to be conducted and easily shared across clinical or research system, regardless of the EHR or health IT solution being used.

The Agency for Healthcare Research and Quality (AHRQ) partnered with the Office of the National Coordinator for Health Information Technology (ONC) on a project that aims to advance the collection and integration of standardized PRO data that would support interoperable sharing of this information. This joint project was funded through the Patient-Centered Outcomes Research Trust Fund, administered by the Assistant Secretary for Planning and Evaluation of the U.S. Department of Health and Human Services (HHS). In this project, ONC developed a Health Level 7 International (HL7®) Fast Healthcare Interoperability Resources (FHIR®) PRO implementation guide (IG)6 that guides developers in implementing FHIR® for the exchange of PROs as well as the capabilities that are required for a successful integration of PROs into the patient record. Subsequently, AHRQ worked with MedStar Health and ONC worked with two research networks, patient-centered SCAlable National Network for Effectiveness Research (pSCANNER), and Research Action for Health Network (REACHnet), to pilot test applications that use the FHIR® technical specification to collect and send PRO physical function data in ambulatory care settings.
This panel will feature presentations by AHRQ and ONC programmatic leads, and representatives from two pilot test sites. Each pilot site leveraged the NIH-funded Assessment Center application programming interface (API) technology to collect PROMIS® physical function data. The questionnaires and the responses were mapped into a FHIR® format and stored within a FHIR® server. Each pilot site employed a different approach to facilitate PRO data integration with the organization’s respective EHR systems to make the PRO data available to providers. The presentation of pilot tests will be followed by a discussant-led conversation, intended to stimulate thoughts about opportunities in using the FHIR® PRO implementation guide to facilitate the collection and integration of standardized PRO data, with a particular focus on how best to work with different practices to achieve successful implementations and use these data for clinical care, PCOR, and research broadly.

Chun-Ju Hsiao, PhD (moderator and organizer) is a health services researcher within the Health IT Division at AHRQ. She has published research on the topics of electronic health record systems, quality of care, quality of life, disability, health services utilization in office-based physician practices and by nursing home residents, and survey methodology. Dr. Hsiao will introduce the speakers and the topic including the rationale and motivation for bringing this panel together. She will also provide an overview of this joint project and AHRQ’s related tasks including a challenge competition and MedStar Health’s contract work.

Stephanie Garcia, MPH (panelist and co-organizer) oversees the ONC PCOR portfolio, which is a suite of projects that invests in the health information technology infrastructure that supports the health research enterprise. She has collaborated with public and private stakeholders, successfully executing projects that advance the effective use of health information technology to improve the nation's health. Ms. Garcia’s remarks will focus on the development of the FHIR® PRO IG, the required capabilities for PRO integration, and how the IG can be tailored for other measures which may include social determinants of health. She will also provide an overview of ONC’s IG pilot-testing approaches.

Daniella Meeker, PhD (panelist) is an Assistant Professor in the Department of Preventive Medicine at University of Southern California (USC) Keck School of Medicine. She has contributed to standards development for research networks and PROs. She is currently the Informatics Program Director for the Southern California Clinical Translational Sciences Institute Informatics Program, a co-principal investigator of the pSCANNER clinical data research network, and the faculty sponsor of the Los Angeles County Department of Health Services Informatics Core Facility. Dr. Meeker will discuss the challenges and lessons learned of using the FHIR® PRO IG and incorporating PROs into an EHR system. pSCANNER’s solution includes leveraging Clinical Decision Support (CDS) Hooks and integrated services with a SMART on FHIR® app so that providers can order PRO measures.

Joseph Blumenthal, BA (panelist) is a clinical informatics developer with the MedStar Health National Center for Human Factors in Healthcare. Mr. Blumenthal works on process improvement projects to improve patient safety both at MedStar Health and across the country. Mr. Blumenthal will present a novel framework for a system-agnostic implementation of PRO data collection which leverages SMART on FHIR® technology in support of a patient-centered workflow The presentation will highlight creative solutions to the often resource-intensive and protracted process of integration into different EHRs. Mr. Blumenthal will also present the design of a provider-facing visualization to present PRO data in the EHR.

Keith Marsolo, PhD (discussant) is faculty in the Department of Population Health Sciences in the Duke University School of Medicine. His research falls in to two major areas: infrastructure to support the use of EHRs and other real-world data sources in observational and comparative effectiveness research, and standards and architectures for multi-center learning health systems. He participates in the Patient-Centered Outcomes Research Institute’s (PCORI) National Patient-Centered Clinical Research Network (PCORNet), serving as a co-investigator in the PCORNet Coordinating Center. He led efforts to develop version 4.0 of the PCORNet Common Data Model (CDM), which overhauled the way PRO data are stored in the CDM. Dr. Marsolo was a presenter in AMIA 2018 Informatics Summit panel “Capacity Building for PRO Data Sharing across the Federal Networks: EHR Data Quality, Modeling, and Harmonization.” Dr. Marsolo will lead the panel and the audience, in a conversation about challenges and opportunities in using FHIR® to collect and integrate PRO data, focusing on considerations of different IT approaches and architectures. Discussion questions may include:

- What are the pros and cons of different technical approaches and architectures presented today?
- What was required in terms of expertise and resources to implement standardized PRO data collection and integration?
• How might you use the FHIR® PRO IG for domains other than physical function?
• What challenges may occur when utilizing the FHIR® PRO IG?
• What are the pros and cons of different technical approaches and architectures presented today?
• How could you decide which model works better for your organization?
• What considerations your organization will need to take into account in order to adopt any of the models presented today? What kind of technical assistance may be needed?
• What are some potential impacts on workflow?

Topic Rationale:
Increasing value in healthcare by empowering patients with data and information to help them take an active role in making decisions about their care is an HHS priority. The patient perspective is central to health care decisions affecting prevention, diagnosis, treatment and long-term care. PROs critically inform patient-centered outcomes research and can inform clinical management of individuals, shared decision making, patient self-management support, care planning, goal setting, and goal attainment. There is a clear need to understand implementation challenges and find methods to mitigate them. This panel features approaches that can make PRO data available under different health IT infrastructures. Patients, providers, and researchers can use these data for clinical care and research purposes.

Statement of Agreement to Participate
All panelists have approved of this submission and agreed to participate.

Educational Communities in the Academic Forum: Sharing Knowledge and Promoting Standards

Stephen Johnson, PhD, FACMI, New York University Langone Health, New York, NY

Saif Khairat, MPH, PhD, School of Nursing, University of North Carolina, Chapel Hill, NC

Suzanne Boren, MHA, PhD, Department of Health Management and Informatics, University of Missouri, Columbia, MO

Vishnu Mohan, MD, MBI, FAMIA Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR

E. LaVerne Manos, DNP, RN-BC, FAMIA, Center for Health Informatics, School of Nursing, University of Kansas, Kansas City, KS

William Hersh, MD, FACMI, Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR

Abstract

The mission of the AMIA Academic Forum is to foster the development, growth and improvement of academic units that educate students and conduct research in the discipline of biomedical and health informatics. The Forum provides a vehicle for academic units to interact, consider, and act jointly on issues important to them. This didactic panel describes the new organizational structure of the AMIA Academic Forum based on “educational communities”. The learning objectives for the panel include: 1. Understand how educational communities enable Forum members to engage with their peers to share knowledge, collect data, and promote standards across their institutions. 2. Understand the goals and activities of five different communities for informatics education: baccalaureate, professional master’s, postdoctoral clinical fellows, nursing, and biomedical informatics academic leaders. 3. Understand the benefits for creating and participating in new educational communities within the Forum.

Description

The moderator (Johnson) is the current chair of the Academic Forum, and will briefly describe the goals of the Forum and the recent organizational change to develop educational communities. [1] Mohan will describe the current state of the Clinical Informatics Program Directors community, and discuss recent activities and future goals. [2] Manos will describe the Nursing Informatics Program Directors community, and discuss past achievements as well as new work related to accreditation. [3] Khairat will describe the Baccalaureate Education Community, which is currently being formed, and discuss potential goals and activities. Boren will describe the Professional Master’s Community, which is also being formed, and discuss the relationship to related AMIA efforts regarding accreditation. [4] Hersh will discuss the goals and activities of the community for the Academic Leaders Community.

The panel sessions will consist of five 7-minute presentations, each followed by five minutes of questions. The last 30 minutes of the panel will be devoted to closing discussion, using a list of discussion points to increase audience participation.
Rationale

The topic of this panel is important to update and disseminate to AMIA members the recent organizational changes to the Academic Forum including the expansion into educational communities of practice and benefits of Academic Forum membership. The anticipated audience of AMIA members, academic leaders, program directors and educators can benefit from learning about educational communities to enhance networking with their peers.

Discussion Questions

1. What should be the role of the Academic Forum going forward?
2. How can the AF help programs and faculty members? Examples include network, educational pipeline, teaching collaborations, and building resources or capacity.
3. How can educational communities best serve the needs of individual and organizational members?
4. Which community or communities are most relevant to your institution or program?
5. Which educational communities should the Academic Forum focus on creating next?
6. What should be the relationship between the Academic Forum and the Education Working Group?
7. What should be the relationship between the Academic Forum and other Working Groups?
8. How could industry become more engaged in the Academic Forum?

Agreement to Participate

All participants have agreed to take part on the panel.

Rethinking Health Data Privacy

Bonnie Kaplan, PhD, FACMI¹; Elizabeth J. Davidson, PhD²; George Demiris, PhD, FACMI³; Richard Schreiber, MD, FACP, ABPM-CI⁴; Ari Ezra Waldman, PhD, JD⁵
¹Yale University, New Haven, CT; ²University of Hawaii at Manoa, Honolulu, HI; ³University of Pennsylvania, Philadelphia, PA; ⁴Geisinger Holy Spirit, Camp Hill, PA; ⁵New York Law School, New York, NY

Abstract

Privacy is protected both ethically and legally as a foundation for creating enough trust during clinical encounters for health care decisions to be based on honest discussion and accurate information exchange. Research, public health surveillance, advances in artificial intelligence (e.g., machine learning and predictive algorithms for health care), and the promise of personalized medicine all depend on accurate, complete data. However, health-related data generated and used outside of clinical settings is not protected through privacy regulation. Data aggregators and companies combine data from multiple sources for health and other purposes, while individual behavioral and social practices are being incorporated into medical records. Meanwhile, boundaries and distinctions are breaking down between different categories of protected health data, and between protected data and data collected via commercial apps and services. Privacy of health-related data requires rethinking in this rapidly changing landscape. Panelists will consider challenges in health data privacy, data governance, and privacy policies and practices, including privacy vs the value of data sharing, the adequacy of current legal and regulatory regimes, and how technological developments affect health data privacy.

WG Endorsements: ELSI, POI, CIS

Panel Description

Privacy is a linchpin of the doctor-patient relationship and a foundation for creating enough trust during clinical encounters for health care decisions to be based on honest discussion and accurate information exchange. Research, public health surveillance, advances in artificial intelligence (such as machine learning and predictive algorithms for health care), and the promise of personalized medicine all depend on accurate, complete data. Without privacy, data, as well as care, is compromised.

Health data is protected in the US both by contracts and by law. For example, commercial devices such as wearables, mHealth applications, on-line genetic services, and insurance, are governed by companies’ privacy policies and click-through agreements, enforceable by the Federal Trade Commission, which also enforces the Children's Online Privacy Protection Act (COPPA). A variety of sectoral laws, most notably HIPAA for medical data, the Common Rule for research data, and GINA for genetic data, protect medical data collected primarily in clinical settings. Under these laws, different sources and kinds of data are governed differently, even if covered by the same law (e.g., potentially stigmatizing data related to mental health, substance abuse, and sexually transmitted disease are more protected than other clinical data, while the military and VA have their own practices). Both US and EU data protection are based on Fair Information Practice Principles (FIPPs) that emphasize privacy as an individual’s ability to control data about that person. This depends on the person’s knowing what data is collected, by what entity, for what purposes, for how long, and how it is secured. These are addressed through notice and consent policies, permissions for access, and the ability to correct and remove data. Is the current regimen sufficient?

The current legal regimen assumes competent, autonomous individuals who are responsible for making appropriate decisions, and organizations responsible for compliance through policies that check the boxes of the FIPPs and thereby treat privacy requirements as a ceiling rather than floor for data protection. Further, laws and regulations rely on de-identification or anonymization, yet as data from multiple sources gets combined, it becomes easier to re-identify individuals. Being able to share patient records across settings benefits patients and their health care providers, but depends on identification and thereby makes the information more vulnerable. Identification makes it easier to link data about one individual for such valuable purposes as research and personalized medicine, but also makes privacy harder to protect.

Meanwhile, boundaries and distinctions are breaking down between the different categories of protected data, and between protected data and data collected via commercial apps and services. When wearable device data becomes part of an EHR, or EHR data is mined for business purposes as well as research purposes, or shared across a variety of patient portals and social media, how should data and data uses be governed? How well is privacy protected when medical and pharmacy records are sold and aggregated with data from multiple sources for purposes as disparate as selling advertisements, assessing credit-worthiness, determining insurance eligibility and rates, evaluating potential employees, personalizing diet
advice, policing and crime prevention, pharmaceutical marketing, public health surveillance, and further secondary and tertiary uses, even if originally de-identified?

Moreover, not all data related to health care is legally protected. Examples include: Facebook’s review of posts to flag potential suicides and detect flu outbreaks; Internet of Things applications that issue alerts when assisted living residents may need help; and patient portals that encourage individuals to upload data from on-line and mobile phone apps and medical devices. Especially with the growing recognition of the importance of behavioral and social practices, the promise of personalized medicine, and the incorporation of related data into medical records and healthcare practices, more and more data is potentially health data. However, data often is decontextualized when moved from one place to another, making it harder to assess social, behavioral, and health practices.

The law can do only so much and has difficulty keeping up with rapidly changing social and technological norms. Currently, both privacy and beneficial uses of health data are threatened. This session will rethink privacy law and also privacy policies and practices. Participants and audience will discuss crucial questions, such as:

1. What can law and regulation achieve, what are limitations of regulation given the market value of health data and new technological developments, and what more is needed to ensure privacy?
2. Is sectoral data protection sufficient in light of the combining of all kinds of data sources and means of collection for multiple purposes that may include health?
3. How protective is the notice-and-consent approach? Can privacy policies be protective? How well do they fulfill the goals of notice or consent? Must they be, as commonly is the case, legalistic and non-negotiable (the user either accepts the policy or doesn’t become a user) to the point where virtually no one reads or understands them, if they exist at all? What alternative approaches are viable?
4. Is it effective to protect patient-generated data as part of medical records or tethered patient portals when that same data is shared across social media or collected and sold by private entities?
5. How protective are technical approaches such as de-identification, encryption, and granular permissions? How might privacy by design be implemented? What new approaches are being developed?
6. How well does de-identification serve individual privacy or research and health care needs? How can research, public health, and personalized medicine be better served while protecting privacy?
7. How can health data maintain value when sharing it between clinical encounters and other settings strips it of clinical context, or if collected as part of daily activities, remove significant aspects of that individual’s life from understanding of the data? How does decontextualization as data is removed from its original setting, means, and sources of collection, affect its interpretation, accuracy, and inference made from it? How will privacy norms that change with context be preserved when context changes?
8. What protections should individuals who do not fit the ideal of autonomous, rational actors have? Are special protections needed for the elderly, the mentally ill, people who are very ill, and others more vulnerable? How should teenagers’ privacy be protected?
9. How can health care delivery organizations, businesses, and the general public incorporate practices more in line with public expectations for privacy and the role of privacy in health care?
10. How should the need for privacy be reconciled with the value of data for research, public health, learning health systems, and innovation? How will artificial intelligence advances that could produce new health insights affect health data governance and challenge the current regime? To what degree should the individual’s right to privacy be primary, when sharing data has societal benefits?
11. What non-legal practices and actions (e.g., education, privacy design, social practices) can improve privacy while facilitating beneficial data sharing?
12. How can privacy be reconceptualized to provide a better approach to data protection and to health care? What do new theories, laws, and practices offer?

Discussion will move from front-line experience to empirical work, theoretical models, and potential solutions. After Dr. Kaplan introduces the panel and issues to be discussed, Dr. Schreiber will provide an overview of an on-the-ground discussion of how health care organizations such as the Geisinger Health System address privacy and data governance dilemmas concerning patient portals, OpenNotes, Geisinger’s work with Apple, and teenaged patients. Dr. Demiris then will consider how evidence-based needs of older adults and persons with varying degrees of cognitive ability can expand the concept of “privacy” to concerns such as intrusiveness of technology, burden on users and families, and patient safety. Next, Dr. Davidson will draw on legal and organizational theories and her empirical studies to address how different stakeholders’ views of privacy and rights can be protected or threatened when privacy norms and data governance change as data is shared across settings and used for a variety of purposes, including artificial intelligence and machine learning. Lastly, based on his ethnographic and legal studies, Dr. Waldman will propose a rethinking of health data privacy based on trust and transparency to address problems with current laws, regulations, policies, and their implementation; disparity between views of privacy by privacy officers, technologists and programmers, and the public; how routinized privacy practices
subvert goals of privacy regulation and policy; and how these issues affect health care data. Finally, Dr. Kaplan will summarize the presentations and suggest the need to address privacy for health-related data from multiple perspectives.

Participants

Elizabeth J. Davidson, PhD, professor in the Department of Information Technology Management, Shidler College of Business, University of Hawaii Manoa, serves as Editor-in-Chief of Information and Organization. Her publications include studies of the adoption and diversity of use of integrated clinical systems into hospitals and small physician practices, the evolution of personal health records into patient portals and mobile health apps, and AI and personal health data governance models and cases. She and collaborators are studying the implications of wearable health monitors on physician-patient communication; the integration of telehealth, mobile-enabled glucose monitors, and text messaging in chronic care management in low SES rural communities; the integration of smart technologies in family care for persons with dementia; and health data governance organizations, focusing on the evolution and development of all payer claims databases (APCDs).

George Demiris, PhD, FACMI, Penn Integrates Knowledge University Professor in the School of Nursing and Department of Biostatistics, Epidemiology and Informatics in the Perelman School of Medicine, University of Pennsylvania. In addition to his many papers, he is co-author of Behavioral Intervention Research in Hospice and Palliative Care: Building an Evidence Base (Academic Press, 2018). A Fellow of the Gerontological Society of America, his expertise includes designing and evaluating “smart home” solutions for aging, and understanding the potential of wearable devices or digitally augmented residential settings to facilitate passive monitoring and support independence and quality of life for community dwelling older adults. His research provides evidence-based recommendations for designing systems that are easily adopted by older adults and integrated in their lives.

Bonnie Kaplan, PhD, FACMI, (panel organizer, moderator), of the Yale Center for Medical Informatics, is a Yale Interdisciplinary Bioethics Center Scholar, a Faculty Affiliated Fellow of the Yale Law School's Information Society Project, and Faculty Affiliate of Yale’s Solomon Center for Health Law and Policy, Yale University. Her research addresses informatics ethical, legal, and privacy issues; user perspectives and experiences with health information technology; and ethnographic sociotechnical evaluation. Among her many publications and presentations, are journal papers and book chapters on health data privacy and on socio-technical approaches for cybersecurity and for evaluating health information systems. She twice served as chair of the AMIA Ethical, Legal, and Social Issues Working Group; AMIA's People and Organizational Issues Working Group; and the IMIA Organizational and Social Issues Working Group.

Richard Schreiber, MD, FACP, ABPM-CI, is Associate Chief Medical Informatics Officer, Geisinger Health System, and Chief Medical Informatics Officer at Geisinger Holy Spirit (GHS) in Camp Hill, PA, and Regional Assistant Dean of the Geisinger Commonwealth School of Medicine. He is board certified in Clinical Informatics and Internal Medicine, and a Fellow of the American College of Physicians. He spearheaded physician EHR adoption at GHS, and after 10 years of successful use, then led the transformation to a system-wide EHR which is essentially paperless. He is Vice-Chair of AMIA’s Clinical Informatics Systems Working Group. His clinical informatics research focuses on clinical decision support, CPOE, drug-drug interaction alerting, documentation improvement, problem list curation, and CDS anomalies.

Ari Ezra Waldman, PhD, JD, is a Professor of Law and the Director of the Innovation Center for Law and Technology at New York Law School. An internationally recognized thought leader on privacy and online safety, he is the Founder and Director of the Institute for CyberSafety. A sociologist and legal scholar, he studies how law and technology mediate social life, focusing on privacy, technology design, and speech online. His first book, Privacy As Trust: Information Law for an Information Age (Cambridge University Press, 2018), argues that privacy law should protect information disclosed in contexts of trust.
The Path Forward: Recommendations from the U.S. Health IT Advisory Committee on Interoperability Standards Priorities and the U.S. Core Data for Interoperability

Kensaku Kawamoto, MD, PhD, MHS1, Steven Lane, MD, MPH, 2
Christina Caraballo, MBA,3 Terrence O’Malley, MD4

1Department of Biomedical Informatics, University of Utah, Salt Lake City, UT,
2Sutter Health, Sacramento, CA,
3Audacious Inquiry, Baltimore, MD
4Partners HealthCare, Boston, MA

Abstract

While substantial progress has been made in recent years to improve health care through standards-based interoperability, much remains to be done. The U.S. Health IT Advisory Committee (HITAC) was established in the 21st Century Cures Act of 2016 to provide recommendations to the National Coordinator for Health IT to advance the electronic access, exchange, and use of health information. In this session, the co-chairs of the HITAC U.S. Core Data for Interoperability (USCDI) and Interoperability Standards Priorities (ISP) Task Forces will describe the HITAC recommendations for advancing interoperability in the U.S. in these areas. These recommendations encompass the process for expanding the data elements included in the USCDI; the specific data elements with highest priority for near-term inclusion in the USCDI; the priority uses of health IT; gaps in standards or their implementation that hinder these priority uses; and recommended industry and government action to address these gaps. Following an overview of the HITAC recommendations in these areas, the panelists will engage in an interactive dialogue with the audience on what is most needed to advance health care in the U.S. through standards-based interoperability.

Description

The overall learning objective of the panel is for the learner to be able to describe key needs and potential solutions for standards-based interoperability in the U.S., in particular with regard to the interoperability needs identified by the HITAC’s U.S. Core Data for Interoperability (USCDI) and Interoperability Standards Priorities (ISP) Task Forces. The panelists will pursue achievement of this learning objective by describing the recommendations of the HITAC in these areas for improving health care in the U.S. through standards-based interoperability.

The panel will be organized as follows:

**Kawamoto:** Dr. Kawamoto is Associate Chief Medical Information Officer of University of Utah Health, as well as Associate Professor and Vice Chair for Clinical Informatics in the University of Utah Department of Biomedical Informatics. Dr. Kawamoto is also co-chair of the HL7 Clinical Decision Support Work Group, a Board Member of Health Level 7 International (HL7), and co-chair of the HITAC ISP Task Force. Dr. Kawamoto also leads the University of Utah’s ReImagine EHR initiative, which is a multi-stakeholder effort to improve patient care and the provider experience through standards-based, interoperable extensions to the EHR.

Dr. Kawamoto will serve as the moderator and introduce each of the panel members and their role in the HITAC. Dr. Kawamoto will then briefly describe the central issue at hand: the need for improved standards-based interoperability to support more efficient and effective health care. He will then provide an overview of the HITAC, which was established in the 21st Century Cures Act of 2016 to provide recommendations to the National Coordinator for Health IT to advance standards-based interoperability. The HITAC unifies the roles of, and replaces, the Health IT Policy and Standards Committees that existed prior to the enactment of the 21st Century Cures Act. HITAC members are appointed by the U.S. Government Accountability Office as well as by the Secretary of the U.S. Department of Health and Human Services, the majority and minority leaders of the U.S. Senate, and the Speaker and minority leader of the House of Representatives. As of March 2019, the HITAC consists of 26 members who represent stakeholders including patients, healthcare providers, and technology vendors. The HITAC conducts much of its work through Task Forces. Each task force is co-chaired by HITAC members and is comprised of both HITAC members and non-HITAC subject matter experts. Task Forces present draft recommendations to the full HITAC, which are then discussed, revised as needed, and then adopted as formal recommendations of the HITAC. HITAC recommendations are provided to the Office of the National Coordinator for Health IT (ONC), which considers the recommendations in making policies and furthering standards-based interoperability. Specific policies for which HITAC recommendations are considered include proposed rules on Interoperability, Information Blocking, and the ONC Health IT Certification Program pursuant to the 21st Century Cures Act.

**Caraballo:** Ms. Caraballo is Director of Audacious Inquiry and co-chair of the HITAC U.S. Core Data for Interoperability (USCDI) Task Force. Ms. Caraballo is a leading global subject matter expert on consumer engagement strategies and initiatives and has been at the forefront of the global culture shift to put patients and families at the center of care. Ms. Caraballo acts as an advisor to the Department of Commerce on global exports of health IT, is on the Board of Directors for the National Association for Trusted Exchange, is the Chair of the HIMSS Technical Guidance for Interoperability Work Group, and was one of seven inaugural recipients of the HIMSS 2016 Most Influential Women in Health IT Award.

Ms. Caraballo will provide an overview of the charges of the USCDI Task Force, which broadly encompass formulating recommendations on how the USCDI is to be expanded, as well as on what should be included in the USCDI in its next stages. The USCDI is a standardized set of health data classes and constituent data elements for nationwide, interoperable health information exchange. Following the overview of the Task Force charge, Ms. Caraballo will briefly describe the membership of the Task Force, which includes HITAC members as well as external subject matter experts. Ms. Caraballo will then describe the recommendations that were made to the HITAC, and subsequently adopted following some modification, for the Promotion Model Lifecycle of proposed data elements. This lifecycle includes articulation of the need for the data element, the weighing of benefits and costs, the development and refinement of standards, and real-world implementation and validation of the proposed standards.

**O’Malley:** Dr. O’Malley is a geriatrician at Massachusetts General Hospital with experience providing care to patients with complex medical needs. Together with Ms. Caraballo, he serves as co-chair of the HITAC USCDI Task Force. Dr. O’Malley is an instructor at Harvard Medical School, and he previously held various administrative leadership positions, including as the Medical Director for Non-acute Care Services at Partners HealthCare and Partners HealthCare at Home. His areas of expertise are in quality measurement and process improvement, systems design, and clinical care, particularly in long-term and post-acute settings.

Dr. O’Malley will describe the HITAC recommendations on the data elements that should be included in the USCDI in the next phases. These deliberations are currently ongoing, with a specific focus on data elements including clinical notes, provenance, and pediatric data elements. Dr. O’Malley will describe the recommendations that result from these deliberations.

**Kawamoto:** Dr. Kawamoto will provide an overview of the charge of the ISP Task Force, which is to formulate recommendations on priority uses of health IT and the associated standards and implementation specifications that
support such uses. He will also briefly describe the membership of the Task Force, which includes representatives from Epic, Cerner, IBM, Apple, and Google. Dr. Kawamoto will then describe the process used by the Task Force to identify and rank the priority use cases, as well as the results of that prioritization process: 1) Orders and Observations; 2) Referrals and Care Coordination; 3) Medication and Pharmacy; 4) Point-of-Care Guidance (including evidence-based disease management, prior authorization, and price transparency); and 5) Social Determinants of Health. Dr. Kawamoto will then describe the process by which the ISP Task Force identified standards gaps in these prior use cases and formulated recommendations with the assistance of invited subject matter experts. He will outline draft ISP Task Force recommendations in the area of point-of-care guidance.

**Lane:** Dr. Lane is Clinical Informatics Director for Privacy, Information Security & Interoperability at Sutter Health, and he serves as co-chair of the HITAC Interoperability Standards Priorities (ISP) Task Force. Dr. Lane is also a practicing primary care physician and has been a leader in advocating for interoperability in California and around the country through lowering barriers to information sharing and optimizing the utility of the data exchanged. Dr. Lane has served as a member of various state and national-level work groups focused on interoperability, privacy, and information security, including the Certification Commission for Healthcare Information Technology (CCHIT). He currently serves on the boards of Carequality and The Sequoia Project, as a member of the HL7 Da Vinci Project Steering Committee, the international Epic Care Everywhere Governing Council, co-chair of the DirectTrust Clinicians Steering Workgroup, and Clinical Professor of Family & Community Medicine at UCSF.

Dr. Lane will describe the adopted and draft recommendations of the HITAC in ISP priority areas other than point-of-care guidance. These recommendations will encompass those areas for which recommendations have already been completed (priority areas 1 and 2 above), as well as those areas for which recommendations are under development (the remaining priority areas, except for the point-of-care guidance topic covered by Dr. Kawamoto).

Following panelist presentations, Dr. Kawamoto will lead a moderated discussion with the audience. The objectives of this discussion will be to answer questions from the audience, engage in a stimulating exchange of ideas, and receive feedback on the recommendations of the HITAC Task Forces co-chaired by the panelists. The questions listed below will be presented to stimulate this discussion, and the audience will be encouraged to engage in discussion in areas that are most important to them.

**Significance of panel topic and anticipated audience**

With the rapid adoption of EHR systems in recent years, there is significant potential for electronic data and health IT systems to improve patient care and reduce clinician burdens. Yet, due in no small part to challenges with standards-based interoperability, the gap between the promise and reality of health IT remains significant. Thus, it is imperative for biomedical informaticists to understand the gaps that still exist regarding standards-based interoperability, as well as national-level efforts to address these gaps.

**Discussion questions**

How do you think data elements should be added to the U.S. Core Data for Interoperability?

Which data elements do you think should be added to the U.S. Core Data for Interoperability?

What do you think are the priority uses of health IT? In particular, what are priority uses related to health information exchange?

What recommendations do you have for addressing gaps in standards or their implementations for these priority uses?

What challenges have you encountered in adopting interoperability standards?

**Participation statement**

All proposed panelists have agreed to participate in the panel if the proposal is accepted.
Lessons Learned Using Standards-Based Decision Support Frameworks in Commercial EHRs: Opioid Decision Support Case Study

Kensaku Kawamoto, MD, PhD, MHS¹, Bryn Rhodes², Nitu Kashyap, MD³, Cole Erdmann⁴

¹Department of Biomedical Informatics, University of Utah, Salt Lake City, UT,
²Dynamic Content Group, Orem, UT,
³Yale New Haven Health, New Haven, CT,
⁴Cerner, Kansas City, MO

Abstract

Commercial electronic health record (EHR) systems are beginning to provide support for standards-based clinical decision support (CDS) frameworks in their general-release software. Initial support is focusing on the HL7 Clinical Decision Support (CDS) Hooks standard, and some EHR vendors are beginning to support the HL7 Clinical Quality Language (CQL) standard as well. EHR vendors are also supporting the US Core Fast Healthcare Interoperability Resources (FHIR) profiles for data access. This panel will describe lessons learned from a Centers for Disease Control and Prevention (CDC) and Office of the National Coordinator for Health IT (ONC)-sponsored effort to pilot the use of opioid CDS knowledge resources using these EHR-supported CDS interoperability frameworks. Important lessons learned include the need for EHR support for additional CDS Hooks trigger events, in particular for medication ordering; the still early nature of direct CQL support in EHR vendor systems; the need to combine standards-based CDS with supplemental logic implemented using EHR platform-specific CDS rules engines; and the need for expansion and EHR vendor support for US Core FHIR profiles and interfaces, including for placing orders and for retrieving information on dispensed medications.

Description

The overall learning objective of the panel is for the learner to be able to understand the current state of standards-based CDS frameworks as well as their degree of support in commercial EHR systems. The panelists will pursue achievement of this learning objective by describing their experiences attempting to leverage these EHR vendor-supported frameworks to address the opioid epidemic.

The panel will be organized as follows:

<table>
<thead>
<tr>
<th>Time</th>
<th>Speaker</th>
<th>Topic</th>
</tr>
</thead>
<tbody>
<tr>
<td>15 min</td>
<td>Kawamoto</td>
<td>Need for interoperable CDS&lt;br&gt;Overview of HL7 CDS Hooks, CQL, and US Core FHIR standards&lt;br&gt;Initiative to develop and disseminate standards-based CDS for opioid use</td>
</tr>
<tr>
<td>15 min</td>
<td>Rhodes</td>
<td>Details of relevant standards and state of EHR vendor support&lt;br&gt;Description of standards-based knowledge artifacts for chronic pain management with opioids</td>
</tr>
<tr>

Kawamoto: Dr. Kawamoto is Associate Chief Medical Information Officer of University of Utah Health, as well as Associate Professor and Vice Chair for Clinical Informatics in the University of Utah Department of Biomedical Informatics. Dr. Kawamoto is also co-chair of the HL7 CDS Work Group, a Board Member of HL7, a member of the U.S. Health IT Advisory Committee (HITAC), and co-chair of the HITAC Interoperability Standards Priorities Task Force. Dr. Kawamoto leads the University of Utah’s ReImagine EHR initiative, which is a multi-stakeholder...
effort to improve patient care and the provider experience through standards-based, interoperable extensions to the EHR.

Dr. Kawamoto will serve as the moderator and introduce each of the panel members and their organizations. Dr. Kawamoto will then describe the central issue at hand, which is the need for interoperable CDS to enable effective CDS at scale. He will then provide an overview of the standards relevant for integrating CDS at the point of care, with a focus on the HL7 CDS Hooks, CQL, and US Core FHIR standards. He will then note that commercial EHR vendors are beginning to support these standards, and that the panel will focus on early, real-life implementation experience with these EHR-supported frameworks to help advance their use and continued maturation. Finally, Dr. Kawamoto will introduce the case study, which is a project sponsored by the Centers for Disease Control and Prevention (CDC) and the Office of the National Coordinator for Health IT (ONC) to facilitate the standards-based implementation of the 2016 CDC Guideline for Prescribing Opioids for Chronic Pain (CDC Guideline).

Rhodes: Bryn Rhodes is Principal of Dynamic Content Group. Mr. Rhodes is also co-chair of the HL7 CDS Work Group, the lead author of the HL7 CQL standard, and a co-author of the HL7 CDS Hooks standard. He is also a core subject matter expert on the CDC-ONC standards-based opioid CDS initiative. Mr. Rhodes will provide details on the relevant standards for which Dr. Kawamoto has provided an overview, using the CDS knowledge artifacts generated for the CDC Guideline, which are CDS Hooks services using CQL as the underlying knowledge representation formalism. The Table outlines the 12 CDS knowledge artifacts that will be developed by September 2019 for this project, with each knowledge artifact corresponding to one of the 12 recommendations in the CDC Guideline. Six of these recommendations have already been completed, and recommendations #10 and #11 are being used for the current pilots.

Table. CDC Recommendations Supported via Standards-Based CDS Knowledge Artifacts

<table>

*Currently implemented. Others are specified and undergoing implementation (completion = September 2019).

Kashyap: Dr. Kashyap is Associate Chief Medical Information Officer and Executive Director of Medical Informatics at Yale New Haven Health. Dr. Kashyap will describe Yale University’s experiences piloting the standards-based opioid CDS knowledge artifacts using the Epic EHR and its native support for the CDS Hooks “patient-view” hook, which was introduced in its August 2018 software version. This piloting began in February 2019, and includes hosting of a local copy of the CDS Hooks service, ensuring that local data are mapped to the appropriate standard codes, configuring the native CDS rules engine to restrict the CDS Hooks service to only be invoked for appropriate providers and for appropriate patients, and creating and evaluating test patients in the Epic testing environment. Dr. Kashyap will describe important lessons learned, with a particular focus on issues that need to be considered for widespread dissemination. Already, lessons learned have included the need for EHR support for additional CDS Hooks trigger events, in particular for medication ordering; the need to combine standards-based CDS with supplemental logic implemented using EHR platform-specific CDS rules engines; and the need for expansion and EHR vendor support for US Core FHIR profiles and interfaces, including for placing orders and for retrieving information on dispensed medications.
**Erdmann:** Finally, Mr. Erdmann will describe Cerner’s experiences ingesting the opioid CDS knowledge artifacts into the Cerner HealtheIntent platform and the integration with Cerner Millennium running at Indiana University Health. This piloting began in May 2019, and includes direct translation of the CQL logic from the opioid decision support artifacts into an Apache Spark data pipeline, evaluating the decision support for the relevant population to create appropriate recommendations, and displaying those recommendations to providers using Cerner EHR functionality. Lessons learned have included feedback on the way the shareable decision support logic is expressed to support more streamlined ingestion into the Spark environment.

Following these panelist presentations, Dr. Kawamoto will lead a moderated discussion with the audience. The objectives of this discussion will be to answer questions from the audience, engage in a stimulating exchange of ideas, and identify key steps that the informatics community can take to achieve more effective and comprehensive CDS leveraging standards-based interoperability. The questions listed below will be presented to stimulate this discussion, and the audience will be encouraged to engage in discussion in areas that are most important to them.

**Significance of panel topic and anticipated audience**

No single organization has the resources or expertise required to meet all of the CDS needs of health care on its own. The emergence of native EHR support for CDS Hooks, CQL, and US Core FHIR profiles provides a highly promising avenue for healthcare systems, EHR vendors, government agencies, and various other organizations to come together to improve health and health care. At the same time, our initial experiences indicate that there are important challenges that still must be overcome. Thus, it is imperative for biomedical informaticists to understand not only the promise of standards-based CDS interoperability but also the current state of the field and the challenges that must be overcome to achieve this promise.

**Discussion questions**

What experiences have you had with using standards-based CDS at your organization, and what lessons have you learned?
What is your vision for the future of interoperable CDS?
What challenges do you see to achieving this vision?
What steps can you take to help us overcome these challenges?

**Participation statement**

All proposed panelists have agreed to participate in the panel if the proposal is accepted.
Abstract: Biomedical Informatics (BMI) is the pillar of a functioning Learning Health System (LHS) that enables bringing translational clinical research findings into clinical practice and thereby, improving the health of patients and populations. It is a compelling promise; hence, medical centers invest toward establishing sustainable BMI programs in the form of a Center for BMI or an academic division. The Wake Forest School of Medicine (WFSoM) and the Wake Forest Clinical and Translational Science Institute have been striving to create a LHS, and correspondingly, a BMI program to support the successful implementation of a LHS. Wake Forest Center for Biomedical Informatics (WFBMI) attempts to foster learning from care experiences and develop and/or deliver better and more robust algorithmic models (e.g. Clinical decision support [CDS] systems, etc.) utilizing its integrated data ecosystem. In this panel, starting with a historical background, we will discuss challenges and opportunities of establishing a BMI program to support the operation and necessary changes to the institution. Given the demand for BMI services and the associated resource needs of establishing a program, some organizations may benefit from to-be shared experiences in order to alleviate potential struggles for such a costly endeavor.

Enabling A Learning Health System with Biomedical Informatics

Healthcare data introduces unparalleled opportunity to learn from each patient-care event, notwithstanding, the collection, storage, retrieval, communication, and optimal usage of such data present tremendous challenges. Biomedical Informaticians pioneer tools and algorithms to transform data into best practice knowledge that is rapidly available at the point of care. However, due to the variation of data types and the institutional implementation approaches, these data reside in repositories with differing data formats, models, and semantics. BMI aims to tackle the aforementioned challenges via its tri-partite mission. First is the provision of informatics services to the school of medicine or the health center that support the needs of biomedical research and care delivery not usually met by the IT departments. Second is the independent or collaborative scientific research development to continuously capture, curate, and validate new evidence. The last mission is the training and education of the next generation of informatics professionals and translational researchers who may benefit from basic informatics expertise. In this panel, we will discuss challenges and lessons learned for beginning a BMI program and respective missions in the following order:

1- **Dr. Marty Kohn** will moderate the panel and introduce the program with a historical narrative, setting the foundation for the need of BMI programs and centers: As a veteran clinical informatician, Dr. Kohn has been heavily involved in the development of BMI programs across the country and has been a thought leader to our community through AMIA and other venues. He will provide an evaluation of the BMI programs that have obvious similarities to other specialties becoming a self-sufficient academic entity within medical schools.

2- **Dr. Metin Gurcan** will follow with a brief overview of the WFBMI and proceed with a discussion of WFBMI’s research efforts and the vast knowledge resulting from ongoing studies. Building a data ecosystem to support LHS requires established research efforts for evidence generation that provide benefits as well as unique challenges to a medical center. For instance, medical imaging plays a critical role in clinical decision making starting with detection, diagnosis, prognosis and later with treatment and monitoring of diseases. Traditionally, these decisions (e.g. in radiology, pathology, dermatology) have been carried out by expert physicians who subspecialize in various disease groups. Yet, these experts are subject to perceptual and cognitive pitfalls that negatively affect their decision making which unfortunately lead to poor healthcare outcomes. Researchers in WFBMI have been successfully designing, developing, validating, and deploying machine learning algorithms in imaging to help physicians make more accurate and consistent decisions. Importantly, these algorithms produce data that can be readily combined with other sources of data (e.g. -omics, electronic healthcare) to improve the quality of decisions. We will discuss two pilot projects where machine learning is being employed. First is the AutoScope for Acute infections of the middle ear (acute otitis media [AOM]), which is the most commonly treated childhood disease. We have been developing a simple and objective
method of analyzing an image of a patient's ear to diagnose or rule out AOM with the aim to drastically reduce overtreatment. The second project is the Follicular Lymphoma Grading System (FLAGS). Currently, the inter-reader agreement between pathologists in grading Follicular lymphoma is extremely low: in a multi-site study, the agreement among experts for the various grades of follicular lymphoma varied between 61% and 73%. We have developed an effective computer-aided system to assist pathologists in the histological grading of follicular lymphoma. For both AutoScope, and FLAGS, we will discuss the importance of good data hygiene and best evaluation practices while paying attention to design, development, validation and project research team composition.

3- Dr. Umit Topaloglu intends to deliberate upon Operational Informatics and WFBMI services towards establishing an infrastructure that enables repeatable and cost-effective learning. In order to address the computational needs of the researchers and business operations at our institution, WFBMI has invested prudently in elastic computing infrastructures resulting from a contractual engagement and a Business Associate Agreement with Google Cloud Platform (GCP) and Microsoft Azure. GCP serves as the flexible research computing framework with available tools to address the needs of precision medicine and other large-scale computing endeavors. WFBMI also utilizes Microsoft Azure as a common computing model for several data sharing and federated learning projects with three other medical centers in the region.

While the reuse of clinical data is hampered by the still prevailing disconnect between the data standards used in patient care and the ones used in clinical research, some efforts to bridge this gap are finally reaping their benefits in the form of clinical research and Electronic Health Record (EHR) system integrations. Substitutable Medical Applications and Reusable Technologies (SMART) on Fast Health Interoperability Resources (FHIR) is a web based standard platform that enables developing solutions to enhance interoperability with EHRs and other systems, including clinical research data capture (e.g. REDCap). The REDCap has implemented a SMART on FHIR module to bridge the gap between clinical care and data capture systems, improving operational efficiency of clinical research by reducing duplicate data entry and redundant workflows. WFBMI has obtained necessary security and compliance approvals and has begun the pilot implementation of REDCap and Epic integration.

To facilitate a comprehensive and semantically rich data ecosystem, the WFBMI has built a Translational Data Warehouse (TDW). The TDW serves as a central resource for a gamut of research and quality improvement needs in the institution. Data is mapped to the standards and extracted from primary sources via utilizing Extract, Transform, Load (ETL) and FHIR based processes. WFBMI is committed on developing thoughtful semantic frameworks to minimize data misinterpretation and discovery challenges and maintains a UMLS repository and a local terminology system. Investigators can perform queries on the TDW using i2b2 and upon appropriate IRB approval, they can download automatically generated datasets through a self-service tool. In addition to EHR data, the TDW has been linked to outside data sources, most notably US census data, and the NC State Death Registry. TDW is also our conduit for participation in the federated data networks for obtaining larger sample sizes and realization of the full potential of population research. WFBMI enables WFSoM’s involvement and contributes to regional and national clinical data research networks, including a) Carolina Collaborative, b) STAR (Mid-South) PCORNet Clinical Data Research Network, c) Accruals to Clinical Trials (ACT) Network of NCATS, d) TriNetX, and e) AACR Genomics Evidence Neoplasia Information Exchange (GENIE).

4- Dr. Brian Wells will present the educational and training efforts of the WFBMI towards training physicians and non-clinician researchers. Example initiatives include Clinical Informatics Board Certification Subsidies through which practicing clinicians are able to become board certified in Clinical Informatics (American Board of Preventive Medicine) through the practice pathway. After which, diplomates will be required to complete a formal 2-year Clinical Informatics fellowship. WFBMI provides financial support for review course as well as the cost of the exam, through which we have increased the number of board certified clinical informaticians in the medical center to cope with the dynamic clinical informatics needs.

WFBMI also organizes Short Course on Clinical Informatics annually that provides a general overview of medical informatics for academic researchers from diverse backgrounds. The hands-on sessions include courses such as creating a statistical model for predicting the risk of readmission for adults admitted for pneumonia. Each iteration of the short course has involved approx. 32 hours of in-class time spread out over a 3-6-month period and we incorporate feedback into the subsequent sessions.
Another Subsidy WFBMI established is the Epic – Physician Builder Certification for which WFBMI provides $3,000 for each clinician to travel to Epic for the 2-part Physician Builder program. The certification focuses on front-end workflow optimization or analytics areas, serving as necessary authorization for certified clinicians to gain elevated user rights in WFSoM Epic. With new user roles, certified builders can create EHR optimization tools such as standardized data capture forms, CDS at the point of care, and dynamic logic-based order sets, registry frameworks for population health and analytics capabilities to facilitate EHR data extraction. Most importantly, the coursework enhances the clinicians understanding of the architecture underlying the EHR and a broader concept of system’s capabilities. The hope is that this training will empower the institution to take advantage of the continuously growing capabilities of the system. In particular, the WFBMI is interested in supporting clinicians who will use this new knowledge and these new skills for QI, clinical innovations and research related projects that support the realization of the LHS.

WFBMI spearheads another initiative in the form of Clinical Informatics Affinity Group to gather researchers throughout the institution with research or interest in clinical informatics and seek their contribution for improving LHS with informatics. The bidirectional nature of such learning and education opportunity reaches group members with ongoing announcements about upcoming educational and funding opportunities. A smaller core group of researchers meets monthly to discuss hurdles that researchers may face in their informatics related research, to discuss ongoing institutional initiatives, barriers, and to contrive ways to catalyze informatics research at the institution. The group also sponsors periodic “Lunch and Learn” sessions that highlight ongoing research projects or topic areas of interest.

5. Dr. Ajay Dharod will discuss the Clinical Scholars in Informatics (CSI) and how applied informatics training shapes clinical workflows and decision making. The CSI is a two-year applied educational and mentorship pathway for internal medicine residents to develop skills in applied informatics. At residency completion, CSI residents are prepared to tackle most health-system challenges with additional comprehensive understanding of informatics (e.g. CDS, workflow, change management, IT systems, EHR, database structures, database querying, regulatory issues, Security and Privacy, etc.). The CSI pathway translates a resident derived project (addressing system pain points) into reality. Furthermore, the CSI yields mutual benefits for the resident physicians (learning the mechanisms for completing an applied clinical informatics project end-to-end with academic capital) and for the LHS. CSI enables residents to pursue career opportunities in informatics complementing a career in internal medicine specialties or subspecialties. Dr. Dharod will also talk about the WFBMI’s newly established internship program that acquires and mentors undergraduate and graduate students from surrounding colleges to train next generation informaticians.

**Summary:** WFBMI is pragmatically designed to contribute to Wake Forest Baptist Health and School of Medicine’s evolution as a learning health system whilst also enhancing better health across the local and national community by advancing and promoting informatics research, practice and education. This panel will discuss how we have designed the program, the challenges faced along the way, and the cost-effective solutions we have been applying.

**Audience and Timeliness**
The benefit of LHS is becoming more evident, this session will be of interest to all biomedical informatics professionals and administrators who are in process or planning to establish a BMI to support

**Other notes** All participants have agreed to participate to the panel.

**Acknowledgement:** This effort is partly supported by the National Center for Advancing Translational Sciences (NCATS), National Institutes of Health, through Grant Award Number ULLTR001420 and by the Cancer Center Support Grant from the National Cancer Institute to the Comprehensive Cancer Center of Wake Forest Baptist Medical Center (P30 CA012197). We also thank all the faculty, staff, and students of the WFBMI for their contribution and diligent work.

- **A list of discussion questions**
  - Advantages of designing a BMI program aiming for LHS success
  - Achieving project sustainability through funding
  - Working with institutional IT and effective IT-BMI collaboration
  - Establishing an effective computational infrastructure to address unique needs of BMI
  - Training residents and approaches to consider the residency programs
Maturity Models for Improving Health Information System and Digital Health Capacity in Low Resource Settings: Sharing and Discussing Implementation Experiences

Authors

M. Kumar, MPH, MSc, MEASURE Evaluation, University of North Carolina at Chapel Hill
X. Santas, BA, Associate Director for Informatics and Information Resources, Centers for Disease Control and Prevention, Atlanta
J. Kariuki, MPH, BSc, Centers for Disease Control and Prevention, Atlanta
P. Mechael, PhD, MHS, Principal and Policy Lead, Health Enabled, Washington, DC
A. Waugaman, MA, BA, Senior Advisor, Digital Health, United States Agency for International Development, Washington, D.C.

Abstract

This didactic panel aims to share global and country-specific experiences in implementing national digital health and health information system (HIS) assessment tools to facilitate the transition from data to knowledge to action—namely the Global Digital Health Index, HIS Stages for Continuous Improvement, and the HIS Interoperability Maturity Model. The panel presentations and discussion are targeted toward policy makers, health managers and health informaticians engaged in design and use of digital health technologies to inform data-based decision making at the policy, program and service delivery levels. Discussion is expected to focus on emerging trends and findings from the assessments and what the global health and HIS community can do collectively to address them.

Introduction

While digital technologies are fueling the growth of digital health data, evidence shows the necessity of adopting an holistic approach to facilitate the transition from data to knowledge to action in the healthcare system in order to accelerate the goal of improved patient and population health outcomes.1 In the context of lower- and middle-income countries (LMICs), the healthcare system operates in a complex and resource-constrained environment2 and delivers health care services at multiple levels, i.e., community, county, region and national levels. A tiered health care system demands contextualization of interventions aimed at facilitating the progression from data to knowledge to action. These different levels of the health care system have diverse, often competing, health information needs and structural inequalities in terms of decision-making authority, access to financial resources and a skilled workforce, and availability of technology infrastructure. HIS management often includes competing challenges such as service delivery vs. mandates from program administration, and whether to focus on reporting data up in the hierarchical health care system or to prioritize local use of data for action to improve health outcomes. The diversity within and across the health care system of LMICs reaffirms the value of contextual adaptation of digital health technologies for transforming the work, the health workforce that delivers health care, the enabling digital health infrastructure, and their relationships with each other and with patients3 to achieve the stage of data to knowledge to action which then contributes to improved health outcomes.4 A key area of unmet need within these strengthening efforts is the lack of standardized frameworks, tools, and metrics for holistically assessing progress and to inform further improvement. National governments and institutions need measurable strategies, that are aligned with national and global health priorities, for investing and continuously improving their HIS, digital health capacity, and interoperability among diverse HIS. To meet this need, global expert groups have developed and implemented maturity models5 to guide in-country discussions and establish standard metrics within and across various institutions to enhance HIS performance and digital health capacity. These tools include the Global Digital Health Index, HIS Stages for Continuous Improvement, and the HIS Interoperability Maturity Model.

Panel presentations will share global and country-specific implementation experiences highlighting how countries are identifying gaps and executing appropriate interventions to ensure the enabling environment for the effective use of digital health and HIS that translates data to action. Presentations will also offer insights about how the tools can be
used together in the same country while working with a homogenous group of stakeholders besides engaging participants on potential next step in the adaptation and application of these maturity models and metrics.

**Audience**

The panel presentations and discussion are targeted toward policy makers, health managers and health informaticians engaged in design and use of digital health technologies to inform data-based decision making at the policy, program and service delivery levels. The discussion aims to elicit feedback about the benefits and challenges associated with the implementation of multiple digital health interventions in resource constrained environment of LMICs.

**Speaker Contributions**

The panel consists of four speakers and a moderator. Xenophon Santas will serve as the panel moderator and explain the purpose and content of the panel discussion. Manish Kumar will share an overview of maturity model-based tools and discuss the coordination in the design and development processes. Patricia Mechael will share experiences and trends from the implementation of the Global Digital Health Index. James Kariuki will present the findings of the HIS Stages of Continuous Improvement assessment in Uganda and discuss its implications for HIS improvement in Uganda and elsewhere. Adele Waugaman will share experiences from leading a global expert group under the Health Data Collaborative supporting development and harmonization of global goods and also present about donor alignment efforts focused on harmonization of HIS and digital health tools and their application in East Africa.

**Expected Discussion**

Discussion is expected to focus on emerging trends and findings from the assessments and what the community can do collectively to address them.

**Timeliness of the Panel Topic**

This panel focuses on a topic of high priority for international organizations, donors, and national governments in their efforts to adopt and use digital health technologies to strengthen data-based decision-making necessary for improving both patient and population health outcomes. The Sustainable Development Goals (SDG) for health aim to improve access to and delivery of healthcare services for individual clients while addressing population health issues. In this context, international organizations, donors, and national governments in LMICs are prioritizing digital health interventions such as electronic health records (EHR). For instance, the digital health effort for Africa launched recently by the World Health Organization-Africa Region Office and the International Telecommunication Union emphasizes generic adoption of digital technologies in the national health system. Also, the Digital Regional East African Community Health Initiative is another large-scale effort to use health information technology to improve healthcare outcomes but is focused on the larger health system. Furthermore, the World Health Organization of the United Nations is in the process of publishing the first state of the art HIS status report by September 2019 that will highlight accomplishments, identify gaps and recommend appropriate interventions and tools to overcome gaps hindering progress towards the health SDGs.

**Organizer Statement**

All participants have agreed to take part on the panel.

Current Applications of Blockchain Technology in Biomedical Research and Healthcare

Didactic Panel

Tsung-Ting Kuo, PhD1, Amar Das, MD, PhD2, Kim Augustine, MS, BSBA, BFA3, Peng ("Dana") Zhang, PhD4, and Lucila Ohno-Machado, MD, PhD1,5

1 University of California San Diego, La Jolla, CA; 2 IBM Research, Cambridge, MA; 3 Deloitte, Rosslyn, VA; 4 Vanderbilt University Medical Center, Nashville, TN; 5 VA San Diego Healthcare System, La Jolla, CA

Abstract

In this 90-minute didactic panel, we will discuss the latest biomedical research and healthcare blockchain applications and implementations. Blockchain is a novel and emerging technology. However, its use in biomedical informatics is still emerging. The target audience includes medical informatics researchers, clinicians, health IT professionals, and leaders of healthcare organizations. The moderator and panelists, who are experts from academia and industry, will provide insights and representative use cases. We will discuss the utilization of blockchain to advance healthcare informatics, the use of blockchain in clinical research, the combination of blockchain and HL7’s Fast Healthcare Interoperability Resources (FHIR) to share clinical data, as well as the integration of blockchain with privacy-preserving predictive modeling. Our panel provides a unique and timely opportunity to see experts discussing myths, advantages, and potential concerns of adopting blockchain technology in healthcare and biomedical research.

Learning Objectives: Participants will understand the various use cases of blockchain in healthcare, clinical research, biomedical data sharing, and privacy-preserving modeling.

Keywords: Data Sharing, Interoperability and Health Information Exchange, Privacy and Security, Blockchain, Distributed Ledger Technology

Programmatic Theme: Clinical Informatics

Track: Application

Statement of Participation: All panelists have agreed to take part on the panel.

Introduction

Overview ( Moderator: Lucila Ohno-Machado, 10 minutes opening + closing discussion)
I will introduce the panelist and summarize the objectives of the discussion, placing it in the context of state-of-the-art medical blockchain applications and implementations, with a short introduction to the concepts being used in the panel. I will briefly list issues related to data integrity and the setup, design and pros/cons of using blockchain, with brief general examples. Panelists will discuss specific use cases, including blockchain use as an immutable ledger, smart contracts, the combination of blockchain and HL7’s Fast Healthcare Interoperability Resources (FHIR) to share clinical data, and the integration of blockchain with predictive modeling to preserve privacy.

Blockchain and Healthcare Informatics (Panelist: Kim Augustine, 20 minutes talk)
Blockchain technology has the potential to transform healthcare by increasing the security/privacy/ interoperability of health data. This presentation will discuss blockchain and its potential impact to healthcare informatics. The presentation will cover: 1) Results of a survey or trends regarding blockchain adoption and legislation. 2) Guidelines and considerations for organizations that are interested in adopting a blockchain solution. 3) Demonstration of Deloitte’s blockchain proof-of-concept, developed for managing healthcare credentials, and lessons learned.
Blockchain for Clinical Research (Panelist: Amar Das, 20 minutes talk)

Controlling data access and ensuring data integrity are central to the management of data collected in clinical research. Blockchain can meet these technical requirements with its immutable distributed ledger, formal verification protocols, and fine-grain data sharing. In this presentation, I will illustrate the use of the open-source Hyperledger blockchain technology in supporting two clinical research applications: dynamic consenting and clinical trials. In particular, I will discuss network setups for each use case, the design of smart contracts and the use of private channels for data privacy. I will contrast the use of blockchain technology to database solutions for clinical research, and discuss the advantages and disadvantages of each approach.

Blockchain Clinical Data Sharing on FHIR (Panelist: Peng ("Dana") Zhang, 20 minutes talk)

For collaborative clinical decision making, a secure and scalable way to share data is essential. However, conventional clinical data efforts are often siloed, which can create barriers to timely information exchange and delay effective treatment decision-making for patients. This presentation will introduce a conceptual framework called "FHIRChain" that leverages blockchain technology to facilitate clinical data sharing in the context of the technical requirements defined in the Office of the National Coordinator for Health Information Technology (ONC)’s “Shared Nationwide Interoperability Roadmap”. First, we provide analyses of these requirements and their implications for blockchain-based systems. Second, we present the FHIRChain architecture designed to meet those ONC requirements using FHIR standards for shared clinical data. Finally, we summarize key lessons learned from designing the architecture to demonstrate the value and limitations of blockchain technology’s applications in healthcare applications.

Blockchain-based privacy-preserving modeling (Panelist: Tsung-Ting Kuo, 20 minutes talk)

The protection of individual privacy is imperative for predictive modeling on healthcare data across institutions. However, current state-of-the-art privacy-preserving predictive modeling methods are mostly centralized, which may incur risks such as single-point-of-breach. Therefore, we leveraged blockchain, a distributed ledger technology that has been proposed for many healthcare applications, to decentralize the predictive model learning process, and therefore mitigate the risks of single-point-of-breach. Specifically, we adopted blockchain to store the partially trained models as transactions, and to update the models in a peer-to-peer way. Blockchain also enabled additional benefits, such as immutability and easy availability of the transactions. We designed an algorithm to integrate blockchain’s transaction metadata and privacy-preserving machine learning. Our algorithm also benefited from blockchain technology to address security and robustness weaknesses. The integration of blockchain and privacy technologies for cross-institution healthcare modeling can help minimize privacy risks and can support biomedical researchers in building and testing high-quality predictive models in a distributed, yet privacy-preserving, way.

Significance

Blockchain is an emerging technology. Considering the rising number of studies related to blockchain-based biomedical applications, our panel, composed of experts from academia and industry, will provide insights and describe uses cases in a way that is accessible by non-experts. Our panel provides a unique and timely opportunity to discuss myths, advantages, and potential concerns of adopting blockchain technology in healthcare to a wide and diverse audience that includes biomedical informatics researchers, clinicians, health IT professionals, and leaders of healthcare organizations.

Discussion Questions

1. What are the main commonalities and differences between data sharing solutions (e.g., the proposed FHIRChain for health information exchange, typical approaches for clinical data research networks)?
2. What concerns have organizations voiced regarding blockchain?
3. How would you prioritize blockchain features for adoption in your healthcare system?

HCD and HIT Modernization: Engagement of End Users in Health IT Modernization through Human-Centered Design

Maia Z. Laing, MBA1, Theresa Cullen, MD, MS2,3, Jennifer Shivers, BS, MFA2, Joseph Amlung, MPH2, Sabrina Fonseca, BA4
Office of the Chief Technology Officer, Immediate Office of the Secretary, U.S. Department of Health and Human Services, Washington, DC1, Global Health Informatics, Regenstrief Institute, Indianapolis, IN2, Indiana University School of Medicine, Indianapolis, IN3, PRTNRS (&Partners) Product Design and Development Studio4

Abstract
The HHS IHS HIT Modernization Project is sponsored by the U.S. Department of Health and Human Services Office of the Chief Technology Officer (HHS OCTO) in conjunction with the Indian Health Service (IHS) to provide an analysis and recommendations to HHS concerning the modernization of the IHS Health Information Technology (HIT) system (RPMS). This project is anticipated to be the first step of a multi-faceted project. Human-Centered Design (HCD) is an integral methodology for the evaluation of the current state and is being used to evaluate the current state of HIT across the I/T/U (Indian Health Service/tribally operated/urban programs) and to identify alternatives.

This panel will demonstrate the value of a human-centered research approach early in the software development lifecycle and will provide participants with methods, tools and recommendations for applying HCD in other health informatics projects. They will share the experience of applying HCD methodology to help answer “What does modernization look like from the end-user perspective?” The methods described were applied during IHS hospital and clinic site visits and during analysis sessions. Lessons learned, including appropriate tools to use for gathering, synthesis and analysis, will be shared.

Introduction and Background
Over the last several years, it has become common to apply human-centered design methods to the user interface design aspects of medical informatics projects1. Historically, these projects focus on reducing medical errors and on designing interfaces and user interactions with the system. More recently, key stakeholders have begun to request that human-centered approaches be applied to broader aspects of informatics projects, such as a Veterans Affairs project that evaluated the current use of a clinical information system in intensive care units3. This 2015 study broadened the use of HCD to include interviews, and found that the system existed in a “complex sociotechnical system” to encompass factors beyond the computer interface. In addition, similar HCD methods are being used to design global health technology solutions3. A human-centered approach is outlined in the US Government’s Digital Services Playbook4. This playbook outlines the importance of understanding the technology that people need and addressing the complete user experience. The IHS first used HCD methodology in 2004 to help design graphical user interfaces for a limited number of software applications in RPMS, and has been committed to this methodology when funding has been available. The HHS IHS HIT Modernization Project supported the use of integrated HCD methods from the inception of the project to assess what is working well, and more importantly, to understand system users’ challenges. The team employed an HCD approach designed to uncover technological issues, and the HCD methods highlighted challenges with the technology process and training. The panel will share the methods and processes used and the challenges of using a human-centered approach. They will also address the challenges of analyzing qualitative data with a team that is scattered geographically and will identify the process and methods the team used to analyze qualitative data. Results specific to RPMS, including the impact of a commitment to health equity impacts, HCD results, and lessons learned will also be shared.

Panel Description
Maia Laing will lead a discussion addressing how the team applied HCD to the information-gathering phase of the HHS IHS HIT Modernization Project. She will emphasize the importance of HCD methods in understanding the system user’s perspective and needs. The panel discussion will include an overview of the role of HCD within the U.S. Department of Health and Human Services, CMA, as well as in this current project. The decision to employ HCD methods and how this decision advances the study will be shared. The panel will describe the HCD methods used and will share the iterative process employed to refine methods and streamline the information gathering and analysis of qualitative data. Finally, key learnings will be shared with a discussion regarding how these methods can be applied to other health informatics projects.
Presenters

Overview of IHS Project -- How HCD Fits into the Project

Dr. Cullen will discuss the project goals and purposes, and how HCD fits in with the other project methods that are being used. She will share the early experience of using HCD in software development since 2004 within HIT in Indian Health Service, and lessons learned working cross-culturally. Dr. Cullen will also discuss the reasons behind embracing an HCD approach and the perceived and actual value of using an HCD approach in the discovery or fact-finding phase of the project. Finally, Dr. Cullen will address the balance between a design team and a technical assessment and how the team approached that challenge. Dr. Terry Cullen is a family physician who retired from the US Public Health Service as Rear Admiral in 2012 after leading multiple software development and deployment initiatives within the IHS. Between 2012 and 2015, Dr. Cullen worked as the chief medical information officer for the Veterans Health Administration.

HCD Project Approach and Methods

Jennifer Shivers will discuss the importance of aligning the methods with the context, team skills, and the phase of the project. She will share the HCD methods such as listening openingly\(^2\) and shadowing\(^5\) that were used to engage with system users in determining “What does modernization look like from the end-user perspective?” She will discuss and provide examples of the affinity mapping method\(^3,6,7\) used to analyze the findings from site visits. She will also discuss synthesis and how that process was used on the project. Finally, Jennifer will share information on how the team, who had little HCD experience, prepared and planned for executing the methods in a human-centered way and discuss how other teams might apply these types of methods to early phases of research. Ms. Shivers has a BS in computer science and a terminal master’s degree in human-centered design from Indiana University. In addition, she has previous experience teaching Human Computer Interaction and systems analysis classes at a university level.

HCD Tooling, Process, Findings and Next Steps

Joseph Amlung is a Business Analyst with the Global Health Informatics group at the Regenstrief Institute. He utilizes his background in public health to bridge the gap between research and practice; this involves designing and carrying out the process for data collection, along with orienting team members to the overall goals and the methods used to achieve them. Mr. Amlung works with the IHS HIT Modernization Project to enhance data collection by applying methods of human-centered design to team visits to American Indian/Alaska Natives (AI/AN) healthcare facilities. He will describe the processes used to capture, digest, and communicate findings and how those processes were iterated to make it easier to operate with a team that is not geographically co-located. Additionally, he will describe the information that was collected at these healthcare facilities and how it contributed to the overall goals of the HIT Modernization Project. Finally, Mr. Amlung will share the process for turning research into insights and actionable steps, and he will discuss findings to-date and the next steps for the research team.

Challenges and Lessons Learned

Sabrina Fonseca will discuss challenges in using HCD, training the team using these methods, and best practices for using human-centered methods. She will also discuss the lessons the team learned about group size, fitting the method to the context, making sure participants feel safe to share information. She will also provide learning points and recommendations on training for teams using HCD methods. Ms. Fonseca is the Director of Design Research at PRTNRS (&Partners). She has over 12 years of experience leading every stage of the user-centered design process, focusing on discovery, user research, strategy, conceptual design and iterative user testing. Working at leading design firms, Sabrina has uncovered people's needs, articulated problems, and broken down complicated tasks into easy, delightful experiences for clients such as Walgreens, Tuple Health, Planned Parenthood, Bayer, E*Trade, J.P. Morgan Chase, Nike, and others in the healthcare, enterprise, financial services, and non-profit sectors.
Discussion Questions

1. What are the benefits and challenges of using HCD methods in health informatics projects?
2. What was the process of learning how to incorporate HCD methods into a health informatics project?
3. What are the benefits, barriers and challenges of using HCD methods and research practices for more than application interface design?
4. How can barriers to using human-centered research approaches be reduced or removed?
5. What tooling or strategies can be used to increase the success of HCD?
6. What are some approaches for removing barriers for teams that are not co-located, yet want to analyze and synthesize together?
7. What are some of the challenges in researching and designing for complex systems including multiple user types performing complex team activities?

Justification

The increasing complexity of health care delivery as well as poorly designed health information technology solutions contributes to provider and health care team frustration, as well as inefficiency. Designing with the user in mind is not a novel concept, but it has historically been an afterthought in HIT. In this session, we will share HCD derived lessons learned (including tools and technologies) during an analysis of a currently deployed system in an underserved population that are easily integrated and extensible to others as organizations strive to ensure that HCD is part of their clinical informatics portfolio.

Panel Organizer Statement: All participants have agreed to take part in the panel and discuss the topics as outlined above.

**Decision Support for Genomically-Informed Cancer Therapy**

Funda Meric-Bernstam, MD¹, Matthew Rioth, MD, MS², Assaf Halevy, B.SC.³, Pete Stetson, MD, MA⁴

¹MD Anderson Cancer Center, Houston, Texas, ²University of Colorado, Denver, Colorado, ³2bPrecise, Pittsburgh, Pennsylvania, ⁴Memorial Sloan Kettering Cancer Center, New York, New York

**Abstract**

Next-generation sequencing is increasingly being used for clinical decision-making in oncology. There is a growing number of genomic testing platforms, genomically-selected trials, and rapidly evolving literature in genomic medicine and molecular oncology. Thus there is a tremendous need for decision support to help health care providers and clinician-investigators. Emerging needs include assistance in accessing, displaying, and interpreting genomic reports, appropriately determining actionability of genomic alterations and identifying approved and investigational therapeutic options. The learning objectives of this panel include determinants of actionability for genomic alterations, needs for decision support in annotations of functional implications of specific alterations and therapeutic implications, and resources and approaches for decision support for genomically-informed therapy.

**Panel Description**

Genomic testing with next-generation sequencing is widely utilized for patient care both in the community and academic centers. The growing size of genomic test panels has increased the opportunity for identifying “actionable” genomic alterations targetable with approved or investigational agents. However, it also increases the burden on health care providers to access and accurately interpret genomic test results within the time constraints of a busy clinical workflow. This challenge is compounded by the rapidly evolving literature and changing availability of treatment options.

Key principles of decision support include determination of actionability, with a focus of therapeutic actionability for treatment with approved and investigational agents.¹, ² Access to and visualization of genomic data and incorporation of reports into the electronic health records (EHR) remain specific problems. The large number of emerging testing platforms add challenges in interpretation of reports taking into account differences in the platforms. Tumor-normal testing present different problems as it pertains to interpretation of potential alterations of germline origin.

Interpretation of actionability heavily relies on interpretation of functional impact of genomic alterations.¹, ² This is being addressed by a variety of local and programmatic efforts that lack harmonization. The interpretation of variants of unknown significance is an area of specific concern, both due to concerns that their actionability may be misperceived and because they represent a communication challenge as the knowledgebase evolves.

Although there have been several recent approval for therapies linked to a genomic biomarker, still most genomically-relevant therapies are only available through clinical trials. Clinical trial matching increasingly relies on genomic markers. Thus annotation of gene-drug associations and maintaining trial availability up to date as well as developing methods to alert treating physicians and providers of trial options are important challenges to deliver on the promise of genomically-informed therapy.

**Funda Meric-Bernstam, MD (moderator and organizer)** will review the clinical needs in decision support as well as selected challenges in genomically-informed therapy. She will review a framework of actionability of genomic alterations and potential approaches to developing decision support tools. She will present a use case of local implementation of enterprise-wide Precision Oncology Decision Support.³, ⁴ She will present approaches for building and maintaining a precision oncology knowledgebase, rationale for tools such as on-demand precision oncology decision support reports, clinical trial alerts and clinical trial search engines. Metrics for success in decision support will be discussed.

**Pete Stetson, MD MA (panelist)** will review solutions for ordering and display of genomic testing reports integration in the EHR with actionable annotations.³ He will review the usage patterns of advanced visualization tools by oncologists which augment traditional molecular pathology reports. He will report on methods for incorporating genomic results within provider documentation workflows. He will discuss implementation and governance issues around sharing genomic testing reports with patients in a patient portal. He will report on progress on translational informatics tools to support genomic-driven clinical trials enrollment.
Matthew Rioth MD MS (panelist) will discuss methods of integration of external molecular profiling results within an electronic health record and relevant data standards. A specific case report of this will be presented. He will discuss the handling of “variants of unknown significance (VUS)” as well as their research and potential clinical relevance.

Assaf Halevy, B.SC (panelist) will review the vendor perspective on integration of multiple testing platforms, content development, terminology harmonization, point-of-care workflow integration, and integration of genomic data with relevant clinical data for actionable display. He will present design considerations for both somatic tumor testing, as well as pharmacogenomic testing. He will discuss challenges and opportunities in integrating with medical center clinical systems which otherwise do not have existing genomic decisions support solutions.

Questions to be considered include:
1) What are the best practices for integrating into the EHR workflow for the ordering providers?
2) How do we define actionability?
3) How do clinicians and scientists determine the functional impact of genomic alterations?
4) What are the informatics challenges to creating and maintaining a gene-drug association knowledgebase?
5) What are the best practices for tracking changes in actionability such as VUS that later become important can be acted upon?
6) What are best practices for annotating genomically-relevant trials?
7) How do we provide decision support for genomically-matched clinical trial enrollment?
8) What are the best options for engaging patients and displaying genomic test results and therapeutic interpretations?

Topic Rationale: Genomic testing is increasingly being utilized in oncology. Oncology is an especially important use case for decision support as genomic testing is now a mainstream tool and there is a large number of biomarker linked drug approvals and therapeutic options emerging every day. Thus this panel on Precision Oncology is very timely. The topic presents challenges in multiple informatics domains including bioinformatics, information retrieval, clinical research informatics, clinical decision support and consumer health informatics, and thus it is likely to be of interest to the informatics community at large.

Statement of Agreement to Participate: All panelists approved this submission and have agreed to participate.

Panel Participant Details:
Funda Meric-Bernstam, MD. Chair, Department Investigational Cancer Therapeutics, Medical Director, Institute of Personalized Cancer Therapeutics, University of Texas MD Anderson Cancer Center

Pete Stetson, MD, MA. Chief Health Informatics Officer, Deputy Physician-in-Chief, Office of the Physician-in-Chief, Memorial Sloan Kettering Cancer Center

Matthew Rioth, MD. Assistant Professor, Medicine and Bioinformatics, Director of Clinical Cancer Informatics, University of Colorado Cancer Center

Assaf Halevy, B.SC. Founder and CEO, 2bPrecise

Conflict of interests will be provided.

Unlocking the potential of real-world evidence (RWE) in oncology – technology- and informatics-enabled solutions for clinical care, precision medicine, and discovery

Robert S. Miller, MD\(^1\), Wendy S. Rubinstein, MD, PhD\(^1\), Andrew D. Norden, MD, MPH, MBA\(^2\), Shawn M. Sweeney, PhD\(^3\), William S. Dalton, MD, PhD\(^4\)

\(^1\)CancerLinQ\(^\text{®} \) LLC, American Society of Clinical Oncology, Alexandria, VA, \(^2\)COTA, Inc., New York, NY, \(^3\)AACR Project GENIE, American Association for Cancer Research, Philadelphia, PA, \(^4\)Oncology Research Information Exchange Network, Tampa, FL

Abstract

This didactic panel will describe how real-world data, traditionally defined as those data derived from a source other than a traditional clinical trial, can generate real-world evidence and can be used to facilitate research and inform clinical care. Focusing on the field of oncology and the collection, aggregation, and transformation of cancer data predominantly but not exclusively contained within electronic health records, panelists representing four platforms currently delivering solutions – CancerLinQ\(^\text{®} \), COTA, GENIE, and ORIEN – will provide their perspectives on what it will take to improve cancer data interoperability and make meaningful progress in knowledge- and data-sharing to benefit patients. The panelists will discuss the need for alignment on data standards, challenges around curating and incorporating rich clinical data sourced from unstructured documents and free-text, and the particular data needs of precision oncology.

Panel description and issues to be examined

A model predicated on the principles of a rapid-learning system (RLS) has been advocated as an antidote for the unsustainable cost, unevenness of quality, and lack of patient-centricity plaguing U.S. healthcare, and the field of oncology has been suggested as a compelling first choice to develop and test such a system.\(^1\) A technology-enabled RLS could be foundational in managing oncology’s contemporary challenges – the explosion in the amount of genomic and other molecular data needed to understand cancer development and progression in individual patients and populations, the precipitously rising costs of cancer therapies, persistently low participation in clinical trials by adult cancer patients (3-5% at most), and continued provider- and system-level administrative and reporting burdens that impact data collection for downstream analytics.

While a number of non-profit, academic, and commercial entities have made great strides in building some of the framework and key components of an oncology RLS, a universal, truly interoperable system is not yet a reality. Without question, there remain immense challenges in developing a system that can seamlessly and efficiently aggregate data, analyze it, and provide guidance back to clinicians and insights to researchers, while meeting patients’ needs rapidly enough to be effective. Nonetheless, there is a growing recognition that today’s care delivery systems and the traditional research and drug development framework built on the paradigm of Phase I-IV clinical trials are simply inadequate to close current knowledge gaps in genomics (and other “-omics”), outcomes, and cost/value. Optimizing the capture and use of “real-world data (RWD)” and “real-world evidence (RWE),” variably defined but generally viewed as that arising from sources other than traditional clinical trials,\(^2\) will be required. In this context, RWD/RWE will predominantly focus on electronic health record (EHR) data, since these are the primary transactional systems in use, but is meant also to include insurance claims data, prescription refill data, data from cancer registries, death data, genomics databases, data from patient-reported outcomes collection and wearable devices, and other sources.

This panel will examine the central theme of how oncology RWD is collected, aggregated, and understood and how oncology RWE is then generated. The panelists will review existing technology- and informatics-enabled solutions. All of the panelists have deep and varied domain expertise in data issues and have been directly involved in the creation and operation of some of the solutions. Using examples from their own work, the panelists will help address some broader themes:
Description of panelists’ topics and affiliations

**Wendy S. Rubinstein, MD, PhD (CancerLinQ)**
CancerLinQ is a big-data, health technology platform created and operated by the American Society of Clinical Oncology (ASCO) for quality improvement and discovery. This talk will address some of the approaches used by ASCO and CancerLinQ to improve cancer data interoperability, including work to identify a set of minimal common oncology data elements. Mechanisms of data aggregation and normalization, including integrating and extracting value from unstructured data, will be described.

**Andrew D. Norden, MD, MPH, MBA (COTA)**
COTA is a cancer-focused data and analytics company that applies technology and human experts to create structured oncology datasets from electronic health record (EHR) data for diverse purposes including clinical quality/value improvement and research. This talk will address best practices and quality assurance requirements for combining technology and manual curation of data. A novel, clinically driven patient cohort generation mechanism known as the COTA Nodal Address (CNA), that creates homogenous groups of patients, will be described.

**Shawn M. Sweeney, PhD (AACR Project GENIE)**
The American Association for Cancer Research (AACR) Project GENIE is an international data-sharing consortium focused on generating an evidence base for precision cancer medicine by integrating clinical cancer genomic data with clinical outcomes data from 19 institutions internationally. This talk will describe the need for clinically-annotated, genomics datasets, and describe the numerous challenges in gathering such data including level of annotation/metadata and use of standards.

**William S. Dalton, MD, PhD (ORIEN)**
The Oncology Research Information Exchange Network (ORIEN) is a research alliance between 19 US-based comprehensive cancer centers utilizing a common protocol for tracking patient molecular, clinical and epidemiological data and following them throughout their lifetime. This talk will describe how prospective cohort surveillance of patients may be a solution to accelerate the development of new therapies and improve patient enrollment on clinical trials.

**Robert S. Miller, MD (moderator)**
The moderator will frame the 4 talks in the context of basic informatics principles around data standards and secondary use of data. The critical need for new solutions and models to modernize cancer research, development, and care delivery, especially to make it more patient-centric, will be emphasized.

Importance of panel topic and intended audience

Assessing the value and limitations of RWE has become a necessary competency for clinicians, researchers, regulators, payers, and policymakers alike, particularly in a data-intensive field like oncology. However, the specifics of data capture, aggregation, and transformation, challenges with curating unstructured content, and role for common data elements, remain murky for most unfamiliar with the field. This panel will focus on the needs of oncology clinicians and researchers, who are the primary audience. Oncologists faced with the challenges of managing the care of cancer patients using today’s EHRs, given widespread dissatisfaction and usability issues, nonetheless recognize
the potential of data sources beyond clinical trials. Using practical examples from their own platforms, the panelists will demonstrate how RWE can reveal patterns of care and can inform the comparative assessment of treatment toxicities and costs. Researchers see the limitations of the traditional clinical trial paradigm but remain uncertain of the validity of RWE and how it could complement prospectively-collected trial data. Focusing primarily on the integration of molecular data with phenotypic data, the panelists will demonstrate how RWE databases can be used for hypothesis generation and how innovations such as pragmatic trial designs using an RWE control arm or prospective cohort surveillance can be valuable.

Discussion questions for audience participation

1. How can clinicians be incentivized to improve data capture at the point of care without adding to their current administrative and reporting burdens?
2. How comfortable will treating clinicians be making decisions for the care of individual patients based on RWE (i.e., observational data from large cohorts of like patients) and not guidelines traditionally based on results from clinical trial?
3. Under what circumstances can manual curation of datasets be eliminated or drastically curtailed, while maintaining adequate analytic value?
4. What is the optimal level of granularity for a minimum oncology dataset – only the highest level common data elements applicable to all cancer patients vs. a data specification that is more expansive (i.e., designed for individual anatomic and/or molecular subtypes)?
5. How can oncology clinicians and researchers begin to formulate an approach for engaging their own healthcare organizations and their EHR vendors and sequencing labs (as customers) in supporting better collection of structured data at the point of data generation, particularly molecular data, for better downstream analytics.
6. How do we create a national (global) infrastructure to share data from all networks involved in collecting and studying patient data that will enable all stakeholders to access and learn from the data to better meet patient needs?

ALL CO-AUTHORS HAVE AGREED TO ATTEND THE 2019 AMIA ANNUAL SYMPOSIUM AND TO PARTICIPATE ON THIS PANEL.

5Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA

Abstract
The All of Us (AoU) Research Program has embarked on an ambitious effort to integrate data from a diverse number of sources to create a resource that will enable biomedical research in the next decade and beyond. One large data source is EHR data. We will present the experiences of collecting, submitting, and curating data from various AoU enrollment sites to the Data and Research CEnter (DRC). The topics covered in this panel will include: the goals of the curation pipeline within the DRC; the experience with participant matching at both the DRC and enrollment sites; the data mapping efforts to the Observational Medical Outcomes Partnership (OMOP) vocabulary; and the development of metadata to support data quality.

Introduction
The national All of Us (AoU) Research Program is a historic effort to gather a rich set of data from 1 million people living in the United States to create an unprecedented resource that will enable biomedical research in the next decade and beyond1,2. The goal of the program is to revolutionize how disease is prevented and treated based on individual differences in lifestyle, environment and genetics. One key source of data that is being integrated at an unprecedented scale are the electronic health records (EHRs) of participants. Currently, enrollment sites include over 30 Healthcare Provider Organizations (HPOs) and Federally Qualified Health Centers (FQHCs) that are enrolling participants across the nation and transferring EHR data to the Data and Research Center (DRC). The DRC acquires, organizes and provides secure access to what will be one of the world’s largest biomedical data resource that includes one of the largest consolidation of disparate EHRs into a single central repository for precision medicine research.

Evaluating EHR data quality for secondary use has become an active area of research in the past decade3-6. Predominantly, these evaluations have been done on single data sources and the coordination required to evaluate the data quality of individual sites within a network has additional challenges. In order to create a data resource with consistent data quality for research, all sites within a network need to adhere to a set of standard mapping conventions. Similar to other networks, the DRC is developing guidelines to represent clinical data, such as lab results and medications. Two primary differences between other networks and AoU is the scale at which EHR data is being aggregated and the development of a suite of computational research tools for large-scale analyses of the data in a cloud platform.
The DRC is developing a set of data quality checks to ensure the creation of a data resource that researchers can trust and supports a broad spectrum of research uses. In order to support this objective, the DRC must work in partnership with the EHR data partners (HPOs and FQHCs) to establish curated data submissions to the DRC. This panel will focus on the data curation process of EHR data from both the DRC and HPO/FQHC perspective.

**Topic**
The panel represents informaticians from various HPO/FQHCs and the DRC. They will share their experience in the collection and submission of EHR data, as well as the data quality issues that arise. Each panelist will present processes implemented, successes, and challenges faced with extracting and submitting data. We will discuss the data curation pipeline within the DRC and how it supports EHR data quality checks both locally at sites as well as within the DRC. The panel will conduct a structured conversation on the following topics:

- Goals of the curation pipeline within the DRC
- Experience with participant matching algorithms employed at the DRC and HPOs
- Processes around identifying and improving data mapping to the OMOP vocabulary
- Development of metadata to support data quality

**Panel Participants**

**Robert Carroll (Moderator) - Vanderbilt University Medical Center**
Dr. Carroll is a Research Assistant Professor of Biomedical Informatics whose research focus is on research using EHR data in conjunction with DNA biobanks to study human health and disease. In the field of phenotyping with EHR data, he has developed and applied algorithms and machine learning methods to predict disease state and drug response. He has participated in the eMERGE Network and other consortia, implementing and designing methods intended for EHR-based cohorts and more traditional observational cohorts, in particular studying the ability of such methods to be applied across disparate data sets. His recent efforts have focussed on managing and harmonizing data sets, including directing the transition of the Vanderbilt EHR research repositories, the Research Derivative and the Synthetic Derivative, to the OMOP common data model in part to support the joining of multiple EHRs of data. He has been deeply involved with the DRC and is a co-lead of the data curation effort which is responsible for the creation of a research data set spanning many domains including survey, EHR, and genomics data for the *AoU*.

**Karthik Natarajan – Columbia University Medical Center**
Dr. Natarajan is an Assistant Professor of Biomedical Informatics at Columbia University Medical Center. His focus is on developing scalable information retrieval and data mining methods for clinical data. He is a co-director of the Biomedical Informatics Resource in the CTSA and manages the clinical data warehouse at Columbia University’s Medical Center. Part of that work involves leading efforts to implement the OMOP data model using clinical and administrative data from multiple sources. He is the co-lead of the EHR operations committee for the *AoU* and works closely with the DRC, and is also involved in data modeling efforts of the PCORI-funded New York City-Clinical Data Research Network (NYC-CDRN). Dr. Natarajan will describe the curation process of EHR data within the DRC.
Thomas Campion – Weill Cornell Medical Center
Dr. Campion is an Assistant Professor of Healthcare Policy and Research at Weill Cornell Medical Center. He is the director of research informatics at Weill Cornell where his group helps investigators obtain data from EHR systems, collect novel measures that do not exist in EHR systems, and integrate data from disparate sources. Dr. Campion’s team is responsible for sharing Weill Cornell EHR data with a number of multi-institutional initiatives, including AoU, the PCORI-funded NYC-CDRN, NCATS-funded Accrual to Clinical Trials (ACT) network, and TriNetX. For AoU and other large studies, he has led efforts to support study coordinators with participant identity and relationship management to enable subsequent extraction of EHR data.

Shyam Visweswaran – University of Pittsburgh
Dr. Visweswaran is an Associate Professor of Biomedical Informatics. His research interests include the application of artificial intelligence and machine learning with a specific focus on learning EHR systems and computerized clinical decision support, precision medicine and personalized modeling. Dr. Visweswaran serves as the Director of the Biomedical Informatics Core for the University of Pittsburgh Clinical and Translational Science Institute (CTSI), as a PD/PI for the All of Us Pennsylvania HPO, and as the Data Harmonization lead for the ACT network. He also directs the development and implementation of a EHR research data warehouse at the University of Pittsburgh. Dr. Visweswaran will share the challenges and successes the All of Us Pennsylvania HPO has had with submitting EHR data to the DRC.

Joan M. Grand – MITRE Corporation
Ms. Grand is the project lead for the AoU FQHC Phase II Project. As a registered nurse, Joannie brings more than 25 years of extensive clinical and administrative experience in the ambulatory, critical care and emergency medicine domain. While at MITRE, she has been at the forefront of efforts to leverage data, evidence-based practice and analytic methods to improve the health and health care of the nation while building trusting relationships with various stakeholders to create catalyzing partnerships. Ms. Grand will provide an overview of the FQHCs’ engagement and share their experiences within AoU.

Real World Experiences with Patient-Facing APIs for Interoperability, Access, and Use of Electronic Health Data

Aaron B. Neinstein, MD;¹ Julia Adler-Milstein, PhD;¹ William Morris, MD;² Anil Sethi, MS;³ Elise Anthony, JD⁴

¹University of California, San Francisco, San Francisco, California; ²Cleveland Clinic, Cleveland, Ohio; ³Citizen, San Francisco, California; ⁴Office of the National Coordinator for Health Information Technology, Washington, D.C.

Abstract

Application programming interfaces (APIs) underpin the progression from data to knowledge to action in so many walks of life. In healthcare, APIs have recently received national attention as Medicare and Medicaid began requiring doctors and hospitals to provide their patients with digital access to their health data through patient-facing APIs. Now the Office of the National Coordinator for Health IT has released groundbreaking rules for standardized APIs as a cornerstone of national interoperability and patient access. As healthcare’s API era launches, our panel will present four key perspectives on patient-facing APIs—academic research, frontline health systems, app innovators and developers, and national policy—and strategies and priority use cases in the real world today. We will present findings of a just-completed national study of leading health systems and their uses of patient-facing APIs, including best practices, early challenges, and potential policy implications, followed by initial research on patients’ usage of those APIs, a deeper look at one leading health system’s strategy and experience, a leading app developer’s perspective, and ONC’s major policy proposal this year using APIs to advance patient access and interoperability. This panel provides an eagerly anticipated first look at real-world usage and impacts of patient-facing APIs.

Panel Description

Numerous industries outside healthcare have proven that robust application programming interfaces (APIs) are necessary infrastructure to move from data to knowledge to action. Electronic health records began as and often continue to be health data repositories and billing systems for doctors and hospitals. However, their transformative value rests on the ability to share health data from these silos to the many, varied stakeholders in the learning health system which would benefit from more seamless data access and use. Key among these stakeholders are patients.

In 2015, the Office of the National Coordinator for Health Information Technology (ONC) and Centers for Medicare & Medicaid Services (CMS) proposed to launch a potential democratization of electronic health information exchange by requiring the use of patient-facing APIs. CMS and ONC proposed that patients gain access to their electronic health data stored in EHRs through open APIs that would allow patients to view, download, integrate, and share their health data wherever they chose: a family caregiver, an emergency department, a community clinic, a third-party digital health app, etc. CMS and ONC originally required that these patient-facing APIs take effect on January 1, 2017, but delayed the requirement to January 1, 2019.

Thus, after much anticipation, patient-facing APIs are now live in many places in the United States. However, little information has been published about their real-world usage and impacts. Making the technology available does not necessarily ensure the concomitant culture, business drivers, and workflows needed to use it well. This panel, comprised of national leaders in their respective perspectives, will provide a first look at early real-world experiences with patient-facing APIs from four diverse perspectives—academic research, health systems, national policy, and consumer-facing applications—to provide an important initial synthesis of the promise and real world experience to date. Following the opening presentations, the moderator will lead a conversation among panelists and audience with questions intended to stimulate additional learnings and perspectives on patient-facing APIs.

Aaron Neinstein, MD (moderator and panelist) – National Landscape and Early Experiences

Dr. Neinstein will introduce the panel and topic. He will open the session by presenting data from a recently-completed national study, funded by The Commonwealth Fund, of how health systems are implementing patient-facing APIs. The study involved interviews with ten leading health systems to discover lessons learned from how they are implementing and using patient-facing APIs, including drivers, strategies, use cases, associated organizational
infrastructure, governance, policies, available applications, and processes. The findings reveal variability among these leading health systems with respect to their emphasis on and use of patient-facing APIs.

Julia Adler-Milstein, PhD (panelist) – Patient-Facing API Usage Data

Dr. Adler-Milstein will present new empirical findings on how often patients use their smartphones to connect and download their EHR data from their health systems through Fast Healthcare Interoperability Resources (FHIR®)-enabled APIs. The research asked 12 health systems to share anonymously the numbers and trends of unique and cumulative individuals who linked their smartphones and downloaded their data over a nine-month period (3/29/2018-12/31/2018).

William Morris, MD (panelist) – Health System Perspective

Dr. Morris will describe the experience of a leading national health system and its perspective on strategy, use cases, implementation, challenges, and best practices in using patient-facing APIs.

Anil Sethi, MS (panelist) – App Innovator and Developer Perspective

Mr. Sethi will next discuss the experience of an app innovator and developer, its perspective on the state of patient-facing APIs, and how patient-facing APIs might meet its strategy and use cases to provide access and interoperability to patients.

Elise Anthony, JD (panelist) – Federal Policy Perspective

Ms. Anthony will describe the ONC’s draft regulations on APIs and information blocking, as a major nationwide development to advance patient-facing APIs, patient access, and interoperability.

Questions for Panel and Audience Discussion

- As we look at some of the expectations around patient-facing APIs – driving consumer or patient access and use of health data, driving emergence of a third-party application ecosystem, enabling better health information exchange – how have patient-facing APIs lived up to these and other expectations? Where have results unfolded as expected?
- What have been the unexpected lessons learned in this first year of the national rollout?
- Where are we discovering gaps between what we hoped would happen and what appears to be happening?
- In what ways are patient-facing APIs the same as or different from other types of APIs used in healthcare? What are the implications for how each stakeholder approaches its API strategy?
- What are the predominant current use cases for patient-facing APIs? Do you think they will remain relatively unchanged over the next 2-3 years, or will they evolve or expand?
- How important is inclusion of write APIs alongside read APIs, and why? When might that happen on a significant scale?
- How have patient-facing APIs, and the patient access, use and sharing of health information they enable, changed clinical care?
- What are the remaining policy gaps with respect to patient-facing APIs?

Rationale for Topic and Panel

Multiple forces pushed patient-facing APIs to center stage in 2019 as a national strategy and tool for access and interoperability with patients. CMS and ONC began requiring Medicare and Medicaid clinicians and hospitals to use EHRs with open APIs certified to the 2015 Edition to enable patients nationally to view, download, and transmit their health data. Apple Health used patient-facing APIs to roll out availability to over 190 million patients across America. ONC and CMS proposed new regulations to use standardized APIs to promote national interoperability and access as well as standardized policies to prevent information blocking with APIs. This panel will present early research and insights about health system implementations of patient-facing APIs, including a timely and unique first look at strategies, use cases, policies, challenges and lessons already learned, and issues to come. This will highlight the variability among these leading health systems with respect to their strategic emphasis on patient-facing APIs.
Panel Participants:

- **Aaron Neinstein, MD.** Director, Clinical Informatics, Center for Digital Health Innovation, and Assistant Professor, Department of Medicine, University of California, San Francisco.
- **Julia Adler-Milstein, PhD.** Director, Center for Clinical Informatics & Improvement Research, and Associate Professor, Department of Medicine, University of California, San Francisco.
- **William Morris, MD.** Associate Chief Information Officer, Cleveland Clinic.
- **Anil Sethi, MS.** Founder and Chief Executive Officer, Citizen.
- **Elise Anthony, JD.** Executive Director, Office of Policy, Office of the National Coordinator for Health Information Technology.

Statement of Agreement to Participate:

All panelists approved this proposal and agreed to participate.

Learning Objectives:

- Learn and discuss key perspectives on patient-facing APIs—academic research, frontline health systems, app innovators and developers, and national policy—and strategies and priority use cases in the real world today.
- Learn the key findings of a just-completed national study of leading health systems and their uses of patient-facing APIs, including best practices, early challenges and pitfalls, and potential policy implications.

Presentation Type:

- Panel (traditional)

Programmatic Theme:

- Consumer Health Informatics

Key Words:

- Interoperability and Health Information Exchange
- Patient Engagement
- Patient / Person Generated Health Data (patient reported outcomes).

Additional key words:

- Application Programming Interfaces (APIs)
- Patient Access
- Mobile Access

Tracks:

- Policy
- Applications
Informatics-Enabled Learning Health Systems: Strategies for Success from Four Academic Medical Centers

Eric G Poon, MD MPH FACMI1,2, Charles P Friedman, PhD FACMI3, Philip RO Payne, PhD FACMI4,5, Michael J Pencina, PhD2,6, Kevin B Johnson, MD MS FACMI7,8

1Duke University Health System, Durham NC; 2Duke University School of Medicine, Durham, NC; 3University of Michigan Medical School, Ann Arbor, MI; 4Washington University School of Medicine, St. Louis, MO; 5Washington University McKelvey School of Engineering, St. Louis, MO; 6Duke Clinical Research Institute, Durham, NC; 7Vanderbilt University Medical Center, Nashville, TN; 8Vanderbilt University School of Medicine, Nashville, TN

Abstract

The confluence of EHR adoption, advances in data science, and intensified pressures to achieve the quadruple aim has provided fertile ground for the development and spread of Learning Health Systems (LHS), which the Institute of Medicine has defined as systems in which ‘science, informatics, incentives, and culture are aligned for continuous improvement and innovation, with best practices seamlessly embedded in the delivery process and new knowledge captured as an integral by-product of the delivery experience.’ Informaticians will need to play a key role in these ecosystems, but many socio-technical barriers may stand in the pathway to success. This panel will showcase the experience of four academic medical centers that have been early developers of LHS. Panelists will describe strategies employed and investments made to overcome these barriers and sustain the success of LHS.

By the end of this panel session, participants should be able to i) describe structures, methods, and activities used commonly in learning health systems; ii) articulate the success factors for functional and sustainable learning-health systems, and iii) formulate strategies to optimize the set-up of learning-health system initiatives at their local institutions.

Significance

The wide-spread adoption of EHRs in US hospitals and ambulatory practices coincides with the intensified focus on the quadruple aim to optimize patient outcomes, improve patient experience, contain cost of care, and prevent clinician burnout1. Academic medical centers are staring at the eye of this perfect storm as public2,3 and private payors4 demand provider organizations to compete based on value for patients. Academic medical centers, as bastions for research, innovation, and teaching, need to develop strategies that leverage their core expertise to continuously improve operational excellence and define new paradigms of value-based care5. The construct of Learning Health System (LHS) has been proposed and implemented in various forms across several premier academic medical centers to address these challenges.

An LHS is defined by the Institute of Medicine (now named National Academy of Medicine) as a system in which ‘science, informatics, incentives, and culture are aligned for continuous improvement and innovation, with best practices seamlessly embedded in the delivery process and new knowledge captured as an integral by-product of the delivery experience.’6 As conceptualized by Dr. Friedman, one of the panelists, they are made up of multiple ‘virtuous cycles’ of study and improvement, each with an afferent (blue) and an efferent (red) arm:

![Figure 1. The Learning Health System Cycle](image)

122
Various informatics-related disciplines and their underlying methodological approaches can empower both the afferent and efferent arms of any LHS. For example:

i) Data amassed in the EHR and other clinical information systems enables data-driven inquiry at the local, regional and national levels

ii) Analytic tools allow clinicians, leaders, and researchers to ask question at the population level at the point of care

iii) Recent data science advances allow diverse end-users to synthesize data to make accurate and actionable predictions on which patients might benefit the most from timely and customized interventions and/or wellness promotion strategies

iv) Consumer informatics allows clinicians to see the full picture of their patients and extend the reach of interventions into the daily lives of patients and their loved ones, while also engaging patient as active members of the care team

v) Biostatistical, epidemiological, data science, and qualitative methods allow organizations to measure the impact of programs and continuously optimize or refine them.

In short, LHS embodies the theme of the 2019 AMIA Annual Symposium ‘From Data to Knowledge to Action’. However, adoption of learning health systems is still at its infancy, and informaticians must partner with many disciplines and stakeholders for LHS to be successful. Approaches for LHS vary greatly, and there may be many pathways to success. This panel will allow its participants to learn from early adopters of LHS and apply their lessons learned to their local communities.

Description of Panel

The 90-minute didactic panel session will consist of 4 brief 10-minute presentations by the luminaries in the field of informatics and learning health systems. Each presentation will be followed by 4 minutes for questions and answers. The final 30 minutes will be devoted a moderated discussion between the panel members and the attendees. By the end of this session, participants should be able to achieve the following learning objectives:

i) Describe structures, methods, and activities employed commonly in learning health systems

ii) Articulate the success factors for functional and sustainable learning-health systems

iii) Formulate strategies to optimize the set-up of learning-health system initiatives at their local institutions

The didactic panel will be moderated by Dr. Eric Poon, Chief Health Information Officer at Duke Health. After stating the learning objectives of the panel session, Dr. Poon will propose a working definition of learning health systems, and outline how the confluence of US EHR adoption, advances in data science, and intensified pressures to achieve the quadruple aim provides fertile ground for the spread of learning health systems activities. He will highlight some common socio-technical challenges that might hinder the development of thriving learning health ecosystems.

Dr. Charles Friedman, Chair of the Department of Learning Health Sciences at the University of Michigan School of Medicine, will propose a framework for LHS success and provide an overview of the general state of LHS adoption in the US and European countries. He will discuss the goals, structure, and research agenda of Department of Learning Health Science at University of Michigan. He will describe the bottom-up and middle-out strategy employed to form collaborations with other medical departments on LHS projects, including their campus-wide “LHS Collaboratory” and other collaborations at the state level. Dr. Friedman will also describe ongoing efforts to imbue LHS approaches through the Clinical Decision Support Committee and Clinical Intelligence Committee at Michigan Medicine.

Dr. Philip Payne, Founding Director for the Institute for Informatics at the Washington University School of Medicine in St. Louis, will describe efforts to advance Health IT and Biomedical Informatics platforms to deliver data as a renewable resource, translate data assets into actionable knowledge, and return ensuing insights to both clinicians and patients. He will review approaches for achieving timely and ready access to data assets through the creation and management of appropriate data repositories and sharing platforms that address the privacy and security concerns in a scalable manner. He will then describe efforts to promulgate advanced data analytics and knowledge management techniques across the research and care delivery enterprise. He will particularly emphasize the design and evaluation of data-driven interventions that involve the use of clinical decision support, guideline delivery
systems, population health management platforms, and tailored patient-level or population-level messaging at-scale in order to address the quadruple-aim.

**Dr. Michael Pencina, Vice-Dean for Data Science and Information Technology at the Duke University School of Medicine**, will discuss efforts at Duke Health to create learning health units that empower clinicians, operational leaders, clinical researchers, data scientists, methodologists, IT professionals, and change management practitioners to collaborate on LHS activities on a consistent platform of shared resources. This approach, facilitated by a "Connector" organization, allows efficient access to curated data and methodological expertise, while allowing LHS activities to scale across all clinical departments and service lines at Duke Health under shared governance. He will also highlight how the suite of consultation services, data pipelines, self-service data tools, on-demand burst computing resources in a secure platform, a common Information Asset Repository, and workflow integration approaches support the full-cycle of LHS activities at Duke.

**Dr. Kevin Johnson, Chair of the Department of Biomedical Informatics at Vanderbilt University Medical Center**, will discuss how Vanderbilt is developing a pipeline to connect their successful EHR-based CDS, ordersets, and forms modalities with their LHS to conduct pragmatic effectiveness trials. That pipeline takes advantage of their CTSA Studio Program to shape research ideas into hybrid designs. These studios inform the next step, EHR-powered research workshops, designed to assess the feasibility of implementing the study design within the constraints of the EHR or the existing clinician-EHR workflow. Dr. Johnson will showcase a number of examples, including smoking cessation, pediatric obesity management, and genome-informed pharmacotherapy.

**Discussion Questions:**

1) What are the common gaps in skillsets panelists and attendees have encountered in their organizations while setting up a functional learning health system? What have been some approaches to bridge those gaps?

2) What creative ways have been used to leverage existing resources and identify new funding sources to support learning health activities at your organization and/or your communities?

3) How might one go about proving the return-on-investment from learning health system activities?

4) If the panelists and attendees were given the opportunity to set up another learning health system, what would they do differently?

5) What opportunities exist for separate learning health systems to band together as a system of systems to accelerate knowledge generation and magnify impact?

**Statement of Agreement:** All panelists named on the authorship list have agreed to take part in this panel.

Implementing e-PROs into Clinical Practice

Robert S. Rudin, PhD, SM1, Cynthia LeRouge, PhD2, Danielle C. Lavallee, PharmD, PhD3, Madhu Reddy, PhD, FACMI4, Anuj K. Dalal, MD5

1 RAND Corporation, Boston, MA; 2Florida International University; 3University of Washington; 4Northwestern University; 5Brigham and Women’s Hospital and Harvard Medical School

Abstract

Patient-reported outcomes (PRO) are widely used in research studies, but thus far have limited use in routine clinical care. Despite the potential to make care more patient-centered, improve the accuracy of symptom recognition, facilitate shared decision making, and improve patient outcomes, health systems struggle to implement PROs in a sustainable way that generates value for patients and clinicians. Electronic health records (EHR), patient portals, and mobile Health apps have the potential to collect electronic PROs (e-PROs) more seamlessly, but best practices regarding implementation have not been established. In this panel, four presenters will describe emerging lessons from experiences implementing e-PROs in the clinical setting. Topics include methods for PRO visualization; designing and implementing a practice models that collects e-PROs via smartphone app for patients; integrating e-PROs collected from apps into the EHR for clinicians; and governance considerations. Attendees will learn the current state of knowledge for effective e-PRO implementation as well as key challenges and future directions.

General Description

Patient-reported outcomes (PRO) allow patients to systematically report their symptoms, functional status, quality-of-life and other relevant aspects of their health. Symptoms reported directly by patients have been shown to more accurately reflect patient health status compared with reports by clinicians. Systematic collection of PROs can facilitate the detection of health problems, provide numerical comparisons with other patients, inform treatment decisions, and assess the quality of healthcare delivery. Collecting these data systematically also has implications for population-based health care delivery.

Although PROs are widely used in the context of research studies and some subspecialty settings, they have not been widely adopted as part of routine clinical care. Electronic health records (EHR) have the potential to enable more routine use of e-PROs, such as when collected online, via patient portals, and in-person via kiosks and tablet computers. However, little is known about how to optimally implement e-PROs for their broader and more routine use for clinical care.

This panel presents e-PRO implementation from multiple perspectives at two different institutions: UW Medicine (Seattle, WA) and Brigham and Women’s Hospital (Boston, MA). The panel will discuss a range of topics, such as methods for e-PRO visualizations within the EHR, the design and implementation of a practice model for collecting condition-specific e-PROs via a smartphone app for patients with asthma, infrastructure requirements for integrating ePROs into routine care, and governance considerations for maintaining an e-PRO program. Collectively these presentations will provide a broad overview of the current state of e-PRO use in routine care and will offer suggestions of how to advance the science of e-PRO implementation.

Moderator: Madhu Reddy, PhD, FACMI is a Professor at Northwestern University. He researches topics at the intersection of medical informatics and computer-supported cooperative work (CSCW), with a focus on improving care delivery through use of collaborative health information technologies. He has recently published an evaluation of ePROs used in routine care. He will introduce the topic and each panel member, and lead the discussion.

Panel Members

Cynthia LeRouge, PhD is an Associate Professor in Florida International University and holds an adjunct position at the University of Washington School of Public Health. Topic: Visualizing PROs for providers. As collection of PROs increases across healthcare settings there is a need to develop e-PRO tools that incorporate effective mechanisms (e.g.,
visualizations) for reporting PROs to providers. Many clinicians perceive a PRO system as a potentially valuable addition to augment their patient care process if preferences for use and visualizations are met and if PRO workflow is streamlined. Literature and our action research findings focused on designing ePRO visualizations for providers reveal many commonalities among clinician perspectives of e-PRO data visualization as well as nuances. While a moderate degree of visualization customization may be needed for a system-wide deployment of e-PROs to meet clinician expectations of PRO usefulness and ease of use, some general considerations for e-PRO reports exist. This panelist will review an integrated e-PRO visualization framework that references three critical design domains related to content (i.e. what type of data is provided), visualization design (i.e., how data is visually represented), and functionality (i.e., which capabilities are provided) of e-PRO tools. Review of this framework will showcase common targets for ePRO visualization design as well as key points of customization needed to support various specialties and provider preferences.

Robert S. Rudin, PhD is an Information Scientist at the RAND Corporation. Topic: Designing clinically integrated PROs as part of a practice model: case study of asthma. PROs are beginning to be integrated into routine care in the context of a patient encounter, but they also have the potential to facilitate between-visit monitoring for chronic conditions such as asthma. Current guidelines recommend that clinicians monitor asthma symptoms, but few do so routinely. This panelist will present an asthma symptom monitoring practice model and mobile health (mHealth) app that collects PROs weekly between visits. The practice model and app were designed using user-centered design methods. Results of a 6-month feasibility study in subspecialty care shows high patient retention and adherence and minimal burden on the clinic. The panelist will discuss preliminary designs for adapting this intervention to the primary care setting; considerations for long term scaling and sustainability; and barriers and facilitators to implementation.

Anuj K. Dalal, MD is an Assistant Professor at Harvard Medical School, and Associate Physician at Brigham and Women’s Hospital. Topic: Leveraging the EHR infrastructure to implement a PRO-based practice model for a health system. Effective implementation of informatics interventions require integration with EHRs and other electronic infrastructure. Third party applications offer more flexibility regarding their design and use, but are more challenging to integrate into existing workflow and the EHR. This panelist will discuss how Brigham and Women’s Hospital supports various options for integrating third-party applications into its EHR (Epic Systems, Inc.), and describes how the above example (presented by Rudin) will be implemented. He will describe technical capabilities (e.g., FHIR, web services), workflows considerations (e.g., triage protocols), integration strategies, and governance considerations.

Danielle Lavallee, PharmD, PhD is a Research Associate Professor at the University of Washington. Topic: PRO Governance. The increasing interest in using PROs for clinical care is one example where governance can support clinical implementation efforts while keeping an eye towards needs and priorities of the system. PRO Governance ensures formalized oversight to PRO implementation including decisions related to selection, implementation, analysis, and use of PROs within and across the healthcare system. This panelist will present one example of approaching systemwide governance to manage competing demands for IT resources across different areas of clinical care. She will address the role governance plays in balancing different aspects of PRO implementation. This includes creating community and culture, supporting policy and procedure development, managing stewardship of IT resources, and keeping in mind needs for quality and contractual reporting.

Why topic is timely

The promise of using PROs to make care more patient-centric has so far been elusive. In general, direct patient input regarding their conditions is still not collected systematically or used as part of routine care. Now that EHRs have been widely adopted, collecting PROs electronically is more feasible: in theory, patients should be able to enter their data via online portals or mHealth apps directly into the EHR, simplifying workflows and allowing data to be collected outside of visits. Similarly, clinicians should be able to access PRO data more efficiently and leverage visualizations for comparative and longitudinal assessment of PRO data. As health systems increasingly are pressured to become more responsive to patients’ needs, there is an urgent need to understand how to implement PROs more sustainably in ways that will realize the potential benefits at the individual patient and population levels.

Anticipated audience
Anyone interested in learning how to make care more patient-centric using technology would be interested in attending this panel. Individuals with a focus on PROs, clinically integrated mHealth, health IT governance, and/or patient-centered practice models would be particularly likely to attend this panel.

**Discussion questions**

We anticipate a lively discussion with the audience. The moderator will encourage the audience to share their experience with implementing e-PROs. Possible questions include:

- What are the key benefits of incorporating e-PROs into routine care? How do these benefits differ by context and condition? What conditions are most promising for e-PRO collection?
- Which types of medical specialties would likely be the consumers of e-PROs for clinical care?
- How can e-PROs be presented to providers in ways that makes them clinically useful? What is the range of visualization options?
- How do health systems balance e-PRO standardization while also customizing to specific clinical practice needs?
- What role can mHealth have in e-PRO collection before, during, after, and in-between visits?
- What are workflow barriers and facilitators for clinicians to using e-PROs during visits? How does this differ by clinical profession?
- What are the technical barriers and facilitators to implementing e-PROs in a health system’s EHR?
- What are governance best practices and challenges to implementing e-PROs?
- What incentives are driving adoption (or non-adoption) of e-PROs in routine care?

**Statement from panel organizer** All participants have agreed to take part on the panel.

Sync for Science™ – A Standards-Based Approach to Data Sharing by Patients for Clinical Care and Research

Anita Samarth¹, Kevin Chaney, MGS², Joshua C. Mandel, MD³–⁴, Spencer L. SooHoo, PhD⁵
¹Clinovations GovHealth, Washington, DC; ²Office of the National Coordinator for Health Information Technology, Washington, DC; ³Microsoft Healthcare; ⁴Harvard Medical School Department of Biomedical Informatics, Boston MA; Cedars-Sinai Medical Center, Los Angeles, CA⁵

Abstract

In 2015, the Office of the National Coordinator for Health Information Technology (ONC) and the National Institutes of Health (NIH), in partnership with Harvard Medical School, announced the launch of Sync for Science (S4S) a national collaboration to accelerate adoption of application programming interfaces (APIs) that provide individuals a simplified, scalable, and secure way to share their electronic health record (EHR) data. S4S provides software tools, implementation support, documentation, and a convening platform to foster consistent, standards-based patient API access across diverse EHR systems. Initially tested to support EHR data sharing with the All of Us Research Program under the Precision Medicine Initiative®, S4S is a significant step towards developing a health system that provides patients with greater control over their EHR data, including aggregation of data across multiple provider sites, and sharing it securely and efficiently with other services, providers and research programs via mobile applications (apps). This effort leveraged participation from ONC, NIH, participating developers, researchers, providers, and participants insight regarding barriers to implementing and using S4S, which can inform other similar endeavors. While S4S is testing sharing of EHR data for precision medicine research, the standards powering it can be leveraged for other uses. This panel will discuss key lessons learned from the S4S pilot thus far, and opportunities for leveraging S4S and standards-based APIs to support health care and research.

Introduction

The Health Information Technology for Economic and Clinical Health (HITECH) Act, enacted as part of the American Recovery and Reinvestment Act of 2009, helped spur broad-based adoption of certified electronic health record (EHR) technology across the United States. While this has enabled digitization of health information and relevant health care services, it has not been without its challenges. Seamless sharing of electronic health information with patients, caregivers, or amongst providers is not yet ubiquitous. To address issues with access to health information, Congress enacted the 21st Century Cures Act (Cures Act) in 2016. The Cures Act strengthens ONC’s mandate to improve interoperability and, in particular, directs ONC to “engage in rulemaking to drive patient, clinician, and payer access to clinical data by advancing proposals related to application programming interfaces (APIs)”.

Standards-based application programming interfaces (APIs) are expected to enable individual access to their EHR data for any purpose of their choice. Excitingly, one specific purpose, such as participating in a research study, is currently being piloted by the All of Us Research Program which is part of NIH’s Precision Medicine Initiative® (PMI). The emerging app ecosystem supported by the consumer technology industry- could be an important catalyst for changing how individuals manage, share, and use their health data for their own health and for research²⁻³.

Sync for Science™ and the All of Us Research Program

To advance the goals of the PMI, ONC, in partnership with NIH has launched several activities to assist making this ambitious vision a reality⁴. One of those, Sync for Science (S4S)⁵, seeks to demonstrate how participant data donation can be scaled across large-scale research efforts such as All of Us, using standards-based API technology. Conducted in collaboration with Harvard Medical School and four leading EHR developers, S4S is being piloted at a variety of clinical sites across the country – allowing individuals to share their electronic health data specifically for All of Us. Further, S4S uses technical specifications that allow individuals to share their EHR data with a research study of their choice or care entity, also aligns with the requirements of the Centers for Medicare & Medicaid Services (CMS) under
the Promoting Interoperability Program (MU3), and, ONC’s recent notice of proposed rulemaking, which proposes requiring health IT developers to support API-enabled services. These policy drivers will continue fueling the expansion of S4S and other standards-based APIs. S4S provides important insights into the technical integration, roll-out, and use of S4S - informing our understanding of implementing an API allowing real-world data transfer for health care research. This panel seeks to provide insight into how API technology for participant data donation can be scaled across large-scale research efforts, based on the early experiences of S4S.

Panel Objectives and Presenters

The aim of this panel is to provide an overview of S4S, which is piloting under the Precision Medicine Initiative’s cornerstone program, the All of Us Research Program. Key lessons learned, areas for improvement, emerging challenges facing the field, and priorities for future work will be discussed by the diverse stakeholders involved. The panel brings together the informatics, research, and policy experts leading this work and will highlight pilot experiences from Cedars-Sinai Health System, Duke University Medical Center, Partners HealthCare, and University of Missouri Health Care and S4S lessons-learned from APIs within Allscripts, Cerner, eClinicalWorks, and Epic EHRs.

Ms. Anita Samarth, the CEO and Co-Founder of Clinovations GovHealth, will introduce and moderate the session.

Mr. Kevin Chaney, a Senior Program Manager at ONC, will provide an overview of ONC’s priorities and their relation to S4S to enable data sharing, lessons learned and emerging themes from S4S to improve standards-based API use.

Dr. Joshua C. Mandel, Chief Architect at Microsoft Healthcare, and project lead for S4S, will discuss the specifications, technical integration, and roll-out of S4S in conjunction with the All of Us Research Program.

Dr. Spencer SooHoo will discuss how the pilot is proceeding at Cedars-Sinai Health System, and describe how it is using standards-based APIs within the Epic EHR that are leveraged to enable health data access for S4S and the Apple Health mobile app. Dr. SooHoo will discuss the testing processes with S4S, All of Us, Epic, and Apple Health.

Panel Discussion Questions

- Is the health IT ecosystem keeping pace with the utilization of APIs? Are efforts by consumer technology companies spurring a more robust app ecosystem?
- What technical and policy needs or gaps have been identified through your work limiting the adoption of S4S and other, standards-based APIs? Are there limitations on the kinds of data sent?
- What are the barriers and facilitators for the pilot sites participating in S4S? Are providers familiar with APIs?
- Are the pilot sites interested in continuing their association with All of Us, and/or expanding to other research activities that might be relevant?
- How might ONC’s proposed rules around “APIs without special effort” influence shifts in research?

Panel Learning Objectives

- Participants will have a better understanding of NIH’s All of Us Research Program and how Sync for Science can support participant access and sharing of electronic health record (EHR) data for research.
- Participants will learn about the technical specifications and workflow of implementing S4S, using a standards-based application programming interface (API).
- Participants will learn what challenges and barriers may impact the use of a standards-based API, like S4S, for promoting data access and sharing for research.
- Participants will learn about emerging data types that could be leveraged by S4S for access and sharing by researchers.
- Participants will learn how S4S aligns with federal policy initiatives and emerging challenges that could impede the use of similar APIs.
Conclusion

The *All of Us* Research Program represents an inflection point for conducting research at a scale never seen before, driving a new generation of evidence. Sync for Science plays a critical role in allowing individuals to easily share their health data with any research or care entity of their choice. Therefore, early insights into the development, use, and improvement of open standards for data sharing is critical to the success of S4S – especially as policy drivers are expected to further implementation and usage of APIs.

Statement of Participation

Each of the panelists and the moderator have confirmed that they will participate if this submission is accepted, at the assigned timeslot during the Annual Symposium.

FHiring up Evidence in CDS: Mobilizing Knowledge for Computable Guidelines in Patient Care

Lisa M. Schilling, MD, MPSH1, Robert A. Greenes, MD, PhD2, Brian S. Alper, MD, MSPH, FAAFP3, Bryn Rhodes4, Maria Michaels, MBA, PMP5

1Professor of Medicine, University of Colorado, Aurora, Colorado, 2Ira A. Fulton Chair and Professor in Biomedical Informatics, Arizona State University, and Professor of Biomedical Informatics, Mayo Clinic, Scottsdale, Arizona; 3VP of Innovations and EBM Development, EBSCO Health, Ipswich, MA, USA, 4Co-Chair, HL7 Clinical Decision Support Work Group; CTO, Dynamic Content Group, 5Centers for Disease Control and Prevention, Atlanta, GA, USA

Session Type: Didactic Panel

Abstract

This panel brings together informatics experts in key domains necessary to leverage current and future technologies to efficiently translate evidence into action by making evidence and clinical practice guidelines computable and represented in a standard, interoperable format. There is a recognized lag of about 17 years in the translation of evidence to practice. The Internet, new data sources (such as ‘omics profiles and home sensor data), and new methods (such as causal inference and predictive analytics), and sources of evidence (such as ‘real-world evidence’) will lead to ever faster and broader evidence generation. Computable clinical guidelines, even when they exist, have been difficult to integrate into care processes due to a lack of pragmatism and patient-centeredness, among other factors. The panel will address challenges of guideline creation and adoption in the digital age, and the extent to which the availability of data and ways of acquiring and delivering knowledge provide new opportunities for integration and use of best-practice knowledge. The panel will discuss innovation in FHIR to transfer information regarding evidence (EBMonFHIR), clinical practice guidelines (CPGonFHIR), various types of computable knowledge and standards for biomedical knowledge (the Mobilizing Computable Biomedical Knowledge (MCBK) initiative), and redesigned processes for clinical practice guidelines.

Introduction and Background

The transformation of evidence to action is key for optimal health care delivery and outcomes. Evidence-based practice may best be implemented through the use of clinical decision support tools (CDS) and other EHR-assisted pathways. As methods of evidence generation continue to expand due to new analytic methods (e.g., causal inference, predictive analytics) and growing data availability (e.g., ‘omics, sensors, imaging), while simultaneously becoming more tailored (e.g., personalized medicine) there are even greater opportunities to support clinicians and patients in the practice of evidence-informed care. The reputed 17-year gap between medical knowledge and evidence-based medical practice will continue to exist if computerized methods are not used to assist decision-making.(1)(2)

‘Knowledge application – the act of getting evidence into practice – is fraught with challenges, some of which are specific to given environments (3), and others systematic, such as the efficient translation of guidelines into machine-readable formats. (4)(5). Embedding clinical practice guidelines into CDS system has resulted in improved clinical adherence to recommendations.(6)(7) Despite a decade of innovation, there remains limited progress in the routine creation of computable clinical guidelines and evidence (8), which are still an afterthought of their narrative format. This panel will address recent progress in methods to solve these challenges with use of improved guideline creation methods, FHIR, and other data standards for representing clinical practice guidelines and evidence knowledge to ensure computability, re-usability, and the ability to share.
Outline of Topics
Welcome and Introductions: Lisa Schilling, MD, MSPH will provide a brief overview of the panel, and introduce the presenters.

Panelist Presentations (in order of presentation)

Maria Michaels, MBA, PMP is Public Health Advisor for the Deputy Director for Public Health Science and Surveillance at the Centers for Disease Control and Prevention (CDC). Ms. Michaels leads a multi-stakeholder initiative, Adapting Clinical Guidelines for the Digital Age, which aims to redesign the guideline development and implementation process to include all perspective from the outset of guideline development as well as use standards-based approaches to connect the evidence with the tools needed to apply guidelines in patient care. Part of this initiative includes an HL7 implementation guide on representing clinical practice guideline recommendations in FHIR (CPGonFHIR). Ms. Michaels will discuss the challenges of developing and implementing clinical guidelines which are often likened to a ‘game of telephone’ with inconsistencies and inaccuracies in translation, and a lag time that lead to an average of 17 years before scientific evidence is routinely applied to patient care. Redesigning the process to develop standards-based computable guidelines and include downstream perspectives during guideline development can help minimize translational issues. Ms. Michaels will discuss methods being developed to ensure that guideline developers and implementers are aware of the entire cycle for applying evidence to patient care and the use of standards such as Fast Healthcare Interoperability Resources (FHIR) throughout the cycle.

Robert A. Greenes, MD, PhD, is Ira A Fulton Chair and Professor in Biomedical Informatics at Arizona State University. Dr. Greenes’ research has been in the areas of clinical decision support, in terms of models and approaches for decision making, the knowledge representation to support it, and its clinical application and validation. He has also been active in the promulgation of standards and fostering of group collaborative work, particularly in knowledge management. He is a member of the Steering Committee of the Mobilizing Computable Biomedical Knowledge (MCBK) initiative, and co-chairs its Standards Workgroup. He will discuss this initiative’s goal to enable the curation, dissemination, and application of medical knowledge at a global scale. The management of computable biomedical knowledge will be essential to the success of Precision Medicine, the achievement of high-functioning Learning Health Systems, and more generally to the advancement of biomedical science.

Brian S. Alper, MD, MSPH, FAAFP is board certified in clinical informatics and is the project lead for the EBMonFHIR project, an HL7-approved project. The project’s goal is to develop a standard for computable expression of evidence, a critical underpinning of interoperability across the Evidence-Based Medicine (EBM) community of practice and with other types of computable biomedical knowledge. He will demonstrate precisely how FHIR-based resources for evidence assertions and statistics makes this type of biomedical knowledge computable. Dr. Alper has extensive leadership and practical solutions development across evidence-based medicine including founding DynaMed (a point-of-care clinical reference), defining Systematic Literature Surveillance (a methodology to keep current with best evidence), advancing guideline development (Guidelines International Network working groups), and multiple clinical decision support developments (including Patient-Centered Clinical Decision Support Learning Network).

Bryn Rhodes is Chief Technology Officer of Dynamic Content Group. Mr. Rhodes is co-chair of the HL7 CDS Work Group, the lead author of the HL7 CQL standard, and editor of the HL7 FHIR Clinical Reasoning module, as well as several other quality improvement-related HL7 standards. Mr. Rhodes is also a project champion in the Informatics Stream of the Adapting Clinical Guidelines for the Digital Age initiative and is actively involved in work sponsored by the CDC and ONC to create computable recommendations for the CDC’s Opioid Prescribing

Figure: The Plan-Do-Study-Act cycle: applying evidence to patient care
Guideline. Mr. Rhodes will introduce the CPGonFHIR project. The project aims to collect and document experience from the implementation community with using the FHIR Clinical Reasoning module resources to build computable clinical practice guideline recommendations, helping to apply those recommendations in patient care more easily, quickly, accurately, and consistently.

Summation (10 minutes): Dr. Schilling will provide closing comments and take questions from the audience.

All panelists have agreed to participate in this panel, which will provide important updates in this emerging field.

Educational Objectives
After participating in this session, the learner should be able to:

- Describe current progress in Clinical Practice Guideline (CPG) design and formalization to support computability
- Describe methods for generation of clinical decision support knowledge
- Explain alternative approaches to delivering knowledge at the point of care
- Describe efforts underway and approaches to sharing of best-practice knowledge
- Explain how biomedical evidence (research findings) can be expressed in a computable form

Intended Audience
This session is open to clinicians, informaticians, researchers, and policy makers who have an interest in the lifecycle of evidence generation to clinical guidelines to computerized clinical decision support.

List of Discussion Questions
1. Rethinking what is ‘evidence’: how can we use other data sources and ‘real-world evidence’ to inform clinical guideline updates and/or clinical decision support, and should we?
2. What are some current barriers, especially at the clinical organization level, to fully implementing standards such as FHIR?
3. What factors prevent sharing of knowledge artifacts (such as re-usable decision support rules, quality measures, and other tools) and how can we most effectively address those issues?
4. What are the challenges to implementing standards such as EBMonFHIR and CPGonFHIR?

References
Abstract

Biomedical informatics is at a crossroads with respect to the translation of innovation. The center of innovation and implementation in health IT has shifted from its historic origin in academia to industry. Applied researchers must become familiar with a new context, goals, processes and vocabulary in order to be able to translate their research ideas into practical products and services. Most researchers and business entrepreneurs share a common goal: to make a meaningful difference in people’s lives. But, to do so in the commercial space, academicians must keep several principles in mind, such as: addressing a real problem in a meaningful way; focusing on the customer; considering business development strategies up front; leveraging the core skills and competencies of academia and businesses in a complementary way; planning for scaling the innovation; respecting and protecting intellectual property; considering multiple pathways to commercialization; being realistic about valuation; leveraging a variety of sources for capital; and understanding their institution’s technology management and transfer processes. This panel, composed of successful academic and business entrepreneurs, will discuss a framework that can help attendees in going from research idea to initial public offering through a structured, easy-to-understand process.

Introduction

Biomedical informatics is at a crossroads with respect to the translation of innovation. The center of innovation and implementation in health IT has shifted from its historic origin in academia to industry. Applied researchers must become familiar with a new context, goals, processes and vocabulary in order to be able to translate their research ideas into practical products and services. This panel will provide an overview of how research ideas can be commercialized, and offer an easy-to-understand framework that attendees can apply.

Historically, the academic community has produced many significant and groundbreaking advances in informatics and health IT. For the most part, it did so by partnering with or integrating in local healthcare institutions, identifying relevant problems, and solving them with innovative basic and applied research. Sometimes, these solutions were disseminated and adopted beyond their origin. However, it was not uncommon for academic informatics organizations to function like loosely federated islands of innovation with little translation to the broader context of health IT. They also only used local, idiosyncratic processes for translating research ideas into production.

Panel description

The advent and growth of the health IT industry, the adoption of health IT at scale, as well as the relatively recent entry of large commercial players into the health IT space have fundamentally changed innovation in health IT. The center of gravity for health IT innovation has now shifted from academia and theory to industry and practice. Academic informaticians are slowly starting to pivot to innovating within electronic health record (EHR) systems. Newer technologies such as Fast Healthcare Interoperability Resources (FHIR) are facilitating this trend. At the same time, many academicians continue to pursue standalone research projects based on local needs.

What makes the current situation challenging is that the context, goals, processes and vocabulary that informaticians must understand in order to effectively translate their research ideas into practical products and services was typically not part of their training and/or experience. Added to this challenge are the sometimes significant hurdles in administrative red tape and opaque processes at their institutions, making the commercialization of research difficult if not impossible. How can researchers become more successful at translating their ideas into commercial applications?

Most researchers and business entrepreneurs intrinsically share a common goal: to make a meaningful difference in people’s lives. While their respective incentives differ, this common ground can become the basis of successful collaborations. A few considerations are important for academicians as they consider pathways to commercialize their ideas:
● **Address a real problem in a meaningful way**: Both researchers and business entrepreneurs must create value through their work. Projects that will not have significant impact on workflow, healthcare delivery, or patient outcomes, or meaningfully improve on status quo in the industry, will excite neither peer review panels nor investors.

● **Focus on the customer**: Solutions produced both in academia as well as in business must ultimately satisfy a customer need and demand. If that demand does not exist or cannot be stimulated, there is no market for the resulting product.

● **Consider business development strategies up front**: Many researchers spend years developing and testing their ideas, and often consider only fairly late in the development cycle how to translate their work into a commercial product/service. This behavior pattern often results in disappointment due to a variety of factors, such as competitive pressures, shifts in the technology landscape or changed market demand. Much better is a research and development strategy in which translation is a key consideration from the very beginning.

● **Leverage the core skills and competencies of academia and businesses in a complementary way**: Many academicians are very good at generating innovative ideas, but not as capable in translating those ideas into robust production applications. Successful businesses, on the other hand, tend to develop products/services that can stand up to the challenges of daily use. Productization by capable companies is one of the most direct routes from research idea to impactful product.

● **Planning for scaling the innovation**: An innovation that cannot be scaled for widespread adoption will not succeed. New technologies like the Apple Health Record coupled with the ubiquity of the iPhone means that innovations deployed through this platform could rapidly be scaled to 100 million users in the US—something completely out of reach for academia.

● **Respect and protect intellectual property (IP)**: Many researchers are justifiably proud of the IP they develop, but IP never exists in a vacuum. Other entities may own or have rights to or interests in the same or similar IP. Sometimes, partners contribute their respective IP in order to create something that is greater than the sum of its parts.

● **Consider diverse pathways to commercialization**: Very often, academics primarily focus on creating a spinoff company as a pathway to commercialization. However, there are other ways of leveraging IP, such as licensing to a business partner.

● **Be realistic about valuation**: One of the challenges with IP produced through research is that it is often difficult to value. Many universities spend inordinate amounts of time negotiating the potential value of an innovation and how any returns should be split. Very often, those negotiations lead nowhere, especially when the university has unrealistic expectations of financial returns. In the end, 50% of $0 is still $0.

● **Leverage a variety of sources for capital**: Researchers and business entrepreneurs can draw on a variety of sometimes complementary sources of capital. However, many researchers focus solely on research grants to fund their efforts. There are other options, however, such as SBIR/STTR grants and foundation awards. On the business side, angel investors and venture capitalists can provide capital for investment.

● **Educate yourself about your institution’s technology management and transfer processes**: Many universities have fairly complicated technology commercialization processes. One of the first things faculty must do is understand the commercialization process from their institution’s perspective, starting with the invention disclosure and ending with licensing/spinoff procedures.

The panel, composed of academics and business entrepreneurs who have brought a broad range of innovations to the market, will provide both academic and business perspectives on how to translate applied research to commercial use. It is targeted at biomedical informatics researchers and developers who produce innovations that are intended or appropriate for application in real-world clinical, administrative, research or educational environments. The topic is timely and relevant for a number of reasons, including the need to produce more impactful innovations that make a significant difference in practice, and the declining feasibility and usefulness of the concept-grant-paper cycle.

**Panelist Biographies**

**Titus Schleyer, DMD, PhD**, is Professor of Biomedical Informatics in the Department of Medicine, Indiana University School of Medicine, as well as a Research Scientist at the Center for Biomedical Informatics at the Regenstrief Institute. As a former programmer, he has developed several health IT production implementations over the course of his career, and recently refocused his research entirely on applied work that is implemented and evaluated in practice. His FHIR-based Chest Pain App was the winner of the inaugural AMIA Pitch IT Competition in 2018, and he is currently working with Intelligent Medical Objects in commercializing a derivative innovation.
Frank Naeymi-Rad, PhD, is the Chairman of the Board and co-founder of Intelligent Medical Objects, Inc. where he leads a team of informaticists, clinicians, and innovators in delivering industry-leading informatics services using medical terminology for electronic medical records (EMR) systems. Prior to founding IMO, Dr. Naeymi-Rad was co-founder of Intelligent Medical Systems, Inc., which was sold to Glaxo in 1994. His thought leadership in clinical informatics led to nomination for the Oracle Corporation Smithsonian Award in the category of Medicine. He will present a step-by-step journey showing his move from teaching computer science, AI and innovations with medical students and faculties to transactions with private equity firms. Dr. Naeymi-Rad will cover steps in his journey from seed money from friends and family, Angels, VC, Investment Bankers, Private Equity and strategize about his “secret sauce.”

Barbara Rapchak is the Vice President of Academic Innovation for Intelligent Medical Objects (IMO) and the Academic Innovation Accelerator (AI²). She is the founder of Leap of Faith Technologies, Inc., a digital health company, and eMedonline, a patented software-as-service platform for mobile medication therapy management that improves adherence and facilitates care transition and disease management, resulting in reduced healthcare costs for providers and payers, and enhanced drug use for pharmaceutical manufacturers. She has led sponsored research and technology development for the National Institutes of Health (NIH), collaborating with hospitals, universities, major corporations, and government agencies on a wide range of healthcare projects, and has been very successful in the NIH Small Business Innovation Research (SBIR) program. She will be the moderator for the panel.

Patricia Weber, DrPH, is a Program Director with the Small Business Innovation Research (SBIR) Development Center at the National Cancer Institute (NCI), National Institutes of Health. She manages a diverse portfolio of grants and contracts awarded by the NCI with an emphasis on digital health and health IT. She works with small businesses at all stages of the process from pre-application, award, post-award, as well as NCI program initiatives that assist with follow-on funding to commercialize NCI-funded technologies. Dr. Weber will discuss the NCI/NIH grant application process with a focus on the research scope of both early and later stage projects, the review process and interacting with program staff to get the early help that applicants need to be successful. In addition, she will discuss post-award I-Corps and commercialization assistance programs along with NCI specific initiatives such as the Investor Initiatives program.

Craig Feied, MD, is Chief Strategy Officer for the Microsoft Health Solutions Group and Professor of Emergency Medicine in the Georgetown University School of Medicine. Dr. Feied was a cofounder of the Informatics Section of the American College of Emergency Medicine. He was the first emergency physician in the United States to hold a position as Director of Informatics, and first to head an institute of medical informatics. He is a Diplomate of the American Board of Emergency Medicine, as well as a fellow of the American College of Emergency Physicians, the American Academy of Emergency Medicine, and the American College of Phlebology. Dr. Feied developed a unique practical software architecture ("Azyxxi") for the rapid integration, organization, display, and mining of all data present in any medical setting—including data from all legacy systems, across many regions—in real time. In 2006 the Azyxxi system was acquired by Microsoft Corporation as the enterprise core of a new Health Solutions Group, and in 2008 the system was renamed "Amalga."

All panelists have agreed to participate in this panel.
Ten Years of CTSA Outputs and Moving Forward: How We Succeeded, What We Learned, and Moving Forward in the Open Science Environment

Juliane Schneider\textsuperscript{1}; Kristi Holmes\textsuperscript{2}; Marc Ciriello\textsuperscript{1}; Griffin Weber\textsuperscript{1}; Diane Keogh\textsuperscript{3}
\textsuperscript{1}Harvard Medical School, Boston MA; \textsuperscript{2}Northwestern University Feinberg School of Medicine, Chicago, IL; \textsuperscript{3}i2b2 tranSMART Foundation, Boston MA

Abstract

This panel will follow the stories of three informatics tools or methods developed by CTSAs to look back on the successes and failures of ten years supporting clinical and translational science. The stories will highlight successes where they were perhaps not expected, lessons learned about tool development and outreach, how sustainability is supported, or why a great product never got widely adopted. The discussion will then turn to the current environment of open science, and how the changes in the research lifecycle could have impacted the success of tools that were ahead of their time, or made formerly widely used tools obsolete, and how future development needs to take into account open science best practices to maximize data and software reusability and funding requirements for data management. A discussion will elicit ideas and opinions from other stakeholders in the CTSA program, and how we can use the lessons of the past to ensure success in the next five-year cycle.

Description

The CTSA program was founded in 2006, with over 60 sites across the United States\textsuperscript{1}. Over the years, these sites have developed programs and tools to support the accomplishments of clinical and translational researchers, with targeted tools in response to needs within their local institutions and through collaborative efforts aimed at benefiting bioscience on a national level. Some tools have been widely adopted, some have not.

Since 2006, the scientific research cycle has gone from siloed, invisible processes to one that is increasingly working towards openness. This idea of openness pervades every step of the cycle, from the tools used, to how the data is gathered, stored and described, to the publication of results and attributions. How do the tools that have been developed, especially in the early years of the CTSA program, fit into the quickly changing research environment, and how does this new environment affect current efforts? What have we learned from successes and from the good ideas that were not widely adopted?

With ten years behind them, and the next five year cycle beginning, it is the time for the CTSAs to look back on successes, failures, and how they are going to incorporate the open science environment that is profoundly changing the research lifecycle. A discussion including all stakeholders - CTSA members, researchers and those interested in open science should take place in order to move forward with a clear idea of what is needed to succeed. We expect the discussion of past efforts will inform the discussion of the future.

This panel will review the successes and near-successes of some of the CTSA products in the context of the change to an open science model. The discussion will center around three CTSA-developed tools/methods and their success or failure, and how those results may have been different in the new era of open science. The stories of the tools presented will provide the context for a lively discussion on effective support of clinical and translational science, the lessons learned on outreach, implementation, technology, and collaboration over ten years, and how it all fits into the new open science environment.
Panel

Enabling Interoperable Electronic Quality Measurement using HL7 FHIR®

Anne Smith, BSN, MHSA,1 Lisa Anderson, MSN, RN-BC,2 Rob Samples, MS,3 Moderator: Viet Nguyen, MD4

1National Committee for Quality Assurance, Washington, DC; 2The Joint Commission, Chicago, IL; 3ESAC, Incorporated, Rockville, MD; 4Stratametrics, LLC, Salt Lake City, UT

Abstract

Challenges to some of the Centers for Medicare & Medicaid Services (CMS) quality incentive programs have cited provider burden and feasibility concerns related to electronic clinical quality measures (eCQMs.) The move to use Health Level Seven International’s (HL7’s) Clinical Quality Language (CQL) for 2019 reporting allowed greater expressivity and more precise, unambiguous logic statements. However, retrieving data expressed in CQL is challenged by mapping requirements to access data entered and shared as part of healthcare delivery. This fact also limits sharing expressions with clinical decision support (CDS) artifacts to enable real-time workflow enhancements to improve performance. Panelists will describe how HL7’s Fast Healthcare Interoperability Resources (FHIR) and emerging HL7 implementation guides can improve measure precision and expressivity and provide insights into expectations for more straightforward implementation. Panelists will use examples of eCQMs developed using these new standards and tested in FHIR Connectathons and in real world pilots.

Learning Objectives:

- Understand the value of FHIR quality measurement on clinical systems including the potential for clinical burden reduction.
- Describe how FHIR quality measurement can mitigate the current challenges of eCQM management.
- Learn how new FHIR implementation guides can be used to represent clinical concepts needed for eCQM development, data retrieval, reporting.

General Description of the panel and the issue(s) that will be examined and a brief description of each panelist’s presentation.

The panel will discuss the current processes for electronic clinical quality reporting, evolution of eCQM standards, and associated challenges with quality measurement. eCQMs use data electronically extracted from EHRs to measure the quality of healthcare provided in order to identify opportunities for clinical improvement. The results of quality measurement are used throughout the healthcare system, including clinicians, researchers, and payers. Evolution of the existing standards to use CQL, a FHIR based data model, and FHIR Clinical Reasoning resources is necessary to align with rapid adoption of FHIR by the health information technology (IT) community as a platform for interoperable exchange of clinical information.

An eCQM is composed of three parts: the structure, the expression logic, and the data model. Figure 1 shows these measure components. The structure provides the comprehensive composition of a measure, including metadata (information about the measure) and the measure’s sections (e.g., population, numerator, denominator). It is not intended for human readability or consumption, but it can be represented using a style sheet for human readability.

The second part of a measure, the expression logic, enables articulation of information needed to determine if the subject of the measure meets the criteria for each of the measure’s sections. The expression addresses specific metadata about all data elements and their interrelationships required to meet such criteria. The third part of the eCQM, the data model, describes each data element and what metadata the expression logic can use to represent the measure’s intent.

Currently published eCQMs use a conceptual data model, the CMS Quality Data Model (QDM), to represent data, CQL as the expression logic, and Health Quality Measure Format (HQMF) as the structure. 2019 is the first reporting year using CQL as the expression logic.

![Figure 1. eCQM Structure.](image-url)
The data model represents the clinical concepts needed to measure and report quality. The QDM is conceptual, based on requirements of clinical quality measures used for manual data abstraction from clinical records. In the ten years since QDM’s creation, it has evolved to be more consistent with data that may exist in clinical settings. However, the data model is unique to the eCQM development environment and not implemented directly within a clinical environment. HL7 FHIR includes a set of resources based on data required for direct patient care, intended for defining semantically interoperable messages to communicate clinical, administrative, and financial information such that sender and receiver understand each other. FHIR has the potential to alleviate the additional burden of data model implementation by aligning eCQMs with other health data exchange scenarios.

Based on requirements defined in QDM and those defined in a CDS data model, and the virtual medical record (vMR), HL7 published a common approach based on FHIR for measurement and for CDS. The implementation guide, Quality Improvement Core (QICore) includes additional constraints on using FHIR for eCQMs and CDS artifacts to limit requests for data that may be excessive and add provider burden. Quality Improvement Clinical Knowledge (QUICK) further presents the QICore content in a logical view to help eCQM and CDS developers choose reasonable data within their CQL logic expressions. The current QICore implementation guide also provides a detailed mapping from QDM to guide eCQM developers considering transition to FHIR-based measures.

The FHIR Clinical Reasoning Module (Figure 2) incorporates the resources to express either an eCQM or a CDS artifact using the standard metadata, expression logic and data model. A measure report provides results, i.e., information retrieved about individual subjects measures (the individual report), evidence regarding which data elements were retrieved (based on the data model) and how the measured entity performed with respect to each measure section and the measure as a whole (aggregate report). Existing eCQMs use HL7’s Quality Reporting Document Architecture (QRDA). QRDA Category I is used for the single patient report and QRDA Category III for the aggregate report. FHIR Clinical Reasoning provides the Measure Report resource, based on QRDA, but interoperable with FHIR standards. It contains the patient, patient list, and aggregate reports that map to QRDA Category I and III, respectively; it also addresses reporting requirements that QRDA never adopted.

Currently system developers are required to use the HQMF, a standard based on HL7 V3 messaging to extract eCQM data from a system. When reporting quality data to a payer, this data is typically sent using QRDA, which is based on HL7 Clinical Document Architecture (CDA). This creates a misalignment between the standards for retrieving information from a system and producing a report for sending that information. FHIR Clinical Reasoning aligns these standards under a common framework.

The methodology used for generating, sending, and receiving quality reports can be a burdensome process and is prone to error. By aligning standards throughout the eCQM lifecycle, the panel will show how to improve the overall process and quality of data, while reducing the steps necessary for implementation. The use of Smart on FHIR Application Programming Interfaces (APIs) can provide a secure mechanism for exchange of data in a quality
reporting scenario. In addition, implementation of FHIR quality measurement has the potential to produce eCQM results in near real-time. Figure 3 shows the information flow for FHIR quality reporting.

An explanation why the topic of this panel is timely, urgent, needed, or attention grabbing is required with a discussion of anticipated audience.

Quality measurement programs continue to be an important topic that have the ability to impact clinical practices. This will continue to be the case as we transition to value-based healthcare at both the federal level and through private payers. As the requirements for reporting quality data increases, new methods are needed to promote interoperable exchange that align with industry standards and reduce the burden to care providers. FHIR is a new standard which is being rapidly adopted by the health IT community as a platform for interoperability. Nearly every EHR vendor and healthcare system in the US is involved in adoption of FHIR to some extent. If quality measurement is not included in this adoption cycle there is potential for misalignment with payment programs and systems development. In order to transition to FHIR quality measurement in a timely fashion, with minimal impact to providers, user feedback is needed. Audience participation for this panel is focused on getting this feedback to help shape implementation decisions and timelines.

Viet Nguyen, MD (moderator) will introduce the panelists and provide an overview of quality incentive programs and the need for improved quality measurement to enable value-based care. He will discuss FHIR’s potential to reduce the burden of reporting eCQMs by aligning with other data exchange scenarios, and discuss challenges with quality measurement in a provider setting. Dr. Nguyen will moderate the discussion.

Robert Samples will discuss the existing HL7 FHIR standards available to author eCQMs: the FHIR Clinical Reasoning Module, FHIR Quality Measure Implementation Guide, Data Exchange for Quality Measures (DEQM) Implementation Guide and Quality Improvement Clinical Knowledge as a logical data model and its alignment with CDS.

Anne Marie Smith will provide an example of an ambulatory care measure, comparing the existing version using HL7’s CQL-based HQMF with QDM to FHIR Quality Measure and DEQM Implementation Guides with the QUICK data model.

Lisa Anderson will provide an example of hospital-based care measure, comparing the existing version using HL7’s CQL-based HQMF with QDM to FHIR Quality Measure and DEQM Implementation Guides with the QUICK data model.

Discussion questions to enhance audience participation.

- How will transitioning to FHIR address the following challenges of quality measurement?
  - Access to real time information for measure performance
  - Data collection at the point of care
  - Accessing data needed for reporting from clinical systems
  - Exchanging quality data with vendors, payers, etc.
- How will aligning quality reporting with other data exchange scenarios impact clinical care?
- How would having a system that allowed a receiver of quality information to pull information without intervention be beneficial?
- What are the major challenges, roadblocks, or considerations of transitioning to FHIR for quality reporting?

All participants have agreed to take part in the panel.
Clinical text mining in mental health

Jessica D. Tenenbaum, PhD¹, Ramakanth Kavuluru, PhD², Thomas McCoy, MD³, Ozlem Uzuner, PhD⁴, Sumithra Velupillai, PhD⁵

¹Duke University, Durham, NC; ²University of Kentucky, Lexington, KY; ³Massachusetts General Hospital, Boston, MA; ⁴George Mason University, Fairfax, VA; ⁵King’s College, London, UK

Abstract

It has been shown that application of natural language processing (NLP) and text mining of clinical notes in electronic health records (EHRs) can help facilitate deeper and more accurate phenotyping in many disease areas. These methods are particularly useful in the context of mental illness, where disorders are highly heterogeneous and lacking diagnostic lab tests, medications are non-specific, and diagnosis codes are used inconsistently by different care providers, if not left out altogether. However, NLP approaches in mental health EHRs also pose a number of challenges, some common across all of medicine, some unique to mental illness.

The assembled panelists represent a geographically and scientifically diverse set of perspectives in the field of clinical NLP for mental health. They will discuss how their respective groups have addressed both scientific and infrastructural challenges and how they have helped to advance the field. They will also describe lessons learned as well as tools and artifacts they have developed that will be of use to other groups who are interested in similar questions.

Introduction

Mining electronic health record (EHR) data in the area of mental health is particularly challenging for a number of reasons. Psychiatric disorders are heterogeneous and lack diagnostic tests and robust biomarkers. Psychiatric medications are non-specific and the categorical diagnostic system is unreliable and used idiosyncratically. In light of this, natural language processing (NLP) is particularly powerful when applied to clinical documentation in the domain of mental illness.

Approaches to NLP span a continuum from simple bag-of-words to sophisticated grammar-based parse trees, with many levels of complexity in between. More recently, deep neural networks have demonstrated utility in analysis of free text. NLP may be used for cohort selection, deep phenotyping, identifying novel terms, enabling clinical decision support, and health outcomes research, among other purposes. Challenges in NLP include term extraction based on limitations of existing terminologies, the labor intensive nature of annotating datasets for training and testing, and the subjective and often ambiguous nature of clinical notes.

Topic importance and timeliness

Applying NLP methods on mental health EHR data holds particular promise not only because this type of documentation is predominantly written in free-text, but also because EHR data provides means to gather large samples for complex and rare clinical constructs that are otherwise challenging to pool. NLP in mental health has grown to be such an active field that it now has multiple satellite meetings devoted to it.¹³ Moreover, as neuropsychiatric illness is the leading cause of disability adjusted life years lost in the United States these illness are increasingly well resourced as clinical and scientific priority areas.⁴ ⁵

Speakers:

Dr. Jessica Tenenbaum- Moderator

Dr. Tenenbaum is an Assistant Professor of Translational Biomedical Informatics at Duke University. Dr. Tenenbaum is co-founder and Chair of AMIA’s Mental Health Informatics Working Group and Member-at-Large for the ELSI (Ethical, Legal, and Social Issues) WG. Current research projects focus on using EHR data for patient stratification in mental illness. Dr. Tenenbaum uses NLP to extract symptom-related terms from clinical notes for a machine learning approach to analysis and stratification beyond heterogeneous DSM-based diagnoses. Dr. Tenenbaum will introduce the panel and moderate the discussion.

Dr. Ozlem Uzuner- CEGS N-GRID Challenge, a.k.a., RDoC for Psychiatry Challenge
Dr. Uzuner is an Associate Professor at the Information Sciences and Technology Department of George Mason University. She also holds a visiting associate professor position at Harvard Medical School and is a research affiliate at the Computer Science and Artificial Intelligence Laboratory of MIT. Dr. Uzuner specializes in Natural Language Processing and its applications to real-world problems, including healthcare. Her current research interests include information extraction from fragmented and ungrammatical narratives for capturing meaning, studies of consumer generated text such as social media and electronic petitions, and semantic representation development for phenotype evaluation notes.

Dr. Uzuner will describe the CEGS (Centers of Excellence in Genomic Science) N-GRID (Neuropsychiatric Genome-Scale and RDoC (Research Domain Criteria) Individualized Domains) challenge to determine lifetime maximum symptom severity of patients in positive valence domain, based on their psychiatric intake interview reports. In this work, highlighted in Dr. Jim Cimino’s 2018 Year in Review talk at AMIA’s 2018 Symposium, 1000 reports were de-identified and annotated by experts for positive valence symptom severity.6, 7 The reports were shared with the community for de-identification and for symptom severity prediction of positive valence domain disorders. Findings from the shared task showed that a variety of approaches may succeed in extracting symptom severity information from these records. The shared task also demonstrated that mental health records differ from other clinical records in both content and presentation such that de-identification systems developed on discharge summaries may not automatically generalize to mental health reports.

Dr. Thomas McCoy- Annotation for gold standards

Dr. McCoy is the Director of Research at the MGH Center for Quantitative Health and Harvard Medical School Assistant Professor of Medicine and Psychiatry. His research focuses on development of computed phenotypes in, and applicable to, secondary use of healthcare data generated as part of routing care. His current interest is in developing methods to identify free text based phenotypes from expert knowledge without strict dependence on expert annotation.

Dr. McCoy will describe the painful practicalities of getting expert annotation of emerging transdiagnostic concepts like those in the CEGS N-GRID RDoC challenge and his team’s search for annotation-free methods to make these estimates.8 He will further describe how these methods were also conducive to scale out in the Partners Healthcare biobank where early genetic associations were identified9 and the full health record for use in suicide risk stratification.10 By removing the need for expert annotations this work was able to scale to cover the all domains of the NIMH RDoC system and by prioritizing run time simplicity it was able to scale up to both genetic discovery and clinical significant risk stratification within the confines of existing infrastructure.

Dr. Ramakanth Kavuluru- Deep Learning for NLP

Dr. Kavuluru is an Associate Professor in the Division of Biomedical Informatics (Internal Medicine) at the University of Kentucky. He primarily works in natural language processing for biomedicine using scientific literature, clinical narratives, and social media posts with the broad goal of extracting actionable information from these unstructured sources. High-level applications of his research include cohort selection for clinical trials, literature based knowledge discovery, knowledge-based exploratory search, and clinical decision support for precision medicine. He employs machine learning methods (including deep learning) and other data mining approaches to drive his research agenda.

Dr. Kavuluru will present two projects involving deep neural networks in clinical NLP, addressing how deep models compare with linear models for quantifying mental illness from clinical text. The first involves an overall ordinal four-level symptom severity scale as proposed by the 2016 CEGS N-GRID RDoC challenge.11 The second predicts specific mental health conditions based on the “history of present illness” portion of psychiatric evaluation notes.12 Results showed that linear models fall behind deep models in general but tend to complement deep models when building superior ensembles. Neural attention mechanisms also provide an excellent framework for error analyses (model debugging) and interpreting model predictions.

Dr. Sumithra Velupillai- NLP and Mental health outcomes research in a UK population

Dr. Velupillai is a Lecturer in Applied Health Informatics, at the NIHR South London and Maudsley Biomedical Research Centre (SLaM BRC), Institute of Psychiatry, Psychology and Neuroscience, King’s College London, UK. Dr. Velupillai has worked on clinical NLP since 2007 and on mental health-related research since 2016, particularly
on information extraction techniques. Dr. Velupillai’s team focuses on developing approaches for extracting temporal information as well as data-driven approaches for deep phenotyping and vocabulary development.

The Clinical Record Interactive Search (CRIS) system at the SLaM BRC provides a rich resource for NLP-based translational research. Knowledge-based, symbolic NLP approaches have been developed and applied to CRIS over the past 10 years to derive variables such as symptoms, medications, and risk factors from mental health records for subsequent large-scale clinical research. Extracting clinically important constructs from mental health notes using NLP poses some particular challenges, especially when NLP outputs are used for health outcomes research. Novel approaches are required for evaluation practices in this context. Suggestions for rigorous evaluation in mental health outcomes research will also be presented.

Questions to be addressed:

- What large-scale datasets exist for performing NLP in mental health?
- What are the biggest challenges for using clinical notes for deep phenotyping of mental health constructs?
- How is mental health different from, and similar to, the rest of medicine with respect to the opportunities afforded by NLP approaches? With respect to the challenges posed by use of NLP?
- What are some research purposes for which EHR data is “fit for use”, and what are some questions that will simply never be answerable by EHR data based on systematic bias, data missingness, etc?

Conclusion

This collection of panelists represents a diverse set of perspectives and approaches to the exciting and important topic of NLP in mental health. Panel attendees will learn about valuable community resources and cutting edge methods in this area and will be able to participate in discussion with panelists, adding their own experience and perspectives to the conversation.

Harnessing Data from mHealth Apps: Opportunities and Challenges for Clinicians and Researchers

Victoria L Tiase, MSN, RN-BC, FAMIA1; Robin R Austin, PhD, DNP, DC, RN-BC2; Christie L Martin, MN, MPH, RN, PHN, L_HIT-HP3; Ruth Masterson Creber, PhD, RN4; Spryros Kitsiou, PhD5

1Department of Information Technology, NewYork-Presbyterian Hospital, New York, NY; 2College of Nursing, University of Utah, Salt Lake City, UT; 3School of Nursing, University of Minnesota, Minneapolis, MN; 4Weill Cornell Medical College, Cornell University, New York, NY; 5University of Illinois at Chicago, Chicago, IL

Abstract
With the proliferation of mobile health (mHealth) technologies and applications (apps), patients are generating more data than ever before. These electronic patient-generated health data (PGHD) have the potential to yield additional insights, decrease nursing documentation burden, and improve patient care. At the same time, PGHD are also raising questions and posing significant challenges for researchers and clinicians. This interactive panel of nursing and consumer health informatics leaders will discuss key findings and challenges from several studies aimed at engaging patients with mHealth applications with the intent of collecting PGHD for research and clinical use, suggest a roadmap for additional research, and discuss future directions for nursing and informatics involvement in the design and implementation of mHealth apps.

General Description
According to the Pew Research Center, 77% of Americans now own a smartphone of some kind, meaning the majority of patients have powerful technology at their fingertips.1 The number of mHealth apps available for use has almost reached 300,000, making mHealth app development one of the fastest growing industries. In a recent report by Accenture, the majority (78%) of healthcare consumers wear or are willing to wear technology to collect data.2 These statistics signify a potential tsunami of valuable data about the patient condition that is not routinely captured from patients during initial assessments due to lack of time or poor recall. These data - also called the “digital phenotype” - can be used along with other information to broaden the biomedical profile of each patient and improve our ability to detect diseases or monitor their progression. The Office of the National Coordinator uses the term patient-generated health data to define these health-related data that are created, recorded, or gathered by or from patients to help address a health concern. PGHD, collected with mHealth apps, can fill in the gaps by providing important information about patients’ conditions between medical visits and on an ongoing basis. PGHD have the potential to efficiently capture needed information for use during care; contribute to cost savings; and improve the quality of care coordination and patient safety.

Unfortunately, there is very little evidence for healthcare professionals to base recommendations for the use of mHealth apps by clinicians or patients. Additional concerns surrounding the use of PGHD in clinical practice include time needed to review data, scope of practice, liability of the data received, and appropriateness of the interpretation and clinical decisions made based on the data.

As the most trusted healthcare professionals, nurses are on the receiving end of patient and family questions regarding which healthcare apps to download and where patients can provide the data that they have collected. Previous studies reveal that nurses are most often the clinicians interacting with patients about PGHD and mHealth apps.5 This puts nursing informatics researchers in a unique position to support work in this area. In order to effectively use PGHD, it is imperative to involve nurses in the design, implementation, and evaluation of mHealth apps and interventions.

The proposed interactive panel will engage a wide variety of clinicians, healthcare administrators and informaticians on a range of topics based on the collective work of the panel participants. Panelists will discuss challenges from several studies aimed at engaging patients with mHealth applications with the
intent of collecting data for research and clinical use, suggest a road map for additional research, and possible solutions associated with the development of mHealth interventions as well as the incorporation of patient-generated health data in electronic medical records for clinical decision making

Discussion Topics
Panel members will present their recent findings, personal perspectives, institutional experience, and engage audience members in a robust discussion to elicit participants’ opinions, experiences, and practices with mHealth applications. The following topics will be addressed:

- Assessing the need to engage patients and families with mHealth apps
- Preferred functionality of mHealth apps
- Implications of performing informatics research using data associated with mHealth apps
- Incorporation of mHealth data into electronic medical records
- Readiness and training of nursing staff in supporting the use of mHealth apps
- Role of nursing in the design and implementation of mHealth technology
- Security and compliance concerns related to mHealth data
- Impact of mHealth data on the nurse/patient relationship
- Nursing involvement in mHealth research initiatives

Moderator:
Spyros Kitsiou, PhD is an Assistant Professor in the Department of Biomedical and Health Information Sciences at the University of Illinois at Chicago and Director of the mHealth Innovation Lab. His research focuses on the development and evaluation of technology-based (mobile health and telehealth) interventions to promote healthy lifestyle behaviors and self-management of chronic disease (e.g. heart failure, hypertension, diabetes, asthma, and chronic obstructive pulmonary disease). His overarching research goal is to make a difference in people’s lives through the development of novel interventions, and evidence synthesis reports that target health outcomes and problems of significance to communities, governments, and health agencies. Dr. Kitsiou is currently conducting several randomized controlled trials of mHealth interventions with funding from NHLBI, NINR, and NIA.

Panel Members:
Victoria L Tiase, MSN, RN-BC, FAMIA is the Director of Research Science at New York-Presbyterian Hospital where she has been responsible for planning, organizing, and implementing a range of clinical information technology projects related to electronic health record adoption and meaningful use, clinical workflows, patient engagement, and care coordination. Ms. Tiase is a board-certified registered nurse with experience in perioperative nursing and nursing education. She is currently pursuing a PhD in Nursing from the University of Utah and was recently named a Jonas Nurse Leaders Scholar. Her research is focused on incorporating patient generated data into clinical workflows to impact care and reduce documentation burden. In 2014, she was selected for the Alliance for Nursing Informatics Emerging Leader fellowship. In addition, she currently serves on the AMIA Nursing Informatics Working Group Leadership team and is the Member-at-Large on the Alliance for Nursing Informatics Steering Committee. Ms. Tiase will present her work related to two patient-facing mHealth app pilot and the lessons learned with incorporated these data into clinical care. She will also discuss the policies and procedures of a large academic medical center in regards to mHealth apps.

Robin R Austin, PhD, DNP, DC, RN-BC is a Clinical Associate Professor at the University of Minnesota School of Nursing. Dr. Austin has a broad range of healthcare experience as a board-certified
registered nurse with a Master of Science in nursing focusing on nursing education and a Doctorate in Nursing Practice specializing in Informatics. She recently completed a PhD in Nursing at the University of Minnesota, School of Nursing where her research focuses on leveraging informatics for an integrated health approach to achieve optimal health for patient engagement, lifestyle modification for chronic disease, and health promotion and wellness using digital apps and mobile platforms. In addition, she is the current outgoing chair for the AMIA Consumer and Pervasive Health Informatics Working Group. Dr. Austin will discuss the literacy level of mHealth apps and her PhD research using structured consumer-generated mHealth data.

Christie Martin, MN, MPH, RN, PHN, LHT-HP is a medical-surgical nurse at Abbott Northwestern hospital in Minneapolis. She completed a Master of Nursing and a certificate in Leadership in Health Information Technology for Health Professionals from the University of Minnesota School of Nursing and a Master of Public Health from the University of Minnesota School Of Public Health. Ms. Martin’s research interests include child and adolescent health promotion and consumer health informatics. Ms. Martin serves as the co-chair of the Nursing Knowledge Big Data Mobile Health for Nursing working group, is an active member of the American Medical Informatics Association Consumer and Pervasive Health Informatics Working Group, and is the student representative for the University of Minnesota School of Nursing Research Committee. Ms. Martin will speak to the types of mHealth research that are being conducted by nursing informaticians and opportunities for collaboration.

Ruth Masterson Creber, PhD, RN is an Assistant Professor of Healthcare Policy & Research, Division of Health Informatics at Weill Cornell Medicine. Her research focuses on using mobile health to support patients with chronic disease management from diagnosis through the end of life and is funded by the National Institute of Nursing Research, R00NR016275 grant, “mHealth for Heart Failure Symptom Monitoring.” Throughout this work she has applied participatory design principles to the development of a web-app for older, chronically-ill adults with limited English proficiency, low health literacy and limited technology experience. She is also the Principal Investigator of a study focused on optimizing symptom management at the end of life for patients on hospice with the Visiting Nurse Service of New York. Dr. Masterson Creber will speak on the preferred functionality of mHealth apps, the role of nursing and healthcare informaticians in the design and implementation of mHealth technology and mHealth research initiatives.

Acknowledgements
Ms. Tiase would like to acknowledge the support of Jonas Philanthropies. Dr. Masterson Creber’s work has been funded by the National Institute of Health/National Institute of Nursing Research (R00NR016275).

Informatics Architecture for the Future of Cancer Immunotherapy Research

Theresa L. Walunas, PhD¹, Abel N. Kho, MD, MS¹, Nike Beaubier, MD², Nikesh Kotecha, PhD²
¹Center for Health Information Partnerships, Northwestern University, Chicago, IL, USA, ²Tempus, Chicago, IL, USA, ³Parker Institute for Cancer Immunotherapy, San Francisco, CA, USA

Abstract

Immunotheapy represents the next generation of cancer therapeutics and have shown dramatic impact and durable responses on a wide variety of tumor types. However, these therapies only provide durable outcomes for 20-40% of patients and up to 90% of patients are expected to experience a so-called immune related adverse event. Large scale EHR data from multiple institutions, linked to genomic information as well as other environmental data could be used as an underlying architecture to drive the future of precision medicine in cancer immunotherapy research. Participants in this panel discussion will learn more about 1) current lessons learned and challenges faced by those using informatics approaches to understanding cancer immunotherapy outcomes, 2) the availability of data to support precision theapeutics in cancer, 3) the challenges with using EHR data as a source for phenotypic and treatment data linked to genetic data to identify markers for successful treatment as well as risk factors for adverse events.

Introduction

Immunotheapy, including immune checkpoint inhibitors (ICI) and chimeric antigen receptor T cell (CAR-T) therapy, represent the next generation of cancer therapeutics and have shown dramatic impact and durable responses on a wide variety of tumor types. They are already in use in standard of care settings for melanoma, lung cancer and most recently breast cancer. However, these therapies only provide durable outcomes for 20-40% of patients¹ and 75-90% of patients² are expected to experience a so-called immune related adverse event (irAE) that range from mild rashes, to irreversible autoimmune complications, to death as a result of complications from severe inflammatory reactions. Understanding factors that impact treatment outcomes and the development of immune toxicity is critical for precision strategies for matching cancer patients with the therapies most likely to have the most significant impacts while minimizing adverse events.

While many clinical trials examining the function and outcomes of ICI and CAR-T therapies have been performed, they often represent small populations of people with cancer and outcomes and adverse events are tracked and recorded variably across studies, making it difficult to compare studies and develop generalizable conclusions³. In addition, these studies represent many different cancer types and may not represent a diverse patient population. Thus it is challenging to use these studies to develop effective models to understand risk factors that are associated with poor outcomes and the experience of adverse events. In fact, while there have been a few reports of biomarkers for successful therapy⁴ there are still relatively few means of predicting durable outcomes or the likelihood of experiencing adverse events and almost no studies that have demonstrated genetic linkages to outcomes.

ICI therapies have been approved for treatment of a variety of human cancers since 2011 and these therapies have expanded beyond clinical trials into common use. In 2010 the US Federal government enacted a series of reforms that spurred the adoption and use of electronic health record systems (EHR) across the US healthcare system. As of today, greater than 90% of hospitals and more than 80% of outpatient healthcare providers use EHRs to track patient care, including documentation of diseases and clinical conditions, treatments and laboratory test results. Providing a unique foundation on which to understand cancer therapy as well as to identify factors that improve or detract from therapeutic success. In addition, consortia, such as the NHGRI funded Electronic Health Records and Genomics network (eMERGE)⁵, have demonstrated that EHR data collected as a part of routine clinical care can be used to accurately phenotype patients across multiple institutions for well powered genomic analyses. Put together, this suggests a mechanism by which large scale EHR data from multiple institutions, linked to genomic information as well as other environmental data (such as a patient’s geolocation) could be used as an underlying architecture to drive the future of precision medicine in cancer immunotherapy research.
Panelists and Topics

1) Nikesh Kotecha, PhD is the Vice President of Informatics at the Parker Institute for Cancer Immunotherapy. Dr. Kotecha has expertise in computational immunology and biomedical informatics. He will moderate the discussion and will introduce the “The Informatics of ImmunoOncology – From Synthetic Biology to Translational Approaches Incorporating Real World Evidence for Managing Toxicities, a View from the Parker Institute” with a focus on the role of informatics in immuno-oncology using experiences from the Parker Institute, a new effort that has brought together pioneers in the immunotherapy space and 7 top cancer centers (Stanford University, UCLA, UCSF, M.D. Anderson Cancer Center, the University of Pennsylvania, Dana Farber Cancer Institute and Memorial Sloan Kettering Cancer Center).

2) Theresa Walunas, PhD is an Assistant Professor of Medicine and Associate Director for the Center for Health Information Partnerships at Northwestern University. Dr. Walunas has expertise in immunology and medical informatics and participated in early research studies elucidating the function of the first checkpoint inhibitor to be identified, CTLA-4. She will discuss “Managing Toxicities in Cancer Immunotherapy: Closing the Gap Between the Bench and Bedside to Improve Outcomes” with a focus on the intersection of clinical and research data to develop actionable, testable hypotheses to help improve therapeutic outcomes and reduce immune related adverse events.

3) Abel Kho, MD, MS, FACMI is an Associate Professor of Medicine and Director of the Center for Health Information Partnerships at Northwestern University. Dr. Kho has expertise in integrating EHR data across diverse care settings as part of several national networks including PCORnet 2.0, the All of Us Research Program, and EvidenceNOW. He will discuss “Integrating Medical Record Data as a Foundation for Cancer Immunotherapy Research – Challenges and Opportunities” and outline practical and efficient strategies for developing data pipelines that address data quality and granularity issues inherent in using EHR data.

4) Nike Beaubier, MD is Director of Pathology and Medical Lab Operations at Tempus. Dr. Beaubier has expertise in molecular genetic pathology with additional sub-specialization in gastrointestinal and surgical pathology. She oversees the laboratory operations at Tempus which processes over thousands of specimens per month. Dr. Beaubier will discuss "Building a High Throughput, Rapid turnaround, and High Quality Molecular Genetic Laboratory” with a focus on novel processes and tools developed to manage specimens, annotation, and analysis at scale.

Panel Rationale

Immunotherapy has advanced beyond clinical trials to become a core, mainstream cancer therapy that is now used in the treatment of a wide variety of tumor types. Given the wide reach of these therapies beyond the academic medical center and into community settings, there will be a dramatic expansion of real world clinical evidence that, when effectively linked to other data sources will be critical tools to understand factors that are predictive of durable outcomes in response to treatment as well as risk factors for severe immune adverse events.

Real world data sources come with a host of challenges that must be navigated successfully in order to create an effective platform for exploration of cancer immunotherapy outcomes and toxicities. This panel will explore lessons learned and the current state of the art in immuno-oncology informatics incorporating real world data sources; how real world data can be intersected with more traditional research data sources to create in silico disease models; the viability of EHR data as a foundation for large scale investigations and the intersection of EHR data with other key information (such as genetic information, cellular profiling and social and environmental determinants) to explore markers for successful treatment as well as risk factors for adverse events.

This panel is a multidisciplinary team reflecting complementary perspectives on the science and technology required to develop effective informatics architecture for exploring immuno-oncology. Drs. Kotecha and Walunas will be able to reflect on key research questions and challenges in the field and Drs. Kotecha, Kho will frame the data space, informatics infrastructure and challenges and Drs. Kho and Beubier will discuss the intersection of genomics and pathology data with real world clinical data.

The anticipated audience for this presentation would be those interested in understanding the current challenges facing cancer immunotherapy informatics, current data science approaches for exploring cancer immunotherapy, and those who are interested in developing the next generation infrastructure for informatics-based cancer immunotherapy research and care quality improvement.
Discussion Questions

• How do we intersect clinical information with bench information and develop frameworks that can be used to develop actionable, testable insights?

• What kinds of tools would be essential additions to an integrated EHR-based data platform to support effective investigations and identification of biomarkers?

• In addition to the data, what kinds of people, i.e. data scientists, clinical researchers, clinicians and basic scientists are needed to provide the subject matter expertise to develop an effective platform for research?

• How can patient reported data be integrated into this architecture? How could it best be used? What would be the existing challenges to integrating patient reported and wearables data?

• What are the best strategies for integrating human data with non-human animal models to support mechanistic studies that cannot be performed in humans?

• How do we protect patient privacy in this system? Cancers are often rare and cancer + a specific therapy even rarer.

• What are the experiences from an end user perspective? What are the clinicians struggling with compared to the physician researchers? How are they manifesting themselves in different cancer specialties?

Organizer Statement

All of the participants in this panel have reviewed this abstract for this panel and have agreed to take part in the panel should it be accepted.

f Canandaigua VA Medical Center, Canandaigua, New York, USA

Abstract
Deep neural network models (DNNs) are being explored in the clinical domain, following the recent success in other domains such as image recognition. For clinical adoption, outcome prediction models require explanation; however, due to the highly non-linear inner transformations, DNNs are viewed by many as a black box. In this panel, we will discuss the interpretability and statistical inferences of the prediction using DNN model, in the context of real clinical outcome prediction use cases. The panel will begin by providing a brief overview of the deep neural network and latest research to interpret DNN results. We will then describe two novel explanation methods. We will also introduce methods to construct confidence intervals and p-values for the explanations and validate them through simulations and data application. Finally, we will discuss the challenges and future work to improve the understanding and acceptance of DNN models by researchers and clinicians.

Learning Objectives
1. Understand the challenges and needs of explaining deep neural network models in the context of clinical research and clinical decision support.
2. Describe state-of-the-art approaches to explain deep neural network models.
2. Compare the explanations of deep neural network models with statistical regression models.

Introduction
Deep neural network (DNN) models are one of the key approaches in artificial intelligence (AI). Recent studies have shown that DNN can outperform traditional machine learning (ML) methods and statistical methods in clinical and non-clinical domains1-8. To influence clinical practice, a prediction model must also have sufficient discriminating power, calibration, face validity and clinical utility. Thus, to gain clinical acceptance and impact, we must provide interpretation of the DNN models. Traditional statistical models, especially linear models such as logistic regression, are popular not because they often have the best prediction performance, but rather they provide simple interpretations of each independent variable’s significance in the prediction process (e.g., in the form of odds ratio). However, the DNN models are particularly difficult to explain due to the highly complex transformations carried out between the “deep” layers.
DNN models are viewed as black boxes, and understanding and explaining their behaviors is the subject of ongoing research. Compared to clinical data, images of natural scenes, recordings of speech, or game board layouts are much easier for humans to grasp. As a result, most published work about the DNN explanation focus on confirming human interpretation, e.g., if an image feature critical to the prediction of being a dog looks like the outline of a dog. With clinical prediction, human users do not have such prior knowledge and expect the model to yield information that justifies the outcome prediction.

Approaches are being explored to explain DNN models include Attention Mechanism, Local Interpretable Model-Agnostic Explanations (LIME) and Layer-wise Relevance Propagation (LRP). Each of these approaches has strengths and limitations. One key challenge is to interpret and draw statistical inferences based on the explanations generated by these approaches. Another key challenge is to validate the DNN explanations. With background in biomedical informatics, computer science, mathematics, statistics, and outcomes research, our panel of experts will provide an overview of explainable AI methods and describe two explainable AI methods in more detail.

This panel is intended to address biomedical informatics professionals, who would like to learn about the new approaches in explainable AI and their application in specific clinical uses. This topic is timely as there is increasing use of deep neural networks in the biomedical domain while their adoption in the clinical settings is limited by the difficulty of explaining them.

Presentations

The first panelist, Dr. Zeng-Treitler, is an informatics expert with a background in computer science. Dr. Zeng-Treitler will provide a brief introduction to DNN and describe the need to explain DNN models in the context of several specific clinical research projects, including the prediction of post-surgery outcomes, prediction of outcomes in patients with serious mental illnesses, and the assessment of severity of illness in hospitalized pediatric patients. She will then compare and contrast several existing explainable AI approaches: Attention mechanism provides a window to observe how features are utilized by a DNN but its explanation is tied to the DNN design. LIME is agnostic about a model’s inner structure and assesses the role of a feature purely based on the change in the output. LRP starts with an input (i.e. a set of features) and the probability of an output. It works backwards layer by layer to redistribute this probability to each input feature. A relevance score is then computed for the feature.

The second panelist, Dr. Shao, is an informatics expert with a background in theoretical and applied mathematics. He will describe a novel LIME method called Impact Assessment to explain DNN. To measure the importance of each variable on the predicted outcome, the Impact Assessment method defined impact scores on observational, individual, and population levels. The Impact Assessment method was validated by comparing its results with odds ratios derived from logistic regression, showing strong but not perfect correlations as expected. Another validation approach is to use a dataset with known underlying relationship between predictors and outcome. Without complete knowledge of underlying relationships in real patient datasets, a simulated dataset with 100 variables and a mixture of linear and none-linear relationships was generated. Noting that simulated data are far less complex that real patient datasets, the Impact Assessment was shown to be highly accurate (90-95%) in estimating the contribution of a variable to the outcome.

Third panelist, Dr. Dao, expert in biostatistics with a background in statistics, will talk about the statistical inferences of the impact score. She will describe the idea behind the non-parametric bootstrap method for constructing confidence intervals without assumptions. Then, a parametric method for confidence intervals and p-values based on large sample theory can be used for faster computation, given the assumptions are reasonable. The theory and intuition behind these methods will be discussed and evaluated based on the simulations and data application.

Fourth panelist, Dr. Intrator, is a health services researcher trained in statistics and applied mathematics. She will introduce a method that demonstrates the effects of inputs on output of neural networks by using novel robustification techniques. Simulated data from known models are used to demonstrate the interpretability results of the neural networks. Graphical tools are used for studying the interpretation results, and for detecting interactions between covariates. The effects of different regularization methods on the robustness of the interpretation will be discussed. An application to an ANN model predicting 5-year mortality following breast cancer diagnosis will be presented.

Moderator, Dr. Goulet, is the Director of the Methodology and Biostatistics core of the VA’s Pain Research, Informatics, Multi-morbidities, and Education (PRIME) HSR&D Center of Innovation, and PI of VA funded administrative data-based studies including the Association of Complementary and Integrative Health Interventions with
Opioid Use and Related Risks among Veterans with Musculoskeletal Disorders and PTSD. He will lead the discussion on the interpretation of DNN results in the broader context of clinical research.

**Discussion Questions**

- What are the pros and cons of training traditional statistical models, traditional machine learning models, and deep neural networks in clinical research?
- What types of DNN explanations do we need to enable clinical adoption?
- How to balance accuracy and interpretability in the design of predictive models?
- What roles do ground truth and human validation play in the development of explanation methods?
- What is the meaning of “statistical significance” in the context of DNN explanation?
- What are the key challenges in the understanding of DNN models as well as future steps?

**Participation Statement**

I, Qing Zeng-Treatler, hereby confirm that all speakers have agreed to participate in this panel. Panelists are aware that there are no travel funds available.

Informatics approaches to collecting, analyzing, and addressing social determinants of health in healthcare

Yiye Zhang, PhD,1 Evan Sholle, MS,2 Marianne Sharko, MD, MS,1 Yongkang Zhang, PhD,1 Jessica S Ancker, MPH, PhD,1
1. Weill Cornell Medicine, New York, NY; 2. Information Technologies & Services Department, Weill Cornell Medicine, New York, NY

Abstract

It is well-established in the public health literature that health is strongly influenced by socioeconomic, cultural, and environmental conditions, community factors, and lifestyle. As healthcare organizations are becoming interested in these social determinants of health (SDH), informatics has multiple opportunities to shape and facilitate the collection, analysis, and application of SDH data to improve health equity. In this panel, we discuss multiple challenges and opportunities around three areas: how to collect SDH data; how to analyze these data; and how to apply these data to improving healthcare operations and health equity. Panelists will also analyze methodological reasons why, when the direct effects of SDH on health are so clear, modeling approaches using large clinical data sets sometimes fail to find effects of SDH. After participating in this session, attendees should be able to define SDH, identify multiple barriers to the efficient and accurate collection and analysis of these data, describe several informatics approaches to overcoming these barriers, and demonstrate how SDH influence the course of a chronic disease (heart failure).

Keywords

Social determinants of health, socioeconomic status, electronic health records, geocoding, natural language processing

Introduction

Social and environmental factors such as education, housing, employment, living and working conditions, social relationships and networks, and lifestyle are strong predictors of health outcomes. These factors have historically been considered beyond the purview of medicine. However, current and pending changes to payment and reimbursement models in the United States are encouraging healthcare organizations to reframe their domain more broadly and consider ways to identify and address the influences of social factors on medical outcomes.

This increased interest is manifested in multiple new projects nationwide to infer SDH from patients’ home residence or from other data, administer questionnaire screening to collect SDH directly, incorporate SDH into research data sets and data models such as i2b2 as well as directly into electronic health records, and explore how to adjust for SDH in reimbursement models and risk models.

In this panel discussion, we demonstrate how the informatics community can play a central role in helping to collect, analyze, and apply data on social determinants of health (SDH) to improve health equity and patient outcomes. Panelists will discuss the current landscape of SDH data collection, including existing tools such as electronic health record-based screening instruments. We also discuss some of the potential problems and unintended consequences of incorporating SDH into healthcare, and will invite the audience to join in discussions about improving the collection and utility of these variables.

Panel Moderator: Why Are SDH Important for Improving Health Equity?

Jessica S Ancker, MPH, PhD will open the panel with a short overview of public health and informatics research on the impact of social determinants of health globally, ongoing informatics innovations around SDH data nationwide, and the implications of leveraging SDH data for health equity. She will also discuss some of the potential harms and unintended consequences arising from SDH adjustment or collection.
Dr. Ancker, associate professor at Weill Cornell Medicine, has conducted extensive research on health literacy and numeracy as SDH and is also leading a retrospective cohort study that combines clinical data with SDH data to examine the impact of SDH on 30-day hospital readmission.

Combining Neighborhood with Clinical Data Shows That Parks Are Good for Your Health

Yiye Zhang, PhD, will describe how, by linking electronic health record data with publicly available data about patients’ place of residence, her team of health informatics and environmental engineer researchers demonstrated that living farther from parks in New York City increases the chance that heart failure would worsen. The relationship holds true even when controlling for demographics, clinical risk factors, and neighborhood poverty rates. This rich combined dataset of clinical indicators and neighborhood metrics also revealed other aspects of the built environment associated with disease progression. In this talk, she will discuss geographic mapping methods and the analyses linking individual-level and neighborhood-level social determinants data with heart failure outcomes.

Dr. Zhang conducts research on developing and applying methods for analyzing the progression of health and healthcare utilization for the purpose of clinical decision support. She is interested in understanding how non-clinical factors including SDH and the built environment may affect disease progression and access to health.

Extracting SDH From Medical Records Reveals Biases in Data Collection

Evan Sholle, MS, will show how, despite regulatory efforts to encourage structured documentation of race and ethnicity, many patients still lack informative data in the electronic health record. In a recent study, WCM informatics and health services researchers collaborated to use natural language processing information extraction techniques to infer race and ethnicity from free-text notes in the EHR. The results showed that a substantial portion of patients described as Black and/or Hispanic in notes were not documented as such in structured EHR fields. Of greater concern, patients with missing or inconsistent data differed from those that were recorded as Black and/or Hispanic in structured documentation in significant ways. In this talk, he will discuss the evidence these findings provide for systemic bias behind the capture of SDH documentation in the EHR, and the need for informatics methods to fill in these gaps.

Evan Sholle is the manager of research informatics services at Weill Cornell Medicine. His research centers on the secondary use of electronic patient data to support clinical and translational research.

Should We Be Asking Patients About Their SDH?

Marianne Sharko, MD, MS, will address issues surrounding collecting potentially relevant SDH that are known only to the patient. For example, literacy level, history of domestic violence, or food insecurity would presumably be most accurate if reported directly by the patients affected. Several large-scale efforts to screen patients are ongoing. Unfortunately, screening for SDH (in addition to being pragmatically challenging) also has the potential to alienate or alarm patients. Some initiatives have shown that patients feel embarrassment about physicians recording some of these variables, or worry that their answers may be used to harm them. In this presentation, Dr. Sharko will discuss challenges and opportunities surrounding the direct collection of SDH.

Dr. Sharko, a pediatrician who received her master’s degree in health informatics at Weill Cornell Medicine, has research interests including the study of the unique privacy and confidentiality concerns for vulnerable patient populations in the context of electronic health records, patient portals, mobile health technology, and health information exchange.

When SDH Do Not Show an Effect, What Are the Reasons Why?

Yongkang Zhang, PhD, will show how, despite the demonstrated strong connections between social factors and health outcomes, many recent literature and modeling projects demonstrate that when SDH are added to models that already contain clinical data, they make little difference to predictive accuracy. This talk will analyze some of the previously published literature for reasons why SDH failed to predict health-related outcomes, and present analyses from our own data sets comparing predictive models with and without SDH. We will discuss how data quality
limitations, correlations between causally related variables, and healthcare utilization patterns of socially vulnerable patients explain some of the situations in which predictive accuracy is not improved by adding SDH.

Dr. Zhang’s research focuses on improving care delivery to high-need, high-cost patients, including those with vulnerable social conditions. His current project examines the association between SDH and healthcare utilization among Medicare and dual-eligible patients.

**Learning Objectives:**

After participating in this session, attendees should be able to:
- define social determinants of health;
- identify multiple barriers to the efficient and accurate collection and analysis of these data;
- describe several informatics approaches to overcoming these barriers;
- demonstrate how SDH influence the course of a chronic disease (heart failure).

**Panel Organizer Statement**

All participants have agreed to participate in this panel.

**Conflict of Interest**

The panelists have no conflicts of interest to disclose. Dr. Ancker’s healthcare disparities research is funded by the Office of the Weill Cornell Dean (Dean’s Diversity and Healthcare Disparities Grant Award), the National Library of Medicine (R01 LM012964), and the Patient-Centered Outcomes Research Institute Health Systems PCORnet (Patient-Centered Clinical Research Network) Demonstration Project (HSD-1604-35187, PI: Kaushal). Dr. Zhang is also funded by the Office of the Weill Cornell Dean (Dean’s Diversity and Healthcare Disparities Grant Award) and the US Department of Transportation-funded Center for Transportation, Environment, and Community Health. Dr. Zhang is funded by the Patient-Centered Outcomes Research Institute Health Systems PCORnet Demonstration Project (HSD-1604-35187, PI: Kaushal).
Team-Centered Informatics: A Necessary Adaptation to Translational and Implementation Science?  
Suresh K. Bhavnani PhD1, Shyam Visweswaran MD PhD2, Erich Kummerfeld PhD3, Carlos Clark DO4, Rebekah Penton DNP RN5

1Inst. for Translational Sciences, 4Dept. of Int. Med., 5School of Nursing, Univ. of Texas Medical Branch, Galveston, TX; 2Dept. of BMI, Univ. of Pittsburgh, Pittsburgh, PA; 3Inst. for Health Informatics, Univ. of Minnesota, Minneapolis, MN

Introduction

The rapidly maturing fields of translational science1 and implementation science2 have recognized the multidimensional nature of health outcomes, and the need for a holistic and integrative approach to address them. For example, several NIH-funded organizations have assembled multidisciplinary translational teams (MTT)3 consisting of biologists, clinicians, informaticians, and statisticians to help accelerate the integration of multi-omics data across the basic-clinical-community continuum. Similarly, implementation scientists draw from many disciplines to overcome cultural, political, and technical hurdles that prevent the broad uptake of research results produced from translational science.

Unfortunately, such teams face numerous barriers in integrating multidisciplinary knowledge, ranging from differing conceptualizations of a problem,4 to narrow social and technical identification within a single discipline.5 These hurdles often result in many teams having “low integrative capacity”.6 One approach, proposed by team science researchers to increase integrative capacity in teams, is through the use of “boundary objects”,7,8 which are external representations of information that facilitate the integration of diverse disciplinary knowledge. For example, as shown in Fig. 1, a boundary object could be designed to enable members of a multidisciplinary translational team to integrate their disciplinary knowledge, with the goal of generating novel insights that transcend individual disciplines.9

However, while boundary objects are used by the team science community to improve integrative capacity in teams, current informatics tools are mostly targeted to individual researchers. For example, powerful tools such as CRISPR10 and Genome Browser11 enable deep analyses of a few biological datatypes, but provide little support to investigators for integrating and interpreting results across multiple tools and disciplines. We therefore pose the question: Could the fields of translational science and implementation science benefit by a new class of informatics tools that are team-centered?

Goals and Structure of the Panel

Building on the concept of boundary objects from team science, this panel will explore the concept of “team-centered informatics”9 designed to help members of multidisciplinary teams integrate knowledge from diverse disciplines. Fig. 2 shows an example of a computational boundary object, which simultaneously models both molecular and clinical information. Being computational, this representation can be partitioned, filtered, layered, and intersected with different combinations of variables from each discipline to enable comprehension of how they are related to each other. Such a representation on the one hand could be meaningful to individual experts specializing in one dimension of the data such as genes, but on the other hand could also provide an integrated understanding of how those genes interact with other dimensions such as the environment, leading to insights that transcend individual disciplines. However, to make such representations more amenable to teams, we need to develop new interaction methods and algorithms for enabling the real-time collaborative exploration of diverse information in massive datasets.

To debate whether we need to invest in such team-centered informatics tools, this panel brings together a diverse set of researchers from human-computer interaction, machine learning, causal modeling, hospital administration, and nursing. Each panelist will present a use case from their research to explore two challenge questions: (1) is team-centered informatics old wine in new bottles? In other words, do collaborative tools already exist that are sufficient for teams to integrate diverse disciplinary knowledge? (2) does team-centered informatics provide low bang for the buck? In other words, does the extra cost of building new ways to interact with complex data provide much added benefit to researchers?
Position Statements

1. **Why do we Need Team-Centered Informatics?** (Moderator: Suresh K. Bhavnani, PhD)

Dr. Bhavnani, is professor of biomedical informatics at the Institute of Translational Science in the University of Texas Medical Branch, with a background in human-computer interaction. As PI of the Discovery and Innovation through Visual Analytics lab, he specializes in (1) the discovery of complex patterns in big biomedical data such as discovering heterogeneity in diseases and their respective pathways,12 and (2) the innovation of novel visual analytical methods to analyze and comprehend large and complex biomedical datasets.13 His research has received 5 distinguished paper awards from AMIA, and an outstanding paper award from the Science of Team Science (SciTS) conference.

Dr. Bhavnani will provide a brief overview of the motivations underlying translational science, and implementation science, and how they both benefit from conducting research through multidisciplinary scientific teams. Next, he will discuss the importance of external representations of data and knowledge such as visualizations and flow diagrams for (1) reducing a researcher’s cognitive load and freeing up resources to enable problem solving,14 and (2) as a “boundary object”,7 to help other members in a team span disciplinary boundaries, leading to novel insights.9 Using examples from translational science and implementation science, he will argue that the concept of a boundary object from team science could be the foundation for team-centered informatics solutions.9 He will then ask the panelists to present use cases from their research, and address the two challenge questions: (1) *Old wine in new bottles?* (2) *Low bang for the buck?*

2. **What is the Role of Team-Centered Informatics in Clinical Decision-Making?** (Shyam Visweswaran, MD PhD)

Dr. Visweswaran is associate professor of biomedical informatics in the Department of Biomedical Informatics and the Intelligent Systems Program, at the University of Pittsburgh. He specializes in the application of artificial intelligence and machine learning to problems in clinical medicine and translational bioinformatics. As PI of the Vis lab, his research includes (1) computer-aided diagnosis and prediction, (2) discovery and prediction from high-dimensional genomic data, and (3) patient-specific predictive modeling for personalized medicine.

Dr. Visweswaran will present a use case from his research15 focused on the use of Bayesian modeling and decision trees for clinical decision-making in multidisciplinary clinical teams. He will then address the two challenge questions with a focus on explainability of machine learning models in clinical decision-making.

3. **What is the Role of Team-Centered Informatics in Identifying Causal Mechanisms?** (Erich Kummerfeld, PhD)

Dr. Kummerfeld is research assistant professor in the Institute for Health Informatics at the University of Minnesota. He specializes in logic and computation applied to developing novel algorithms for discovering causal relationships, including relationships that involve, are between, or are confounded by latent variables, and applying them to health data to inform new treatments.

Dr. Kummerfeld will present a use case from his research16 focused on the use of causal modeling in biomedical data, focused on the identification of disease mechanisms and design of targeted interventions. He will then address the two challenge questions with a focus on the social dynamics of collaborations between data scientists and domain experts.

4. **What is the Role of Team-Centered Informatics in Hospital Administration?** (Carlos Clark, DO)

Dr. Clark is Chief Medical Information Officer (CMIO) at the University of Texas Medical Branch hospital. He specializes in quality improvement including decreasing the smoking rate of clinic patients, improving the transition of care to reduce hospital readmission, and leads endeavors in population health for alignment of UTMB as a high value practicing organization.

Dr. Clark will present a use case from his research17 focused on enabling providers to practice evidence-based medicine through EMR decision-support. He will then address the two challenge questions with a focus on overcoming social, political, and technical hurdles in implementing evidence-based practices.

5. **What is the Role of Team-Centered Informatics in Designing and Implementing Discharge Protocols for Skilled Nursing Homes** (Rebekah Penton, DNP RN)

Dr. Penton is Assistant Professor of Nursing in the School of Nursing at the University of Texas Medical Branch. Her research focuses on using methods from implementation science, and her 10 years of professional experience as a nurse practitioner, to improve care for geriatric patients in skilled nursing homes (SNFs).

Dr. Penton will present a use case from her research focused on the design and implementation of interventions to reduce hospital readmissions from SNFs. She will then address the two challenge questions with a focus on overcoming implementation hurdles related to hospital-SNF communication.
Discussion and Engagement of Panel Attendees

After each of the above position statements, the attendees will be first asked (with a show of hands) how many agree or disagree with the answers provided to the two challenge questions. For example, if a panelist claims that team-centered informatics is “old wine in new bottles”, then the attendees will be asked if they agree or disagree with that conclusion. The moderator will then invite attendees to voice their opinions about the issues being discussed. The panel members will engage with these opinions, and the moderator will determine when the next position statement will begin. After all the positions statements are delivered and responded to, the attendees will be asked through a final show of hands to determine if team-centered informatics is “old wine in new bottles” or not, and whether it has “low bang for the buck or not”. The results will be summarized by the moderator, and if the discussions lead to compelling arguments, will be documented in a report for publication. The first author has used the proposed panel format at the AMIA Informatics Summits in 2015, which resulted in high engagement among the panelists and attendees.

We expect this debate to enable attendees to comprehend the issues related to the design and use of team-centered informatics tools for a wide range of team-centered tasks in translational science and implementation science. The panel discussion should be of benefit to (1) researchers engaging in translation science and in implementation science, and (2) program managers from funding agencies who wish to understand how best to support the development, evaluation, and use of team-centered informatics approaches that have the potential of wide impact in making medical discoveries, and implementing them to improve patient care.

Acknowledgements

This research is funded in part by UTMB CTSA grant (UL1 TR001439), and PCORI award (ME-1511-33194).

The first author affirms that all panel members have agreed to participate, and have contributed to the preparation of this document.

Thriving in Your Biomedical Informatics Career
While Balancing Work, Personal, and Family Life

Sponsored and presented by the Women in AMIA Career Advancement Committee (CAC)
Lesley Clack, MS, ScD1, Qing T. Zeng, PhD2, Gretchen P. Jackson, MD, PhD, FACS,
FACMI, FAMIA3, William Hersh, MD, FACP, FACMI4, April Mohanty, MPH, PhD5

1University of Georgia, Athens, GA, 2George Washington University School of Medicine and Health Sciences, Washington, DC; Veterans Affairs Medical Center (VAMC), Washington, DC, 3IBM Watson Health, Cambridge, MA; Vanderbilt University Medical Center, Nashville, TN, 4Oregon Health & Science University, Portland, OR, 5University of Utah School of Medicine, Salt Lake City, UT; Salt Lake City VAMC, Salt Lake City, UT,

Abstract
A career in biomedical informatics typically requires a significant time and energy commitment, which must be balanced with other areas of life. An informatics professional can serve in multiple roles, such as domestic partner, dependent caregiver, etc. which may be challenging to their career trajectory and opportunities and may be hard to blend, though all of these roles can contribute to an enriching and fulfilling life. Biomedical informatics is especially challenging, given its interdisciplinary nature and wide breadth and depth. Key topics relevant to work-life balance include identifying values and priorities, creating a career matrix/timetable, family planning (e.g. family leave, dependent care), time management, burnout and managing daily struggles, work arrangements, dual-careers. In this interactive panel, a diverse group of informatics professionals will present different perspectives and discuss relevant issues, resources and recommendations related to balancing personal and family life while advancing their biomedical informatics careers. As these issues affect women and men, all informatics professionals who are interested in gaining insight about and advancing their informatics careers from various perspectives and engaging in a discussion about work-life balance issues are encouraged to attend. This interactive panel supports AMIA’s strategic directive of professional growth and leadership development of our members.

Learning Objectives: 1) Describe the issues related to work-life balance in biomedical informatics raised by scientific literature and from various perspectives including clinical, non-clinical settings and domains such as government, industry, and academia and across a wide range of career stages. 2) Describe the resources and solutions available to help caregivers achieve success both at home and in biomedical informatics professions.

Introduction
Studies of academic and industry professionals suggest that family responsibilities can have a major impact on career advancement and contribute to the salary gap. For instance, one study suggests that family formation has the “largest negative effect during the early stages of a woman’s career and that each child depresses a woman’s salary by 5%.” Another study found that women in science with children are 35% less likely enter tenure-track positions than men who are married with children. There are major gaps in research into work-life balance issues faced by informatics professionals, issues faced by the myriad family and work arrangements that exist such as single parents, minorities, LGBTQ members, male caregivers, dual career couples, super-commuters. Also, there have been few formal discussions on resources associated with success in achieving work-life balance in biomedical informatics.

Aim of the Discussion: Our aim is to facilitate a positive discussion regarding the current issues faced by male and female biomedical informatics professionals with multiple and competing life roles and to share resources, insights, and recommendations about achieving a balanced personal and family life while advancing professionally. Our panel will cover a variety of perspectives from different career stages, work settings (i.e. academic, healthcare, government, and industry), and backgrounds and will present on research, research gaps, and personal experiences,
to facilitate an interactive discussion with the audience. Examples of discussion topics and questions, in addition to those previously mentioned, include:

1. **Work-life balance issues in STEM professions identified by the scientific literature and strategies to support balance from the employer and employee perspective.** (Qing Zeng) The number of publications discussing work-life balance is increasing. About 70% of men and women in the workforce report work-life conflict. Motherhood poses additional challenges. Social and employment contexts also play an important role in work-family balance. Difficulties in work-life balance can lead to burnout and affect physical and mental health. Commonly recommended strategies include priority setting, self-assessment, support network, time management, flexible workplace and work schedules, and segmentation of work and life. No work life study has focused on biomedical informatics specifically, but research has been done in related STEM fields.

2. **Planning for and Managing Family as a Clinician Scientist and Healthcare Tech Executive** (Gretchen Purcell Jackson) Many clinicians and clinician-scientists face prolonged job-related stress across many workplace settings and there are gender differences in time spent on parenting/domestic responsibilities. For example, among 1,049 junior physician-researchers, women (vs men) were more likely (86% vs 45%) to have spouses or domestic partners who were employed full-time. Topics to be covered include considerations for, and potential solutions or resources relevant to planning for family, parental leave, caregiver guilt, work-work balance (i.e. juggling clinical, research and education responsibilities), returning to work, transitioning from academia to industry and into leadership positions and pros/cons related to work life balance for various workplace settings, and strategies for staying sane, happy and well.

3. **Work-life balance issues from the perspective of a male leader, educator, and mentor.** (William Hersh) While there are many work-life balance issues that are unique to women, some are common to all professionals such as prioritizing relationships, hobbies/outside interests, health and wellness, and avoiding burnout. Also, more men are facing the work-life balance struggle, as suggested by the National Science Foundation 1977 and 2008 surveys of dual-career couples, where stress from work-family conflict increased, from 35% to 60% in men vs 41% to 47% in women. Also, more men are taking on more domestic responsibilities, are married to, or interact with professional women. Relevant discussion topics include: How are work-life balance challenges faced by men changing? What are the common issues faced across gender/caregiver-role? What challenges are unique to dual-career professionals and related strategies and resources? How do we enable and empower mentees to build sustainable work-life balance? What are leaders and institutions doing to empower women to develop and thrive? How do we engage everyone on these issues and avoid making this a “women’s issue”?

4. **In the Trenches- new mom-new academic faculty life hacks and resources for caregivers and minorities at early career stages.** (April Mohanty) It has been said that “a female faculty member who is interested in starting a family finds that her biological clock is directly at odds with her tenure clock.” Many new mothers (or caregivers) cope with their responsibilities by “satisficing”. Relevant questions to junior faculty for discussion include: What are some examples of “satisficing”? How can junior and minority faculty develop a professional and personal environment that supports their success in their various roles as caregiver, professional, and personal life and what are some available resources? What are some time/stress saving tips for new parents?

**Intended Audience** includes all biomedical informatics professionals, including both women and men, who would like to learn about balancing multiple life roles or are interested supporting colleagues with multiple roles. This topic is timely as there is limited research on work-life balance issues in the biomedical informatics field and a growing number of potential/current caregivers are entering the workforce.

**Lesley Clack, ScD, MS** is Assistant Professor and Member of the Health Informatics Institute at the University of Georgia College of Public Health in Athens, GA. She teaches undergraduate and graduate courses across the informatics spectrum. Dr. Clack is actively involved with professional informatics associations, serving as Member on the AHIMA Informatics and Data Analytics Practice council, Member of the University System of Georgia Health Informatics Advisory Board and member of the Women in AMIA CAC. Dr. Clack will moderate the panel.

**Qing Zeng, PhD** is Director of the Biomedical Informatics Center, Professor in the Department of Clinical Research and Leadership at the George Washington University. She is an expert in research on text mining. She is also the Associate Director of the Center for Health and Aging at the Washington DC VA Medical Center. Dr. Zeng has over 20 years of experience in informatics, published over 80 peer-reviewed articles, and served as PI and Co-PI on a number of VA HSR&D, NIH, and DoD funded projects. Dr. Zeng serves as Co-Chair of the Women in AMIA CAC.
She will review the latest scientific research on work-life balance, including reported gender gaps (e.g. in compensation, tenure, publishing) in biomedical informatics and related fields.

Gretchen Purcell Jackson, MD, PhD, FACS, FACMI, FAMIA recently transitioned to a new position as Vice President and Chief Science Officer at IBM Watson Health and is an Associate Professor of Surgery, Pediatrics, and Biomedical Informatics at Vanderbilt University Medical Center since 2014. In her new role as an industry executive, she has faced new challenges in managing her family including more responsibilities and more travel for work. She has practiced as a pediatric surgeon, contributed as consumer health informatics researcher, a wife, a mother, and a stepmother. Dr. Jackson’s biomedical informatics research focuses on using technologies to empower patients and their families to take an active role in their health and healthcare. Dr. Jackson is a member of the AMIA Board of Directors and the Women in AMIA CAC. As a clinician and an executive, she will provide a unique perspective and discuss issues related to family planning, including career planning, work-work balance (clinical, research and education responsibilities), parental leave, caregiver guilt, and wellness.

William Hersh, MD, FACP, FACMI, FAMIA is Professor and Chair of the Department of Medical Informatics & Clinical Epidemiology in the School of Medicine at Oregon Health & Science University (OHSU). He is a leader and innovator in biomedical informatics in research and education. His research, in the area of information retrieval, includes over 200 scientific publications as well as the book, Information Retrieval: A Health and Biomedical Perspective, 3rd Edition (Springer, 2009). In education, he serves as Director of OHSU’s Biomedical Informatics Graduate Program, which is one of the oldest and largest in the world. Dr. Hersh is also involved in educational efforts in the physician clinical informatics subspecialty and also teaches clinical informatics to medical students, nursing students, graduate biomedical science students, and undergraduate health science students. There are four women faculty in his department who have career development (K) awards that he (and other faculty) mentor.

April Mohanty, MPH, PhD is Assistant Professor in the Department of Internal Medicine, at the University of Utah School of Medicine since 2018. She is also Health Research Scientist at the Salt Lake City VA, completed a Medical Informatics postdoctoral fellowship at the VA in 2017, and received a 5-year VA Career Development Award (a Historically Black Colleges and Universities-Research Scientist Training program) in 2016. Since 2017 she has Co-chaired the Women in AMIA CAC. As a Hispanic, 1st generation 4-yr college graduate, mother of two (toddler and newborn), and recently appointed faculty member, Dr. Mohanty will present her varied perspectives on some of the challenges and rewards related to becoming a new parent in academic and government settings as well as resources and advice for parents and minorities on navigating junior faculty member expectations.

Participation Statement I, April F. Mohanty, hereby confirm that all speakers have agreed to participate in this panel. Panelists are aware that there are no travel funds available. Panelists are also aware that the Working Groups are unable to reimburse registration costs.

Flipping Clinical Documentation on its Head

1Vanderbilt University Medical Center, Nashville, TN; 2OpenNotes/Beth Israel Deaconess Medical Center, Boston, MA; 3Stanford University School of Medicine, Palo Alto, CA; 4American Medical Informatics Association, Bethesda, MD

Abstract

Electronic health records (EHRs) have become ubiquitous tools and represent the standard of care for 96% of hospitals and 86% of ambulatory physicians in the United States. With adoption of EHRs came the promise of improved efficiency, higher quality care, and lower costs. Unfortunately, some clinicians are now spending twice as much time on documentation as they spend seeing patients, and the documentation paradigm of problem-oriented medical records is contributing to this imbalance. It is time to consider new innovations. In this panel, we present several ways that we can overturn the current paradigm, with a focus on increased readability, shareability, and information channels other than raw text. Clinical documentation serves many masters and exists within a complex regulatory environment, but we will tackle the implications of change head-on. We anticipate that this panel will be of interest to innovators and disruptors across the care continuum.

Learning Objectives: Upon completion of this panel, attendees will be able to:

- Understand why the current clinical documentation paradigm exists, and what can be done to improve it
- Enumerate some strengths and weakness of the collaborative wiki for clinical documentation
- Consider ways in which patients can interact with documentation, including co-editing
- Anticipate the role that voice-based agents will play in both the information retrieval and data creation stages of clinical care
- Name at least three examples of where visualizations can be preferable to written documentation

Panel Description

This interactive panel will present several new innovations with a common intent: changing the current paradigm of clinical documentation. Clinical documentation has been named by the National Academy of Medicine as one of the prime drivers of clinician burnout, which is estimated to affect up to 50% of those in the profession.1 The current method of encounter-based documentation is the evolution of several decades of policy, which have had the unintended effect of stymying innovation. In fact, some consider the Subjective/Objective/Assessment/Plan (“SOAP”) note introduced by Larry Weed M.D., in the late 1960’s to be the last true innovation in clinical documentation.2 In this panel we aim to turn common convention on its head through the introduction of several new innovations in this space. There will be one moderator and four speakers, as follows:

- **Jeffery Smith M.P.P.** (Vice President of Public Policy, AMIA) will moderate the panel. Jeff is responsible for planning, initiating, and managing AMIA’s overall public policy and government relations programs. Working with members, stakeholders, AMIA staff and relevant external organizations, Jeff consistently develops, communicates and disseminates AMIA’s public policy positions to advance the field of biomedical and health informatics. Specific to this panel, Jeff will discuss and field questions related to new and emerging policy directions pertinent to clinical documentation.

- **Jeremy L. Warner M.D., M.S.** (Associate Professor of Medicine and Biomedical Informatics, Vanderbilt University) will present “Collaboration, not Compendium: a Wiki-based Approach to Clinical Documentation”. In this presentation, he will introduce a new proposal for clinical documentation using the wiki format, based on a Perspective published in Academic Medicine.3
The collaborative wiki format offers many opportunities to ease the burden of documentation as well as to increase the usefulness of the recorded clinical data. Wikis support multiple authorship, have built-in features to track edits and changes, allow for contextual linkages (e.g., linking medical problems to their treatment), and support new technologies such as application programming interfaces, which allow for safe and secure exchange of information.

- **Liz Salmi** (Senior Strategist, Outreach & Communication, OpenNotes) will present “Our Health, Our Notes: Patients as Readers, Co-Authors, and Agenda Setters”. As a patient advocate and brain cancer survivor, Ms. Salmi has direct experience with the frustrations around access to notes. Once she obtained access, she became an avid reader of notes and quickly realized the benefits of reading, but also limitations in patient portal user experience. Now, through her work with OpenNotes, she is beginning to see a paradigm shift in both access and content of notes. A nascent initiative of OpenNotes, which is an international movement advocating fundamental change in the way visit notes are managed, is to put patient’s in the driver’s seat. This includes new innovations in shared note authorship, as well as pre-visit agenda setting by patients.

- **Yaa Kumah-Crystal M.D., M.P.H., M.A.** (Assistant Professor of Biomedical Informatics and Pediatric Endocrinology, Vanderbilt University) will present “Let’s not Mince Words: Voice as the Means to Read and Write Notes”. Apple has Siri, Google has Google Assistant, and Amazon has Alexa. A team at Vanderbilt University Medical Center (VUMC) led by Dr. Kumah-Crystal is creating voice-controlled virtual assistant to help people interact with electronic health records (EHR) using natural speech. They call their project VEVA, the Vanderbilt EHR Voice Assistant. VEVA represents a new way to interface with the medical record to collect and concatenate data, and in the future will also work bidirectionally as a content generator. The future of natural language processing in medicine could mean virtual assistants functioning as virtual scribes. Voice is a natural medium of communication that may help re-humanize the EHR.

- **Chethan Sarabu M.D.** (Clinical Instructor of Pediatrics, Stanford Medicine) will present “Show, Don’t Tell: How Visuals Improve Healthcare Visits”. Dr. Sarabu recently completed his fellowship in clinical informatics and his primary focus was around laying the groundwork for collaborative documentation in different ways from OpenNotes in pediatric populations to patient questionnaires populating note templates. His presentation will challenge the predominance of text-based documentation of verbal conversation. There is a need to bring more visuals into documentation, such as timelines, photographs, or even emoji to communicate information in ways that can provide rich meaning with brevity. Furthermore visuals can bring down communication barriers in populations such as children and non-native English speakers. The use of visual narrative in documentation may be especially powerful for patients with complex longitudinal diseases, as well as for those who learn best from methods other than text-based.

**Intended Audience:** We anticipate that this panel will be of interest to a wide range of individuals attending the AMIA Annual Symposium. Specifically the following: (1) Clinicians who create clinical documentation; (2) Patients who have an interests in participatory medicine including co-authorship of clinical documents; (3) Clinical researchers and informaticians interested in extracting information from healthcare data; (4) Policymakers who are considering changes to the current paradigm of clinical documentation; (5) Students and trainees interested in learning more about the past, present, and future of clinical documentation.

**Timeliness**

We feel that this panel could not come at a better time. After decades of static policies, federal agencies have recently proposed changes to the way clinicians must document care. Specifically, the Centers for Medicare & Medicaid Services (CMS) has committed to E/M documentation guideline reform, which will take effect in 2021, allowing practitioners greater flexibility to exercise clinical judgment in documentation. Further, CMS and the Health & Human Services’ Office of the National Coordinator for
Health Information Technology (IT) have published a sprawling strategy to reduce health IT-related regulatory and administrative burden. When considered alongside broader changes to the health IT landscape, these federal efforts provide stakeholders with a unique opportunity to consider alternatives to long-standing documentation dogma.

**Statement from the Panel Organizers**

Dr. Warner, the panel organizer, affirms that all panel participants have agreed to participate and have contributed to the preparation of this document (as of March 9, 2019).

The Nuts and Bolts of Sponsorship: Perspectives in Informatics

Tiffany I. Leung, MD, MPH, FACP, FAMIA¹, Marion J. Ball, EdD, FAAN, FACMI²,³, Cynthia Brandt, MD, MPH⁴,⁵, Gretchen Purcell Jackson, MD, PhD, FACS, FACMI, FAMIA⁶,⁷, Titus Schleyer, DMD, PhD, FACMI, FAMIA⁸,⁹

¹Maastricht University, Maastricht, The Netherlands; ²Center for Computational Health, IBM Research; ³Johns Hopkins University School of Nursing, Johns Hopkins School of Medicine, Baltimore, MD; ⁴VA Connecticut Healthcare System, West Haven, CT; ⁵Yale University School of Medicine, New Haven, CT; ⁶IBM Watson Health, Cambridge, MA; ⁷Vanderbilt University Medical Center, Nashville, TN; ⁸Indiana University School of Medicine, Indianapolis, IN; ⁹Center for Biomedical Informatics, Regenstrief Institute, Inc, Indianapolis, IN

Abstract

Sponsorship is important for career development, but infrequently discussed and often not well understood. Sponsors are advocates for their protégés, recommending them for promotion, connecting them with senior leaders, promoting their visibility – pulling them up the ladder with them¹. In this panel, the speakers will introduce the concept of sponsorship, its impact on careers of young, mid- and experienced informaticians, and describe their own experiences from both sides of the sponsorship relationship. The objectives of this panel are to: (1) learn the importance of sponsorship in one’s career; (2) learn how to be a sponsor or to find one; (3) share experiences with others; and (4) develop an action plan for what to do during the AMIA symposium to put into practice what is learned.

Introduction

Sponsorship is as important for career development as mentorship, but less often discussed and often not as well understood. Being a sponsor may mean being well-connected and well-established in a field and a talent scout, while being a protégé may mean being proactive, loyal, and focused on specific opportunities ², such as promotion, award nomination or recognition, and other specific episodes in career progression. Sponsors are advocates for their protégés, recommending them for promotion, connecting them with senior leaders, promoting their visibility – pulling them up the ladder with them¹,³. In essence, sponsorship aims to enhance the visibility and credibility of talented individuals⁴. There is also growing attention to the importance of diversity and inclusivity in science; sponsorship can be a pathway towards overcoming biases that disfavor individuals based on ethnicity, race, gender orientation, health or disability status, age, beliefs, religion, and other characteristics⁵,⁶. However, this also means deliberate practice of sponsorship, as a sponsor or a protégé, must be intentional and focused in order to benefit individuals and their organizations.

In this interactive panel, sponsored by the Women in AMIA Subcommittee on Awards & Leadership, the speakers will introduce the concept of sponsorship, its impact on careers of young, mid- and experienced informaticians, and describe their own experiences and lessons learned from both sides of the sponsorship relationship. The objectives of this panel are to: (1) learn the importance of sponsorship in one’s career; (2) learn how to be a sponsor or to find one; (3) share experiences with others (through small group and pair-and-share activities); and (4) develop an action plan for what to do during the AMIA symposium to put into practice what is learned (individual reflection). Audience participants’ comments and panelists’ presentation content will be synthesized and shared electronically after the session to provide a reference for sponsorship best practices.

### Research & Recognition

Sponsoring or receiving sponsorship for *research and recognition.*

**Schleyer**
10 minutes

#### Interactive Component: Pair & Share or Small Groups of 4 or less

Discuss in pairs or groups of 4 or fewer individuals one of these two perspectives:*  
- As a sponsor, *how would you identify those to sponsor?*  
- As a sponsor, *how would you know that you could be a sponsor?*  
- As a protégé (recipient of sponsorship), *how can one be proactive about connecting with a sponsor? For what purpose(s) would you look for sponsorship?*  
- As a protégé, *how would you ask for sponsorship?*

**All speakers**
10-15 minutes

#### Interactive Component: Report out

Pairs or small groups share their key discussion points, which will be compiled into a shareable document.*

**All speakers**
10 minutes

#### Job Transitions & Changes

How does sponsorship support navigating the “jungle gym” of career advancement within and between academics, industry, etc?

**Jackson**
10 minutes

#### Diversity & inclusivity

How is sponsorship as aligned with principles of diversity and inclusivity?

**Brandt**
10 minutes

#### Interactive Component: Self-Reflection

Each participant reflects on the content of the panel and write down one thing they will do during the AMIA Symposium or within the next 1 week to *seek or be a sponsor* for one of their professional goals. Goal should be specific:  
- *Who will you engage as a sponsor/protégé?*  
- *What is the aim of such sponsorship (e.g. recognition, promotion, etc)?*  
- *What action(s) will you take towards that goal? When?*

**Leung**
5 minutes

#### Closing

Moderator summary  
Open discussion, during which participants may share their self-reflection tasks or make other comments, and Q&A

**Leung**
10 minutes

* Panelists and members of the Women in AMIA Subcommittee on Leadership and Awards who are in the audience may engage the small groups also in discussion, facilitate their sharing with the larger audience.

### Possible Discussion Questions

Questions to be used as prompts for the interactive components of this panel are detailed as above.

### Panelist Biographies

**Tiffany I. Leung, MD, MPH, FACP, FAMIA** (moderator) is a U.S.-trained Internal Medicine physician, Assistant Professor and also a PhD candidate at Maastricht University in the Netherlands. Her current work focuses on implementing value-based health care at Maastricht University Medical Center +; her research examines value-based health care redesign using a systems thinking approach. Dr. Leung is also studying healthcare professionals’ competency and professionalism development in the context of system redesign, and aims to design interventions to overcome knowledge and skill boundaries among workers engaged in such work. She recently took on the role of chair of the Women in AMIA Subcommittee on Awards & Leadership, succeeding Jessie Tenenbaum, PhD, FACMI.

**Marion J. Ball, EdD, FCHIME, FHIMSS, FMLA, FAHIMA, IAHSI** is a member of the National Academy of Medicine (NAM). She currently serves on the Board of Health on the Net (HON) in Geneva, Switzerland, was elected to membership of the IBM Industry Academy. She has also served on a variety of boards in the area of health information technology: the Board of Regents of the National Library of Medicine (NLM), as President of the International Medical Informatics Association (IMIA), as a board member AMIA, CHIME, AHIMA, and Co-Chaired...
the HIMSS Board, and also served as Board Co-Chair of the TIGER Foundation. She received the Morris F. Collen Lifetime Achievement Award from ACM/AMIA, and is an honorary member of Sigma Theta Tau, the Honor Society of Nursing, and the Medical Library Association (MLA). She received the Award of Excellence, an International Medical Informatics Association (IMIA) Lifetime Achievement award. In 2017, she was recognized by HIMSS as one of The Most Influential Women in Health IT, and also named as one of the Most Powerful Women in Healthcare IT by Health Data Management. She is the author/editor of over 25 books and over 230 articles in the field of Health Informatics. Her book, Consumer Informatics, received the HIMSS Book-of-the-Year Award. Several previous editions of the nursing books have been translated into other languages.

**Cynthia Brandt, MD, MPH** is the Director for the Yale Center for Medical Informatics, Professor of Emergency Medicine, Anesthesiology and Biostatistics at Yale Schools of Medicine and Public Health, and Director of the Informatics Core for the Center of Innovation at VA Connecticut. Dr. Brandt completed a general Preventive Medicine residency at Madigan Army Medical Center in 1989 and a postdoctoral fellowship sponsored by the National Library of Medicine at Yale School of Medicine in 1997. She is board certified in Preventive Medicine and Clinical Informatics. Her research is interdisciplinary and focuses on issues related to the design, development and use of informatics tools in the domain of clinical research, as well as health services research. She is PI of the National Library of Medicine T15 Training Grant at Yale, and Co-Director of the Medical Informatics and Women’s Health Research Fellowships at VA Connecticut.

**Gretchen Purcell Jackson, MD, PhD, FACS, FACMI, FAMIA** is Vice President and Chief Science Officer at IBM Watson Health and an Associate Professor of Surgery, Pediatrics, and Biomedical Informatics at the Vanderbilt University Medical Center. She is an internationally recognized informatician and surgeon with accomplishments spanning over 25 years of. Dr. Jackson is a member of the AMIA Board of Directors. She earned her PhD in Medical Informatics at Stanford University in 1997 and held informatics faculty and leadership positions at three universities during surgical residency and fellowship. Dr. Jackson is a member of the editorial boards of the *Journal of Biomedical Informatics* and *International Journal of Medical Informatics*, and an associate editor of *Applied Clinical Informatics* and *JAMIA Open*. Her current research focuses on evaluating clinical decision support systems and empowering patients and families through health information technologies.

**Titus Schleyer, DMD, PhD, FACMI, FAMIA** is Professor of Biomedical Informatics in the Department of Medicine, Indiana University School of Medicine, as well as a Research Scientist at the Center for Biomedical Informatics at the Regenstrief Institute. Primarily funded by the National Institutes of Health, Dr. Schleyer's current research is focused on making information from various sources more accessible in clinicians' workflows, big data mining for population health management and research, developing analytics and visualizations to address the opioid epidemic, and the development of the Indiana Learning Health Systems Initiative. He co-directs (with Dr. Brian Dixon) the National Library of Medicine-funded Public & Population Health Informatics (PHI) Fellowship at Indiana University.

**Participation Statement**

All participants have agreed to take part on the panel.

**Introduction of the Topic.** A decade after the Meaningful Use Program was first established, over 95% of inpatient settings use certified electronic health records (EHRs) and over 80% of office-based practices use certified EHRs. We are now entering the next phase of health IT development, as a clear pathway toward interoperability among different systems emerges—a universal, standards-based, public application programming interface (API). The 21st Century Cures Act, a bill that enjoyed strong bipartisan support which was signed into law at the end of 2016, requires that certified health IT products have an API that allows all of a patient’s health information to be accessed, exchanged, and used “without special effort.” This requirement follows from years of advances and real world implementations under the SMART on FHIR project and development and maturation of the Fast Health Interoperability Resources (FHIR) standard.

The panel is extremely timely—two new HHS draft rules were recently released, following on from the Cures Act, firmly establish FHIR as the lingua franca for health data representation and SMART as the API between health data in certified systems and the innovators that use those data. At the time of this panel, the public comment period will have ended and final rule-making will be in process.

Under the Argonaut consensus working group, all the major EHR vendors have implemented the SMART API in their products. To date, the two most impactful SMART on FHIR implementations are the Apple Health App, which connects to hundreds of health systems via the SMART API, and the CMS Blue Button 2.0, which uses the SMART API to provision claims data to its beneficiaries. The total number of SMART apps in the various public and commercial app galleries, however, have been relatively modest.

Possibilities for the resulting ecosystem, and the dynamics underpinning it, are just beginning now to come into focus. It is widely believed that genomic medicine and artificial intelligence will enter patient and physician workflows through SMART on FHIR apps. With the regulated uniformity in how clinical data are represented and how apps connect to health IT, we expect that billions in capital will be invested in extending the digital, AI, and genomics capabilities of healthcare well beyond where we are today.

**Intended Audience.** The panel is directed broadly at the AMIA membership, especially those focused on biomedical informatics from a clinical translational perspective. We expect it will be of particular interest to those engaged in genomic medicine, machine learning, decision support, app development, enterprise IT, and EHR innovation.

**Aim of the Discussion.** This panel brings together leaders representing public API development, the government agency spearheading health IT interoperability, the two largest EHR vendors, as well as relatively new entrants into the space—major cloud services companies. This interactive discussion will engage the audience in exploration of barriers to and opportunities for creating a burgeoning health apps economy, one that accelerates the translation of innovation to care, well established in provider workflows.

**Specific Contribution of Each Speaker.**

The moderator, and each speaker will offer framing remarks for 5 minutes and then engage with the audience in a brisk, interactive, moderated discussion. The moderator will keep the flow moving fast, alternately posting questions to the panelists and taking questions from the audience.

**Ken Mandl,** Director of the Computational Health Informatics Program at Boston Children’s Hospital and a founder of the SMART Health IT project, will moderate the panel. He will begin with a brief overview of the current state and present a scenario of a hospital attempting to both purchase third party apps, but also to internally develop and deploy SMART apps. The use case will outline opportunities to use native EHR FHIR APIs as well as “side car” approaches. Challenges to physician workflow, app validation, and commercial success of third party apps will be highlighted.
Don Rucker, National Coordinator of Health Information Technology, will discuss the Administration’s strategy in promoting interoperability through the Cures API and information blocking provisions.

Aashima Gupta, Director of Global Healthcare Solutions for Google Cloud, will discuss their FHIR cloud strategy, including its offering of the SMART API. She will address approaches and challenges to offering secure, turnkey solutions for API-enabled FHIR servers.

Isaac Vetter, Integration Lead for the Epic App Orchard will present current and upcoming technologies which enable healthcare apps, considerations for protecting security & privacy and the evolution of Epic's App Orchard as shaped by health system & developer feedback as well as regulation.

Josh Mandel, Lead Architect for SMART Health IT and Chief Architect at Microsoft Healthcare will discuss the challenges of scaling an app ecosystem across Health IT, especially from the perspective of open specifications and standards. He will describe challenges of consensus, outlining the role of open source projects; small communities focused on specific problems; and the wider, formal standards development process. He will describe the pivotal role of open standards in Microsoft's healthcare cloud computing strategy.

Matt Obenhaus, Director and Solution Executive for Open Developer Experience at Cerner, will discuss the Cerner App Gallery and evolving models to encourage developers to create value. He will also discuss a roadmap for exposing new data types across the SMART API on Cerner.

Expected Discussion. At a pivotal time for change and progress, the audience will be brought to the cutting edge of progress and decision making in the largest health IT companies in the world, and in the federal agency that both promotes health IT and regulates it. Who will produce the next generation of EHR-connected apps. Where will the now regulated APIs sit? How will workflows develop across EHRs and Cloud hosted side cars? Audience members will no doubt be key informants to the discussion as many will have used the open APIs, deployed apps, and begun to creatively use the cloud services.

Sample topics for discussion:
- Will EHR vendors rely on “side car” FHIR servers with near real time data for app functionality as well?
- What are plans for triggering decision support, e.g., CDS Hooks?
- What is the vision for app reusability—an app written once will run anywhere in healthcare?
- What health IT services do the cloud vendors envision offering?

Panel Organizer Statement. All participants have agreed to take part on the panel.
Results from a Multi-stakeholder Action Plan to Better Leverage Patient-centered Clinical Decision Support in Addressing the Opioid Misuse Crisis

Jerome A. Osheroff, MD\textsuperscript{1}, Craig Robbins\textsuperscript{2}, MD, MPH, Brian Alper, MD, MSPH\textsuperscript{3}, David Little, MD, MS\textsuperscript{4}, Edwin A. Lomotan, MD\textsuperscript{5}
\textsuperscript{1}TMIT Consulting, LLC, Naples, FL; \textsuperscript{2}Kaiser Permanente, Denver, CO; \textsuperscript{3}EBSCO Health, Ipswich, MA; \textsuperscript{4}Epic, Verona, WI; \textsuperscript{5}Agency for Healthcare Research and Quality, Rockville, MD

Abstract

Over 50 individuals from many stakeholder groups convened in 2018 to develop and begin executing an action plan to improve pain management, opioid use, and opioid use disorder treatment through more widespread and effective patient-centered clinical decision support (PCCDS). The opioid action plan (OAP) includes five consensus, highly desirable opioid-related future vision scenarios for PCCDS-enabled care. The scenarios reference 19 PCCDS interventions that are not widely or well implemented today but could be highly valuable. The OAP includes recommendations for various stakeholder groups to make the future vision and underlying interventions widely implemented. Most importantly, the OAP includes over two dozen examples of specific steps toward the future vision that organizations have taken as a result of contributing to the OAP. During this panel, the OAP lead author will outline the future scenarios and recommendations, and 4 individuals who helped develop the plan will describe OAP-driven actions they have taken and/or implications for their work with healthcare systems, CDS suppliers, electronic health record vendors, and government agencies. Half the session will be interactive discussion between panelists and audience members to surface opportunities to further accelerate PCCDS-enabled pain and opioid management within and across organizations.

Introduction

The United States is experiencing an opioid misuse and overdose epidemic that results in staggering costs, morbidity, and mortality and has caused a national crisis\textsuperscript{1}. Poorly managing pain - a highly prevalent and distressing symptom - is a key underlying driver for this epidemic\textsuperscript{2}, as is the underuse of effective treatments for opioid use disorder (OUD)\textsuperscript{3}.

Evidence-based guidance is available for pain management, opioid use and OUD treatment\textsuperscript{4}, though approaches to putting this information into practice are suboptimal. Clinical decision support (CDS) can enhance health-related decisions, actions and outcomes by delivering the right information (e.g., evidence-based guidance and tools) to the right people, in the right formats through the right channels at the right times\textsuperscript{5}. CDS strategies enabled by modern healthcare information technology offer many targeted opportunities to provide information when, where and how it’s needed to optimize patient and care team decisions, actions and partnership.

“Patient-centered Clinical Decision Support” (PCCDS) is a CDS subtype that focuses on highly patient-focused strategies, interventions and tools for enhancing communications, decisions and actions by and between patients and clinicians\textsuperscript{6}. For example, PCCDS interventions for pain and opioid-related care include tools such as smartphone apps that patients can use to help them track and manage pain and function according to a care plan developed with their care team, shared decision-making tools for selecting pain management strategies, and screening tools to detect patients at high OUD risk.

A PCCDS Opioid Action Plan (OAP) was produced as a central 2018 project of the Patient-Centered Clinical Decision Support Learning Network (Learning Network), an Agency for Healthcare Research and Quality (AHRQ)-funded initiative to more fully leverage PCCDS in making care more patient centered while broadly improving care delivery and outcomes\textsuperscript{7}.

Developing and Executing the PCCDS OAP

The Learning Network chartered an OAP Workgroup (OAPWG) in April 2018 to develop the OAP. This group grew to include over 50 individuals from many stakeholder groups and met by teleconference 17 times between April and December 2018. They also worked on OAP elements using online collaboration tools (Google docs) and the OAP was a focus of the Learning Network’s Annual Meeting in October 2018. Figure 1 below illustrates the various stakeholder groups and individual organizations represented in the OAPWG or that otherwise supported OAP development.
Figure 1: Stakeholder Groups and Interactions (Shaded boxes represent groups most directly involved in realizing the future vision scenarios; CDO=care delivery organization, PHM=population health management systems, CDSS=clinical decision support systems; EHRs=Electronic Health Records)

Key OAP elements the OAPWG developed included a consensus future vision of PCCDS-enabled pain management, opioid use, and OUD treatment; an initial survey of current resources and activities that could be leveraged to achieve the future vision; recommendations for different stakeholder groups to drive progress toward this vision; and actions triggered by the OAP development process that begin implementing these recommendations.

Figure 2 below outlines the topic areas for the five consensus future vision scenarios that the OAPWG developed.

Figure 2: Overview of Future Vision Scenario Focus Areas

The scenarios are each about a page long and outline PCCDS-enabled workflow and information flow that follows patients across settings – e.g., self-care at home, office visit, and hospitalization. The scenarios contain personas with different patient ages, genders, and clinical conditions. Even though they are specific in this way, the scenarios exemplify very broad opportunities for PCCDS to better support pain management, opioid use and OUD treatment.

As part of outlining desirable workflows and information flow for each clinical scenario, the OAPWG defined specific PCCDS interventions that could be used to implement these enhanced care processes. These interventions include care plan development and tracking tools, condition-specific pain/opioid-related order sets, OUD detection and notification algorithms, dashboards outlining patient-specific pain management treatments and results, shared decision-making tools, and many others. The scenarios outline where and how these interventions support care.

Another key OAP element is recommendations for various stakeholder groups (i.e., as outlined in Figure 1) to make the future scenarios – enabled by the underlying PCCDS interventions - widely implemented and highly valuable. These recommendations include steps to ensure that health IT suppliers provide the needed interventions, that providers implement these tools successfully in workflow to realize the future scenarios, that patients likewise use the interventions independently and with their care teams to achieve the desired processes and outcomes, and that all the other stakeholder groups support these core activities as appropriate.
Most importantly, the OAP was developed in an action focused way, and it includes over two dozen examples of specific steps that organizations have taken as a result of their engagement in developing the OAP to drive progress toward implementing the recommendations and achieving the desired future vision scenarios.

**Proposed Panel**

The goal of this panel is to build on the valuable dialog, activities, and collaboration reflected in the OAP to benefit more organizations from this work and accelerate widespread progress toward the future vision. Annual Symposium attendees typically reflect many of the stakeholder groups listed in Figure 1, and this panel is aimed at such participants that have pain management, opioid use and/or OUD treatment as a focus.

After a brief OAP overview, JAO will describe the future vision scenarios and underlying PCCDS interventions to stimulate attendees to reflect on whether/how their professional and organizational goals can be supported by leveraging them as guideposts for their efforts. He’ll also briefly summarize the recommendations and OAP-driven actions to implement the scenarios as a model for attendee action. CR will describe actions that Kaiser Permanente has taken to execute the OAP, e.g., sharing tools they’ve developed and exploring collaborations with other panelists to develop new, integrated PCCDS tools to realize the future scenarios. BSA will describe new offerings that EBSCO created as a result of his OAPWG participation – i.e., a new patient-facing tool with evidence-based guidance for selecting between opioid and nonopioid alternatives for common chronic pain scenarios. BSA will share implications more broadly for CDS suppliers and international consortiums working on standards for interoperability. DL will describe how Epic has used the future scenarios to inform its product development and implementation support team efforts to provide more powerful CDS opioid-related CDS and ensure clients fully leverage the pertinent capabilities already available. He will also share activities and implications more broadly for EHR vendors and the EHR Association (EHRA). EAL will describe how the OAP fits in AHRQ’s CDS portfolio and implications for OAP execution.

The panel’s second half will be devoted to interactive discussion among panelists and audience members to surface opportunities to further accelerate PCCDS-enabled pain management and opioid use within and across individual organizations. Prompts for this discussion include: Do the future scenarios seem valuable for your efforts? If so, how? Are there ways your organization can benefit from actions/collaborations the panelists pursued? If so, what/how? How could any subsequent activities to execute the OAP most benefit your organization? Are there ways you or your organization could contribute to further OAP execution?

All participants have agreed to take part in the panel.

**Conclusion**

Patient-centered clinical decision support is a promising but underutilized approach to addressing the national opioid misuse and overdose crisis. A broad, multi-stakeholder initiative has outlined a shared future vision for broader and more effective PCCDS use for this target, and many organizations have already started implementing recommendations for achieving this vision as part of developing the OAP. This interactive panel will build on this work and leave attendees with valuable insights and opportunities to advance their efforts in this area.

Abstract:

Advances in the understanding of oral and systemic connections and a paradigm shift in delivering person-centered care has created a demand for incorporating principles of interprofessional education and healthcare delivery. Historically, dentistry and medicine have evolved as separate domains, and this has influenced education and healthcare delivery. Lack of interprofessional training during professional school critically influences practice patterns of dental and medical providers. Interprofessional health information exchange and integrated medical-dental electronic health records are critically vital to integrated care delivery. The lack has raised challenges as well as opportunities for establishing informatics infrastructure to support interdisciplinary care delivery in the context of oral-systemic health conditions. The purpose of this panel is to provide considerations for the establishment of informatics infrastructure and required training of the integrated care delivery team. Our goal is to achieve a roadmap for alignment of informatics and interprofessional efforts to maximize the broad positive impact on continuity of care.

Brief description of each panelist’s presentation:

- **Dr. Chad Novince**, “Need for the development/integration of interprofessional curriculum across medical schools and dental schools”
  This presentation will focus on how interprofessional healthcare knowledge and patient care experiences during professional school critically influence whether dentists and physicians will practice interprofessional healthcare post training. Interprofessional medical – dental curriculum could be designed in various formats, but importantly should include both didactic and clinical interprofessional training experiences.

- **Dr. Amit Acharya**, “Beyond the Integrated Medical-Dental Electronic Health Records”
  This presentation will discuss how a Healthcare System in Wisconsin has applied an integrated medical-dental EHR platform to solving many medical-dental practice divide. The topics will include a, point of care clinical decision support to better manage conditions with oral-systemic associations, b, secondary use of clinical data for
research: how routinely collected clinical data from the integrated medical-dental EHR platform is enabling research to better understand the several oral-systemic associations, and c. development of quality improvement measures to better support the management of conditions with oral and systemic associations.

- **Dr. Muhammad Walji. “Towards a Person-centered care Learning Health System”**
  This presentation will discuss the concept of building a sustainable dental learning health system focused on continuous quality improvement and providing patients with safe and effective oral healthcare. The presentation will highlight how a group of large academic health systems are working together to setup a practice-level learning health system supported by an effective informatics infrastructure, interprofessional collaborations, relevant data governance and a culture allowing for self-reflection and learning.

- **Dr. Thankam Thyvalikakath. “Leveraging patient information through regional health information exchange to improve oral health”**
  This presentation will discuss the process of matching dental patient data with their medical record data available through a regional health information exchange to promote continuity of care across medical and dental care settings. Dr. Thyvalikakath will describe through a case study that determined the Sjögren’s Syndrome diagnosis of dental patients and the influence of dental clinicians’ awareness of their patients’ diagnosis on managing oral health.

**Relevance of topic and anticipated audience**

The oral and systemic health has been a priority area for the NIH National Institute for Dental and Craniofacial research. Informaticians and data scientists will need to learn what opportunities exist to improve health by integration of dental and health medical record data. Healthcare providers including dental and medical providers will need to expand their understanding of the impact of their practice on other areas of their patients’ health and how to improve their own treatment decisions by holistic understanding of their patient. Educators will learn how to incorporate interprofessional education paradigms to cross-train physicians and dentists in essential concepts of both areas. Finally, the researchers will learn about the resources that can drive further understanding between oral and systemic health.

**Discussion questions:**

1. How does interprofessional education influence practitioners’ delivery of care?
2. What translational value does an integrated care system hold?
3. What are the technical and non-technical barriers for implementing a learning health system?
4. Why is it important to practice in an interdisciplinary environment?

**Learning Objectives:**

1. Identify how to capitalize on the opportunities for developing an integrated medical-dental curriculum that will support interprofessional healthcare delivery.
2. Understand and recognize the potential application of an integrated medical-dental EHR platform in solving several medical-dental delivery system challenges and further identifying translational areas for establishing integrated models of care.
3. Understand the key components of developing a multi-institutional learning health system.
4. Learn the potential of utilizing regional health information exchange to enhance continuity of care across dental and medical care settings.

The organizer members confirm that all participants have agreed to take part on the panel.
Creating a Learning Health System for Measurement of Diagnostic Safety: Emerging Implications for Health Information Technology

Hardeep Singh, MD, MPH1, Dean Sittig, PhD2, Ashley N.D. Meyer, PhD1, Traber D. Giardina, PhD, MSW1 and Divvy Upadhyay, MBBS, MPH3

1Michael E. DeBakey Veterans Affairs Medical Center and Baylor College of Medicine, Houston, TX; 2University of Texas Health Science Center, Houston, TX; 3Geisinger, Danville, PA

Abstract

Diagnostic errors pose a significant threat to patient safety.1 Learning health systems (LHS) provide opportunities to investigate, monitor, and measure diagnostic errors in real time within a healthcare system. A multidisciplinary panel will discuss emerging priorities and research opportunities related to health information technology (HIT)-enabled measurement of diagnostic errors, now considered the next big patient safety challenge.2 This session will explore how to use multiple sources of data from the health system (electronic triggers), providers, and patients, to identify and analyze missed opportunities in diagnosis. These data can be used to understand how health systems can learn and enhance the safety and accuracy of the diagnostic process. The learning objectives of this panel include: 1) how HIT-enabled health care organizations can become LHS for improving diagnosis; and 2) how informaticists can help implement pragmatic approaches to measure and understand diagnostic errors and engage in development of institutional infrastructure and feedback processes to promote individual and organizational learning.

Panel Description

Diagnostic errors affect at least 5% of US adults every year,3 leading to an estimated 40,000-80,000 deaths yearly. Yet, learning health systems approaches for investigating causes and potential solutions to diagnostic error are underdeveloped. Measurement is the first step to understanding the problem scope. The National Academy of Medicine’s 2015 report, Improving Diagnosis in Health Care,1 recommended measurement strategies that use HIT and involve both patients and health care professionals. In the last decade, research in both learning health systems and informatics have advanced the science of measurement and the time to engage AMIA audience is ripe.

This panel will take a deep-dive into HIT-based measurement methods and concepts, and current gaps in measurement related to diagnostic quality and safety. This will provide a multidisciplinary perspective into what challenges and opportunities others might encounter as they attempt to delve into the messy world of diagnostic error research, implementation and improvement activities. Because diagnostic quality and safety is still an emerging area of measurement, we will discuss current informatics research and potential measurement strategies in the three broad domains: provider/care team perspectives on use of HIT tools to find and reduce diagnostic errors; health care delivery system and policy perspectives aimed at using HIT to measure, monitor, and intervene to prevent diagnostic errors; and patient/family/caregiver perspectives on use of HIT to improve communication with providers and health systems about diagnosis-related care gaps. We will include discussion of studies related to activating the patient’s role in monitoring the diagnostic process. Strengths and weaknesses of various HIT-enabled measurement methods used in diagnostic safety research will be discussed, along with the importance of multidisciplinary research, the triangulation of research findings and methods, and partnering with clinicians, patients and health systems. We will also introduce more audience and panel interaction by using an audience response system called Slido, which would generate not only questions but also comments to address in Q&A. This content, as well as the interactive methods for delivering it, will contribute to more discussion, debate and audience engagement.

Panel Members

Hardeep Singh, MD, MPH (moderator, organizer, and panelist – 10 minutes) will start off the panel by introducing the panelists and the topic including its greater significance and context in the current healthcare landscape. Dr. Singh will also describe the rationale and motivation for bringing this diverse panel together.

Then, Dr. Singh will provide an overview of systems-based methods to measure diagnostic errors. He will discuss use of trigger tools to mine patient data to identify signals indicative of potential errors or adverse events. He will discuss the use of validated electronic trigger algorithms that analyze electronic health record (EHR) data to identify patients with potential diagnostic safety concerns. A newly developed data mining and knowledge discovery framework, the
Safer Dx Trigger Tools Framework, will be used to illustrate the application of electronic algorithms to identify targets for improving diagnosis.

Ashley N.D. Meyer, PhD (panelist– 10 minutes) will discuss provider-based measurement methods. She will discuss using diagnostic performance measures and other data to create and deliver actionable feedback to clinicians, allowing them to learn from and improve upon their diagnostic performance. Potential reluctance of clinicians to receive diagnostic performance feedback and other potential issues will be discussed, along with potential recommendations for providing feedback in a way that improves diagnosis and harmonizes with a learning health system.

Traber D. Giardina, PhD, MSW (panelist– 10 minutes) will discuss patient-based measurement methods. She will describe the value of learning from patient/family/caregiver reports of adverse events and using patient experience data to supplement current patient safety initiatives. She will discuss emerging challenges in this area and describe recently used methods for examining diagnostic errors from the patient perspective, including incident reporting and patient complaints. Dr. Giardina will discuss recent evidence from a patient-focused study and highlight possible measurement strategies that include the use of HIT to effectively capture patient experiences.

Divvy K. Upadhyay, MBBS, MPH (panelist– 10 minutes) will discuss challenges and barriers to LHS approaches in HIT-related measurement. Discussion will include early lessons from the Safer Dx Learning Lab, a unique partnership that uses multiple sources of data from the health system (risk management, electronic triggers), providers and patients to identify and analyze missed opportunities in diagnosis. The lab aims to understand how health systems can enhance the safety and accuracy of the diagnostic process and involves a close partnership between multidisciplinary diagnostic safety researchers, a pioneering health system, and a Safer Dx Researcher in Residence based at the health system.

Dean Sittig, PhD (discussant– 5 minutes) will put all the presentations in context of health care systems that now have access to increasing amounts of longitudinal electronic clinical data. He will discuss how there is an unprecedented opportunity to implement new measurements to identify risks and events related to the diagnostic process. He will use some of the audience responses to frame his comments.

Panel members represent a diversity of people, thought, expertise, and experience.

Topic Rationale
The session will focus on the intersection between informatics, patient safety and diagnostic accuracy and discuss implementation of recommendations and innovations to understand and improve diagnostic safety. It will thus be of interest to any informaticists with interest in using HIT to prevent diagnostic harm, a high-priority patient safety challenge for clinicians, health care organizations and policy stakeholders.

Over a period of about 45 minutes, moderated audience interactions will explore questions related to:

1. What are the most common measurement challenges encountered in using LHS approaches to improving diagnosis?
2. What types of experiences have audience members and their organizations had with overcoming measurement issues, including access to EHR data warehouses to develop algorithms to identify patients with quality and safety issues?
3. What types of methods and models are most useful in HIT-enabled measurement of diagnostic error from systems, providers and patients? How have audience members used EHR data in measurement of communication or diagnosis-related care gaps?
4. How can application of electronic health record (EHR)-based triggers be used to improve measurement of diagnostic safety? How do we encourage health systems and CMIOs to help perform measurement related to diagnostic safety in the absence of any incentives and in the presence of so many competing priorities?
5. How can a measurement approach that uses a specific set of diagnostic safety triggers be implemented in an organization using EHRs? Who would be the key stakeholders? How will data be analyzed and who would the data be communicated to? What sort of dashboards may be useful? How can better feedback systems to clinicians be better developed?
Participation statement
All proposed panelists are aware of this panel submission and have agreed to participate in the panel.

Panel Participant Details

- **Hardeep Singh, MD, MPH** is Chief of Health Policy, Quality & Informatics Program at the VA Center for Innovations in Quality, Effectiveness and Safety (IQuESt), a practicing internist at Michael E. DeBakey VA Medical Center and Professor of Medicine at Baylor College of Medicine.
- **Dean Sittig, PhD** is a professor of biomedical informatics at the University of Texas Health Science Center in Houston, TX. Dr. Sittig will be one of the discussants.
- **Ashley N.D. Meyer, PhD** is a cognitive psychologist and a VA funded health services researcher and career development awardee at IQuESt in Houston, TX.
- **Traber D. Giardina, PhD, MSW** is a patient safety researcher and an AHRQ funded K01 awardee. She is an Assistant Professor at Baylor College of Medicine in Houston, TX.
- **Divvy K. Upadhyay, MBBS, MPH** is the inaugural Researcher-in-Residence of the Safer Dx Learning Lab and scientist in the Division of Quality and Safety at Geisinger.

2) How informaticists can help implement HIT-based pragmatic approaches to measure and understand diagnostic errors and engage in development of institutional infrastructure and feedback processes to promote individual and organizational learning.
**Dissemination of Tuberculosis Clinical Evidence - An Application of Network Analysis to Publicly Available Resources**

Meredith Abrams, MS, MPH; Dongwen Wang, PhD  
Biomedical Informatics, Arizona State University, Scottsdale, AZ

**Abstract**

Effective dissemination of Tuberculosis (TB) clinical evidence to healthcare providers is essential to address this pandemic. To identify, organize, and aggregate online TB information resources, we analyzed the websites of four CDC-funded TB Centers of Excellence (COE), identified the hosted resources, examined the outward linkages, and collected the external resources. We obtained 154 primary resources from TB COEs and 1521 linkages to external resources. We leveraged a network analysis approach to construct resource networks at the individual resource and parent site levels. We computed the degree of connectivity and PageRank for each node in the networks. Based on these analyses, we successfully identified important TB information hosting sites beyond the four TB COEs and individual TB resources widely cited. The initial results indicate that it is promising to use network analysis approaches to identify online clinical information resources. The generalizability of this approach needs to be examined in future research.

1. **Introduction**

One-fourth of the world’s population is estimated to be infected with Tuberculosis (TB)\(^1\). Quick dissemination of TB clinical research is imperative to minimize the impacts of this disease. TB testing and treatment recommendations are often complicated due to the nature of the disease and the dependence on a patient’s pre-existing medical conditions. Clinical guidelines for TB can become very long, complex, and arduous for healthcare providers to understand, to implement, and to adhere to\(^2\). To address these challenges, various online resources and tools have been created to facilitate TB clinical education and patient care through clinical decision support.

The Centers for Disease Control and Prevention (CDC) is the prevailing authority in the United States for development and dissemination of clinical evidence for public health. CDC has funded four regional Centers of Excellence (COE) for TB Training, Education, and Medical Consultation: (1) Curry International Tuberculosis Center (CITC); (2) the Global Tuberculosis Institute (GTI); (3) Heartland National Tuberculosis Center (HNTC); and (4) Southeastern National Tuberculosis Center (SNTC)\(^3\). The missions of these TB COEs are: “increasing human resource development through education and training activities” and “increasing the capacity for appropriate medical evaluation and management of persons with TB disease and latent TB infection through medical consultation”\(^4\). To serve for these missions, the four COEs have accumulated a variety of online TB information resources. Many of these online information resources are inter-connected through hyperlinks (for webpages) or citations (for documents).

Analyzing the linkages among the existing internet-based resources is a hot research topic in computer science. A popular research method is network analysis, which “can help in identifying the underlying network of relationships in a collaboration that people rely on to find information and solve problems”\(^5\). Network analysis assists in delineating the underlying structures within organizations or, in the case of online information, identifying effective approaches for resource dissemination\(^6\). It can also be utilized as “an invaluable tool for visualizing the structure of a collaboration and in identifying key roles, information flows and collaboration”\(^6\). Yet, few studies have leveraged network analysis to determine potential key sites of online information resources for specific clinical domains or diseases\(^6\).

The primary aim of this research is to collect, organize and aggregate online TB information resources. The secondary aim of this study is to identify the critical online TB information resources and their hosting websites through network analysis. The overarching goal of our work is to develop effective approaches to disseminate TB clinical evidence.

2. **Methods**

2.1 **Collection of Online TB Resources**

To identify the available online TB resources, we reviewed the websites of the four regional TB COEs for publicly available resources. Each TB COE maintains on its website a resource section that contains a list of materials for healthcare providers to utilize in practice.
2.2 Identification of External Resources through Outward Linkages

We reviewed the “outward linkages” from each TB COE’s website to identify the linked resources. For this purpose, a co-author (MA) evaluated each page from the websites of the four TB COEs and assessed all outward hyperlinks from the webpages and references from the documents to identify the external resources.

2.3 Analyses of TB Resources and Linkages

We analyzed the identified TB resources and linkages with respect to the following characteristics:

1) Format of Resource
We analyzed the format of the linked resources and identified the specific types of resources such as webpages, pdf documents, and multimedia objects (for example, videos).

2) Content of Resource
We reviewed and recorded the specific content of each linked resource to identify the detailed information provided.

3) Category/Theme of Resource
We catalogued the linked resources into specific themes. These themes were derived from a detailed review of the content of each target resource. For example, the theme “medication administration” includes all resources that contain information about medication injections or specific antibiotic instructions.

4) Linkage Context
We assessed the context for each outward linkage to determine the contextual clues of a linkage from a hosting webpage to a target resource.

5) Parent Site of Target Resource
For each target resource, we recorded the information of its parent website. This analysis aimed to identify the organizations that sponsor the target resources.

2.4 Construction and Analysis of TB Resource Network

We constructed the TB resource networks on two separate levels:

1) Individual Resource Level
We treated each linked resource as a node. We treated a linkage (hyperlink or citation) from a resource A to another resource B (webpage, document, or multimedia object) as a directed edge from node A to node B. Each referral to a target resource counted as a single instance. If a resource A is linked to the same target resource B multiple times, the total number of the linkages was assigned as the weight of the directed edge from A to B.

2) Parent Site Level
We treated each parent site as a node. We treated a linkage (hyperlink or citation) from any resource on parent site A to any target resource on parent site B as a directed edge from node A to node B. If a parent site A is linked to a parent site B multiple times, the total number of the linkages was assigned as the weight of the directed edge from A to B.

With the TB resource network constructed, we computed the following measures at both the individual resource and parent site levels for network analyses:

1) Degree of Connectivity
At the individual resource level, we calculated the degrees of connectivity to identify the number of inward and outward linkages for each linked resource. The degree of connectivity is defined as the “the number of nodes that a focal node is connected to, and measures the involvement of the node in the network”7. For this study, out-degree was calculated as the number of outward linkages from a specific resource, whereas in-degree was calculated as the number of inward linkages to that resource. The total degree was calculated as the sum of the in- and out-degrees.
At the parent site level, we treated each parent site as a node and calculated the in-degree and out-degree based on the linkages between the sites. Since we identified all the resources through the outward linkages from the four TB COEs (see Sections 2.1 and 2.2), only those four TB COE sites have an out-degree. Meanwhile, all the identified resources have an in-degree. We therefore focused on in-degree for the analysis at the parent site level.

2) PageRank

The PageRank measure was originally developed by Google as a means to indicate the “importance” of a single webpage. In network analysis, “PageRank can be thought of as a model of user behavior”8. This model identifies the probability that a random user transitions from one page to another and thus gives a score of “importance” calculated as a probability to each page in the network.

The calculation of PageRank for an example page “A” is based on the following formula:

\[ PR(A) = (1-d) + d \left( \frac{PR(T_1)}{C(T_1)} + ... + \frac{PR(T_n)}{C(T_n)} \right) \]

Here \( T_1 \) to \( T_n \) are all the other webpages with hyperlinks pointing to \( A \), \( C(T_i) \) is the count of hyperlinks from webpage \( T_i \) to \( A \), where \( d \) is defined as a damping factor, set between 0 and 1, to indicate the probability a user continues to browse webpages following a hyperlink. A common default value for \( d \) is 0.85, which was used for this study8. We utilized a software package for network analysis, Gephi (version 0.9.2), to calculate the PageRank for each individual resource and parent site.

2.5 Visualization

Visualization is an intuitive approach to allow direct observation of the structure and other characteristics of a network. For this study, we leveraged the Gephi software package for visualizations.

3. Results

3.1 Online Resources Published by the Four TB COEs

Over the period from February 2018 through December 2018, we analyzed a total of 154 online resources published by the four TB COEs. A majority of these resources (133, 86.4%) were downloadable PDF documents or informational webpages. The remaining 21 (13.6%) resources included multimedia files, toolkits, and continuing medical education (CME) courses. With regard to the topics and prevailing themes of the resources, we identified 29 (18.8%) patient education materials, 19 (12.3%) geographic guidance for clinicians, and 13 (8.4%) for cultural competence training. Among the identified resources, 123 (79.9%) included the date for original publication or revision, ranging from 2001 to 2017. In terms of the size of the materials, the PDF documents ranged from 1 to 326 pages (on average 33 pages), and the multimedia files ranged from 31 seconds to 85 minutes (on average 28 minutes and 29 seconds). A summary of the identified TB resources and their catalogue is shown in Table 1.

3.2 Identification of Outward Linkages

We recorded a total of 1521 outward linkages from the 154 resources identified. The top linkage contexts included 494 citations (32.48%), 359 referrals for detailed information on specific topics (23.60%), 307 links to patient appropriate educational resources (20.18%), 270 general resources such as printable documents or videos (17.75%), and 29 provider education materials (1.91%). The top linkage topics included materials related to improving clinician’s cultural competency (521, 36.28%), general TB information (254, 17.69%), TB/HIV coinfection (112, 7.80%), TB medication (88, 6.13%), and TB directly observed therapy (84, 5.85%). The parent sites with the most linked target resources included CDC (8.42%), CITC (5.98%), World Health Organization (WHO) (5.92%), SNTC (3.88%), GTI (3.74%), EthnoMed9 (2.43%), and the United States Department of Health Services (USDHS) (1.97%). The details of the outward linkage metrics are shown in Table 2.

3.3 Network Analysis - Degree of Connectivity

At the parent site level, we recorded an out-degree of 170 for SNTC, 113 for CITC, 38 for GTI, and 30 for HNTC. The in-degree of the four TB COEs is between 3 and 4, and the total degree ranges from 33 to 174. The details of this analysis are shown in Table 3.

After combined all the resources from the four TB COEs and other organizations, the top parent sites based on the in-degree are: SNTC, GCI, CDC, WHO, Management Sciences for Health, HNTC, CITC, University of California San Francisco, EthnoMed, Find TB Resources, TB Controllers of America, Diversity Rx, and Stop TB Partnership. The remaining parent sites had an in-degree below 3. The detailed result of this analysis is shown in Table 4.

#### 3.5 Visualizations

Visualization of the TB resource network based on the PageRank of parent site is shown in Figure 1. A parent site with a higher PageRank is presented as a node with a larger size. The thickness of an edge indicates the weight of that edge. The top 10 parent sites and all four TB COEs are pinpointed in Figure 1.

Visualization of the TB resource network based on the PageRank of individual resource is shown in Figure 2. Resources hosted under a top-ranked parent site are presented as nodes in the same color. A resource with a higher PageRank is presented as a node with a larger size. The thickness of an edge indicates the weight of that edge. The details of a specific top-ranked individual resource is zoomed at the lower-right corner of Figure 2.

![Figure 1. Visualization of the TB Resource Network Based on the PageRank of Parent Websites](image-url)
4. Discussion

In this study, we assessed the existing web-based TB resources and their linkages. For this purpose, we started from the websites of the four national TB COEs and identified additional resources through hyperlinks and citations. We examined each resource to record its format, content, and theme. This analysis provided important information to understand the structure of online resources, the characteristics of these resources, and the potential strategies for their dissemination, which are essential for biomedical informatics research.

By leveraging network analysis approaches and the associated software tools, we constructed TB online resource networks at both the individual resource and the parent site levels. In particular, we identified major TB resource hosting sites beyond the four TB COEs, such as CDC, WHO, Management Science for Health, University of California at San Francisco, TB Controllers of America, Diversity Rx, and Stop TB Partnership. While sites like CDC and WHO are well known for their informational resources, this analysis identified less-known websites, such as EthnoMed and Diversity Rx, which hosted highly useful information for TB healthcare providers.

We utilized two network measures to identify the top sites, i.e., degree of connectivity and PageRank. Each measure has its own advantages and limitations. The degree of connectivity only focuses on the local structure, which makes it very easy to compute. However, simply linked to other nodes may not necessarily mean that such linkages are important. PageRank provides a quantitative measure on value of different linkages by considering the global importance of the linked nodes, and therefore can provide a more accurate evaluation of resources. On the other hand, calculation of PageRank becomes more complex due to this global consideration. It is interesting to note that a significant portion of the identified top sites based on degree of connectivity are overlapped with those based on PageRank. A potential explanation is that we only had two levels of resource linkages when developing the network (the four TB COEs and their linked resources) and therefore the difference between the local and global structures is...
insignificant. Our future work will explore multiple levels of resource linkages and re-examine the use of specific network measures to identify important hosting sites for TB resources.

Through analysis at the individual resource level, we identified several useful TB resources, such as those about sputum collection and active TB hosted at New Mexico Department of Health. These two resources had a high level of connectivity, with linkages from all four TB COEs. We also found external resources with a high PageRank, such as the Amikacin Administration page hosted at Drugs.com. By identifying resources with high PageRank, we can further examine the specific information that is perceived as important by the TB COEs and their targeting clinicians.

Visualization of the TB resource networks allowed us to directly examine the important parent sites or individual resources identified from the analysis. For example, visualization of the parent site network placed CDC and WHO at the central location, with a node size (indicating PageRank) even larger than the four TB COEs. Visualization of the individual TB resources, on the other hand, requires more efforts to examine due to the large number of nodes in the network. Nevertheless, it still allowed us to identify certain important resources, such as the GTI homepage. Meanwhile, the color coding of resources made it intuitive to observe those hosted at the same parent site as well as the linkages within and beyond the hosting site.

There are a few limitations in this research. First, the collection of online TB information resources was constrained to only the four TB COEs and their direct linkages. Although these four TB COEs represent the major national resources for TB, the completeness of the collected TB resources needs to be further verified. Second, all the online resources were manually reviewed by a single person, which may introduce potential selection bias and reduce the reliability of data collection. Although this reviewer has extensive experience working with TB, ideally we should have multiple independent reviewers to ensure a high quality and fair process of the analyses. Third, the network analysis was limited to two levels of resource linkages. To further examine the use of specific network measures to identify the important resources and the hosting sites, we will need to perform network analysis with multiple levels of resources linkages. Last, this study focused specifically on TB information resources and their linkages. The generalizability of the findings from this study to other diseases and clinical problems needs to be verified in future studies.

Our work in the next steps includes: (1) expanding the review of TB resources to the sites beyond the four COEs; (2) leveraging web crawling technologies to automatically identify linked resources and to facilitate the construction of resource networks; (3) integrating semantic analysis techniques to provide another perspective on content of the resources identified; (4) performing larger scale network analyses with multi-level resource linkages and additional measurement on network properties to identify a complete set of TB information resources; and (5) generalizing the study approaches for applications to other diseases, clinical problems, and public health challenges.

5. Conclusion

We have analyzed online TB information resources through manual reviewing the websites of the four national TB COEs and their linkages. Based on this analysis, we have successfully constructed TB resource networks at both the parent site and the individual resource levels. Leveraging network analysis methods and the associated tools, we have identified important TB resources and hosting sites. The initial results from this study indicates that it is promising to use network analysis approaches for identification and dissemination of online clinical information resources. Our future work will expand the scope of resource review, develop automated processes to identify resources and linkages, perform larger scale network analysis, and examine the generalizability of the study approaches, with an ultimate goal for more effective dissemination of clinical evidence and better care of patients with TB and other diseases.

Abstract

While natural language processing (NLP) of unstructured clinical narratives holds the potential for patient care and clinical research, portability of NLP approaches across multiple sites remains a major challenge. This study investigated the portability of an NLP system developed initially at the Department of Veterans Affairs (VA) to extract 27 key cardiac concepts from free-text or semi-structured echocardiograms from three academic medical centers: Weill Cornell Medicine, Mayo Clinic and Northwestern Medicine. While the NLP system showed high precision and recall measurements for four target concepts (aortic valve regurgitation, left atrium size at end systole, mitral valve regurgitation, tricuspid valve regurgitation) across all sites, we found moderate or poor results for the remaining concepts and the NLP system performance varied between individual sites.

Introduction

Echocardiography is currently the most widely used non-invasive cardiac imaging in the diagnosis, treatment, and follow-up of patients with cardiovascular diseases. Various measurements in echocardiography provide key insights into the mechanisms and health of a patient’s cardiovascular system. Aortic, mitral and tricuspid valves are assessed for abnormal structure, thickness, and valve dysfunction (regurgitation, stenosis). Left ventricular systolic performance indicates severity of heart disease, and most laboratories quantify Left Ventricular Ejection Fraction (LVEF) to a value ranging from 5-75 percent of total blood volume. Echocardiography measurements are generally stored as an echocardiogram (echo) report in electronic health record (EHR) systems, which is frequently an unstructured or semi-structured text document. This limits the downstream use of the report data by automated systems for clinical research (e.g., phenotyping), care management and point-of-care clinical decision support.

Natural language processing (NLP) of unstructured clinical narratives, such as echo reports, holds tremendous potential to extract meaningful information and fill this knowledge gap. NLP utilizes various algorithms to automatically extract relevant clinical information from free text and semi-structured data sources. However, a recent review of the literature by Demner-Fushman and Elhadad suggests that NLP remains an “emerging technology”, with a significant gap between promise and reality. One of the major challenges in broader adoption of NLP systems and technologies is their portability across multiple EHR systems. While several studies, including work done by our study team, have demonstrated varying levels of success in portability of NLP technologies across institutions, recent work by Carrell et al. argue that there remain significant challenges in adapting NLP systems across multiple sites, which include assembling clinical corpora, managing diverse document structures and handling idiosyncratic linguistic expressions. These barriers and the requirement for significant upfront “investment” limit wide-scale adoption of NLP tools and systems across health systems, particularly those in low-resource settings and environments.

To understand these barriers further, in this study we investigated the implementation of an existing NLP system - Leo, developed by the Department of Veterans Affairs (VA) Informatics and Computing Infrastructure (VINCI) - across three academic medical centers. The goal of the current study was to assess the portability of EchoExtractor by installing, without any system modifications whatsoever, and evaluating its performance at three non-VA medical centers. This project, as part of the Phenotype Execution and Modeling Architecture (PhEMA), was motivated by the fact that EHR based computational phenotyping using both structured and unstructured data is a key requirement for deriving high quality phenotypes from EHRs, and a portable NLP system that can be run across multiple institutions is much needed.
Materials and Methods

System Description and Target Concepts

Leo provides a set of services and libraries that facilitate the rapid creation and deployment of NLP analysis tools. A major strength of this approach is the use of Unstructured Information Management Architecture (UIMA), which provides a set of standards for creating, discovering, composing and deploying a broad range of text analytics capabilities and integrating them with search technologies. This standard is very attractive for NLP research because it is open-source (available through Apache), and enables incorporation of NLP tools developed elsewhere. The distribution package for EchoExtractor was made available through a VA GitHub repository. Installation of EchoExtractor using UIMA-AS 2.8.1 was deemed to be relatively straightforward, and was completed within a day at WCM and Northwestern. Installation at Mayo Clinic was performed using installation instructions found for Leo where an alternate version of UIMA (UIMA-AS 2.9.0) was installed to support Leo, yet the installation process was still also completed within a day. We tested the performance of the pipeline without any custom modification to evaluate the true portability of the NLP system.

While previous studies have shown success in extracting echocardiography measurements from Echo reports using NLP methods, the focus has been primarily on extracting one key concept - LVEF. The VINCI team created a specific instance of Leo named EchoExtractor to extract 27 different important cardiac concepts from echo and radiology reports. A preliminary analysis of results obtained after processing 100 echo reports from WCM center through the NLP pipeline revealed that not all target concepts were present. Concepts such as left ventricular contractility, left ventricular hypertrophy and aortic valve max pressure gradient were not identified. Therefore, we focused on the remaining 24 elements in our extended evaluation study. Later, we observed that the above three concepts were in fact present in echo reports originated from other centers, however we did not include them in our performance evaluation. The 24 target concepts we investigated in this study is listed in Table 1. For a description of these concepts, we refer readers to Patterson, et al.

Data collection

We obtained Echo reports from all three medical centers participating in this study. Weill Cornell Medicine (WCM) uses the EpicCare® Ambulatory EHR platform to document clinical care, from which we collected all echocardiograms used as the basis of this study. We obtained 200 echocardiograms for 200 patients who were 18 years or older at the time of the echocardiogram results and one of the study team members (PA) manually annotated the data elements extracted by the EchoExtractor to create the gold standard at WCM. These reports in general formatted into multiple sections containing semi-structured, and unstructured data. Reports have a subject meta-data section, one or more tabular sections, and a comment section. The tabular sections contain quantitative measures such as wall thicknesses, chamber dimensions, or flow velocities. Unstructured fields contain descriptions of clinically relevant findings as interpreted by the technician. For example, the descriptions could say “Normal aortic valve and aortic root”, “Normal left ventricular size and function”, “There is trace mitral regurgitation”. Furthermore, left ventricular function is often subjectively quantified as “mild”, “moderate”, “mildly to moderately reduced” or “severely reduced”.

Mayo Clinics implemented an Unified Data Platform (UDP) to provide practical data solutions that creates a combined view of multiple heterogeneous EHR data sources (including Epic) through effective data orchestration, along with a number of data marts based on common data models. We retrieved the echocardiogram reports from the Mayo Clinic UDP platform from patients over 18 years old at the time of the echocardiogram results after verifying authorization to use the data in accordance with the Minnesota Health Records Act. Patient records were found in two formats: Rich Text Format (2000 to 2012), and Portable Document Format (PDF) from 2012 to 2018. For the echocardiograms generated between 2012-18, using a custom-built Python application, original text from the PDF documents was extracted. We randomly selected 200 echocardiogram reports for this study from each document format. The text portions of these reports were extracted, PHI was censored, and other elements such as visual elements (charts and graphics) and metadata were discarded. Echo reports found at Mayo Clinic generally consisted of three types of sections: unstructured text, numbered final impressions, and semi-structured tables of echocardiogram data. These reports were manually annotated with data elements extracted by the EchoExtractor by an experienced nurse at the Mayo Clinic which generated an annotation corpus as Mayo Clinic’s gold standard.

At Northwestern Medicine, we retrieved 251,521 free-text echocardiogram reports for patients over 18 years old at the time of the echocardiogram between 2000 and 2017 from Northwestern Medicine® Enterprise Data Warehouse (NMEDW). The NMEDW hosts a comprehensive and integrated repository of the most used clinical and research data sources, at the time from 2 hospitals: Northwestern Memorial Hospital (NMH) and Lake Forest Hospital (LFH). Echo reports typically contained a mixture of semi-structured tables of echocardiogram data, along with unstructured impressions and findings. Overall structure of reports was primarily a metadata section containing patient and procedure information, semi-structured tabular results, followed by the impression (although many variations in this structure were observed). We randomly selected 200 echocardiogram reports and multiple study team members (YZ, YD, LY, JP, LR, YL) manually annotated the data elements extracted by the EchoExtractor. Across reviewers, we have discordant findings reconciled in a group setting to ensure consistent coding and interpretation, sometimes in
consultation with a cardiovascular physician colleague. The final consolidated list of annotations was used as the gold standard at Northwestern.

We also obtained echocardiograms from the Medical Information Mart for Intensive Care III (MIMIC-III) database. The latest version, MIMIC-III, contains de-identified patient records for >40,000 critical care patients admitted to Beth Israel Deaconess Medical Center between 2001 and 2012. We extracted 44,559 echo reports from 21,645 adult patients who were 18 years or older. We then randomly selected 200 echo reports for 200 unique patients and a study team member (PA) manually annotated the data elements extracted by the EchoExtractor to create the gold standard for the MIMIC dataset. Unlike the Echo reports from three medical centers, MIMIC reports were in free-text format with no tabular or semi-structured sections. In general, these reports have an interpretation section comprising subsections for findings and conclusions. Findings section has detailed descriptions about left atrium, right atrium, left ventricle, right ventricle, aorta, aortic valve, mitral valve, tricuspid valve, and pulmonic valve/pulmonic artery. MIMIC reports are for patients admitted to the intensive care unit; hence, patient characteristics are different from those patients treated at various outpatient settings in WCM, Mayo Clinic and Northwestern. At each medical center we limited the number of reports for manual review to 200 mainly due to limited resource availability, and also due to the fact that, in general, echo reports tend to follow same format(s) within each clinical setting. Figure 1 shows typical examples of echo report from the four EHR systems investigated in this study.

![Figure 1. Typical examples of echocardiogram originated from multiple EHR systems](image)

**Extraction methodology**

Patterson et al. has described in detail the logic for concept extraction employed in the present study. Various target concepts were extracted through a multi-stage process in a rule-based algorithm that involves identifying a concept mention in the text, identifying a value mention in the text, and linking appropriate concept and value mentions in a relationship. Term identification and term mapping was used to detect a concept mention in the text. Term identification was performed using regular expressions matching and term mapping was achieved by building a custom term lookup dictionary. Value identification was achieved through regular expressions that match both quantitative and qualitative values.

and qualitative values for concepts. Finally, a relationship between a concept and value was established through pattern matching, from a set of patterns identified for the clinical subdomain of echocardiograms.

Reference standard and performance evaluations

For all three study sites and for the MIMIC dataset, we determined performance of the NLP pipeline individually by developing independent gold standard datasets (see above). Results of EchoExtractor output were tabulated and compared against the gold standard through manual reviews. For each concept, a reviewer compared the output generated by EchoExtractor to each of the 200 reports. The reviewer identified all mentions of a concept and the associated quantitative or qualitative values. The reviewer also confirmed that the concepts not found by EchoExtractor in a given report were truly not mentioned in the respective report. The reviewer identified both numeric values as well as qualitative descriptions such as normal, mild, moderate, dilated, and severe. If a numeric value is documented as a range, then we identified both the values as the minimum and maximum. In reports containing multiple instances of a concept, we identified all instances. In cases where concept value is expressed using a greater than or less than symbol (e.g. LVEF >55), the reviewer simply identified the value ignoring the symbol. Some echo reports express uncertainty about certain concepts such as LVEF value using a question mark (e.g. LVEF ?55-70). In such cases, the reviewer extracted the value, ignoring the question mark.

Each report was classified as one of four possible cases: true positive (report had the concept present and EchoExtractor identified the “concept-value pair” and matched with the value given in the reference standard); false positive (report had the concept absent, but EchoExtractor produced a concept-value pair); true negative (report had the concept absent, and EchoExtractor did not find any concept-value pair); and false negative (report had the concept present, but EchoExtractor did not identify a concept-value pair, or the value extracted did not match with the corresponding value in the text). A value for a concept can be either a quantitative measure as in “systolic function (LVEF>55%)” for ejection fraction, or a qualitative assessment as in “no aortic regurgitation”. Note that we are not assessing if a given concept is present or absent in the report, rather whether the NLP method correctly identified the concept-value pairs documented in the report. For example, for a statement such as “There is no aortic valve stenosis”, if the NLP system extracted ‘no’ as the assessment for the concept ‘aortic valve stenosis’, we will consider this as a true positive case. For a given target concept, when there were multiple instances of concept-value pair extracted by EchoExtractor, we used the following heuristic measure to select a given instance of the concept in order to compare directly with the reference standard: we selected the last concept-value pair, normally in the conclusion part of the report (as the order of results and text in the reports was usually chronological). The total outcomes of the four possible cases were then used to calculate various statistical performance measures, namely, precision (positive predictive value), recall (sensitivity or true positive rate), and the F-score (the harmonic mean of recall and precision).

Results

Results of EchoExtractor validation performed on echo reports from WCM, Mayo, Northwestern and MIMIC datasets are presented in Table 2. Among all datasets aortic valve regurgitation, aortic valve stenosis, left ventricular size, LVEF, mitral valve regurgitation, pulmonary artery pressure, and tricuspid valve regurgitation were the most frequently mentioned concepts. Other concepts were mentioned infrequently or in some cases absent all together as indicated by the letter ‘A’ in Table 2. While target concepts such as aortic valve regurgitation peak velocity, mitral valve regurgitation peak velocity, tricuspid valve mean gradient, and tricuspid valve orifice area were absent from the echo reports from WCM, Mayo Clinic and MIMIC reports, only aortic valve regurgitation peak velocity was absent from the Northwestern dataset. In addition, mitral valve mean gradient was absent from the WCM echo reports and mitral valve orifice area was absent from the MIMIC and Mayo echo reports. At WCM, aortic valve mean gradient, aortic valve orifice area, inter-ventricular septum dimension at end diastole, left atrium size at end systole, left ventricular dimension at end diastole and left ventricular dimension at end systole were also found in high frequency. Among Mayo, Northwestern and MIMIC echo reports, left atrium size at end systole was found frequently. Both WCM, Northwestern and MIMIC reports showed high recall and precision in extracting LVEF, with an F-score of 0.99, 0.99 and 0.95 respectively. We observed that EchoExtractor showed high precision (99%), while low recall (55%) for extracting LVEF from Mayo Clinic echo reports. Across all four datasets a F-score >0.90 was found on only two target concepts: aortic valve regurgitation and left atrium size at end systole. At WCM, Mayo Clinic and Northwestern, an F-score >0.90 was observed for aortic valve regurgitation, left atrium size at end systole, mitral valve regurgitation, and tricuspid valve regurgitation. Between WCM, Northwestern and MIMIC reports, a F-score >0.90 was observed for the concepts aortic valve regurgitation, aortic valve stenosis, left atrium size at end systole, left ventricular ejection fraction, and tricuspid valve regurgitation. Between WCM and Northwestern sites, mitral valve regurgitation showed an F-score >0.90.

</table>

Error analysis of the echo reports from the study datasets revealed that false positive cases are mainly due to term mismapping or the reference range for a concept being wrongly mapped as the measured value. For instance, in WCM echo reports several target concepts are documented in semi-structured tabular format where a given concept is documented by the measured value followed by the reference value (e.g. “Aortic Valve Area 1.1 > 2.4 cm2”).
When there is no measured value documented as in several instances of aortic valve orifice area (e.g. “Aortic Valve Area > 2.40 cm2”) or left ventricular ejection fraction (e.g. “Ejection Fraction 0.55 - 0.75”) or mitral valve orifice area (e.g. “Mitral Valve Area > 3 cm2”), then the NLP system extracted the value given for the reference range as the measured value. For aortic valve orifice area and mitral valve orifice area, 23% and 94%, respectively, of reports were found to be false positive this way. Term mismapping also leads to a higher proportion of false positives. For example, the term “e:a” ratio being wrongly mapped to e/e prime ratio as in “Mitral E:A Rt 2” accounting 18% of false positive cases for the target concept e/e prime ratio. Although rare, the system wrongly mapped to terms “dilated aorta arch” to target concept left ventricular size with no apparent reason. In MIMIC echo reports, majority of false positive cases are due to term mismapping. Examples are “interatrial septum” being mapped to the concept interventricular septum dimension at end diastole, left ventricular cavity being mapped to the concept left ventricular dimension at end diastole, dilated descending aorta being mapped to left ventricular size, or mitral valve jet being mapped to tricuspid valve regurgitation peak velocity. Also, when a short representation of a target concept is part of a word preceded by a space character; the system wrongly mapped that concept. An example is “ava” for aortic valve orifice area being mapped to the word “available”. Also, some false positive cases were due to wrong mapping of the qualitative assessment of one concept to another. For example, the assessment “mildly thickened” of aortic valve leaflets was mapped to aortic stenosis as in “The aortic valve leaflets (3) are mildly thickened but aortic stenosis is not present.”

Error analysis on false negative cases revealed several instances where the system missed the target concept due to variations in the terms used to represent that concept in different clinical settings. For example, in WCM echo reports, the concept aortic valve max pressure gradient is consistently documented under peak aortic gradient, and since this is not one of the lookup terms for that concept and missed entirely. A second cause for false negative cases was when a line break (\n) or special characters (;, ~ , &), or parentheses appear between a concept and the corresponding value or qualitative assessment. Yet another cause for false negative cases was when a term for a target concept appears in two lines (e.g. right “\n” atrial pressure), and the system failed to extract the concept. Similarly, when two target concepts appeared too close to each other, the system failed to map those concepts with the correct value or assessment. For example, in MIMIC echocardiograms, there were several instances where aortic stenosis was described along with aortic valve orifice area (e.g. Mild AS (AoVA 1.2-1.9cm2)), and the system failed to correctly extract aortic valve area.

For the Mayo Clinic’s echo reports, we found that semi-structured table format had negative impact on the performance of the concept extraction. For example, “e/e prime ratio” listed in the table entries could not be detected consistently and accurately. Therefore, the semi-structured tables were excluded from the performance evaluation. Otherwise, the Mayo Clinic’s echo reports appeared to have relatively consistent syntax. We also found that semicolon (;) was used in place of colon (:) for the representation of some concept values such as “Calculated left ventricular ejection fraction; 65 %”, which resulted in roughly half of the false negatives being recorded for this concept. In addition, some phrase patterns appeared to be more commonly used at Mayo Clinic (e.g. Mitral valve sclerosis without stenosis), which resulted in 58% of the false negatives for the detection of the mitral valve stenosis concept and 47% of the false negatives for the aortic valve stenosis concept. A similar issue occurred for “Aortic valve systolic mean Doppler gradient 12 mmHg”, where the insertion of “Doppler” term caused a failure to detect the gradient concept. The high occurrence rate of these specific phrase patterns appeared to be institution-specific and needed to be handled in the future.

At Northwestern, we also found multiple semi-structured table formats in the echocardiogram reports, which also led to poor NLP performance for some of the target concepts. Also, we found many of the other sources of errors as in other datasets, including the interjection of spacing and special characters in the reports, omissions of spacing between concepts and values (e.g., Ao valve open2.2 cm), different concept terms used, and multiple concepts in the same sentence. Of the few false positives we found, the NLP did not recognize some less common abbreviations such as those for aortic insufficiency (AI) that were not listed in most reports. Many of the false negatives were due to the above reasons; in particular, multiple concepts were frequently missed as they were in a separate table and the description of the measures were partly abbreviated (vs. fully spelled out or completely abbreviated as in other reports). For example, left ventricular size measures such as left ventricular dimension at end systole were listed in the table as “LV Size-end systole” instead of “LVESD” or “left ventricular size-end systole.” The remaining few false negatives were due to missing values in sentences where other concepts were mentioned. For example, some reports started their summary section at the end of the report with summarizing multiple normal measures in 1 statement, such as “Left ventricular size, systolic function, wall thickness, and wall motion are all normal.” There were very few instances of
FNs where the value extracted by the NLP was the wrong value for the concept-value pair; thus, the NLP algorithm was good at finding the correct value when it found a concept.

Discussion

While many modern EHR systems record various concepts from echocardiograms in a more structured manner, semi-structured or unstructured echocardiogram reports are still the primary source in most clinical settings. In the past a number of NLP methods have been developed to extract various cardiac measures documented in echocardiography reports. While majority of these studies focused on the extraction of LVEF \[12,23-25\], some have attempted to extract a broader range of cardiac concepts \[21,26\]. However, to the best of our knowledge these methods have not been tested for their performance on data originated from clinical sites other than the original NLP algorithm and method development site. As a result, “true portability” of the developed NLP systems has never been rigorously assessed. The present study fill this knowledge gap by adopting a system developed initially by the VA, and then subsequently implemented at three non-VA medical centers without any modifications, to test its performance in processing echocardiogram reports.

In particular, the NLP system under investigation - EchoExtractor - was designed to extract 27 concepts from narrative text, echocardiograms, and radiology reports, and the original developers reported an average precision of concept-value extraction of 0.982 in echo documents, 0.969 in Radiology, and 0.936 in narrative text, with F-score of 0.844, 0.877, and 0.872 respectively. Specifically, the system reported precision and recall values for 20 data elements in echocardiograms. The remaining 7 target concepts were either absent or too low in total mentions to report performance concepts. Out of the 20 target concepts in echocardiograms, 17 elements have been reported with a precision of 0.90 or higher\[21\]. When compared to the reported data, the overall performance of the NLP system was found to be mixed. For an NLP system to be portable, a low variability in the recall and precision values across sites is needed. As shown in Table 2, this is true for some target concepts but not for others. For those concepts where we found low inter-column variability, EchoExtractor can be deemed as an effective NLP tool. In WCM dataset, target concepts such as inter-ventricular septum dimension at end diastole, left ventricular dimension at end diastole, and left ventricular dimension at end systole are documented as part of a tabular format within echo reports and appeared consistently across all reports, and hence resulted high performance for these concepts. On the other hand, concepts such as aortic valve orifice area and mitral valve orifice area, although appear in a tabular format and are typically documented along with a reference range in the echo reports. For these concepts we observed that the NLP system often failed to correctly identify the measured values from the reference range, thereby resulting in lower precision.

The Mayo Clinic dataset comprised of semi-structured tables to represent the echocardiography concepts. While the table formats had modest variations over the years, the NLP system was generally unable to detect concepts located in these tables successfully. Our evaluations suggest that the representation of target concepts using a table format is likely to decrease the NLP system performance, and alternative approaches to capturing data in these sections should be evaluated. Specifically, we observed 16 target concepts in the Mayo Clinic dataset, out of which the NLP system achieve a high precision and F-score >0.90 for only 4 concepts. A notable exception in Mayo Clinic dataset compared to other datasets is the low recall observed on LVEF. While WCM, Northwestern and MIMIC echo reports showed high recall (99%, 97%, and 91%, respectively), Mayo Clinic echo reports showed only 55 percent. On further analysis, we concluded that the high rate of failure to detect LVEF is due to a semicolon ‘;’ character (e.g. ejection fraction; 67) that appeared between the concept and value, which was causing system error. Common institutional phrasings such as “sclerosis without stenosis” that do not fit into the predefined patterns can be a significant source for concern and poor performance.

We observed 23 target measurements on Northwestern echo reports, out of which the NLP system showed a precision and F-score values >0.90 for 10 elements. Unlike echo reports from other sites, the concept tricuspid valve regurgitation peak velocity was found with high recall and precisions. Although this concept was mentioned infrequently in reports from other datasets, they were mentioned in ~50% reports at Northwestern using system recognized concept names. Similarly, the measurement tricuspid valve orifice area is found only in Northwestern echo reports, and extracted with a high recall and precision.

Unlike the echocardiograms from WCM, Northwestern and Mayo, MIMIC reports are entirely in a free-text format. Of the 16 target concepts found in MIMIC dataset, NLP system achieved a high precision and F-score values for 6 concepts. Majority of false positive and false negative cases in datasets that are more semi-structured arise out of differences in local document formats. Thus, the differences in performance between MIMIC and other datasets indicates a possible correlation between structure and tool usefulness. This is particularly important, since an ideal NLP system should be able to perform well when analyzing unstructured narratives. For those concepts observed with
low performance, it is also possible that physicians entering data in MIMIC are constrained by internal guidelines to use peculiar phrasing or punctuation and the NLP system missed to correctly identify those concepts.

Conclusion

The work described in this paper details a case study to adopt a specific instance (EchoExtractor) of a NLP system (Leo) previously developed by the VA. The adopters (WCM, Mayo Clinic and Northwestern) individually led the NLP system implementation without any modification, drawing on existing resources, and employing conventional software skills. The study demonstrates that concept-value extraction from echocardiograms can vary depending on local text formats and variations in lexical terms used to document various concept across different clinical settings. The NLP system used a custom lookup dictionary as part of its extraction algorithm\(^2\), and our analysis showed that the performance of the system for several of the target concept can be improved significantly by extending this lookup dictionary with additional terms specific to individual sites. Many of the false negative cases resulted because of the absence of terms in the custom dictionary. Despite the fact that this system was developed based on documents originated at thousands of points of care and authored by a multitude of clinical professionals within the VA, it also suffers from some of the same drawbacks as other NLP systems have reported including the need for a local customization of extraction logic and extending the lookup dictionary based on local data source.

Using Priorities of Hospitalized Patients and Their Caregivers to Develop Personas

Elena Agapie¹, Logan Kendall², Sonali R. Mishra¹, Shefali Haldar¹, Maher Khelifi¹, Ari Pollack¹, Wanda Pratt¹,
¹University of Washington, Seattle, WA; ²Palantir Technologies, Washington, DC

Abstract
Hospitalized patients and their caregivers often access technologies like patient portals to understand what happens during their hospital stay. Although this access can lead to more patient engagement and positive health outcomes, many find that the technology does not support their needs. As a first step toward improving patient-facing technologies we create personas for hospitalized patients and their caregivers by following the Q Methodology, a technique for quantifying subjective opinion. We clustered 28 hospitalized patients’ and 19 caregivers’ attitudes towards receiving and managing information and working with their care team. We contribute three patient personas: patients who are (1) accommodating information seekers, (2) involved safety guardians, and (3) self-managing participators. We identify three caregiver personas: (1) cooperative information seekers, (2) vocal participators, and (3) hands-off safety guardians. These personas can inform future tools designed to support communication and information management for hospitalized patients and caregivers.

Introduction
Allowing patients to access their health information while in the hospital enables them to be active participants in their care, to have increased satisfaction, to engage in healthy behaviors, and to have improved understanding of their care. Patients want to understand many different aspects of their care, including their medications, the plan of care, and the workflow of activities. However, patients and caregivers (i.e., friends or family members who help or accompany the patient during their hospital stay) face substantial barriers to receiving information and engaging in their care while in the hospital. These challenges include the lack of supportive tools, poor setup of their hospital room, challenges communicating with their care team, cognitive challenges from treatment as well as their illness, and ergonomic limitations due to their environment.

Research thus far has highlighted the needs of patients and the difference between their needs and the needs of clinicians. Missing from existing work is an understanding of how patients’ needs differ from each other, and how patient-facing technologies should be designed to accommodate those differences. Researchers have found that hospitalized patients differ in their interest and approach to engagement with their care, and that people managing a chronic disease differ in their use of technology. Yet, more work is needed to understand how hospitalized patients’ and caregivers’ values and priorities differ, and how the design of patient-facing technologies can better support those differences. A common approach to designing for such different types of users is to use personas. To identify personas in order to support the information needs of hospitalized patients, we use the Q methodology and semi-structured interviews. We identify hospitalized patient and caregiver user groups based on how they prioritize information in the hospital and how they want to work with their care team. We base these user groups on our study with 28 hospitalized patients and 19 caregivers. Through this work, we contribute (1) an explanation of six distinct personas that represent hospitalized patients and caregivers, and (2) implications for the design of tools that support the varied information and communication needs of hospitalized patients and caregivers.

Related Work
In a hospital environment, patients and their caregivers find it challenging to maintain up-to-date awareness of the patient's health status and plans of care, managing their information and communicating with their care team. We briefly summarize this research and how creating personas for patients and caregivers contributes new insights.

Patient and Caregiver Information Needs in the Hospital
Patients want to receive a variety of information about their care such as the plan of care, the schedule of activities, information about their vitals, food, and providers on their care team. Patients also want to know that information such as their allergies or preferences is effectively communicated to their care team. They want to ensure that information they communicate is properly propagated to the care system, for example that their current clinical team
knows their allergy information\textsuperscript{15} or contextual information about their treatment routine\textsuperscript{16}, and that such information is properly transferred to clinical staff from one shift to another to achieve continuity of care\textsuperscript{16}.

Caregivers play an important role in managing care. Caregivers act as a proxy in the care of patients to make treatment decisions\textsuperscript{17,18}, or to communicate on behalf of the patient\textsuperscript{17}. They also provide social support in transition periods or when the patient faces cognitive challenges\textsuperscript{16}, normalize the patient experiences\textsuperscript{19,20}, and act as companion, assistant, representative, navigator, and planner for pediatric patients\textsuperscript{17}. In a critical care environment, patients and families have limited cognitive resources to be able to process and manage their health information. Patients may forget 40-80\% of what was said during a medical consultation almost immediately\textsuperscript{21}. The order and modality in which information is presented, perceived importance, and health context can all impact the patient’s likelihood of remembering information\textsuperscript{21}.

In addition to needing to receive a variety of types of information, patients and their caregivers want to effectively manage, capture, and communicate information to the care team\textsuperscript{16}. Without tools to accomplish this, patients would have to remember all the information providers share and be responsible for keeping their providers aware of their needs during shift changes and transitions in care\textsuperscript{16}. Further, critically ill patients often need substantial help from caregivers for managing information from clinicians\textsuperscript{22}.

This prior work has helped identify the multitude of information needs that patients and caregivers have. Our study adds to this knowledge by investigating how patients and caregivers prioritize different information needs and how they cluster together based on shared priorities.

\textit{Patient and Caregiver Communication with the Care Team}

The Institute of Medicine has emphasized that providers should engage in patient-centric care, “responsive to individual patient preferences, needs and values and ensuring that patient values guide all the clinical decisions”\textsuperscript{23}. Even though patient and caregiver engagement in the hospital is important, it can be heavily impacted by the relationship they have with their care team. A high-quality relationship with the provider might make people more comfortable communicating certain questions to providers, such as information seeking questions about medication\textsuperscript{24}, and more interested in engaging with their care team around improving safety issues\textsuperscript{9}. A good quality relationship is associated with lower disease burden and greater uses of preventative care services\textsuperscript{25}. When patients have an increase in perceived control and communication with the provider, it leads to improvements in trust in their provider\textsuperscript{26}. But when the relationship with the care team is not as strong, patients encounter significant barriers in communicating with their care team, such as asymmetrical power dynamics that are typically dominated by the physician\textsuperscript{27}, fear of being perceived as a “difficult” patient\textsuperscript{27}, and lack of comfort asking challenging questions such as asking if a health care provider washed their hands\textsuperscript{9}.

The patient’s level of engagement in their care and their attitudes to their care team play a role in the information they receive in the hospital and how they engage with it. In this work we contribute empirical findings about how patients and caregivers prioritize and balance relationships and communication with their care team relative to their information needs.

\textit{Personas in Health Domains}

Although some technologies exist to support patients’ needs for information about their care and engagement with the care team\textsuperscript{14}, existing tools insufficiently support tailored, patient-specific information\textsuperscript{14}. To understand how technologies might offer tailored support to patients and caregivers with different needs, we seek to identify different patient and caregiver personas based on their information and collaboration needs. Personas are user archetypes that characterize users based on their attitudes, goals and behaviors\textsuperscript{11}. They are informed by a variety of types of data and methods, from qualitative insights on user goals\textsuperscript{11} to data driven personas based on behaviors\textsuperscript{33}. Personas are used during the design process to help: build empathy towards users\textsuperscript{10}, facilitate communication about design choices\textsuperscript{10}; reduce conflicts about what the perceived user goals are\textsuperscript{10,11}, and summarize data about users and their needs. Personas have helped characterize users in many health domains such as heart failure self-management\textsuperscript{28}, home healthcare technologies\textsuperscript{29,30}, child cancer survivors\textsuperscript{31}, or older adults\textsuperscript{32}. Based on the demonstrated usefulness of personas in these health domains, we characterize users of patient facing technologies based on attitudes towards information and communication needs.

\textit{Methods}

We used a mixed methods approach to identify the attitudes and opinions of patients and caregivers around information needs, information engagement, information management, and the relationships and social perceptions surrounding care delivery in the hospital. We used the Q methodology\textsuperscript{14} to structure data collection with the patient and caregiver, and interviewed the participants twice, first during the study session, and second during a follow up a week after discharge. The study was approved by the researchers’ institutional review board.
**Q Methodology**

To understand how patients prioritize and make sense of getting and managing information while hospitalized, we used the Q Methodology\(^{12,34}\) to structure our data collection and analyze our data. The method quantifies subjective opinions through two key features—a set of statements about a topic, and a grid for ranking those statements in the shape of a normal distribution (Figure 1). By quantifying subjective opinions, the Q Methodology leads to the creation of personas by understanding what people feel most strongly about. It provides many of the advantages of qualitative methods, such as discovering themes in rich subjective data. The Q methodology is a small-sample technique that offers statistical validity to the qualitative interpretation of subjective data, making it useful for small samples (<50 people)\(^{12}\). The Q methodology has increasingly been used to cluster types of users based on beliefs and reactions to technology\(^{12}\), and to describe the tradeoffs and attitudes individuals have about health technology in a structured way\(^{9,13}\). This method showed how common attitudes towards health and technology supersede typical demographic segmentations like gender, age, and ethnicity in the context of a chronic disease population\(^8\).

The Q methodology requires participants to order a set of statements relative to one another using a grid like the one shown in Figure 1. Researchers created a set of 34 statements, as described below. To identify patient priorities, we use the Q sorting activity: a highly structured data collection activity in which participants need to organize the subjective statements in a grid shaped like a normal distribution. The extremes of the distribution are the statements that participants agree or disagree with the most, with Neutral in the middle. The statements placed at the extremes receive the most weight in the quantitative data analysis. Based on this distribution, we can compare each person’s ranking with the statistical technique of factor analysis, and thus, identify patterns of subjective opinions.

Participants were asked to read through the statements and place them into a grid based on how much they agree or disagree with the statement relative to all the other statements. The researchers then probed the participants to explain their reasoning for the placement of statements and their general opinion about the statements. After participants organized all the 34 statements into the grid, we interviewed them about topics such as their routines during their hospital stay, communication with staff, families and friends, or the use of technology while hospitalized. A follow-up phone interview was conducted within 7 days of the discharge. The patients and caregivers conducted the Q sorting activity and interviews separately, then discussed together, and took breaks as needed. The information from interviews is used to complement participant agreement with statements by adding qualitative insights.

**Creating the Q Statement Set**

For the Q sorting process we started with a set of 89 statements that described different attitudes related to interacting with information and people in the hospital environment, based on prior research on patient-provider communication, patient information needs, and based on data from prior surveys on patients and caregivers\(^4,14\). These statements pertained to communication preferences, empowerment, information management, information needs and relationships. Based on pilots with children and adults, we narrowed down the Q set to 34 statements [link to the Q set](https://patientsassafeguards.ischool.uw.edu/wp-content/uploads/2019/07/AMIA19Q.pdf), such as “(6) It’s important to speak up to doctors and nurses when I have a question”, “(3) It’s important to know why each medication is given to me”, or “(12) It’s important that I am not a bother to my doctors and nurses”. Caregiver statements were almost identical, with adjustments to the pronoun where appropriate. Since caregivers and patients can play different roles in care, using identical Q statements between these two populations allowed us to find where caregivers and patients converged and diverged from each other.

**Analysis**

Each participant’s ranking of statements was transcribed and entered into the freely available PQMethod software\(^{35}\). We separated the Q rankings created by patients from those created by caregivers. We used principal component analysis and rotated using the varimax method\(^6\). This analysis surfaces unique clusters where participants’ Q statements clustered together. Each identified cluster was therefore a selection of participants who unambiguously load highly in the cluster. Each cluster had a set of distinguishing statements that characterized a unique point of view, ranked from -4 (Disagree the most) to +4 (Agree the most). The distinguishing statements for each cluster are statistically significant, meaning that participants ranked those statements much higher or lower than participants in other clusters, at minimum threshold of p<0.05. In the results we will refer to the distinguishing statements by marking...
their relative ranking with an asterisk. For example, we will refer to knowing information about medication (+4*) to refer to a statement that participants strongly agreed with, is a statistically significant (at p<0.05), and is a distinguishing statement for that cluster. To supplement the quantitative analysis, we analyzed interviews qualitatively based on codes grounded in the original statement categories, with additional codes developed based on emergent themes identified during the content analysis.

**Participants**

We recruited 28 patients and 19 caregivers at two study sites: an adult tertiary care hospital and a pediatric hospital. Patients (13 male, 14 female) had a median age of 53 for adults, and 12 for children. Caregivers (2 male, 15 female) were of age: one was 18-29, seven were 30-39, six were 40-49, three were 50-59 years old, and two did not specify the age. Participants had diverse educational and racial backgrounds: Hispanic/Latino (6), American Indian/Alaska Native (2), Asian (5), Native Hawaiian/Pacific Islander (1), Black/African American (7), White/Caucasian (30).

Based on regional population demographics, we used purposeful sampling to identify eligible participants based on age, gender, race, ethnicity, and we sought an even distribution across hospital services (medical or surgical). Research coordinators approached patients who had been in the hospital for at least 24 hours, spoke English, and were able to participate in a conversation about their current care. The coordinators obtained informed consent, and conducted a verbal questionnaire to collect demographics and information about the current hospital stay. In our pediatric cohort, participants needed to be at least 7 years old and have parental consent as well as their own assent to participate. Caregivers included family members and friends who actively observed and participated in the care for the patient.

**Results**

The Q-sorting principal component analysis surfaced three clusters, from the PQMethod software analysis, for patient attitudes and three clusters for caregiver attitudes. We present these clusters described as personas in the next section. Of the 28 patient participants, two were not able to complete the Q sort process because of interruptions related to their health condition or hospital stay. Adult patient quotations are indicated by an “A” and youth quotations by a “Y”, followed by a number (e.g. A02), or “C” for caregiver, followed by the participant number (e.g. C08). A complete list of the distinguishing statements is available at https://patientsassafeguards.ischool.uw.edu/wp-content/uploads/2019/07/AMIA19Q.pdf.

The personas are different between the patient and caregiver groups, however patient and caregiver personas also share dimensions. Both patients and caregivers have safety guardian personas, but they differ in how engaged they are with the care team. Both patients and caregivers have information seeker personas, but they differ in how cooperative or accommodating they are with the care team. Both populations have personas that are interested in being active participants in their care, either holistically, or focused specifically on self-management.

**Patient Personas**

Patients fell into three clusters with shared attitudes towards managing and receiving information in the hospital, and collaborating with the care team. These patient clusters account for 45% of the variance in the patient group, and were relatively evenly split between Cluster 1 (n=9), 2 (n=6), and 3 (n=7). Four patients did not have significant associations with any of the clusters, or fit across multiple clusters, so they are not included in the persona descriptions below. The clusters had an even distribution between hospital sites (adult and children’s), gender, and type of service (medical vs. surgical). All patient participants cared about actively engaging with their care in that they strongly disagreed with statement #30: "I prefer to leave decisions about my medical care up to my doctor". The patients expressed general agreement with statements about wanting to know what will happen with their care for the day (#2), the importance of speaking up when they have a question (#6), and feeling like their doctors and nurses listen to them (#21). However, key differences emerged regarding how the participants prioritized types of information, relationships, and level of engagement. Based on these differences, we describe three patient personas.

**Patient Persona 1: The Accommodating Information Seeker**

The persona emerging from the first cluster of the Q analysis (n=9) is distinguished by 8 statements, summarized in Table 2. We call this persona the “Accommodating Information Seeker”, based on their priority for knowing different types of information as well as their apathy in learning more about or interacting with their care team.

The “accommodating information seeker” strongly values getting information about various aspects of their care, with an emphasis on information immediately relevant for them. For example, accommodating information seekers think it important to know about their medication (+4*), about rapidly changes of situation like the severity of their condition (+4*), and the way to get information when they are worried (+3*). Many patients spoke specifically about wanting to know changes in their medications. For example: “knowledge is power and [knowing] what medications I'm taking
These patients are “accommodating” to their care team in the sense that they are willing to let their clinicians go about their business without interruption. Accommodating information seekers found it less important to engage with their care team and know either the care team’s workflow (-3*), or their names and responsibilities (-2*). Despite patients’ interest in getting access to information when they are worried, patients did not think it important to feel like clinicians had time to answer their questions (-1*). Nonetheless, they were not concerned about being a bother to the care team (+1*) and were willing to assert their voices about topics they cared about, like medication (+4*): “If you’re still confused [and] nobody can help now, you worry. So you need something, like ask doctor what I have to do to keep my body continue to working” (A02).

Compared to other clusters, participants associated with this cluster felt that cost concerns and respecting privacy were least important. In contrast to the “accommodating information seekers”, patient participants in this group were less concerned about understanding the seriousness of their medical situation.

Patient Persona 3: The Self-Managing Participator

The third persona comprises participants in the third cluster of the Q analysis (n=7), and is distinguished by 9 statements, summarized in Table 2. We call this persona the “Self-Managing Participator”, based on patients’ interest in being active participants in their care and performing self-management of their condition.

Patients associated with this cluster placed greater emphasis on “active” participation (+4) as one of the highest ranked items in their sorting grid compared to the “Accommodating Information Seekers” (+1) and the “Involved Safety Guardians” (0). These patients found it important to know the reasoning of their doctors (+3*), and they were not concerned that they might be a bother to their care team (-4*). Patients in this cluster were also interested in the longer-term trajectory of their care, indicating “self-management” interest, such as when they would leave the hospital (+3*). One patient stated: “I’m a control freak, I like to be in control so it’s important that I am, if not totally in control, ... you really want to be an active participant so that you understand the consequences later on, because you expect to be living the consequences later on” (A05). These patients cared about aspects like illness severity (+4*), similarly to the “Accommodating Information Seekers”. But this cluster focused primarily on how their illness would impact the future: “I don’t want to know if it’s worsening, but I want to know how serious it is so I can do stuff myself to help.” (Y12).

Compared to the other clusters, patients in this cluster were least concerned about the way information is communicated (0*), possibly because they appreciate information in any form. These patients rated the question about

and for what condition and is this a medication that’s just temporary related to this condition that I have or is this one of my regular medications that I take for a different condition? “ (A06).
Concerns with possible safety errors the lowest (-3), compared to the "accommodating information seekers" (+1) and the "involved safety guardians" (+3).

**Caregiver Personas**

Using the Q sort analysis, we identified three caregiver personas from the 19 caregiver participants. Our caregiver sample size was determined by the caregiver presence at the research site. All pediatric patients had at least one caregiver present (16 participants), but far fewer adult patients in this study had such active caregivers (3 participants). The three caregiver clusters identified in the Q analysis account for 59% of the variance in the caregiver group. Three participants fit across multiple clusters, so their data is not included in the analysis of the personas below. Each cluster included caregivers from the adult and the pediatric patients.

In contrast to the patients, the caregiver group had a greater consensus in attitudes, both agreement and disagreement, about the Q statement ranking. Thus, fewer statements distinguished each caregiver cluster. Some topics that caregivers commonly agreed upon included (1) giving importance to having information that's easy to share with others (#24), and (2) having someone else help keep track of things is important (#19). Caregivers also said they wanted to feel doctors had time to answer their questions (#14) and to know about different treatment options (#7). Caregivers did not agree with the statement that they should know only what the doctors think is important (#31).

**Caregiver Persona 1: The Cooperative Information Seeker**

The persona resulting from the first caregiver cluster of the Q analysis (n=10) is distinguished by 8 statements, summarized in Table 3. We call this persona the "Cooperative Information Seeker" based on the caregiver’s interest in specific details and information about the care being given to the patient and their value of getting along with members of the care team.

These caregivers were “information seekers”, wanting to know how serious the patient's condition is (+4*), having medications explained to them (+4), and knowing different treatment options (+3). These caregivers also found it important to be an active participant in the patient care (+2). These caregivers disagreed with “only wanting to know what the doctor thinks is important” (-4), or leaving the decisions about the patient to the care team (-2). These caregivers wanted to be “cooperative” with the care team, to have a positive relationships with the care team (+2*), and, that it is important to feel like doctors have time to answer their questions (+3). One caregiver placed the responsibility of a good relationship to the care team, instead of the patient-caregiver team. In a statement reflecting their own role as patient proxy, they said: “a bad start is a bad start. And that's why it's good rapport, and I think as a patient, I don't need to worry about that. Nurses and doctors need to” (C08).

This caregiver cluster is different from the other caregiver clusters in terms of interest in tracking. They expressed greater agreement with statements around the importance of information tracking (0), compared to the second cluster, the “Vocal Participators” (-3), and the third cluster, the “Entrusting Safety Guardians” (-3). These caregivers also strongly disagreed with relying on memory (-3), compared to the “Vocal Participators” (+1) and “Entrusting Safety Guardians” (0). The information seeker caregivers were relatively neutral in their attitudes about information management, compared to cluster 2 and cluster 3 who strongly disagreed with statements about tracking (#18).

**Caregiver Persona 2: The Vocal Participator**

The second caregiver persona is based on the second caregiver cluster of the Q analysis (n=3), and is distinguished by 8 statements, summarized in Table 3. We call this persona the “Vocal Participator” because the place the greatest importance on the idea of being an active participant.

Table 3. Example distinguishing statements for each attitude cluster, (P>0.05, +4=Most Agree, -4=Most Disagree)
Caregivers in this cluster are “Vocal participators”. Across clusters, caregivers ranked statement #17, about being an active participant in the patient’s healthcare as the most important statement in the entire Q set (+4*), but participants in this caregiver cluster ranked it significantly higher than those in other clusters. They agreed with other statements such as being listened to by doctors and nurses (+4*), or speaking up when they have a question (+3*). This group strongly disagreed the most with the statement about leaving decision-making solely up to the clinicians (-4*). One caregiver summarized this sentiment: “I'm very active in her care, so I really don't prefer to leave any of it all the way up to the doctor. Her doctor, specific doctor who we don't get to see all the time because he's not on call, but always asks me my opinion first because he knows that I read up on the disease” (C03). These caregivers place importance on knowing the names and responsibilities of the doctors and nurses (+2*), and were not concerned about being a bother to their care team (-4*).

**Caregiver Persona 3: The Hands-off Safety Guardian**

The third persona resulting from the third caregiver cluster of the Q analysis (n=3) is distinguished by 6 statements, summarized in Table 3. One of the most representative statements for these “safety guardians” is to know about safety errors (+2*), to understand the doctor's reasoning when making a decision (+4), severity of patient illness (+4), medication information (+3). We call this persona the “Hands-off Safety Guardian” based on their focus on concerns about safety but neutral in controlling the patient’s care or even receiving information at their own convenience.

However, the caregivers in this cluster are more hands-off regarding their role relative to clinicians. They did not strongly agree or disagree with statements about leaving decisions about the patient care to the doctors (0*), and knowing only what the doctor feels is relevant (-1*). These caregivers are more balanced in leaving decisions to the care team (0*) than the “Cooperative Information Seekers” (-2) and the “Vocal Participators” (-4), who explicitly prioritized not leaving decisions to the care teams. Consistent with a more hands-off engagement, are the distinguishing statements that these caregivers do not find it important to get information at a time when they can focus (-4*), or that the care team needs to listen to them (-2*).

**Discussion**

This study demonstrates that using a mixed method approach for clustering patients and caregivers can identify different persona types for how hospitalized patients and their caregivers want to engage with their care and prioritize information. Although other work has described personas for people managing chronic conditions—such as heart failure, or cancer—this work adds insights into the type of personas we encounter in the hospital environment, for both patients and caregivers. Our analysis contributes knowledge that individual patients and caregivers place different relative values on three types of needs: information seeking about their care (e.g. updates about care, information about self-management), patient safety, and the active engagement in self-care and communication with the care team. Our personas demonstrate how, while individual patients and caregivers may care about all three types of needs, they prioritize each of these needs differently. This difference in relative values means that patient-facing technologies must include features to support a variety of approaches to receiving and engaging with information and communication in the hospital. We describe a variety of features based on prior work that patient facing technology might include to support the multitude of priorities highlighted by the personas.

**Designing for Information Seeking**

Two of the personas we identified prioritize access to information over a strong active participation in their care, so technology should be proactive in providing information, without people having to seek it out. Inpatient-facing systems need to offer a range of detailed information, including the status of the patient, often related to the immediate care in the hospital, plan of care, medication, changes in their condition, or information about severity of the patient’s condition. For medication information, systems should provide patients with information about what the medicine is, why they are taking the medicine, how to take and how much of the medicine to take, or what alternatives exist.

Because both the patient (Accommodating Information Seeker) and caregiver personas (Cooperative Information Seeker) reflect a need to have a good relationship with providers or to not be a burden, information should be delivered in a way that is very easy for them to understand it. For example, the provided information could adapt to the level of health literacy of the patient and use delivery modalities like audio and video.

To prioritize caregiver’s needs, inpatient portals could support sharing features or the ability to have several caregivers interact with the portal. For example, technology should enable collaboration between several caregivers in tracking data about what is happening in the hospital, such as symptoms, or what the providers communicate about patient care. These features should be designed with special considerations for maintaining privacy between the patient and caregiver when appropriate.
The different priorities in being an Accommodating Information Seeker patient versus a Cooperative Information Seeker caregiver leads to different design implications for how these personas want to engage with the care team. Because caregivers are not as worried about being a burden to providers, systems can facilitate cooperation with the care team by sharing the names, photos, roles, and schedules of individual care team members. This can make it easier for the caregiver to engage with the team. To support the Accommodating patient, systems can enable the patient to communicate their needs while providing flexibility in the modality of this communication. Systems can prioritize asynchronous electronic communication, and flag which questions are urgent to the care team, to reduce patient concerns about being a bother and allow them to perform question “triage”\(^{40}\). To make patients more comfortable in contacting specific providers to ask questions, systems can include information about how each member of the care team prefers to be messaged, or the ability to choose which member of the care team they contact.

**Designing for Safety**

Being a safety guardian is often associated with being a vigilant monitor, in particular of communication with clinicians\(^{41,42}\). Systems should include a variety of features to support the different levels of involvement that Safety Guardians want to have. The needs reflected by the Involved Safety Guardian suggest that patient-facing portals should include features that promote active participation from patients, and enable keeping patients aware of safety issues, medication, and errors that can occur. Systems could support patients in actively reviewing their medication and preventing errors\(^{40,43}\). Through active engagement, patients could use checklists where to monitor whether they are getting the correct medication, alerts and reminders to monitor provider’s hygiene, and other potential hazards.

For the Hands-Off Safety Guardian caregiver persona, who is less engaged in managing safety issues, systems can provide ways to monitor their safety that do not introduce greater cognitive or physical burdens, such as FAQs about safety, common questions by patients like me, notification about important safety issues (e.g., changes in medication), or issues to watch for when taking medication. By including a variety of features, patient-facing technology can appeal to patients and caregivers with varied levels of engagement in care.

**Designing for Active Participation**

Being an active participator in one’s care involves a high interest in both information about care and in engaging with the care team, thus systems should be designed to actively support patients in participating in their care. To support the Self-Managing Participator patient, patient-facing portals should be proactive in offering information about the patient’s care and self-management of their condition, such as changes occurring in their care, changes in medication, severity of their condition, or plan of care. To help patients prepare for discharge and managing care outside of hospital, technology can help patients build up knowledge about how to manage their health, and techniques to build self-efficacy towards managing their health\(^{44}\).

The Vocal Participator caregiver persona prioritized a high level of engagement with the care team. Systems can support them with features that enable high engagement: requesting a second opinion, engaging with doctors and nurses at times that are convenient not only for the clinicians but also for the patient and caregiver, notifications about when their doctor is due to arrive for consultation, what each care provider is in charge of for their care, or the ability to give feedback to the provider about what they did well or what could be improved. This information is of importance to caregivers, because that can help them be present for important communication events such as during rounds or when important decisions are discussed.

**Limitations and Future Work**

Although personas are a commonly used tool to help designers make decisions, they will not capture every user’s needs; rather, personas are meant to identify archetypes of a variety of users. People might have additional needs beyond what has been identified in prior work\(^{41-44}\). In addition, our sample was designed for breadth rather than depth in understanding how the needs and values of patients and caregivers differ between hospital settings or units within a hospital. Our approach offers a broad holistic view of hospitalized patient and caregiver priorities, but it is possible that if medical and surgical patients’ data were analyzed separately there might be a different prioritization of needs across personas. Also, we assessed how patients and caregivers prioritized information and communication needs at one point in time, but patient or caregiver priorities could change during their stay in the hospital. Further research is needed to understand whether these personas can be applied broadly across all hospital contexts, or if certain care contexts bring with them certain priorities. We have found distinctions between the patient and caregiver personas, but more work is needed to understand how the differences in priorities of participants in our study transfer to different population groups, including based on demographics, disease type, settings, or across different types of caregivers.
Conclusion
Our work contributes a new understanding of information management and communication priorities of hospitalized patients and caregivers. Through our mixed-methods approach, we identified three patient personas: accommodating information seekers, involved safety guardians, and self-managing participators. We also identified three caregiver personas: cooperative information seekers, vocal participators, hands-off safety guardians. These personas could be used by designers of technologies to ensure that during the design process the personas facilitate design choices that support the needs of different kinds of people, with different priorities and needs. Abstract

This study captured daily and weekly mood ratings using a smartphone from bipolar disorder (BD) and unipolar major depression disorder (MDD) subjects at high (HRMDD) and low risk (LRMDD) for developing Bipolar Disorder (BD) and healthy controls (HC). Method: 40 subjects (18 – 30 yr) (6 BD, 13 HRMDD, 16 LRMDD and 5 HC) were studied and a total of 2401 daily and 744 weekly ratings were collected. HRMDD and LRMDD subjects were naturalistically treated with antidepressants. We investigate if latent-class analyses of ratings can detect mood instability among MDD and BD groups. Results: Our analyses revealed four underlying mood states correlating with clinical mood states. There was a trend for greater number of state changes in BD and HRMDD subjects compared to LRMDD and HC groups. Conclusion: Smartphone ratings may adequately capture mood instability in BD subjects and at risk HRMDD subjects and offers a prudent way for monitoring development of serious manic symptoms.

Introduction

Depression can manifest itself in two forms – unipolar or major depression (MDD) in which subjects only suffer from episodes of depression (low mood and lack of pleasure, decreased energy, sleep/appetite problems, decreased concentration, hopelessness and suicidal ideation) and bipolar disorder (BD) in which patients suffer from periods of depression but also suffer from periods of mania (elation or irritability, excessive energy, lack of need for sleep, rapid speech, grandiosity, poor judgment and impulsivity). [1] BD is a more serious illness as it is frequently associated with more severe depressive symptoms and with mania that can lead to serious social and legal consequences. Furthermore, the mood instability from periods of depressive symptoms to periods mania can lead to an unstable and chaotic lifestyle.

One critical problem in the treatment of MDD, particularly in young patients, is that some MDD patients may have a hidden risk for developing a (hypo) manic episode and conversion of diagnosis to BD. Many of these vulnerable subjects have a family history of BD or have sub-threshold BD symptoms. [2,3] It is critical to closely follow-up these patients for changes in mood symptoms particularly during antidepressant treatment as the response to treatment can be unpredictable in these patients. Some studies suggest a propensity for precipitation of mania or rapid antidepressant response [4] while others suggest that antidepressants can be safely given to MDD groups at high risk of developing BD. [5] Clinical appointments spaced out over several months may not be able to capture fluctuations in mood or occurrence of (hypo)manic symptoms. Patient reports at these appointments with clinicians are at best subjective retrospective recollections compounded by lack of recognition of (hypo)mania symptoms by the patients in themselves.

Therefore, it is critically important to develop new methods to measure any increase in mood fluctuations in MDD patients that have been recently started on antidepressants. These new methods need to be more sensitive to changes occurring over time as well as be more objective in terms of how they measure changes in mood instability between periods of depressive, (hypo)manic and euthymic states. In this regard, the recent availability of smartphone technology and the emerging field of behavioral informatics has provided a new way of acquiring and measuring mood data. Smartphone applications are being increasingly used to monitor mood symptoms and also deliver
interventions in MDD and BD. [6–10] However, few studies have investigated at-risk mood disorder populations to monitor effect of antidepressant treatment using smartphone technology.

In this study, we used a smartphone application to monitor the effect of antidepressant on mood instability in terms of fluctuations between mania and depression, in young MDD subjects who are at a high risk of developing BD (HRMDD) and compared them to young patients with depression at low risk of developing bipolar disorder (LRMDD) as well as with subjects already diagnosed with BD and Healthy Controls (HC). We perform latent class analyses of smartphone survey ratings. The ratings represent time-series of survey scores collected from subjects while under treatment or from HC. Using a data-driven approach, we aimed to find latent states that may correlate with clinical mood states in these groups. Furthermore, we aimed to find group-level differences in their (latent) state transitions. Our hypothesis was that HRMDD group will be similar to the BD group in that they will show an increase in mood instability over time and will have higher spikes of (hypo) manic symptoms compared to LRMDD and HC groups.

**Methods**

Medication-free subjects were recruited from an ongoing study for treatment of MDD in young adults in which after a baseline assessment, open-label treatment with antidepressants was given and patients were followed up with periodic assessments and ratings of depression and mania scores. In addition to these procedures, the subjects were consented separately to take part in a smartphone mood monitoring study in which they could record their mood on a daily as well as weekly basis using a proprietary smartphone app developed by the company - Ginger.io. (San Francisco, California)

**Inclusion criteria for MDD subjects:** Ages 15-30 years and able to give voluntary informed consent; 2) Satisfy criteria for DSM-IV-TR Major Depressive Episode using a Structured Interview; 3) Never met criteria for mania or hypomania; 4) 17-item Hamilton Depression Rating Scale score (HDRS) [11] > 15 and < 25; 5) Young Mania Rating Scale (YMRS) [12] score < 10; 6) Able to be managed as outpatients during the study as ascertained by the following – i. Clinical Global Severity Scale [13] < 5 i.e. moderately ill, ii. No significant suicidal or homicidal ideation or grossly disabled; 7) Have a smartphone on which the ginger.io mood application can be used; 8) willing to record their mood and activity using the Ginger.io application. **Inclusion criteria for BD subjects:** 1) Satisfy criteria for DSM-IV-TR Bipolar Disorder Depression using a Structured Interview; 2) Rest of the criteria same as that for MDD subjects; 3) on no psychotropic medication. **Inclusion criteria for Healthy Control (HC) subjects:** 1) no personal or family history in first degree relative of psychiatric illness; 2) no significant neurological disorder; 3) no history of alcohol of substance dependence in the past 12 months; 3) on no psychotropic medication. **Ascertainment of HRMDD vs LRMDD is described in a previous publication.** [14]

**Exclusion criteria for all:** 1) meeting DSM-IV criteria for schizophrenia, schizoaffective disorder, or an anxiety disorder as a primary diagnosis; 2) use of psychotropics in the past 2 weeks; use of fluoxetine in the past 5 weeks; 3) acutely suicidal or homicidal or requiring inpatient treatment; 4) meeting DSM-IV criteria for substance dependence within the past year, except caffeine or nicotine; 5) positive urinary toxicology screening at baseline; 6) use of alcohol in the past 1 week; serious medical or neurological illness; 7) current pregnancy or breast feeding.

**Smartphone application:** The Ginger.io Behavior Platform as implemented at the time of the study was used by researcher groups, clinicians, patients and providers alike to collect data. In this paper, we are reporting results from active data collection using surveys and other self-reported data gathered through user input. This was achieved in two ways: (i) the user receives a notification that a survey is available and upon clicking the notification, they are transferred to the survey page, (ii) the user can then manually launch the application and they are shown all the surveys available at that time. The data described above is encrypted and transmitted over a secure 128-bit SSL 3.0 connection using the HTTPS protocol for transmissions between mobile application, web application and secure servers.

**Smartphone surveys:** Daily ratings were for the following items on a 1 – 5 visual analog scale with 1 signifying “Not at all” and 5 “Signifying Most of the day” on the other. The daily ratings for (hypomania) ratings were questions for the last 24 hours for the following items - 1) feeling much more excited or full of energy than usual; 2) feeling so good or so hyper that other people thought you were not your normal self or you were so hyper that you got into trouble; 3) feeling so irritable or grouchy that you either started arguments, shouted at people or hit people; 4) sleeping far less than usual and still not feel tired or sleepy. Weekly ratings were also done to assess bipolar symptoms for the past 1 week on the following items and a visual analog scale from 1 – 7 with 1 signifying “Not at all” on one end and 7 signifying “all the time” on the other. These surveys were done on the following items – 1) did you feel happier or more cheerful than usual; 2) did you feel more self-confident than usual; 3) did you sleep far less than usual and still not feel tired or happy; 4) did you talk more than usual; 5) were you more active either socially, sexually, at work,
**home or school than usual.** The mania items were summed up to get one score for daily and weekly ratings each respectively.

**Treatment:** after the baseline ratings MDD patients were started on antidepressant treatment usually with selective serotonin reuptake inhibitor antidepressant, most frequently fluoxetine, unless patient wanted another antidepressant. Patients were given “real world” open label treatment and dosage was adjusted depending on tolerance or response. Augmentation with another antidepressant such as bupropion or change to another antidepressant such as a dual uptake inhibitor e.g. duloxetine was also done depending on tolerance and treatment response. Bipolar subjects were followed up in the regular outpatient clinic and treated with antidepressants and mood stabilizers as indicated.

**Statistical Methods and Analyses**

Two types of analyses were done for measurement of mood instability: 1) *A priori* defined criteria; and 2) *Latent-class* analyses of weekly rating score time series using a data-driven approach.

**A priori criteria for mood instability:** The aim for these analyses was to measure daily and weekly sub-threshold (hypo)mania symptoms scores in a clinical setting – 1) a priori defined criteria for spikes in scores (>2 threshold and >25% increase from baseline) and fluctuations (change in two consecutive ratings of more than 25%). We also measured differences in subject groups using statistical methods (ANOVA).

**Latent-class Analyses:** using Hidden Markov Model (HMM) [15], mainly to test the hypotheses that the number of latent states in the *weekly mood ratings* correspond to the number of mood states inferred (using overall clinical ratings and assessment) by the clinician. We also hypothesized that the transitions of a subject in underlying latent states (as measured by percent times a subject switches states over the course of the study) will vary in expectation with clinical classification of mood states. Accordingly, HRMDD subjects would have the highest switch rate (as the BD subjects in the study were likely being treated with mood stabilizers).

**Modeling:** The aims of modeling are to a) discover the number of latent states that may represent clinical mood status in weekly mood ratings dataset; and b) gain insights as to the characteristics of these states in relationship to the smartphone surveys and subjects’ sub-groups or class label of HRMDD, LRMD, BD, HC. HC were studied to study the differences from normal for each of the patient group. In this regard, please note that the modeling did not target any particular variable from the smartphone survey or subject-level data.

For the first aim, we constructed several HMMs using the python library (https://pypi.org/project/hmms) and the weekly mood ratings data. The 5 distinct weekly rating questions (measured on a scale of 1 to 7) were summed to get a total score of 1 to 35 per subject for each weekly assessment. Then for learning a model and evaluating its performance, the dataset was randomly split into training and test (held-out) sets of weekly mood rating sequences (70-30% split). To address the need for learning a model from a larger sample or all available data, we use 10-fold cross validation approach, i.e. we used 10 random splits (samples of training and test sets) and performed independent experimental setups (as detailed below). This is in accordance with accepted machine learning practice of evaluating a model to avoid overfitting. [16]

Our primary interest was to find an explainable set of latent states that may correspond with clinical mood status (i.e. euthymia, depression, and range of mania symptoms). Thus, we limit our exploration to the 5 latent states (varied from 2 to 6). It’s possible that a greater number of latent states may increase the model fit but may also reduce explainability. Thus, we sought to compare 5 separate latent state models in the 10 experimental setups. We selected the number of latent states based on a model that maximizes the likelihood of the data (i.e. held-out set). This model can then be explored further for latent state characteristics and decoding of weekly mood ratings. Below we give details of the experimental setup, performance metric and model selection and model-based decoding of the weekly mood ratings data.

**Experimental setup:** In each experiment, we parameterize a model to learn a fixed (N) number of latent states (using the training set), among other model parameters (i.e. initial state, emission probabilities and transition matrix) for an HMM using the Expectation-Maximization (Baum-Welch) algorithm [17] implemented in the python library. To measure model performance, we compute the log-likelihood (probability) of data (i.e. total score of weekly mood rating sequence) for every subject in the held-out set under the model (parameters). We also start each experiment from random initialization (seed) to mitigate the issue of local maxima and repeat the above procedures for every latent state we wished to explore, i.e. we varied N from 2 to 6 latent states in all the 10 experimental setups. Overall,
we performed 50 experiments and computed log-likelihood of held-out set in each.

Performance metric and Model selection: Individual held-out subject probabilities were computed in each experiment, and log summed up for obtaining the log-likelihood (LL) of the (held-out) test set, i.e. predictive LL of the model. This score was used for model comparison of all the latent-states explored. In general, the higher the predictive LL score, the better the model fit to the number of latent states and the observational data (i.e. weekly mood rating sequences). In our setup, we selected a model based on the median value of the predictive LL for all the latent state explored in the 10 random experimental setups. The model that best fit the observational data (D) with the number of latent states (N) is the one with maximum median LL, i.e. argmax(P(D, N | Θ)), where Θ are the learned model parameters. Here we refer to this model as the selected model.

Model based decoding: The selected model was then used to decode an individual subject’s weekly mood rating sequence, i.e. the selected model assigned a latent state to every subject’s weekly mood rating. Here we use the state assignment to draw observational insights and its association to other subject-level characteristics, such as their (known) class label or sub-group. Please note that these analyses are post-hoc and sub-group label was not used for modeling in anyway. In particular, we examine percent (latent) state change by these sub-groups, i.e. number of times the latent state change occurs over the observational period which is defined as the number of subject-level measures. We also examine clinician interpretation of the modeling states and any age or gender differences in these states.

All data were collected in accordance with IRB approval. Cleveland Clinic Foundation IRB approved this study.

Results

A total of 2401 records from 40 subjects (6 BD, 13 HR or HRMDD, 16 LR or LRMDD and 5 HC) were available for daily mood ratings. A total of 744 records were available from 38 patients (6 BD, 13 HRMDD, 14 LRMDD and 5 HC) for the weekly ratings for 2 to 44 weeks. Please see Table 1 for subject characteristics.

A priori defined percent mood fluctuations: For percent mood fluctuations between two consecutive ratings, daily ratings showed differences between groups (BD: 13%, HRMDD, 5%, LRMDD: 6%, HC: 0%) and this difference was significantly different only between BD and HRMDD (p = 0.02). For percent mood fluctuations in weekly ratings, (Figure 1), differences were seen between groups (BD: 25%, HRMDD: 15%, LRMDD: 10% and HC: 0%) and for patient groups this difference was significant between BD and LRMDD (p = 0.05).

A priori defined percent mood spikes: For percent of manic spikes, significant differences were seen between groups for daily ratings (BD: 35%, HRMDD: 6%, LRMDD: 11%, HC: 0%). This difference was significant between BD and HRMDD (p=0.001) and BD and LRMDD (p=0.05) but not different between HRMDD and LRMDD. For weekly ratings, differences were also seen between different patient groups (BD: 49%, HRMDD: 19%, LRMDD: 27%, HC: 2%). For daily ratings this difference was significant only between BD and HRMDD (p = 0.001).
Latent-class analyses of weekly mood ratings: The *predictive LL* was largest for the model with 4 latent states, followed by 5, 2, 3 and 6 latent state models (median values: -3.77, -4.28, -4.46, -4.49, -4.80 respectively). Thus, using a data-driven approach, a 4-state model was selected for further interrogation. A 4-state model also lends itself well to the clinician’s interpretation of mood status as euthymic, depressed, and range of mania symptoms. Therefore, further results here are derived from the best model among the 4-state models (in terms of predictive LL). Below we describe latent state changes as observed in the data.

**Percent latent states change**: Please refer to Figure 2 for the following text. As expected, healthy controls showed no changes (as reflected by latent states in our model), and LRMDD and HRMDD subjects show lower number of (median) state changes when compared to BD subjects.

![Figure 1: A priori criteria percent mood fluctuations](image1)

![Figure 2: Percent latent states change](image2)

*Note: BP refers to BD sub-group (Left), LR is LRMDD sub-group, HR is HRMDD sub-group (Right)*

We further observed the following latent state characteristics as in Table 2. It is likely State 0 corresponds to euthymic mood status as in a HC (i.e. negligible mania symptoms), State 1 corresponds to minimal mania symptoms status, State 2 is few mania symptoms mood status and State 3 is mild mania symptoms mood status. This classification can be made on the basis of higher mania symptom scores as seen in states 2 and 3 (Table 2).

</table>
Furthermore, it is clinically known that subjects in the BD sub-group continue to have mild spikes even when on medications. [18] This is also depicted as higher latent state changes in the BD sub-group in Figure 2. We depict an example decoding of one BD subject’s weekly mood rating sequence (into latent states) in Figure 3 and table below.

A typical BD sub-group subject switches states over the course of time (3 times or 9% for the subject in Figure 3 – marked with * in Table below). We found that overall the mood status (as measured by latent states change) fluctuated up to a third (i.e. 33% of times) in all subjects studied. There was no state fluctuation in HC subjects, and on average 5% in LRMDD, 7% in HRMDD and 11% in BD subject sub-groups. This trend in latent state fluctuations was similar to that calculated directly using our ‘a priori criteria’ for mood score fluctuations, as mentioned above.

**Discussion**

The results of this study indicate the feasibility of assessing daily and weekly mood instability in subjects, particularly undergoing antidepressant treatment, using a smartphone. A few other studies have also reported good feasibility of capturing mania symptoms using daily ratings. [8] However, in this study, we also conducted weekly mood ratings. In general, daily mood and weekly mood ratings changes as measured with a priori criteria were in similar direction indicating that weekly mood ratings may suffice. Weekly ratings may decrease the burden on the subject in terms of answering daily surveys. [6]

In terms of differences among patient groups based on daily and weekly changes in mania symptoms, the BD group showed the greatest number of changes, the LRMDD group the least and the HRMDD group showed intermediate fluctuations (Figure 1) based on a priori criteria for spikes and fluctuations. Adding to face validity of these measures – the healthy controls showed little or no mania spikes or fluctuations. However, the difference between HRMDD and LRMDD for mood spikes and fluctuations, as defined, was not significant. This could indicate no difference between the two groups in terms of mood instability or that the a priori measures as defined were not constructed properly to show the difference. In terms of continuous measures, it is difficult to define mood spikes or fluctuations beyond consecutive ratings as many such measures could be constructed using 3, 4 or more number of ratings grouped at a time.
In this regard, conceptualizing mood and mood disorders as complex and non-linear systems can add to our current understanding of mood regulation [18] and a data-driven latent class model which explores hidden states can be much more objective and informative. The classification of mood ratings by this model also has face-validity as assessed by the clinician author (AA). Using a 4-state model, we found that both HRMDD and BD subjects have a greater number of state changes than LRMDD subjects. The direction of differences between groups (BD>HRMDD>LRMDD>HC) was the same using the ‘a priori criteria’ of fluctuations in mood symptoms and that for the latent mood states. These results suggest that latent class analyses of time series of mood states available from smartphone ratings provides a better analytical framework to identify mood instability.

Limitations of the study were the small number of subjects that were studied though a large number of data points were obtained. Future studies are needed with larger number of subjects particularly within each diagnostic subgroup. Comparison groups also need to be closely matched in terms of age, gender and ethnicity. Another limitation was that subjects started their smartphone ratings at different durations of treatment therefore future prospective studies are needed with all subjects at the same point of their treatment preferably at the start of the study. This study involved open label treatment with a variety of medications along with a naturalistic follow-up. Randomized controlled trials, possibly with placebo will be needed to further confirm the bipolar like mood instability in HRMDD patients while on antidepressant treatment. Smartphone ratings also need to be correlated with clinical ratings that are the gold standard in terms of mood ratings. Correlational analysis between smartphone ratings and clinical ratings along with clinical assessment of severity of illness need to be done to further validate the use of mobile ratings.

**Conclusion**

In summary, the results of the study indicate feasibility of doing smartphone ratings at a daily and weekly basis in mood disorder subjects. Weekly ratings may be adequate to decrease the rating burden on the subjects. In terms of clinical findings, bipolar disorder patients seem to have the most mood instability compared to MDD subjects. Within the MDD group, while on antidepressant treatment, subjects thought to be at high risk of developing BD (HRMDD) exhibited higher mood instability than those at low-risk (LRMDD). As the HRMDD subjects are at a risk of developing full-blown manic symptoms, weekly smartphone ratings may be used to monitor their mood to predict such events.

Abstract

In this work, we utilize a combination of free-text and structured data to build Acute Respiratory Distress Syndrome (ARDS) prediction models and ARDS phenotype clusters. We derived 'Patient Context Vectors' representing patient-specific contextual ARDS risk factors, utilizing deep-learning techniques on ICD and free-text clinical notes data. The Patient Context Vectors were combined with structured data from the first 24 hours of admission, such as vital signs and lab results, to build an ARDS patient prediction model and an ARDS patient mortality prediction model achieving AUC of 90.16 and 81.01 respectively. The ability of Patient Context Vectors to summarize patients' medical history and current conditions is also demonstrated by the automatic clustering of ARDS patients into clinically meaningful phenotypes based on comorbidities, patient history, and presenting conditions. To our knowledge, this is the first study to successfully combine free-text and structured data, without any manual patient risk factor curation, to build real-time ARDS prediction models.

Introduction

Critical care Clinical Decision Support (CDS) systems aim at the early identification and timely treatment of rapidly progressive, life-threatening conditions. In particular, ARDS (Acute Respiratory Distress Syndrome) is a significant cause of morbidity and mortality in the USA and worldwide1,2. Early recognition and evidence-based management of ARDS can limit the propagation of lung injury and significantly improve patient outcomes3.

To date, there exists no accurate and reliable way to anticipate which patients, presenting with respiratory distress, are likely to develop ARDS. Numerous prediction scores have been developed to assess ARDS prognosis and risk of death, such as Lung Injury Score (LIS)4, Lung Injury Prediction Score (LIPS)5, APPS (Age, Plateau, PaO2/FiO2 Score)6, Early Acute Lung Injury (EALI)7, and Modified ARDS Prediction Score (MAPS)8. Using a consensus process, a panel of experts convened in 2011 to develop the Berlin definition, focusing on addressing a number of limitations of prior definitions9. Still, the predictive validities of these tools and definitions have proven to be moderate, for example, as measured by area under receiver operating curve (AUC).

The difficulty in analyzing and predicting ARDS outcomes stems from the fact that this is both rare, and, at the same time, highly heterogeneous condition10. ARDS involves the interaction of multiple risk factors, past history, and current conditions, signs, and symptoms. Hospital alert systems typically rely on highly sensitive screening of structured data, such as vital signs and lab results, which, in the case of such rare conditions, are often associated with false clinical alarms resulting in “alarm fatigue”11.

EMR data depends on what the clinician deems necessary to measure and record in the act of caring for the patient. EMR data is typically entered for the purposes of clinical documentation and billing12, and thus not centered around the needs of real-time surveillance-based CDS systems. The combined physician care related variables and underlying patient-related contextual factors needed for a reliable ARDS risk evaluation are typically dispersed across the patient EMR record, and available at different times throughout the patient stay. Patient demographics, past medical and visit history, chronic conditions, risk factors, current signs and symptoms can be found in diverse combinations of structured elements and clinical notes (e.g. nursing notes, radiology reports, etc.), that record diagnosis and procedure codes, vital signs, lab orders and results, ventilation parameters, etc. The challenge for real-time surveillance-based CDS systems is accommodating for the variability and the availability of real-time electronic data and enabling accurate contextual interpretation of real-time patient data.

In this work, we utilize all available EMR patient information, in the form of structured data and free-text, for real-time predictive modeling. While our experiments are focused on identifying ARDS cases, the described method is
applicable to a variety of disease surveillance CDS use cases, needing information dispersed across the EMR patient record.

A second goal of this study is to utilize the combination of clinician knowledge and experience, and a data-driven approach to identify ARDS patients' phenotypes and risk factors, acknowledging the need for targeted personalized treatments reflecting differences in treatment outcomes across patient subtypes.\textsuperscript{13–15}

**Dataset**

Clinical encounter data of adult patients were extracted from the MIMIC3 Intensive Care Unit (ICU) database.\textsuperscript{16} MIMIC3 consists of retrospective ICU encounter data of patients admitted into Beth Israel Deaconess Medical Center from 2001 to 2012. Included ICUs are medical, surgical, trauma-surgical, coronary, cardiac surgery recovery, and medical/surgical care units. MIMIC3 includes time series data recorded in the EMR during encounters (e.g. vital signs/diagnostic laboratory results, free text clinical notes, medications, procedures, etc.). The dataset contains data associated with over 58,000 ICU visits, including over 2 million free-text clinical notes and over 650,000 diagnosis codes.

For this study, in accordance with previous literature,\textsuperscript{17} we identified ARDS for adult patients older than 18 years with ICD-9 codes for severe acute respiratory failure and use of continuous invasive mechanical ventilation, excluding those with codes for acute asthma, COPD and CHF exacerbations.\textsuperscript{1} This resulted in 4,624 ARDS cases from a total of 48,399 adult ICU admissions. The ICU mortality rate in this population was approximately 59%, somewhat higher than expected for ARDS\textsuperscript{18}, suggesting that the algorithm used is capturing the most severe cases of ARDS, and thus introducing some level noise with possibly containing true ARDS cases marked as negative examples.

Our ARDS predictive model utilized data in the form of free-text clinical notes, ICD codes, and structured physiological and ventilator data. The structured data included in this analysis consists of anion gap (aniongap), albumin, bands, bicarbonate, bilirubin, creatine, chloride, glucose, hematocrit, hemoglobin, lactate, platelet, potassium, partial thromboplastin time (ptt), international normalized ratio (inr), prothrombin time (pt), sodium, bun, white blood cell count (wbc), heart rate (heartrate), systolic blood pressure (sysbd), diastolic blood pressure (diabs), mean blood pressure (meanbp), respiratory rate (resperate), body temperature (tempc), peripheral capillary oxygen saturation (spo2), body mass index (bmi), gender, age, urine output (urine1). All variables are included as min, max, and mean values and are measured over the first 24 hours of ICU admission. The first 24 hour timeframe was chosen, as it has been reported that ARDS develops at a median of 30 hours after hospital admission.\textsuperscript{19} Thus, a 24-hour window provides for the gathering of enough structured data, while at the same time is early enough for real-time CDS.

**Descriptive Analytics**

ARDS patient characteristics and risk factors were first gathered with the help of experienced clinicians. Expert knowledge was gathered in the form of Concept Maps (Cmaps).\textsuperscript{20} Cmaps is a tool developed at the Institute for Human and Machine Cognition (IHMC) that enables collaborative knowledge creation, in the form of concepts, relations, and ontologies, with links to external resources and publications. A snippet of the developed ARDS Cmap developed by our clinical research team is shown in Figure 1.

For example, clinicians coded ARDS precipitant causes include sepsis, aspiration, traumatic injuries, burns, and drugs, including illicit drugs, such as cocaine, heroin, or prescription drugs, such as chemotherapeutic agents, etc.

Initially, the ARDS Cmap was used as a screening rule engine. In addition, the Cmap was used to identify risk factors that were later used in predictive models. Although rule engines based on Cmaps are evidence-based and tend to be highly sensitive, they tend to perform with subpar specificity (e.g. the Berlin definition achieved an AUC of 0.577). Such rule engines are also highly sensitive to missing data. In contrast, data-driven and Machine Learning algorithms have the potential to improve on rule engines from training on large datasets, learning from a variety of clinical data and response patterns, and are able to handle missing data. However, for machine learning to be effective in predicting highly heterogeneous conditions such as ARDS, training data requires both high precision labeling and the identification of features with adequate numbers of samples needed to separate classifications of ARDS classes and subclasses/phenotypes from non-ARDS patients.

\textsuperscript{1}Inclusion ICD9 Codes: 51881, 51882, 51884, 51851, 51852, 51853, 5184, 5187, 78552, 99592, 9670, 9671, 9672; Exclusion ICD9 Codes: 49391, 49392, 49322, 4280.
Figure 1: ARDS Cmap: Clinician-coded representation of ARDS patient characteristics and risk factors.

ICD Embeddings and Patient Vectors

We then looked for a data-driven approach to provide additional insight into ARDS patient characteristics, risk factors, and phenotypes.

Intuitively, even without any additional patient EMR data, clinicians viewing properly coded patient diagnosis codes (e.g. ICD codes in a problem list) are typically able to create a mental summary of the overall patient condition, including medical history, risk factors, presenting conditions. ICD codes are used to describe both current diagnoses (e.g. Pneumonia, unspecified organism: ICD9 486), but also a variety of additional patient information. For example, ICD codes can describe ARDS risk factors, such as patient’s history and chronic conditions (e.g. Chronic kidney disease; Personal history of malignant neoplasm; etc.); information regarding past and current treatments and procedures (e.g. Infection due to other bariatric procedure). In some cases, ICD codes contain information such as the patient age group and/or susceptibilities (e.g. Sepsis of newborn; Elderly multigravida); expected outcome (Encounter for palliative care); patient social history (e.g. Adult emotional/psychological abuse; Cocaine dependence); the reason for the visit, (e.g. Railway accidents; Motor Vehicle accidents).

Using ICD codes for statistical analysis and predictive models, however, poses a series of challenges. Patient ICD codes in EMRs tend to be sparse. There are numerous ICD codes (around 15,000 ICD9 codes and around 68,000 ICD10 codes), with only a very small subset of these applicable to a particular patient (e.g. MIMIC3 admissions have an average of 11 ICD codes). ICD codes also tend to co-occur and overlap. In addition, ICD coding can be, in some cases, subjective and dependent on numerous external factors.

However, the concurrence and mutual information of ICD codes over large data repositories can be utilized. For example, the fact that Pneumonia ICD codes are often accompanied with ICD codes describing Cough, Fever, Pleural effusion, etc. can be utilized to generate vector representations of ICD codes. Inspired by deep learning representation, such as word embeddings, it has been suggested that this medical code co-occurrence can be exploited to generate low-dimensional representations of ICD codes that may facilitate EMR data-based exploratory analysis and predictive modeling.

In this study, we utilized available MIMIC3 patient data to generate the ICD embeddings following the approach of Choi et al. In our approach, we generated a low-dimensional representation of the patient history, symptoms, risk factors, diagnosis, etc., by averaging the patient ICD code embeddings. We refer to this representation of the patient’s medical history and clinical condition as Patient Context Vectors.

To generate ARDS patients groups sharing similar characteristics and risk factors, we then clustered the ARDS Patient Context Vectors via k-means clustering. Clinical review of the generated ARDS clusters determined the optimal number of clusters to be 10.
The Patient Context Vectors were able to clearly separate ARDS patient risk factors and conditions into clinically valid categories, such as Malignancy or Chronic Hepatic Disease. Figure 2 shows the frequency of patients in various clusters, sorted left-to-right according to mortality rate. Table 1 lists the 15 most representative ICD code descriptions (cluster centroids) for the 10 ARDS clusters. The cluster description was provided by clinicians reviewing the corresponding cluster centroids.

![Figure 2: Frequency and mortality rate of MIMIC3 ARDS patient clusters formed by clustering of averaged ICD embeddings.](image)

Interestingly, the manually clinician-curated Cmap appears to overlap to a large extent with the automatically derived ARDS patient clusters. For example, clinicians listed chemotherapeutic agents as a distinct risk factor for ARDS. Our data-driven analysis showed a distinct cluster of ARDS patients with ICD codes describing malignancy. Further analysis could delineate if this is a direct relationship between chemotherapeutic agents and the development of ARDS, or rather reflects an indirect relationship. For example, perhaps chemotherapy-induced immunosuppression acts as a risk factor for sepsis which, in turn, acts as a risk factor for ARDS.

Furthermore, the mortality associated with different clusters was also consistent with clinician experience. Clinicians recognize that patients with advanced malignancy may develop severe infections and ARDS as a final common pathway in their advanced disease. In this context, ARDS may represent a manifestation of their advanced underlying disease, and therapies directed at ARDS and its precipitant may not significantly impact mortality. Indeed, the cluster of malignancy-associated ARDS had a very high mortality rate of 90%.

In contrast, patients who develop ARDS as a result of trauma typically were well enough to be engaged in the activity leading to trauma, and thus ARDS may truly be the primary disease as opposed to a symptom of advanced underlying disease. The likelihood of mortality in this group may be more significantly influenced by the treatments targeted at ARDS. In our analysis, the cluster of trauma associated-ARDS had a significantly lower mortality rate of 30% compared to other clusters.

**Predictive Analytics**

Clustering and manual evaluation by clinicians of Patient Context Vectors proved to be a useful tool in summarizing the overall patient condition, risk factors and history. Real-time CDS systems, however, might not have access to the full set of the patient ICD codes as they might be entered in the EMR system at a later stage. It has been observed that clinical notes, specifically nursing and physician notes, typically contain all of the information available from ICD codes. Furthermore, while past medical history and presenting conditions might not always be ICD-coded, they are typically available in the form of free-text notes. In previous work, we have successfully utilized free-text for predicting Patient Context Vectors, in the case of missing ICD codes. Additionally, we were able to successfully combine information available in ICD codes and in nursing notes and produce an average Patient Context Vector.

A word-level Convolutional Neural Network (CNN) was trained to predict from free-text notes the Patient Context Vector (averaged ICD code embedding). Structured data, in the form of vital signs and lab results, was then combined with the predicted Patient Context Vector and utilized in a machine learning model trained to predict ARDS patients.
Table 1: The top 15 most representative ICD codes for various clusters, based on cosine similarity to the cluster centroid.

Figure 3 summarizes the system workflow during prediction time.

The ARDS prediction model was trained utilizing structured data from the first 24 hours of admission, as described above in the Dataset Section. In addition, the first half of the available patient nursing notes and the first half of entered ICD codes were used to produce Patient Context Vectors of size 50. The patient ICD codes were used to look...
Figure 3: Real-time ARDS prediction workflow. Nursing notes available at prediction time are used to predict Patient Context Vectors. ICD codes available at prediction time are also converted to Patient Context Vectors by averaging ICD code embeddings. Patient Context Vectors are used together with structured EMR data to predict the patient ARDS status.

Table 2: 10-fold cross-validation GBM results of predicting ARDS patients and predicting mortality among ARDS patients. P=Precision, R=Recall, F1= F1-score for the positive class. The Baseline set of features consists of vital signs, lab results, Glasgow Coma Scale score, gender and age, in the form of structured data. "Baseline + first half of notes/ICD" includes also the average of the first half of entered visit ICD codes embeddings, and Patient Context Vectors predicted from the first half of the visit nursing notes.

up the corresponding ICD code embedding and averaged. Each nursing note was used to predict the Patient Context Vector via the trained word-level CNN. All Patient Context Vectors were then averaged and used in addition to the structured MIMIC3 data. As the MIMIC3 dataset ICD codes lack timestamps, we were unable to identify ICD codes available during the first 24 hours of admission. The MIMIC3 ICD Codes, however, are ordered, and we used the first half of the ICD codes, and the first half of notes, as an approximation of data available early in the patient stay.

A Gradient Boosting Machine (GBM) model\textsuperscript{31,32} was used to predict ARDS patients from the total population of adult patients. A GBM model was also used to predict the mortality among all ARDS patients. Table 2 shows the result from the experiments. All results were produced via 10-fold cross validation.

In both prediction models, the inclusion of Patient Context Vectors significantly increased the overall model performance. Intuitively, the patient medical history and overall clinical condition are important predictive factors. Results demonstrate that Patient Context Vectors can be successfully utilized to represent additional knowledge of a patient’s condition. The importance of the Patient Context Vector is also demonstrated by the scaled GBM variable importance shown in Figure 4. Together with critical vital signs measurements, various Patient Context Vector dimensions (shown with prefix embedding) play an important role in predicting the patient’s ARDS outcome. A known limitation of
low-dimensionality representations is the lack of interpretability of individual dimensions (e.g. embedding 39 lacks the interpretability of systolic blood pressure or temperature). Future work will focus on interpretability-imparted patient context vector embeddings, amenable to clinical interpretation.

In terms of practical application, the proposed system can be used in addition to existing high recall/low precision hospital alert systems, and used to prioritize alerts, mitigating the effects of alert fatigue. Furthermore, the imperfect and noisy nature of the automatically created dataset is likely resulting in over-pessimistic evaluation. It has been shown that ML classification algorithms are able to achieve high performance at relatively high levels of noise and that ML models generated from noisy datasets perform significantly better when evaluated on clean test sets (10 to 30% classification accuracy improvement at high training set noise levels)\(^33\)–\(^35\). Future work will focus on creating a clean, clinician-reviewed ARDS test dataset for more precise evaluation of the proposed approach.

**Related Work**

Numerous prediction scores have been developed to assess ARDS prognosis. Gajic et al.\(^5\) developed a Lung Injury Prediction Score (LIPS) formula including predisposing conditions, such as sepsis, shock, pneumonia, alcohol abuse, chemotherapy, FIO2 and respiratory rate measures, found useful in predicting ARDS and mortality in surgical critical care patients\(^36\). Interestingly, over 70\% of score points associated with LIPS score calculation are based on patient context data rather than vials, labs, symptoms.

Other tools, such as Villar et al.\(^6\) base their ARDS prediction score on Age, PaO2/FIO2, and Plateau pressure score. Levitt et al.\(^7\) developed an Early Acute Lung Injury (EALI) score including risk factors, respiratory rate, and oxygen requirement. Xie et al.\(^8\) developed a modified ARDS prediction score (MAPS) based on a hand-crafted set of risk factors, risk modifiers, vital signs, etc.

A number of studies focus on predicting mortality among ARDS patients. For example, similar to our cluster findings, Hyers\(^37\) reports that patients who develop bacterial sepsis and multiple organ dysfunction are at high risk of dying and patients who develop ARDS from trauma or other noninfectious causes have a better prognosis. Navarrete-Navarro et al.\(^38\) report that mortality among ARDS patients correlates with the PaO2/FIO2 ratio on the 3rd day of ARDS, the APACHE III score, and the development of multiple organ system failure. Timmons et al.\(^39\) studied children with ARDS and found significant differences between survivors and nonsurvivors who develop ARDS from trauma or other noninfectious causes have a better prognosis. Villar et al.\(^40\) built an ARDS mortality prediction model based on tertiles of patient age, plateau airway pressure, and PaO2/FIO2 at the time the patient meets ARDS criteria. Similarly, Spicer et al.\(^41\) studied pediatric ARDS patients and determined that oxygenation index and hematopoietic stem cell transplant / cancer history can be used on Day 1 or Day 3 of ARDS to predict hospital mortality without the need for more complex models.

Unlike the current work, the described previous studies utilized only structured patient data, and ICD codes/risk factors, when used, consisted of manually crafted lists.

In a broader context, a large volume of literature on combining structured and free-text EMR data apply Medical Concept detection on the free-text notes for manually curated list of risk factors and other disease-relevant medical
concepts. Ford et al. present a review of various approaches to Medical Concept detection from free-text notes for the purpose of detecting cases of a clinical condition, often in conjunction with structured data.

More recently, deep learning has been used to utilize free-text and structured EMR data. Shickel et al. present a survey of various deep learning techniques. Miotto et al. build a Deep Patient representation in an unsupervised manner via denoising autoencoders, however, similar to previous approaches they first pre-process the free-text notes by extracting medical concepts with an off-the-shelf tool. Various studies use deep learning techniques to generate low-dimensional representations of diagnosis codes and patients utilizing structured data (diagnosis codes, medications, and procedures). Unlike previous work, we combine free-text and structured EMR data for obtaining low-dimensional patient representations, without the use medical concept detection.

Conclusion
This work demonstrates the utility of deep learning techniques to summarize a patient’s medical history, risk factors, comorbidities, and current signs and symptoms in the form of Patient Context Vectors. Automatically generated ARDS patients clusters agree with manually curated clinician knowledge and provide additional insight into the complexities and risk factors associated with ARDS. More importantly, Patient Context Vectors, derived from available ICD codes and nursing notes, can be easily combined with structured EMR data to build real-time ARDS CDS tools, with potential to improve patient outcomes and reduce mortality among ARDS patients.

Non-Negative Matrix Factorization for Drug Repositioning: Experiments with the repoDB Dataset

Gokhan Bakal, M.S.1, Halil Kilicoglu, Ph.D.2, Ramakanth Kavuluru, Ph.D.1

1University of Kentucky, Lexington, KY; 2National Library of Medicine, Bethesda, MD.

Abstract
Computational methods for drug repositioning are gaining mainstream attention with the availability of experimental gene expression datasets and manually curated relational information in knowledge bases. When building repurposing tools, a fundamental limitation is the lack of gold standard datasets that contain realistic true negative examples of drug–disease pairs that were shown to be non-indications. To address this gap, the repoDB dataset was created in 2017 as a first of its kind realistic resource to benchmark drug repositioning methods — its positive examples are drawn from FDA approved indications and negatives examples are derived from failed clinical trials. In this paper, we present the first effort for repositioning that directly tests against repoDB instances. By using hand-curated drug–disease indications from the UMLS Metathesaurus and automatically extracted relations from the SemMedDB database, we employ non-negative matrix factorization (NMF) methods to recover repoDB positive indications. Among recoverable approved indications, our NMF methods achieve 96% recall with 80% precision providing further evidence that hand-curated knowledge and matrix completion methods can be exploited for hypothesis generation.

1 INTRODUCTION
Repositioning previously approved drugs for new indications has become highly desirable in the biomedical and pharmaceutical research enterprises given expected time/cost reductions in identifying new treatment options. With recent estimates putting new drug development R&D costs over $2.5 billion per drug1, repurposing has been gaining mainstream attention over the past five years. With previously approved drugs already passing the required safety tests for use in humans, the cost of repositioning is expected to be substantially lower compared with starting from a blank slate. In 2011, the National Library of Medicine (NLM) introduced drug repositioning (DR) as a new Medical Subject Heading (MeSH term) and as of now there are 1,161 articles tagged with it dating back to a single article from 2009. Almost 85% of these articles are published in the last five years indicating the sudden and deserved surge of interest in this area. Physicians with deep understanding of both the mechanisms of action for drugs and disease characteristics may be able to recommend off-label use2 in an ad hoc manner. However, this does not constitute FDA approved recommendation for specific new indication(s) of drugs for use in designated groups of patients. As such, DR (via FDA approval) for new indications has significant potential to impact care at a broad scale and might also result in lowered costs for patients.

1.1. Computational drug repositioning. Computational drug repositioning (CDR) is the use of informatics and high performance computing methods to prioritize candidates for new indications. With the simultaneous excitement surrounding biomedical data science and the explosive growth of publicly shared datasets, CDR methods are on the rise in the scientific community. A class of such methods exploits the notion of “similarity” between different entities involved in disease and therapeutic mechanisms. For example, shared traits among drugs including chemical structures, molecular activities, and side effects may be used to define a feature vector to represent a drug. Likewise, similarities can also be established between diseases based on established gene–disease associations or graph based proximity in disease ontologies. Zhang et al.4 provide a unified framework that exploits these similarities for CDR. Another direction of CDR is exploiting available large-scale genomic data sources. For instance, Dudley et al.5 utilized drug-gene expression signatures to discover a potential new drug for the inflammatory bowel disease. Topological analyses of drug–target networks and target-involved pathways are another mode of identifying potential new indications.6 Text mining programs that extract different relations from text using natural language processing (NLP) and literature based discovery approaches that build on such relations are also being employed for CDR. A more detailed treatise of CDR methods is available in a recent survey3.

1.2. CDR method assessment. Although CDR is gaining prominence, evaluating CDR methods can be tricky given the lack of datasets that are tailored for it. Specifically, from our literature review we were able to identify very few
standardized dataset\cite{tesinat2018metathesaurus} that are uniformly used across efforts for benchmarking purposes. Furthermore, the datasets used in prior efforts have a serious shortcoming — they only contain positive drug–disease indication pairs; and hence prior efforts assume that all other combinations are negatives, which is unreasonable and potentially rules out novel repositioning predictions as false cases. Brown and Patel\cite{brown2015treatment} highlight this shortcoming and propose a new gold standard database called repoDB for CDR method benchmarking. repoDB draws approved indications from the DrugCentral\cite{drugcentral} database and failed indications from the American Association of Clinical Trials Database (the ‘AACT Database’\cite{aaact}), which is a structured version of information from NLM’s ClinicalTrials.gov service. Given failed indications are part of the dataset, one can directly assess CDR methods with vetted indications and non-indications from repoDB. Since its introduction in 2017, however, we are not aware of any CDR efforts evaluating against repoDB.

In this paper, we present the first CDR attempt that directly tests against repoDB instances. First, a partially observed matrix is built using drug–disease treatment relations drawn from the UMLS Metathesaurus\cite{metathesaurus} and those extracted using automated NLP methods and made available by the NLM as part of the SemMedDB database\cite{semmed}. Next, this matrix is completed by filling unobserved cells via non-negative matrix factorization (NMF) to elicit new indications. Our method uses a small portion of repoDB as a validation dataset and uses the bulk of it for testing purposes.

\section{Materials and Methods}

\subsection{Datasets}

In this section, we describe the data sources from which we derive our training and testing examples. The UMLS\cite{umls} and SemMedDB\cite{semmed} are our essential data resources for training instances while repoDB is our resource for the test examples. We use the terms “training” and “testing” to emphasize that this is still a (weakly) supervised method where the training instances are simply drawn from external resources both manually curated (UMLS) and automatically extracted (SemMedDB). We will briefly describe each data source in the following subsections.

**UMLS Metathesaurus.** UMLS is a longstanding terminological resource that integrates over 160 different vocabularies updated every year by the NLM. The Metathesaurus portion of UMLS aggregates equivalent concepts across multiple vocabularies and assigns to each unique concept a concept unique identifiers (CUI). Besides synonymous names for each concept, there are also inter-concept relations sourced from the original vocabularies. We obtained treatment relations from the MRREL table\cite{mrrel} in UMLS Metathesaurus\cite{umls} version 2017AB. A total of 43,898 such relations are part of our UMLS training dataset.

**SemMedDB – Semantic Medline Database.** SemMedDB is a repository of (subject, predicate, object) triples called semantic predications extracted by a rule-based NLP tool SemRep\cite{semrep} developed by the NLM. SemMedDB is built by running SemRep over all available PubMed citations (over 27 million) where the subject/object entities are normalized to UMLS CUIs. Likewise, the predicate is mapped to a relation type from the UMLS semantic network\cite{umls}. Given a predication can be extracted from multiple sentences, we also have frequency information (number of unique sentences containing it) for each SemMedDB triple. For our experiments, we curated treatment predications (triples where predicate = TREATS) in SemMedDB as additional training examples. As SemRep’s precision is around 75\%\cite{semrep}, we only collected predications which have been extracted at least twice, thrice, and five times to include them in the training set in various configurations (more later). Hence, we were able to obtain three different treatment predication sets of 55,349, 34,802 and 19,977 triples for the frequencies of 2, 3, and 5 respectively as long as they are not occurring in test sets from repoDB.

**The repoDB database.** As indicated in Section\cite{tesinat2018metathesaurus} instances in repoDB come from DrugCentral\cite{drugcentral} and ClinicalTrials.gov\cite{clinicaltrials} resources. It has a total of 6,677 approved and 3,885 failed drug–disease pairs. After removing the duplicates and the ones which appear in UMLS (given UMLS pairs will be part of the training dataset), we were left with 6,218 approved and 2,852 failed pairs. After removing pairs associated with drugs for which there is not even a single positive pair from UMLS/SemMedDB, we are left with 5,172 approved treatments (ATs) and 2,244 failed indications (FIs). This aligns with the nature of CDR to some extent — if we do not even have a single occurrence of a drug treating some disease, we may not be able to repurpose it for other conditions. This is also an inherent limitation of the matrix completion method we propose to use; if the row corresponding to a drug in the drug–disease matrix is empty, matrix completion methods cannot fill that row and hence it is impossible to come up with new indications for it (more later).

\*Specifically, these are the relations where the RELA field in MRREL table is equal to one of these four types: “treats”, “may_treat”, “treated_by”, and “may_be_treated_by”
**Generation of randomly selected negative examples.** The repoDB examples are vetted ATs and FIs, identified based on clinical trials. We also wanted to build a separate dataset of random indications (RIs) which satisfy domain/range constraints for subjects/objects for `treats` predicate. The purpose is to see if our method would have a relatively easier or harder time when dealing with these when compared with FIs from repoDB. In the past we have generated such a dataset for a slightly different task. Basically, these RI examples are created by the following steps.

- Each concept in UMLS has at least one semantic type that represents a class membership. Furthermore, every predicate in the UMLS semantic network has a set of domain/range semantic type constraints defined by the NLM based on domain expert knowledge. Based on the allowable semantic type combination for the `treats` predicate, we randomly select pairs that satisfy the domain/range constraints.
- For the set of pairs selected using the previous step, we simply remove the pairs which appear as treatment relations either in UMLS or SemMedDB. Thus, we ensure that selected pairs do not occur in our training set.

The given steps above pick fairly hard-to-predict potentially negative examples because they satisfy the domain/range constraints and are not present in either UMLS or SemMedDB databases. Ultimately, we obtained 3,318 examples to be used as the RI test set for the matrix completion methods.

### 2.2. Methods

In this section we present the NMF based matrix completion method along with our approach to configure it with different input matrices from external data sources.

#### Matrix completion through NMF

Matrix completion is the process of filling missing entries in a partially observed matrix. These partially observed matrices arise in many real world scenarios especially in recommender systems where preferences of people are encoded. A matrix with customers as rows and and products (e.g., movies, books) as columns is the typical setup. Given information about their prior ratings or product purchases represented as 1s in the corresponding cells, matrix completion would identify what other cells ought to be 1s — which other products would a customer likely enjoy given what they already liked. In a completely random world, there is no way to guess the new 1s. However, assuming the matrix has a much smaller rank than \( \min(m,n) \) for the \( m \times n \) matrix, we can use non-negative matrix factorization (NMF) to come up with a low-rank approximation to the original matrix with \([0,1]\) non-zero entries in blank cells, leading to potential new recommendations. This low-rank assumption is based on the intuition that there are latent themes/trait in user preferences and a typical user’s preferences are not distributed truly randomly across the product space. A similar strategy is also employed in information retrieval for latent semantic indexing for computing document similarity through dimensionality reduction.

One can now see that the CDR problem can be modeled similarly where the training treatment relations can be used to partially fill the drug–disease matrix, with NMF filling empty cells with non-zero values pointing to potential new indications. Since this is an approximation process, the new values in empty cells will be non-zero but generally not exactly 1. Thresholding based on a validation dataset can be used to glean indications if a particular cell’s value crosses the threshold. The intuition here is also to exploit potential latent themes where groups of drugs sharing certain characteristics (e.g., mechanism of action) may treat clusters of conditions with similar traits (e.g., symptoms). Given we do not know what the myriad latent themes may be, we assume a certain number of them are present — the chosen low rank — and proceed with NMF for matrix completion. Thus, given the partially observed \( m \times n \) drug–disease matrix \( X \) with \( m \) drugs and \( n \) diseases, we will approximate it as

\[
X \approx W_{mxn} \times H_{kxn} = \hat{X}_{mxn}, \tag{1}
\]

where \( W \) and \( H \) are the factors with rows of \( W \) representing \( k \)-dimensional drug vectors and columns of \( H \) encoding \( k \)-dimensional disease vectors under the assumption that \( X \) has rank \( k \ll \min(m,n) \). The product \( \hat{X} = WH \) approximates \( X \) helping us glean new non-zero values hinting at new indications, while the rows of \( W \) and columns of \( H \) can be used to compute drug and disease similarities respectively. The objective function to find the best approximation is

\[
\arg \min_{W,H} \|X - WH\| + \beta(\|W\|_2 + \|H\|_2), \tag{2}
\]

where \( W \in \mathbb{R}^{m \times k} \) and \( H \in \mathbb{R}^{k \times n} \) and \( \beta \) is the weight for the regularization penalty term to handle overfitting that corresponds to large norms for \( W \) and \( H \). Next, the construction of the input drug–disease matrix \( X \) is discussed.
Building the input training matrix. The input partially observed matrix was constructed based on treatment relations from UMLS and SemMedDB as indicated in Section 2.1. However, we needed to consider a larger matrix to fill compared with drugs and diseases of positive indications from UMLS Metathesaurus and SemMedDB. Otherwise, the test indications in repoDB cannot be recovered as part of the completion process. For this, we considered all allowed subject/object semantic type constraints for treats predicate (based on SRSTR tables of the UMLS semantic network). Next, we selected all UMLS subject concepts where each has at least one semantic type that belongs to the set of allowed subject types; likewise, we aggregated all UMLS concepts where each has at least one semantic type that is from allowable object types. Based on this, 538,710 subject entities and 314,707 object entities were obtained for the input matrix. However, most subjects do not have a treatment relation with any disease as observed in the Metathesaurus training dataset. Hence, we removed all zero rows (hence the corresponding drugs or treatment agents) and retained only rows that are known to treat \( \geq 1 \) disease in the columns to exploit the shared therapeutic context among the drugs. After this pruning process, we were left with 10,188 drugs (or treatment agents) and 314,707 objects to build our input matrix to be partially filled (from training datasets) and subsequently completed via NMF.

To populate the input matrix with training relations, we have Metathesaurus treatment relations and three different sets of semantic predicates derived from SemMedDB based on extraction frequencies. We have a configuration where training relations are entered in the tables as 1s, which we call the “binary matrix factorization (BMF)” model. In addition to BMF, we have another configuration using SemMedDB treatment predicates with their extraction frequency counts. We term this as the “count matrix factorization (CMF)” model to evaluate the performance when counts are used instead of Boolean indicators.

Finally, as part of the input we have many unallowed input matrix cells (5,531,386 in total) that cannot be 1s because

---

1As an example, (Pharmacologic Substance, Disease or Syndrome) is a popular semantic type combination allowed for treatment relations. (Antibiotic, Disease or Syndrome) and (Therapeutic or Preventive Procedure, Congenital Abnormality) are less common allowed type combinations. Overall, there are 56 different allowed type combinations for treatment relations as per UMLS. There are other additional allowed types that NLM has incorporated as part of the schema design for SemMedDB and those are included for this effort as allowed combinations.

2Note that not all objects are diseases per se, some maybe symptoms and at times different patient groups. For example, the UMLS CUI C4316221 refers to “Patients with a diagnosis or past history of total colectomy or colorectal cancer” and can be an object of some treatment relations. To capture all latent themes we end up using all subjects and objects of treatment relations as part of the input matrix. However, for evaluation purposes, after NMF, we only look at those cells (in \( X \) from Eq. (1)) corresponding to approved and failed indication pairs in repoDB.
the corresponding subject–object pairs do not satisfy the domain/range semantic type constraints. For example, consider this unallowed type combination: \((\text{Drug Delivery Device, Patient or Disabled Group})\). Although \text{Drug Delivery Device} is an allowed subject type for some other type combination(s) and \text{Patient or Disabled Group} is an allowed object type for a different combination, this particular coupling is not allowed. But cells corresponding to this unallowed combination exist in the input matrix given the matrix was built with all allowed subjects and objects as rows and columns, respectively. Thus, these cells corresponding to entity pairs that satisfy this type combination must be designated as unallowed. To avoid such predictions, we assign 0s to the corresponding cells of the input matrix. This is another way to further constrain the factorization process to approximate both positive and unallowed cases while estimating the unobserved cells. We experimented with several input matrices with different numbers of unallowed cases to observe their influence on the prediction task. The levels of these unallowed examples are set to 0% (no unallowed examples), 25%, 50%, 75%, and 100% (all of them) in the input matrix. The overall framework of our approach is demonstrated in Figure 1.

**NMF experimental configurations.** We note that repoDB drugs/diseases for ATs and FIs are already mapped to UMLS CUIs by its creators. Hence, the matrix constructed and completed as described in Section 2.2 naturally suffices for the CDR task. When training, experiments were conducted with singular value decomposition (SVD) to identify a \(k\) value (to be used for the dimensionality in Eq. (1)) that minimizes the mean squared error (MSE) for the cells that are already filled in the training matrix. Since there were not any noticeable differences between MSE values with \(k = 50, 100, 500\), we chose \(k = 50\) for our further matrix completion experiments. Thus results are reported for \(k = 50\) for all experiments. The regularization parameter \(\beta\) was left at the default value (0.1) because tuning it did not yield any apparent gains. To carry out the optimization in Eq. (2), the open source MF library LIBMF\(^\text{23}\) was used for incomplete matrix approximation. LIBMF is an efficient stochastic gradient descent based software package that runs parallel on multiple cores in a shared-memory environment.

3 RESULTS

We assess NMF results from two different perspectives. First we look the actual NMF scores produced for ATs, FIs, and RIs we created as part of Section 2.1. Subsequently, we observe how these NMF scores can be used to come up with precision, recall, and F-score based on ATs and FIs from repoDB.

3.1. NMF scores for repoDB pairs. In Table 1 we show mean NMF scores for ATs and FIs in repoDB and the RIs we generated. The scores are real-valued numbers with which NMF fills unobserved cells as part of the training process for various configurations. Configurations differ from each other with respect to what is included in the input matrix and the proportions of unallowed pairs included as 0s. Due to the optimization in Eq. (2) and encoding of positive cases as 1s, the higher the value estimated for an unobserved cell, the stronger the plausibility of treatment relationship for the corresponding drug–disease pair. We make the following important observations from Table 1:

- Only adding positive training examples to the input matrix and leaving unallowed examples as unobserved (the 0% column) leads to catastrophically bad results where the FIs and RIs are scoring higher. Hence we do not discuss any results going forward where the unallowed examples are left as unobserved. Adding additional unallowed examples (all other columns) as 0s in the input matrix shows more realistic scores following a clear pattern where the ATs score higher than FIs, which fare better than RIs. This confirms a few things: (a). The 0s inserted to account for unallowed cases are providing enough signal to guide the optimization process to distinguish between more plausible indications from random ones (which are mostly useless). (b). NMF based completion is able to score ATs better than FIs in repoDB where the mean AT score is 2–3 times higher than that of the FI score, demonstrating its effectiveness. (c). FIs scoring higher than RIs reflects the reality that FIs actually went through the process of clinical trials, which implies researchers felt that those pairs were plausible indications; RIs however are just random pairs of drugs and diseases. (d). Including more unallowed pairs as part of the input quickly decreases the magnitude of the scores (compare the 25% column with the 100% column); however, the relative differences between ATs, FIs, and RIs persist all across the board.
- Adding more training positives from SemMedDB (rows 4–12) increases the absolute values of the scores and also the differences in scores between ATs, FIs, and RIs, but the relative differences are the highest when using just UMLS Methasaurus relations. For example, in the 25% column, the ratio of means of AT and FIs for

“UMLS only” (0.268/0.119 = 2.25) is higher than the corresponding ratio for “UMLS+SemMedDB (MinFreq. 5)” (0.564/0.357=1.58), which stays at a similar level even as additional relations are added (MinFreq values 3 and 2).

- Count based models (instead of the binary models) where frequencies are included in the input matrix appear not as consistent (last three rows) where for the 25% column, we notice RIs scoring higher than FIs.

We computed 95% confidence intervals that showed that the score differences are statistically significant. Here we disclose the intervals for the three rows of “UMLS+SemMedDB (MinFreq. 2)” (of the 25% unallowed cases column): 0.650 ± 0.010 (ATs), 0.413 ± 0.017 (FIs), and 0.195 ± 0.012 (RIs). The intervals do not overlap further confirming the NMF method’s functionality.

3.2. Precision, Recall, and F-score for ATs in repoDB. The NMF score ranges in Section 3.1 demonstrate that, on average, NMF maps ATs, FIs, and RIs to non-overlapping segments on the real number scale with high confidence. However, we still need a way to make repositioning Yes/No decisions at the instance level based on the score generated for a particular drug–disease pair corresponding to an entry in \( \hat{X} \) in Eq. (1). One way to make such a decision is to choose a threshold for the NMF score and assign all pairs with scores above that threshold as new candidates for repositioning. Here we propose to do that by splitting the repoDB ATs and FIs into validation and test sets. We considered 20% of ATs and 20% of FIs as comprising the validation set while the rest are left for the final test.

We identified a threshold based on grid search over the validation dataset optimized for F-score with a small step size of 0.00001 spanning the range \([T_{\min}^v, F_{\max}^v]\) such that

\[
T_{\min}^v = \min(\{\hat{X}_{i,j} : (i,j) \in T^v\}) \quad \text{and} \quad F_{\max}^v = \max(\{\hat{X}_{i,j} : (i,j) \in F^v\}),
\]

where \( \hat{X} \) is the approximation from Eq. (1) and \( T^v \) and \( F^v \) represent the validation datasets for ATs and FIs, respectively. This range was chosen based on the observation on the validation dataset that \( T_{\min}^v \) is smaller than \( F_{\max}^v \) (so there were some AT scores that were less than other FI scores). Hence choosing \( T_{\min}^v \) as the threshold corresponds to 100% recall and selecting \( F_{\max}^v \) leads to 100% precision. Thus by limiting the grid search to the threshold range \([T_{\min}^v, F_{\max}^v]\), we are exploring the space of compromise between perfect precision and perfect recall.

\[\text{This translates to 4138 ATs and 1795 FIs in the test set and 1034 ATs and 449 FIs in the validation dataset — numbers computed based on the original repoDB counts from Section 2.1.}\]
Once a threshold is chosen to make instance level decisions for test examples, it is straightforward to assess the performance of the method using traditional measures such as precision, recall, and F-score. Thus, in Table 2, we report the performance results for the BMF models for different configurations of the input matrix and different levels of included unallowed examples. The first observation is that the thresholds selected are all very close to zero indicating that boundary case NMF scores were close to zero for ATs across all configurations. The thresholds are identical for configurations with SemMedDB examples but change slightly for UMLS-Only case. We notice that the best F-score of 0.895 (first row, last column) is obtained for UMLS-Only input matrix with 25% unallowed example constraints. This may be explained from the biggest relative difference between mean AT and FI scores for this configuration from Section 3.1. However, adding SemMedDB training instances (with minimum frequencies 2 and 3) seems to lead to a potentially more desirable compromise with recall around 96% and precision over 80%. The results for count based CMF models were disappointing as shown in Table 3. There is no clear pattern as to how the scores are spread with regards to different configurations and overall performance is all across the board inferior when compared to BMF models especially with substantially lower precision values.

4 DISCUSSION

As CDR efforts continue to rise, it is critical to have benchmarking datasets that are realistic in terms of representation of both approved indications and failed indications. repoDB is first of its kind dataset that creates such an opportunity to conduct comparative evaluations of CDR methods on a publicly available gold standard dataset.

4.1. Main takeaways. Matrix completion through NMF based low-rank approximation is an effective method for CDR based solely on datasets of previously approved drugs and corresponding indications. Actually, in this manuscript, we only use public data sources of treatment relations in the form of hand curated UMLS Metathesaurus relations and those extracted with NLP from PubMed citations (from SemMedDB). As such, these are imperfect resources (especially SemMedDB) and may not necessarily constitute FDA approved drugs. Results still show that among recoverable ATs from repoDB, we achieved F-scores close to 90% with the highest F-score achieved with just UMLS relations as input. Using both SemMedDB and UMLS relations helps achieve a better compromise between precision and recall with over 96% recall at 80% precision. The mean NMF score for FIs is at least twice as large as that for RIs, indicating that FIs are indeed much tougher to distinguish from ATs compared with randomly generated pairs. A critical enabler was the encoding of unallowed pairs (derived with incompatible semantic type constraints from UMLS semantic network) as zeros imposing additional structural constraints on the input matrix to be approximated. However, imposing constraints from all unallowed pairs could be detrimental by leading to a 3% recall gain with a 10% precision drop. Experiments showed that introducing 25% of the zeroes from unallowed pairs leads to better outcomes and is computationally less expensive. Count based models that consider frequency from SemMedDB substantially underperform compared with simpler binary models. Overall, NMF based methods applied to carefully curated external knowledge
sources constitute a practical approach towards CDR.

Next we discuss some examples of correct predictions made by our approach. In our training dataset we see the drug vincristine treating malignant neoplasms, follicular lymphoma, and Hodgkin disease and another drug doxorubicin treating the general condition of malignant neoplasms. After matrix completion, we saw high values of 0.89 and 0.93 for the entries (doxorubicin, follicular lymphoma) and (doxorubicin, Hodgkin disease) respectively, which are approved indications in repoDB that were never encountered in training data and were blank cells before the training process. Similar new correct predictions are also made for (bleomycin, follicular lymphoma) and (bleomycin, Hodgkin disease). Next, although, the count based CMF method underperformed overall, there were cases where it lead to correct predications when the binary approach did not. For example, (betamethasone, berylliosis) and (bleomycin, malignant head and neck neoplasm) are approved indications that were missed by the BMF approach but are recovered by the CMF method. Thus there may be some complementary traits in how the BMF and CMF approaches predict that need further examination toward building an ensemble method.

We set out to explore reasons for errors — false positives (FPs) and false negatives (FNs) — incurred by the NMF models in the context of information available about the corresponding drug–disease pairs. To this end, we examined connectedness of FP and FN pairs in the SemMedDB graph, which essentially conveys the potential shared context between associated entities. In our prior work, we identified graph patterns over the SemMedDB graph that are highly indicative of treatment relations using model coefficients of a logistic regression (LR) model. For FPs of the NMF model, we noticed that there were tens of thousands of highly predictive short paths (length ≤ 3) connecting the corresponding drug and disease CUIs indicating that there are many shared neighbors; some of this neighborhood information is encoded in the input matrix, which could have led to positive predictions. This is also not surprising given FPs are essentially failed cases in repoDB but were deemed plausible enough for researchers to launch clinical trials. For FNs, we found relatively fewer and sometimes no such predictive paths in SemMedDB connecting associated entities. For example, for the approved repoDB indication (Dexamethasone, Branch retinal vein occlusion with macular edema), the drug and disease were not connected in the SemMedDB graph using LR model’s top predictive patterns. Without much shared context, NMF appears to struggle to elicit positive indications for such pairs. We plan to pursue a more detailed error analysis involving physician experts, which may yield additional insights on potential reasons for errors.

4.2. Limitations and future work. This current effort is not without a few limitations, which also point to interesting future research directions for CDR experiments with repoDB.

- The method in this paper is clearly not a silver bullet for CDR. repoDB does enable excellent benchmarking but in general scientists are often looking at a particular disease that they want to treat. Hence, for disease specific CDR, more sophisticated methods involving gene expression datasets and methods that consider integration of various modalities of information specific to the disease may be needed, as indicated in other prior efforts (e.g., Nagaraj et al. for cancer). However, our method can be an effective initial step in pruning the space of candidates before more sophisticated methods that require more complex modeling and disease specific information can be applied.

- As discussed earlier, the count based CMF models’ performance was underwhelming (Table 3) when compared with the binary models even though the counts capture additional information about prior knowledge being incorporated into the input matrix. One reason for this could be that we simply employed raw frequencies of treatment predications in SemMedDB instead of standardizing counts using well-known methods (e.g., mean centering, min-max scaling, log transformation). Using raw frequencies may have lead to potential ill-conditioning that needs to be countered with appropriate pre-processing and/or using more sophisticated methods. These experiments will be part of future extensions of our work.

- Matrix completion methods cannot fill a row that does not have at least one nonzero entry. In our case, this means, a drug for which we do not have at least one known treatment relation cannot be linked to new indications with NMF. However, this can be remedied by moving from matrices to tensors with additional relations between entities connected with other predicates including prevents, diagnoses, affects, and causes. Using tensor factorization, even

---

5The LR model, while being effective, is computational prohibitive at times given the explosion of numbers of paths connecting entities in a large graph such as that built from SemMedDB. Our foray into NMF is motivated by these efficiency constraints of the graph pattern based approach.
for a drug with no existing treatment relations, using multi-hop indirect connections, it is possible to elicit a new indication. Similarly, with recent deep learning advances, embedding nodes and edges of the larger SemMedDB graph (including edges arising from other predicates besides treats) with graph neural networks can offer a different way for knowledge base completion. We intend to pursue these directions in the immediate future.

4.3. Benchmarking. To enable future comparisons with our results, we provide the validation/test set splits of repoDB drug–disease pairs used in this study: https://github.com/bionlproc/nmf-repoDB-benchmarking. This will be important for direct comparisons by other researchers using the repoDB dataset, especially given we had to resort to using a subset of repoDB (owing to issues with lack of training instances for certain drugs without a single human vetted treatment relation).

5 CONCLUSION

With valuable time and cost savings in the offing, CDR efforts are expected to increase in the future. With lack of datasets modeling both positive and failed indications, it is encouraging to notice that datasets such as repoDB are being created. However, it is also important to start comparing methods against such datasets for robust assessments of different methods. In this paper, matrix completion through NMF was used to directly predict repoDB approved indications by using publicly available treatment relations. F-scores close to 90% were obtained with various training configurations with this method showing its strong potential for practical applications. Validation and test splits of repoDB used as part of this effort are made available to facilitate direct comparisons with our results by other researchers in the CDR community. More sophisticated methods such as tensor factorizations and neural graph embeddings may hold the promise of recovering novel indications for drug compounds that have not yet been approved for any known conditions. We believe this is the first attempt to employ repoDB for CDR purposes and hope that this will trigger more attempts to pursue this line of work toward rigorous benchmarking.

Abstract
Clinical documentation in the pre-hospital setting is challenged by limited resources and fast-paced, high-acuity. Military and civilian medics are responsible for performing procedures and treatments to stabilize the patient, while transporting the injured to a trauma facility. Upon arrival, medics typically give a verbal report from memory or informal source of documentation such as a glove or piece of tape. The development of an automated documentation system would increase the accuracy and amount of information that is relayed to the receiving physicians. This paper discusses the 12-week deployment of an Automated Sensing Clinical Documentation (ASCD) system among the Nashville Fire Department EMS paramedics. The paper examines the data collection methods, operational challenges, and perceptions surrounding real-life deployment of the system. Our preliminary results suggest that the ASCD system is feasible for use in the pre-hospital setting, and it revealed several barriers and their solutions.

Introduction
Military and civilian medics are responsible for retrieving, stabilizing, and transporting the wounded and ill to a trauma facility. Accurately documenting medical care during transport is complicated for several reasons, including limited staff in the vehicle and ongoing care requirements for trauma and critically ill medical patients. Because it is not possible to manually document all activity during transport as it occurs, medics often first give a brief verbal report to the receiving facility staff, followed by documentation completed after the hand-off has occurred. The initial verbal report typically includes chief complaint, mechanism of injury, vital signs, and procedures performed. This verbal report may be supported by brief notes written on the patient, a scrap piece of paper, the medic’s glove, or in some cases relying only on the medic’s memory. While accurate transmission of this information is essential for safe care transitions and plays a key role in the receiving team’s treatment plans, reporting may be incomplete and include inaccuracies. As a result, communication, safety, and patient care may be impacted.

Communicating some types of patient information can be done successfully with a verbal report alone (e.g., chief complaint, mechanism of injury, age, gender). However, specifics regarding the sequence of procedures performed, medication dosage and timing, and specific vital sign ranges are difficult to accurately recall from memory given the high-intensity setting of trauma care. This information is essential for optimal care management, resource allocation, and triage planning.

An Automated Sensing for Clinical Documentation (ASCD) system leverages a combination of sensors to passively collect data, from which algorithms are used to create an abbreviated care record that describes the procedures performed. This record is designed to be generated in real time, or near real time, and transmitted to providers as a supplement to the verbal handoff. The goal of this system is to increase the accuracy and detail of clinical information transmitted to clinical providers and teams, particularly in high-acuity and trauma settings, without requiring the provider to actively produce the documentation. An ASCD system can be used in a range of environments from civilian patient transport, military patient transport, and operating rooms.
This paper reports on a feasibility study of an ASCD system for patient transport in a civilian metropolitan Emergency Medical Service (EMS). Specifically, this paper outlines the equipment used, the configuration of the equipment in a civilian ambulance, perception of medics wearing devices, data collection processes, and interfaces with the trauma facility. The system was deployed with the Nashville Fire Department (NFD) EMS in partnership with Vanderbilt University Medical Center, a level I trauma center in Nashville, Tennessee, which receives a high volume of acute trauma patients. Cameras were not deployed in the system during the pilot because of concerns regarding patient and provider privacy, although their use would be expected to increase system accuracy.

**Background**

High quality healthcare requires effective and accurate communication among providers, especially during transitions across care settings. The dynamic nature of care by medics in the pre-hospital setting can make it difficult to document procedures in real time and communicate vital clinical information to hospital providers. In their handoffs to emergency department (ED) staff, paramedics dedicate 75% of verbal reports to patient demographics and presenting signs/symptoms and ~7% to pre-hospital treatments, even though pre-hospital treatments and clinical course largely drive resource allocation and treatments upon arrival. Various approaches have been considered to automatically document clinical care including speech-to-text and in-person/virtual scribes. However, given environmental noise, limited vehicle space, and the need for the medic to focus on patient care rather than documentation, alternative approaches to automated documentation systems are desired. Moreover, given the number of and fluctuation in transport vehicles and number of trips, ease of device acquisition and installation is important.

Off-the-shelf sensors offer an opportunity to gather the data necessary to produce documentation, while also being readily available and cost-effective. These sensors include electromyography (EMG) sensors, inertial measurement units (IMUs), such as accelerometers, and cameras. EMG sensors collect data that measure electrical currents during muscular contraction, which can be used to identify different neuromuscular activity. IMUs combine data from accelerometers, gyroscopes, and magnetometers to report the orientation and angular rate of a body. Cameras can track the medic and patient in the scene. These data feeds can be fed into machine learning algorithms for analysis and documentation generation.

For this pilot study, the NFD assisted in the evaluation of the system. NFD provides fire protection and emergency medical care for 533 square miles and transports patients to numerous hospitals within the metropolitan Nashville area. In 2018, NFD responded to approximately 130,000 calls. Of note, NFD EMS protocols for airway management do not include the use of medication for rapid sequence intubation.

**Methods**

An ASCD system for patient transport in a pre-hospital setting has many components. First, a series of sensors are deployed in a clinical environment, in this case EMG sensors and accelerometers measuring provider movement. Second, these data feeds are aggregated and analyzed by machine learning systems to detect the clinical activity that are performed. Third, from the detected activity, an abbreviated care record is produced that can be transmitted to upstream care providers. This paper describes the methods around the feasibility of deploying sensors on clinicians to collect data for analysis.

A range of sensors were considered for the feasibility test ranging from medic worn sensors, mounted cameras, to radio-frequency identification chips on each device and/or medication. Given the desire of a rapid, cost-effective, and simple deployment that protected patient privacy, sensors worn by medics were selected. Sensors worn by medics that were utilized in this study included Myo armbands, which collect EMG data and inertial measurement data (e.g., accelerometers), and Apple Watches, which collect yaw, pitch, roll, and acceleration data.

After obtaining institutional review board approval from the Vanderbilt University Human Subjects Protection Program, physicians, nurses, and paramedics were recruited to perform over 45 hours of procedures in Vanderbilt’s Center for Experimental Learning and Assessment (CELA), which is a high-fidelity simulation center. Each participant was consented and then asked to perform designated procedures multiple times over the duration of a three-hour period using a simulation patient. Data collected from the simulations were used to refine the sensors, data collection systems, and the algorithm prior to real-world deployment. These simulations included use of cameras.
The ASCD system was then deployed in partnership with NFD over a 12-week period in 2019, without cameras. Written informed consent was obtained from the participating paramedics. Paramedic shifts were selected based on the availability of paramedics and research staff. At the beginning of each shift, a trained researcher who is also a paramedic equipped one paramedic with sensors, specifically two Apple Watches and two Myo armbands. In order to collect and transmit the collected information, a laptop and two cell phones were also carried by the research observer (see Data Collection). The data were aggregated into a single server for future analysis.

During the NFD paramedic’s 12-hour shift, the trained researcher observed and recorded all clinical activity with a custom time-motion capture system the “start” and “stop” times for targeted procedures performed inside the ambulance (Table 1). These procedures were chosen based on focus groups with EMS personnel and common procedures performed in the ambulance. Automated time-motion capture was not feasible given the subjectivity and complexity of the procedures. Procedures performed outside of the ambulance were excluded from the recorded observations due to the distance from the laptop and Bluetooth receivers to the Myo armbands and iPhones. The research observer did not participate in patient care.

For the subset of patients transported to Vanderbilt University Medical Center (VUMC) adult emergency department (ED), observations also included the handoff between the team of paramedics and the ED team. Procedures and interventions performed during the ED visits were also documented. At the conclusion of each shift, the paramedic who wore the technology completed a debrief survey. These surveys featured a user-centered design approach, considered the context of use, specific requirements, and areas of design optimization. Between each observation, the ASCD equipment was cleaned using SaniWipes® and all components of the system were charged. No substantial damage was received to the equipment during use.

Data Collection
Transport of Equipment: The following equipment was housed in a Pelican case during transport: 2 Myo Armbands, 2 Apple Watches (Series 3), 2 Apple iPhone 7s, AT&T Unite Express 2 WiFi hotspot, 2013 Apple MacBook Air, and their accompanying chargers (Figure 1). The equipment was delivered at the beginning of each shift and kept with a member of the research team.

**Figure 1**: Pelican case setup

Electromyography: Thalmic Labs Myo gesture control armbands were used as the source for EMG data collection. Myo armbands were connected to the MacBook Air using a Bluetooth connection. After the armbands were pulled onto the forearms, they were calibrated by having the paramedics position their hands as shown in Figure 2.

**Figure 2**: Myo neutral position (A) to Myo sync position (B) to calibrate the armbands
**Accelerometer:** One Apple Watch Series 3 was worn on each wrist with the watch-face outward and was paired with an Apple iPhone 7. Both iPhones were stored in a secure cabinet in the rear of the ambulance. The iPhones were connected to a virtual private network (VPN), which was necessary to securely send data to a VUMC server. We originally used the PulseSecure application to access the VPN, but then the system migrated, causing the switch to F5 Access. To establish an internet connection, a AT&T Unite Express 2 WiFi hotspot was used.

**Data Flow (Figure 3):** Both the left and right Myo Armbands were connected to the laptop using a Bluetooth connection. The laptop was connected to the mobile hotspot over a VPN. The left and right Apple Watches were paired with a corresponding iPhone 7, which also used the hotspot WiFi.

![Figure 3: Flow of data inside the ambulance](image)

**Data Transfer:** At the conclusion of each shift, the Myo data collection files were transferred from the laptop to a shared cloud account (VUMC Box) for review by the data analysts. Due to the large file sizes, the transfer was completed using VUMC WiFi instead of the hotspot.

**Notification of VUMC research team:** An application, Life360, was installed onto one of the iPhones. A geo-fence was set up around VUMC, which notified the clinical researcher at the VUMC ED when the phone was detected within 800 feet of the ambulance bay. In addition, the research observer would send a message via Life360 to the clinical researcher when enroute to VUMC. The clinical researcher met paramedics and the observer in the ED to document the handoff to hospital staff.

**Documentation of Targeted Procedures:** The research team thoroughly discussed the method for documenting the targeted procedures prior to deployment of the ASCD system. The research observer needed a quick and accurate system that allowed for the research observer to note any discrepancies in how the paramedics actually started and stopped each procedure. Variations in procedural equipment or protocols could cause the start and stop times to differ. Original discussions included methods such as (i) keeping field notes and manually keeping track of time, or (ii) creating an iPhone application that allowed the observer to press a start/stop button with pre-selected procedures. The most significant challenge with the former was accuracy of procedure times. For the latter, it was determined that an application with pre-selected options did not allow the observer much versatility to add other comments and raised concerns about accidental selection of a start or stop time. Ultimately, a simple Python logging application was used that allowed for free-text entries and recorded time stamps upon entry.
Research documentation began at the point in which the patient was loaded into the ambulance. During each transport, the observer typically sat in the captain’s or “airway” seat (rear facing), located behind the head of the patient, and documented from that position. Once the patient was loaded into the ambulance, the research observer opened the laptop, ensured proper connectivity of the system, and began recording procedures as they happened in real time. For example, if the paramedic was going to start an IV, the observer would type “IV start” into the log application when the paramedic touched the IV start kit. At the end of the procedure, indicated by taping down of the IV, the observer would type “IV end”. These were used as the gold standard for “start” and “stop” times for each procedure of interest (Table 1; Table 2 for representative data records).

Paramedic Debriefs
After each observed shift, the paramedic completed a debrief survey. The research observer also provided feedback to the research team regarding lessons learned in the field, barriers encountered, and feedback obtained. Survey responses from the paramedic participants were entered into REDCap, a secure web application designed for creating and managing online surveys and databases15.

Establishing Rapport with the Paramedic Participants
The research observer was a paramedic, and this allowed him to build a productive rapport with the paramedic team. The observer arrived at the beginning of each shift, either 0530 or 1730 hours for a day or night shift, respectively. The observer typically stayed for 6 hours, depending on call volume. During busier shifts, the observer stayed with the crew for an extended period of time to collect more data.

Results
Over seven observations, two paramedics wore the system for a total of 49 hours. We observed the transport of 16 patients to 6 different hospitals. Information after handoff for six patients was obtained (Table 3). Using the first procedure logged as a start time and the end of the last procedure logged as an end time, the median time of active treatment during transport was 8 minutes and 15 seconds (standard deviation of 5 minutes and 24 seconds).

Table 4 describes the different barriers encountered during the data collection process and the approaches taken to mitigate the issues. The most common challenge was ensuring that all components of the system were properly
functioning and collecting data simultaneously. Specific solutions are listed below. Additionally, the placement of the laptop in the ambulance and ASCD sensors on the medic are depicted in Figure 4.

**Current Documentation Techniques by Paramedic Participants**

During field observations, the majority of documentation occurred in the ambulance. For “non-critical” patients (e.g., stable vital signs), paramedics typically used the charting software installed on their Toughbook® laptops to document items such as past medical history, current medications, drug allergies, and demographic information. In addition, the cardiac monitors used by NFD had the ability to store vital signs such as blood pressure, heart rate, oxygen saturation, and respiration rate. This log could then be uploaded directly to the patient care report following the transport. During the care of patients who required more attention, or were more critical, documentation typically took place in the form of the paramedic writing on the glove of their non-dominant hand. In other situations, paramedics documented some procedures from memory, which is standard care practice for EMS providers. Patient care documentation into the EMS formal charting system typically occurred post-trip arrival. Paramedics indicated that charting for each patient took approximately 30 minutes in total, which is longer than the transport time but in line with other work assessing time that clinicians spend documenting.16.

**Figure 4**: Laptop in ambulance (A) and a medic wearing two Myo armbands and two Apple Watches (B)
Operational Challenges
Although the study was designed around most patients being transported to VUMC, patients were transported to six different hospitals. This occurred for multiple reasons, including EMS diversion (hospital not accepting patients arriving by EMS), patient request to be transported to a specific hospital, proximity, and the clinical condition of the patient. Additionally, several scheduled observation periods were canceled due to mechanical malfunction of the ambulance, personnel illness, and work schedule changes.

Communication of Procedures to Receiving Facility Staff
Six handoffs between paramedics and ED clinical teams at VUMC were observed. Two handoffs occurred at ED triage, in which paramedics gave a verbal report to a triage nurse. Verbal reports from the paramedic to the ED staff largely consisted of the chief complaint and signs and symptoms. During the handoff of a level II trauma patient, the paramedic relayed all information regarding procedures (IV placement, medication administration, vital signs, and cervical collar application) to the trauma team, which was composed of physicians, nurses, and other ED staff.

General Feedback from Paramedics (Table 5)
The paramedic participants indicated that they could wear the armbands for the duration of a 12-hour shift with no anticipated difficulties. Participants reported that the armbands were tight but did not restrict their overall movement or interfere with patient care. An impression on the paramedic’s skin of the armbands was observed for ~30 minutes following the removal of the armbands. Participants suggested considering other devices that might be more comfortable or fit in clothing. Other comments included that this technology would be useful in situations where there are critical patients or multiple patients.

Discussion
To our knowledge, there have been no attempts to create and deploy an automated clinical documentation system using this range of sensors. We identified challenges surrounding logistics, connectivity, evaluation, and perception by the paramedics. The results of this pilot study support the feasibility of using an Automated Sensing for Clinical Documentation System in the pre-hospital setting. The paramedic debriefs suggest that the equipment used in this study can be deployed in a large study with more paramedics, allowing for more data to be captured.

The system’s aim is to support and supplement the documentation and upstream communication processes that occur during and after transport. For example, the ASCD system would be particularly useful in settings where verbal
communication is limited, such as casualty evacuation from the battlefield or multiple simultaneous patient arrivals. Creation of an abbreviated care record with timestamps identifying which procedures were performed can enable upstream hospital providers to more effectively provide care. Specifically, the precision of such timestamps can aid in decisions regarding subsequent medication administration and other judgments surrounding patient viability.

The pilot highlighted several barriers to the system’s practical deployment. Most of the barriers encountered were logistical in nature. For example, ensuring that the data recorded continuously throughout the duration of the observation was of the most significant, which we addressed through various engineering enhancements. Modifications to the design of the system were made to make it more user-friendly, such as indicating when the system was actively recording data. These steps facilitated more accurate and complete data collections.

We anticipate that deployment of the system into the field would result in greater variation than the simulated procedures recorded in CELA, and therefore, introduce subsequent error into our model. Detection of such error will allow us to refine the current algorithm used for the identification of targeted procedures.

Methods for Future Data Analysis
This paper specifically does not discuss the algorithms used to convert the collected sensor data to an abbreviated care record. Briefly, the algorithms take the IMU and EMG data as input to generate summary statistics (e.g., entropy, power, etc.) and analyze temporal patterns. These data are then fed into classifiers to predict which procedure is being performed, if any. Some data cleaning are also performed such as removing the gravity vector and removing vehicle vibration.

Future processing will include employing a deep neural network using both convolutional and recurrent layers with memory trained classifiers in hopes for a greater efficacy. We plan to move towards a real-time analysis using discrete, rolling windows for classification such that the start and stop of the event is not known by the classifier, which will be the case in real-world deployments.

Limitations
Our study intentionally limited the number of paramedic participants (2) in order to optimize the system and to identify and address system failures. Having a single observer and paramedic participant during the initial deployment allowed us to identify and address challenges before expanding the study. The second limitation can be attributed to the unknown nature of pre-hospital care. Because of the unpredictable nature of pre-hospital care, there were some procedures for which we were not able to collect any data.

Conclusion
This paper reported on the lessons learned from deploying an automated sensing clinical documentation system in a real-world environment. It discussed challenges of configuring equipment, collecting data, and dealing with failures. Many incremental steps were taken to reach the goal of a working system that could be safely deployed in the field and collect data, without interfering with care and patient privacy. Future work will analyze how well the algorithms are able to correctly identify which procedures were performed during transport.

Abstract

The informatics community has a long-standing vision of freely flowing and highly re-usable patient-specific clinical data that improves care quality and safety. We sought to evaluate the extent to which a standards-based mapping approach is sufficient to support semantic interoperability. We simulated large-scale clinical data transmission and measured semantic success between VA and DoD systems via one-way testing (OWT) and round-trip testing (RTT). Simulations were accomplished via SQL queries and production standards-based maps for medications, allergies, document titles, vitals and payers. Success rates for mapping local codes to national standards varied from 62.5% for DoD document titles and medications, to 100% for VA and DoD vital signs. Successful, one-way testing was considerably lower, ranging from 8.52% to 62.7%. Round-trip success rates were lower still, ranging from 1.7% to 76.3%. We present an error framework, lessons learned, and proposed mitigating steps to enhance standards-based semantic interoperability.

Introduction

Calls for the meaningful sharing of standards-based electronic health data are more than 25 years old.¹⁻³ These reports, and others more recent, share a common vision of freely flowing and highly re-usable patient-specific clinical data that improves care quality and safety. The HITECH act of 2009 mandated and achieved widespread national adoption of electronic health records (EHRs) by hospitals and providers.⁴⁻⁵ HITECH-act-driven EHR adoption in tandem with associated regulations requiring the use of specific data standards has helped the US take significant steps towards improving healthcare via shared data.⁶⁻⁷

Demands for health data interoperability between the Department of Defense (DoD) and the Department of Veterans Affairs (VA) share a similar timeline with more challenging technical and organizational requirements.⁸⁻¹⁰ For example, The National Defense Authorization Act (NDAA) for Fiscal Year 2014 required the Secretaries of the Department of Defense and the Department of Veterans Affairs to ensure that “Not later than October 1, 2014 all health care data contained in the Department of Defense AHLTA and the Department of Veterans Affairs VistA systems shall be computable in real time and comply with the existing national data standards.”¹¹ The 2014 NDAA further required “transition to modern, open architecture frameworks that use computable data mapped to national standards to make data available for determining medical trends and for enhanced clinician decision support.”

The Department of Veterans Affairs and the Department of Defense responded to this legislation by developing and deploying the Joint Legacy Viewer (JLV).¹²,¹³ JLV is a product that shares and displays patient data at the point of care. JLV extracts data from legacy EHRs (e.g., VistA and AHLTA) via Corporate Data Warehouses (CDW) and applies data maps between internal data representations and designated national standards to facilitate exchange. DoD and VA also assigned the joint Interagency Clinical Informatics Board (ICIB) to define “all health care data” and necessary standards to meet the NDAA mandate. The ICIB subsequently identified 23 data “domains” (e.g., medications, immunizations) and relevant standards for their exchange. Each Department developed and maintains its data maps independently. JLV is deployed at all VA Medical Centers and Military Treatment facilities. Between March and November of 2018, users logged in to JLV approximately 300,000 times and viewed approximately 1,200,000 records per month.

Saitwal and Hussain both note that data mapping is a more complex activity than might be assumed at first blush.¹⁴,¹⁵ Achieving the long-standing vision of meaningful sharing of standards-based electronic health data
(i.e., semantic interoperability) requires the successful marshaling, mapping, transmission, re-mapping and use of transferred information. This complex pathway requires solutions for mapping and marshaling challenges (e.g., as noted by L’Amore et al). We undertook this study to assess impacts on semantic interoperability of applying standards-based clinical data maps to a large, real-world clinical data set.

**Methods**

**Selected Domains**

We selected the five domains that the JLV is capable of integrating standards-based data for: Document titles (LOINC), medications (RxNorm), allergens (RxNorm + SNOMED CT), vital signs (LOINC) and payers (ASC X12).

**Data Preparation**

We developed a “test region” in VA’s Corporate Data Warehouse for this evaluation. The CDW test region copied the data structures and de-identified clinical data from the CDW production system servicing JLV. Data was de-identified by authorized CDW staff using approved standard “test region” encryption methods prior to being made available to the evaluation team. The same approved encryption methods were applied to the DoD Corporate Data Repository (CDR), ensuring that patients could be matched across data sets but not identified. We calculated counts of all data instances and unique codes for each domain.

**Mapping-Success Analysis**

Mapping to standards is a necessary prerequisite for standards-based interchange. We calculated the numbers and percentages of local codes that were mapped to a standards-based mediating code. We also calculated the number of mediating codes mapped to sets of local codes (i.e., one mediating code mapped to many local codes) stratified by set size.

**Data Transmission Simulation**

We simulated data transmission between VA and DoD systems using two distinct patterns: one-way testing (OWT) and round-trip testing (RTT). One-way testing separately simulated the transmission of VA data to DoD and the transmission of DoD data to VA. In each case, the data was transformed through each map set one time (i.e., the sending system’s local codes were mapped to standards-based “mediating” codes and then into the receiving system’s local codes). Round-trip testing simulated bi-directional data transmission (e.g., from VA to DoD and back again). Simulations were accomplished via SQL queries performed against test region tables using JLV production maps.

![Figure 1](image_url) Simulated Data Flows. VA-DoD Data One-Way Testing (solid arrows, steps 1-3): 1) VA data element retrieved from test region and matched to VA-Standards map (one-to-many). 2) Standards-based data element(s) sent to Standards-DoD Map. DoD map output compared to DoD data elements in test region (one-to-many). Round-trip testing return (dashed arrows, steps 4-6) reverses the process.
**Scoring**

Algorithmically exact matches between input and output data were scored as fully successful without additional human review. One-way testing success occurred when both the sending and receiving agencies shared the same mediating code (which have mappings to local codes and surface forms), regardless of the receiving system’s local code or surface form. If the mediating code appeared more than once in the receiving systems mapping tables (tied to a different local code), each match was counted as a success. This choice was made because sending and receiving local code systems could not be expected to have the same surface forms or internal identifiers.

Round-trip testing success occurred when the local data sent was received back in precisely its original form—i.e., matching codes and surface forms. An unsuccessful RTT means that the precise, original meaning was not sent back to the originating partner. Full success RTT rate is calculated with the numerator equals the number of full successes and the denominator equals “intent to interoperate” (size of domain). We also documented the total number RTT sent messages (“tries”) created by the many-to-one mappings.

**Results**

**Data Extraction**

We extracted de-identified patient-instance data from the VA Corporate Data Warehouse and the DoD Clinical Data Repository. Table 1 shows the number of clinical data elements and unique codes extracted for each domain for each Department.

**Table 1. Data Set Overview**

**Mapping to Standards**

The percentage of mapping successes (i.e., mapping a local code to a standards-based mediating code) for each Department’s clinical data is detailed in Table 3 and Table 4. They varied from 62.5% for DoD document titles to 100% for VA and DoD vital signs. Seven of ten mapping-success proportions exceeded 90%.

We found that in many instances multiple local codes were mapped to a single, standards-based mediating code. For example, two VA source elements “CEFADROXIL 1GM TAB” and “CEFADROXIL MONOHYDRATE 1GM TAB” were mapped to a single RxNorm semantic clinical drug “Cefadroxil 1000 MG Oral Tablet”. Table 2 shows the counts of instances where sets of local codes mapped to a single mediating code. DoD medications, DoD allergens and VA document titles had more than 40 bins (e.g., long tails). There were no cases of multiple standards-based mediating codes mapping to a single local code in any domain.
One-Way Testing Results

Table 3 shows VA→DoD one-way testing results, and Table 4 shows DoD→VA one-way testing results. In Table 3, VA to DoD one-way testing success as percent of total unique document titles, vital signs, medications and allergens were 8.5%, 29.4%, 46.8%, and 26.5% respectively. Payers were successful in no instances.

**Mediating Code Impact**

A mediating code is an SDO code that VA and DoD each map to for any given concept, enabling a one-way trip. Table 5 represents the actual impact of the SDO mediating codes on one-way testing success. This table describes actual instances of mediation, given the number of shared concepts (“mediating codes”). For example, VA and DoD had a partially disjointed, overlapping set of vital signs (e.g., VA audiometric “vitals” not shared by DoD). However, the Departments shared five vital signs (e.g., heart rate). Those five shared vitals mediated 65.06% of VA and 56.30% of eight DoD measurements. A total of 164 million VA vital signs and 8.3 million DoD vital sign instances were examined. Across all five domains, considering both directions, mediation rates (excluding payors) ranged between 26.4% and 91.8%.

</tr>
</tbody>
</table>

**Documents**: 14 LOINC codes mediated 29.9% of all VA document titles and 89.2% of all DoD documents titles in the data set when adjusted for frequency.

**Payers**: Payers have had a mapping file mismatch resulting in 0 mediations. Each Department used different versions of the ANSI X12 standard that were not interoperable (VA used payer typology; DoD used ANSI ASC X120-like codes plus “additions” that were unique to their system).

**Vital Signs**: Five LOINC mediated 65.1% of all VA vital signs and 56.3% of all DoD vital signs in the data set.

**Medications**: 5,731 RxNorm codes mediated 91.8% of VA and 81.2% of DoD medications in the dataset.

**Allergens**: 789 RxNorm and SCT codes mediated 63.1% of VA allergens and 26.4% of DoD allergens in the data set.

**Round-Trip Testing Results**

In round-trip testing, the actual results, excluding Payors, varied between 1.7% and 76.3%. But even when standards were the same (e.g., RxNorm for Medications), differences in formularies (value sets used by each Department) and non-exact mappings meant that round-trip testing could still fail. The table illustrates the results for all five domains and origins from either VA (VA→DoD→VA) or DoD (DoD→VA→DoD). For example, Medication round trips succeeded no more than 29% of the time (in that case, the direction was VA→DoD→VA).

Error Framework

Certain types of errors repeatedly occurred, and so we established a corresponding error framework with the following categories:

**Plausible Mismap:** Codes for same or equivalent concepts mapped to different yet arguably plausibly correct targets.
Example: VA maps to “Body Weight”, DoD maps to “Body Weight, Measured”

**Mapping Error:** Mapping errors can be pernicious but perhaps are not inevitable. Errors may occur at the time of map creation or emerge as the result of terminology and formulary changes.
Example: VA “HEPATOLOGY C&P EXAMINATION CONSULT” incorrectly mapped to LOINC 3\textcircled{3}9867-6 instead of LOINC 3\textcircled{3}8967-6. Error surveillance, including versioning and configuration management, can mitigate this risk. Importantly, each Department or exchange partner should consider using a common methodology for mapping. For example, they might develop and share a common “style guide” for mappers. Consistent use of tooling that helps prompt and even enforce consistent mapping can be useful. Finally, an Independent Verification and Validation (IV&V) of both partners’ mappings can be performed, ideally by the same group and using the same IV&V methodology.

**Granularity Error:** The granularity of a term is a measure of its specificity and refinement. A coarsely granular concept may encompass many finely granular terms (e.g., subclasses). Map granularity can be a design choice based on intended use or reflect patient-instance data-knowledge limits (e.g., patient x is allergic to penicillin(s) (class) vs. Benzathine Penicillin G (precise ingredient)). Example: VA maps document titles to 3416 LOINC terms, DoD maps to 50.

**Formulary Error:** Sending and receiving systems may not utilize or be able to represent the same clinical “items” (e.g., medications, lab tests). Final step expressivity deficits may limit transmission success (i.e., nothing to map to). This could be addressed by maintaining common set of items or by having methods to determine the useful similarity of items. For example, drug-allergy interactions could be computed using an RxNorm semantic clinical drug component rather than the precise RxNorm semantic clinical drug. Example: DoD has “PEAK FLOW” as a vital sign; VA does not.

**Information Model Error:** Differences in information model may make single term mapping impossible. Example: VA maps to BP, DoD maps to systolic BP and diastolic BP. Both systems represent blood pressure metadata such as cardiac cycle, patient position, cuff size, and artery sampled entirely differently.

**Many-to-One Explosions:** Many-to-one mapping explosions induced a large number of errors. The number of RTT tries observed corresponds precisely to the product of the number of codes at each step of the transmission (Table 7). The observed RTT success percentage corresponds to the reciprocal of the number of local codes in the many to one relationship (e.g., 3 codes sent $\times 33\%$ success on return). For RTT tries this is an $O(n^3)$ process. Semantic interoperability cannot be achieved until viable solutions to this issue are implemented.

<table>

</tr>
</tbody>
</table>
We undertook qualitative analysis of many VA NDF codes to one RxNorm Code instances. One consistent cause of many-to-one mappings relates to “Quantity Factors” for liquid preps. A “Quantity Factor” is the amount of medicine packaged in a vial or syringe. For example, VA “DOXORUBICIN HCL 200MG/VIL (PF) INJ” and VA “DOXORUBICIN HCL 10MG/VIL (RDF) INJ” both mapped to RxNorm “Doxorubicin Hydrochloride 2 MG/ML Injectable Solution”. The version of RxNorm used in this study was not able to represent and distinguish quantity factors. New versions of RxNorm now have this capability.

We performed limited quantitative analysis of many-to-one mappings in the domain of medications. Medications provide an extreme example, Medication RTT from VA \( \text{\rightarrow} \) DoD \( \text{\rightarrow} \) VA yielded 54,632 failures: 8,690 from unrecognized medications, and 45,942 from recognized many-to-one mappings. Table 7 demonstrates that many-to-one mappings impact round trips \( O(n^3) \) more than one-way success rates \( O(n^2) \).

**Discussion**

A high percentage of mappings between clinical data and national standards existed within each Department, yet one-way and round-trip testing success percentages based on mediating codes between Departments were much lower. This occurred in part because the Departments share partly disjoint value sets (e.g., no DoD counterpart for VA audiometric “vitals”). The problem is further exacerbated because the Department mappings were done independently and not entirely consistently: there was no examination between Departments when apparently very similar terms, and likely identical concepts, were mapped to different targets. These two factors alone meant that one-way trips would not always equal the proportion of overall mappings. Finally, the combinatorial explosion of one-to-many mappings made successful trips, particularly round trips, even worse. Therefore, for example, 99% of unique document titles in VA were mapped to national standards but the 14 mediating LOINC codes only mapped 8.6% of VA’s unique identifiers in one-way trips to DoD. Likewise, for vital signs, 100% of DoD’s and VA’s local identifiers were mapped to national standards but the 5 mediating LOINC codes matched only 29.4% of VA vital signs and 45.5% of DoD vital signs in one-way tests. Frequency-adjusted mediation proportions were higher because the most commonly occurring concepts were more likely to be shared between the value sets, and because the independent Department experts were more likely to have mapped similarly for such common items. In addition to the error framework presented in the results section, we learned several other lessons about potential challenges in map-based interoperability, namely:

**Standards “Suitability”:** The similarity of the Standard’s information model to the deployed system information model affects success rate. In cases where the deployed information model includes more data than the Standards information model, one-to-many mappings can result, causing decreased full-trip success rate even when all data is known or knowable.

**Style:** Standards may have more than one way to reasonably represent the same concept. This can result in plausible mismappings that must be managed by sending or receiving systems.

**Intent:** Maps, like terminologies(16), should be created with a specific purpose in mind. Maps created for one purpose (e.g., many drugs to one category for drug allergy interactions) may not work well for other purposes (e.g., granular pharmacy inventory management).

**Change Management:** The quality of maps can degrade over time. Two types of change must be managed: terminology versions and change in value sets (formularies) to be mapped and exchanged. We have found, in maintaining JLV maps, that we can expect ca. 12-15% annual change in active domains such as medications. This results from standards-bodies’ changes (e.g., retired RxNorm CUIs), formulary changes and new drug entities.

As a result of lessons learned, we propose several approaches to improve semantic interoperability. First, whenever possible, standards should be used natively in EHRs. In our experience, mapping is a recurrently expensive and inherently lossy process. Reducing the number of mapping translations reduces interoperability complexity and cost. Barriers to native use of standards, potentially including expressivity and update frequency, must be better understood. Second, ongoing standards quality improvement, for example, the addition of the “quantity factor” to RxNorm, can improve interoperability. Additional standards extensions and improvements should be use-case
driven and could contribute reductions in many-to-one, granularity, and formulary errors. Third, we recommend that EHRs should deploy entire terminologies and maintain separate purpose-specific subsets (e.g., ordering medications). The whole terminology could underpin other uses (e.g., CDS and reporting) and provide context for inbound, standards-based data. Additional benefits may accrue by using aggregation hierarchies and class definitions rather than enumerated lists to drive CDS, reporting, and other uses. Chu et al. have found this approach to reduce complexity and knowledge engineering time while increasing completeness coverage of clinical phenotypes.(17) We postulate that this approach may prove to be more resilient than enumerated lists for interoperating with inbound, standards-based data. Finally, our fourth suggestion is to develop robust mapping tools, common mapping procedures (at least a shared “desiderata” of mapping) and undertake strong independent validation and verification (IV&V) to best improve future results.

Conclusion

As our present results show, even when mapping is funded, prioritized and reliably completed, significant clinical information can be lost in one-way and round-trip transmission. Understanding this fact and addressing the underlying causes are important for continued progress in semantic interoperability and achieving the opportunities for improving healthcare quality and safety that it offers.

Clinicians increasingly expect computer-driven decision support, intelligent prompts, error detection and truly comparable data. They want to sum the lifetime Adriamycin dose across a continuum of care, even when the legacy systems in that continuum do not use common drug formularies, much less units of measure. Healthcare systems and practices that acquire systems should better understand the limitations that relate to data quality and interoperability and press for ongoing improvement. We suggest that system and standards developers focus on several problems: 1) the expense, inaccuracy and probable unsustainability of purely mapping-based approaches; 2) the need to support, maintain and natively use in HIT, common and high quality terminology standards; 3) migrating to common information models for complex clinical expressions and conclusions; 4) the idea that HIT software is evanescent and the clinical data are the gold nuggets that matter to patients and clinicians. Interoperability will not happen without ongoing investment and quality improvement cycles. We hope this paper has brought to light new opportunities for progress.

Determination of Marital Status of Patients from Structured and Unstructured Electronic Healthcare Data

Brian T. Bucher, MD, MS1, Jianlin Shi, MD, MS1, Robert John Pettit, BS1, Jeffrey Ferraro, PhD2, Wendy W. Chapman, PhD1, Adi Gundlapalli, MD, PhD1,3
1 University of Utah School of Medicine, Salt Lake City, UT, USA; 2 Intermountain Healthcare, Salt Lake City, UT, USA; 3 VA Salt Lake City Healthcare System, Salt Lake City, UT, USA

Abstract
Social Determinants of Health, including marital status, are becoming increasingly identified as key drivers of health care utilization. This paper describes a robust method to determine the marital status of patients using structured and unstructured electronic healthcare data from a single academic institution in the United States. We developed and validated a natural language processing pipeline (NLP) for the ascertainment of marital status from clinical notes and compared the performance against two baseline methods: a machine learning n-gram model, and structured data obtained from the electronic health record. Overall, our NLP engine had excellent performance on both document-level (F1 0.97) and patient-level (F1 0.95) classification. The NLP Engine had superior performance compared with a baseline machine learning n-gram model. We also observed a good correlation between the marital status obtained from our NLP engine and the baseline structured electronic healthcare data (κ 0.6).

Introduction
Social Determinants of Health (SDoH) are set of constructs that are becoming increasingly identified as key moderators of health-related outcomes1. For example, socioeconomic status, housing availability/stability, and social support affect the health of patients and should not be overlooked when investigating access to health care utilization and outcomes. SDoH can affect healthcare via a number of direct mechanisms including behavioral and disease risk factors, access to and processes of care, and quality of health care received. Recently, the United States Centers for Medicare and Medicaid Services (CMS) has proposed financial penalties to hospitals with high rates of 30-day readmission compared to the national averages2. Although this program’s goal is to improve the quality of health care provided, it fails to take into account SDoH that may drive differences in readmission, thus penalizing hospitals who preferentially care for high-risk patient populations.

Social support and social relationships are an important type of SDoH that can aid patients in access to healthcare and support during acute and chronic health care episodes. In particular, marital status is a traditional construct of social support and has been shown to have a positive effect on healthcare outcomes. Being married or in a domestic relationship has been shown to improve outcomes after hip replacement, heart transplantation, and even positively impact mortality3-5. With regards to resource utilization, being married has been shown to be associated with shorter hospital length of stay and hospital readmission6,7. Being widowed or lacking a partner has also been associated with increased risk of hospital readmission8. It is important to note that marital status is not only dichotomous (married vs not married), and may also include being separated, divorced, or widowed. Furthermore, in contemporary times, domestic partners are also considered under this status.

The challenge in studying the effect of SDoH on health-related outcomes is the lack of reliable data available to clinicians and researchers. SDoHs are inconsistently collected in the electronic health record (EHR) and vary between institutions9. Common SDoH that are routinely collected include: age, gender, and race/ethnicity. However marital status, while commonly collected in structured form as part of an intake to a healthcare facility, has the potential to change over time and may not be updated appropriately or in a timely manner to reflect the changes. In addition, given the constantly changing definitions of marriage and domestic partnership, the structured field may be inadequate to capture a patient’s own view of marital status.

Free text clinical notes provide a rich source of SDoH that has the potential to be accessed using natural language processing techniques (NLP)10. The advantage of clinical notes includes rich text features which provide context around SDoH. In addition, patients may disclose marital status more freely to providers and health care workers who document the social history in clinical notes. In these situations, the advantage of clinical notes is the ability to identify changes in marital status over time.
Previous work by our group and others have demonstrated the value of NLP in the identification of SDoH from free-text clinical notes. In a study from the VA Healthcare System, we developed an NLP system to extract mentions of “social support,” “housing situation,” and “living alone”\textsuperscript{10}. The performance of the system on a held-out test set showed an F1 score of 0.90 for social support, 0.61 for housing situation, and 0.81 for living alone. In a separate study, Navathe et al. develop a rules-based NLP system from 500 annotated clinical notes from a single academic institution to identify the following SDoH: tobacco use, alcohol use, drug abuse, depression, housing instability, fall risk, and poor social support\textsuperscript{11}. They demonstrated excellent performance with F1-scores ranging from 0.75 for Alcohol Use to 0.94 for Poor Social Support. In addition, they demonstrated the value of NLP-identified terms in predicting readmission risk compared to structured data alone.

To our knowledge and literature review, no previous studies have utilized NLP for the ascertainment of marital status. This is likely due to the belief that marital status is commonly collected in structured form in the electronic health record. However, as marital status may change over time, the accuracy of the structured data collection is unknown as it can be prone to error if it is not updated appropriately. The goal of the current study is to describe the development and validation of a rules-based NLP pipeline for determination of marital status from clinical notes. Our rules-based pipeline is then compared to a machine learning n-gram model and marital status obtained from structured data fields in the electronic health record. We subsequently describe the advantages and disadvantages of ascertainment of marital status from both structured data and NLP.

**Methods**

**Study Design**

We performed a retrospective study of patients treated at the University of Utah Health Sciences Center from 2015-2017. The University of Utah has maintained an electronic health record capable of comprehensive electronic data capture since 2013 and the data are stored in an enterprise data warehouse (EDW). Given we are interested in marital status determination, we limited our corpus to clinical Social Work Notes as these notes were highly likely to contain references to marital status.

**Structured Data Acquisition**

In the University of Utah EDW, marital status is treated as a patient level structured data field. This data field is updated on demand with updates in the electronic health record. Therefore marital status is not linked to encounter based information. To work around this limitation we obtained the log records for marital status changes to determine the date of marital status changes at the point of encounters.

**Reference Standard Corpus Creation**

Because there is only one structured field in the EHR for marital status and the structured data field is not linked to each encounter, we consider clinical notes to be a better representation of a patient’s true marital status for each encounter. We obtained 23,794 Social Work notes from 4716 patients between 2015-2017. We performed manual document-level annotation on 865 notes to create a reference standard corpus\textsuperscript{12}. We trained two annotators who performed document level annotation for marital status. The document level categories were: Single, Domestic Partner, Married, Separated, Divorced, Widowed. Overall, the inter-annotator agreement was 0.96. Any discrepancies were adjudicated between the two annotators to create a reference standard corpus. We then split the corpus into a development set (378 notes) to develop our rules-based pipeline or train the machine-learning model, and a blind validation set (487 notes) to measure performance.

**Knowledge Base Development**

To design our knowledge base for our domain, we started by creating a roadmap of the terms and relationships that define the underlying concept of marital status using real-world clinical text (annotations) from the development corpus as a guide. In addition, we enriched the ontology with terms using the Unified Medical Language System\textsuperscript{13}. The knowledge base was revised iteratively based on expert opinion and chart review and was used in our rules-based NLP pipeline.

**NLP Engine Development**

We utilized EasyCIE, a lightweight, rules-based NLP tool, which supports quick and easy implementation of clinical information extractions\textsuperscript{14}. EasyCIE uses a set of highly optimized and customizable NLP components built above n-Trie (a fast rule processing engine)\textsuperscript{15}, including sentence segmentation\textsuperscript{16}, named entity recognition\textsuperscript{17}, and context detection\textsuperscript{18}, feature inferencer, and document inferencer (Table 1).
Table 1. NLP components and corresponding functionality of EasyCIE.

EasyCIE leverages the knowledge base built above with information extraction models (IEM), including a term mapping IEM: a semantic representation of target concepts (“married”, “divorced”, “wife,” “husband”, etc.) and the corresponding contextual modifiers. The context IEMs for this study include four types: 1) Negation, whether a target concept is negated or affirmed, e.g. “not married”; 2) Certainty, whether a target concept certainly or uncertainly indicates the marital status, e.g. “marital status unknown”; 3) Temporality, whether a target concept indicates present, historical, or future, e.g. ”wife recently died”; 4) Experiencer, whether a target concept is referring to a patient or a patient’s family member, e.g. “met with patient’s daughter and her husband.” An annotation schema was defined from these IEMs. For example, “patient has been married for 5 years” would be encoded as Target Concept: Married, Negation: affirmed, Certainty: certain, Temporality: current, Experiencer: patient. Based on the values for these annotations in the document, EasyCIE applies rules to infer the final marital status for each document: Single, Domestic Partner, Married, Separated, Divorced, Widowed, Unknown. The rules were developed from the development corpus by manual review of reference standard annotations and iterative error analyses. The source code for EasyCIE can be found at https://github.com/jianlins/EasyCIE_GUI. The knowledge base and configuration file for ascertainment of marital status can be found at https://github.com/jianlins/EasyCIE_Hub.

Machine Learning Baseline Development

Given the lack of previous studies using NLP to determine marital status from clinical notes, we sought to compare the performance of the rules-based NLP system to a baseline machine learning. We developed an ngram-classifier trained using unigram and bigrams (1-2 word windows as word features) from the development set, excluding stop words. Our final feature set included 1488 binary n-gram features. We then created a word vector for each document in the development and validation set. We used the manual annotations as the reference standard to develop and validate the machine learning approach. We trained a Random Forest Classifier on the development set and used 10-fold cross-validation to tune the regularization parameters. Once we had optimal performance on the development set, we tested the performance of the machine learning classifier on the blind validation set.

Analysis

Performance of both the machine learning classifier and our NLP engine was measured by precision, recall, and F1 score for classifying documents compared against the reference standard annotations. The definitions are shown below

\[
\text{Precision} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Positives}}
\]

\[
\text{Recall} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}}
\]

\[
F_1 = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}
\]

We compared the performance of our NLP approach to the baseline machine learning approach using McNemar’s Test defined below where b and c are the discordant positive and negative classified documents between the NLP and machine learning classifier and \(\chi^2\) is the test statistic:

\[
\chi^2 = \frac{(b - c)^2}{b + c}
\]
We compared the performance of our NLP engine against the structured data fields using Cohen’s Kappa defined below where \( p_o \) is the observed agreement and \( p_e \) is the expected agreement by chance:

\[
\kappa = \frac{p_o - p_e}{1 - p_e}
\]

**Results**

**Patient Cohort and Annotation**

We obtained structured marital status from 4716 patients treated from 2015-2017. Based on the structured EHR data, the majority of patients in the cohort were married (55%), followed by single (23%), divorced (9%), widowed (7%), Domestic Partner (2%), and Separated (2%). Overall, marital status was unknown in 2% of the cohort. Since marital status can change over time, we examined the number of times the marital status changed in the structured data fields (Table 2). Overall, 16% of patients had at least one change in marital status with 2% of patients changing four times or more. Of the changes, 581 (78%) occurred on the same day, indicating a number of changes may be related to duplicate entries or updates to existing marital status.

**Rules-based NLP Engine**

Given the changes and possible uncertainty in the structured data fields, we sought to develop and validate an NLP engine to identify a patient’s marital status from clinical Social Work notes and compare the performance of our NLP engine to the structured data fields.

</tbody>
</table>

The performance of our NLP engine and machine learning approach on the validation set is shown in Table 3. Overall the NLP engine had significantly better performance compared to the baseline machine learning approach (F1-Score 0.97 vs 0.63, p-value <0.001). Examining individual classes, the rules-based approach had excellent performance (F1 score>0.90 in all individual class with “Separated” having the best performance. Compared to the baseline machine learning approach, the rules-based NLP approach did not have significantly better performance for “Divorced” or “Separated” classes. This is likely related to the low number of patients who met these criteria.

We then compared the performance of the NLP engine to that of the structured data field for patient-level marital status classification on the validation set by aggregating across patients and eliminating unknowns. (Table 4) Compared to the NLP engine, the structured data field showed decreased classification accuracy on patient level classification; however, this difference was not statistically significant (p=0.4).

Error Analysis

We analyzed the failures of our NLP engine in the validation set and characterized the errors in Table 5. Overall the majority of errors (42%) were related to lack of appropriate context assignment due to mentions of partners/spouses of relatives. The next most common errors occurred due to lack of negation (25%) or failure of document level inferencing due to multiple conflicting mentions of marital status.

Comparison of NLP vs Structured Data Field

Having established the excellent performance of our NLP Engine, we processed the entire corpus of 23,784 social work notes with the NLP engine and compared classification by NLP against the structured data fields. Since marital status may change over time, we aggregated notes by Year and Quarter to determine the NLP-derived marital status for that particular time. The NLP and structured labels are shown in Table 6. Overall the NLP-engine was unable to determine the marital status on 28% of patients, compared to only 3% for the structured data (p<0.0001).

</tbody>
</table>

We next compared the correlation of NLP-derived labels with those in the structured data. Overall the Cohen’s κ between the NLP-derived variable was 0.37. Excluding the unknown labels, the Cohen’s κ improved to 0.60. The pairwise agreement between the NLP-derived variable and the structured variable is shown in Figure 1. Overall there was a good agreement for Married (73%), and modest agreement for Domestic Partner (45%), Divorced (46%) and Widowed (51%). The largest disagreement was for Single. Of the patient labeled as Single by the structured data fields but not by NLP, NLP assigned the following marital status: domestic partner (14%), Married (10%), Divorced (9%), Separated (1%) and Widowed (1%).

Discussion

We present an analysis of the determination of patient marital status from both structured and unstructured electronic healthcare data. The present study contributes three novel and significant findings. First, marital status can be obtained from structured data fields; however, in our EHR there is only one field per patient, and the value may not correlate with past encounters due to marital status changes over time. In addition, the structured field is prone to manual entry errors or inconsistent updates when changes occur. Second, we demonstrated a rules-based NLP Engine can extract marital status almost as well as a human reviewer. Third, although there was not a statistically significant difference between NLP and structured field assignment of marital status on a small test set, we saw large discrepancies between the NLP ascertainment of marital status and the structured data fields on a large corpus. This work demonstrated the utility of NLP derived variables in the supplementation of structured electronic healthcare data. For the patients the
NLP Engine was unable to identify a marital status, the distribution of structured labels is shown in Figure 2. The two most common structured labels were Single (39%) and Married (38.5%).

In our cohort, based on the structured data fields, approximately 50% of the patients were married, with single being the next most common status at 25%. The advantage of using structured data is easy for storage and extraction in the electronic healthcare record. However, there remain challenges in the use of structured data fields. First, the marital status definitions can have diverse interpretations, especially culturally sensitive topics in health disparity populations such as racial/ethnic and sexual/gender minorities. Second, the marital status may change over time. This can pose a problem in EHR design, especially if marital status is a patient-level variable. In our institution, marital status is determined at the patient level and changes are only stored in the log databases of the enterprise data warehouse, thus limiting the use of marital status in encounter level analyses. Second, data entry errors may cause multiple entries for marital status. In our analysis, 78% of the changes in the structured marital status fields occurred on the same day. This indicates either data entry errors or conflicting information from different tables in the EHR.

To supplement the limitation of the structured data fields, we developed and validated an NLP engine to ascertain marital status from clinical notes. We elected to limit the notes to clinical Social Work notes as these documents have a high likelihood of containing marital status information. Overall our NLP engine had excellent performance on both a document level (F1 Score 0.97) and patient level (F1 Score 0.95).

Figure 1 – Normalized Comparison of NLP and Structured Data

We compared the performance of our NLP engine with the structured data fields on our full cohort of patients. After analysis of 23,794 notes, the NLP engine was able to make a determination on 72% of notes; however 28% of notes did not contain references to marital status. This large number of unknowns is a limitation of NLP due to the limited information contained in the clinical text. Given we only used Social Work notes, we hypothesize the inclusion of other clinical documentation may decrease the number of unknowns. Eliminating the patients that NLP was unable to make a determination on, we saw good agreement between our NLP engine and the structured data fields (Cohen’s κ 0.6). There was good agreement with married, divorced, widowed, and domestic partner. We saw the most disagreement in patients labeled as Single in the structured data fields. NLP was able to determine those patient are married (10%), domestic partner (14%), divorced (9%). This demonstrated the value of NLP in that sensitive topic such as domestic partners or divorce may be misrepresented in the structured data fields. The largest number of disagreements in each structured data class was related to the NLP engine being unable to ascertain marital status. We analyzed the distribution of structured data labels in those the NLP system was unable to determine marital status.
The distribution of marital status in the unknown patients matched the overall distribution of the structured data fields. This indicates our NLP engine is not biased toward the ascertainment of one particular marital status class.

Figure 2. Structured marital status labels for patient’s without NLP obtained marital status

Overall, based on the results of our study we feel a hybrid approach to the ascertainment of a patient’s marital status should be used. NLP can be used to supplement structured data fields especially in instances where the structured field is Unknown or Single.

Limitations and Future Work

We acknowledge several limitations. First, this study was limited to the traditional definition of marital status as is currently captured in electronic health records. As there is insufficient knowledge of how the spectrum of social/domestic relationships (including same-sex partnerships) are currently documented in the health record, there is an opportunity to extend our work in this direction in the future. The study was limited to one large academic medical center and to one electronic note type (social work notes that were predicted to be of high yield for marital status). These findings merit extension to other note types and other healthcare facilities. Marital status is one of many social risk factors which have become increasingly identified as drivers of health care utilization. Moving forward, we seek to expand out ascertainment of other social risk factors using NLP tools.

Conclusions

In conclusion, we described the determination of marital status from electronic health record data. We developed an NLP engine to inference a patient’s marital status from clinical notes. Overall our NLP engine had excellent performance on both a document level and patient level classification. There was good agreement between the NLP method compared with structured data entries present in the electronic healthcare record. This work demonstrated the value of combining structured and unstructured data for determination of marital status. Our techniques are can be extended to other SDoH and provide researchers valuable insight into the role these factors play in healthcare utilization.

Abstract

Greater transparency in salaries overall and in factors associated with differing salaries can help students and professionals plan their careers, discover biases and obstacles, and help advance professional disciplines broadly. In March 2018, we conducted the first salary survey of American Medical Informatics Association members. Our goal was to summarize salary information and provide a nuanced view pertaining to the diverse biomedical informatics community. To identify factors associated with higher salaries, we reviewed average salaries for different groups (physician status, academic status, and different leadership positions) by gender. We also fitted multiple linear regression models for all participants (\(N = 201\)) and for gender, physician- and academic-status subgroup. The mean (standard deviation) salary was \$181,774 (\$99,566). Men earned more than women on average, and especially among professionals from academic settings. More years working in informatics and full-time employment were two factors that were consistently associated with higher salary.

INTRODUCTION

Understanding salaries overall and the factors associated with higher salaries in biomedical informatics can aid individuals at all stages of the profession in career planning and negotiation. In addition, greater insight into the characteristics associated with higher compensation in biomedical informatics may help advance the field by identifying potential pay gaps, including gender disparities, which can then be addressed.

In several scientific fields, studies were conducted to explore and discover factors associated with salary.\(^1\)-\(^9\) The majority reported that on average men earned higher salaries than women.\(^2,3,5\)-\(^9\) The American Association of University Women (AAUW) tracks the pay gaps using data from the Bureau of Labor Statistics and the Census Bureau for different characteristics such as race, geographical location and industry. In Fall 2018, they reported a gender pay gap of almost 20% and listed ‘physicians and surgeons’, ‘registered nurses (RNs)’, and ‘medical and health services managers’ among the 10 occupations where the collective loss is the highest for women.\(^10\)

Focused surveys in the medical domain report findings that are in line with the AAUW report. For example, male internists earned 14% more per hour than female internists\(^6\) and male RNs earned \$3,792 to \$17,290 more per year than female RNs, depending on the setting, specialty and position.\(^5\) Among early career physician-researchers, males’ salaries were about \$10,921 higher, after taking other factors into account.\(^3\) Males with a PhD degree earned \$18,000 more annually than females with PhDs.\(^9\) However, a few studies found no gender differences in salary, for example, among radiologists working in public medical schools.\(^1,4\)

The existing work rarely examines factors that may lead to higher salaries for professionals in biomedical informatics and related fields such as health IT. One exception is the 2018 Health Information and Management Systems Society (HIMSS) US Compensation Survey report, which is based on a salary survey of US health IT professionals and conducted annually since 2006. In 2018, responses from 885 participants provided a nuanced view.\(^11\) There were several disparities reported, including lower salaries for women (vs men) and non-white (vs white) professionals in health IT. Compared to males, females earned \$22,797 (accounting for 14%) less on average, and the disparity persisted from 2006 to 2018. Although this study estimated gender and race disparities overall and stratified over several factors separately including age, geographic region, job type, and managerial status; other
factors including educational degree, years of work experience, workplace setting (e.g. industry, academia, government), area(s) of expertise, and professional duties were not examined and may be important to consider.\textsuperscript{3,4,12}

The American Medical Informatics Association (AMIA) is a non-profit professional association dedicated to the development and application of biomedical and health informatics.\textsuperscript{13} Founded in 1989, the association includes over 5,600 informatics professionals.\textsuperscript{14} The members belong to several different groups; they include academic and industry members as well as clinical and non-clinical members. AMIA members also have a wide range of experience levels, ranging from students to Chief Medical Informatics/Information Officers/Chief Health Informatics Officer (CMIO/CHIO) or higher. As such, analysis of this community may provide a diverse and nuanced view on salary and pay differences between different groups. Understanding the range of members' salaries for various informatics roles can inform the AMIA community about existing gaps and may facilitate activities aimed at ensuring fairness and transparency in compensation for all informatics professionals.

The objectives of this paper are to (1) describe the methods of the first AMIA member wide salary survey, (2) describe the distribution of survey participants' salaries overall, (3) describe the factors associated with higher salaries, including a possible gender disparity, and (4) to explore some of the potential barriers to salary and career advancement among AMIA members.

METHODS
Survey Development

In 2017, the Career Advancement Committee ([CAC] formerly named Academic Career Advancement Committee), a subcommittee of the Women in AMIA Steering Committee, created a survey by adapting content from existing surveys to obtain information from AMIA members about their titles, areas of expertise, years in those areas, gender, and salary, in part to identify potential gender-based salary disparities. The CAC collaborated with several members from the Women in AMIA Steering Committee and other AMIA members and staff with expertise in survey development, including reviews of the American Health Information Management Association’s (AHIMA’s) Salary Survey,\textsuperscript{15} to iteratively develop the AMIA Salary Survey. The final AMIA Salary Survey was hosted on SurveyMonkey Inc. and included 34 questions focusing on demographic, education, salary and other forms of compensation, informatics expertise, and current informatics position.

Participant Recruitment and Data Collection

The survey was launched through AMIA eNews on March 22, 2018 as well as two AMIA online communities (the Women in AMIA and Implementation forums) and closed on May 16, 2018. Our goal was to keep the survey open until we reached at least 200 participants. After closing the survey, there were 225 participants. We excluded from the current report those who reported that they did not currently have a salary or were retired (N = 21) or listed a salary of $0 (N = 3).

Statistical Analysis

In descriptive analyses, we present summary statistics overall and statistics stratified by gender, physician (vs non-physician) status, and academic (vs non-academic) status. For analyses stratified by gender we excluded participants who either did not report their gender or reported non-binary/other gender (N=9, 4.5%). For analyses stratified by physician-status we excluded 1 participant who did not report this information. Student’s t-tests and Chi-square tests were conducted to compare mean and proportion difference in areas of informatics expertise and career barriers between two stratified subgroups (i.e., male vs female, etc.).

To estimate the factors influencing salaries of the study cohort, including gender, we fitted a regression model including all participants as well as prediction models for each subgroup of participants, stratified by gender, physician status, and academic status. For each model, we conducted a multiple linear regression with a backward selection procedure, using the zero-skewness logarithm of salaries, as a dependent variable, and all other factors (except for outcome questions such as benefits including health insurance, life insurance, retirement plan, bonus, flex schedule, etc.) collected from the survey as independent variables. To optimize our models, several steps were taken before fitting the multivariate models: 1) if a factor was categorical, we reclassified the original categories in order to get the lowest Akaike Information Criterion (AIC) of that factor in univariate analysis; 2) if factors were highly correlated, we combined them into a single factor (e.g., factors about faculty/faculty rank, similar informatics expertise, etc.); 3) each workplace setting, informatics area, informatics expertise, and career barrier category was modeled as a yes/no indicator variable. The significance level for factor removal from the model was set as 0.1. Multicollinearity was checked using Variance Inflation Factors (VIF) with the rule of thumb that VIF ≥ 5 indicates
If one or more factors had a VIF ≥ 5 in a model, we excluded the factor with the highest VIF and then checked VIF again after exclusion. The process was conducted iteratively, until all factors in the model had a VIF less than 5. The residual normality assumption of each model was checked using plots and tests of skewness and kurtosis. All the analyses were conducted using Stata 13.0.

RESULTS

Overall Participant Characteristics

Among participants who reported a salary greater than $0 (N = 201), more than half were female (62.7%), and physicians and academics were accounted for 38.3% and 59.2%, respectively. Regarding the education of our study sample, the smallest group were participants with a bachelor’s or master’s degree (17.4%), while majority had a Ph.D./DSc (42.8%) or a professional doctorate such as MD, PharmD, and JD (39.3%); and 27.4% reported having two or more doctorate degrees. Among the 201 participants, 91.0% were full-time employees. The number of years of experience as an informatics professional was distributed evenly among the participants, with 17.9% ≤ 4 years, 21.9% 5-9 years, 22.4% 10-14 years, 14.9% 15-19 years, and 22.4% ≥ 20 years. Figure 1 compares the representativeness of the survey participants with AMIA members of 2018. Compared to AMIA members, survey participants had a higher prevalence of females and academics, but a lower prevalence of students. The prevalence of physicians among survey participants was similar to the prevalence in the broader AMIA population.

Figure 1. Demographic characteristics of survey participants and 2018 AMIA members

The lowest salary for someone engaged full-time in informatics activities was $37,000, for a full-time student, while the highest salary reported was $1,900,000. The top two highest salaries ($750,000 and $1,900,000) were identified as outliers (using the empirical rule which identifies outliers beyond 3 standard deviations of the mean of the logarithm of salary). However, we further explored the other self-reported data associated with the top two salaries to determine the plausibility of the high salaries. Based on the other self-reported data (e.g. title, years of experience, and other factors) for the participant who reported the highest salary of $1,900,000, we suspect a data entry error for the salary and used $190,000 instead of $1,900,000 in the data analysis. As for the second outlier, $750,000 could be a true value according to the self-reported data, so we kept it in the data. Tables 1-3 show overviews of the salary data overall and for different groups. The overall mean (standard deviation [SD]) annual salary of the AMIA participants in this study was $181,774 ($99,566) and median (interquartile range) was $165,000 ($111,000-$230,000) (Table 1).

Figure 2 shows that the salary distribution was skewed to the right (p < 0.001), but the zero-skewness logarithm of salary, ln(salary+57,011.99), was normally distributed (p = 1.000).

Figure 2. Salary and zero-skewness logarithm of salary distribution shown in histogram graphs
Unadjusted Comparisons by Gender

On average, men earned $206,091 (SD: $118,865) per year, compared to $165,369 (SD: $80,807) per year for women, resulting in a gap of $40,722 (Table 1). The largest unadjusted difference in mean salary, where men earned more than women, was for academics ($49,903), followed by non-academics ($23,667) and physicians ($23,135) (Table 2 and 3). However, among non-physicians, men earned slightly less ($391) than women. In general, men and women had a similar number of informatics expertise areas (5.8 vs 5.7). Figure 3 shows the distribution of members who had a leadership position. There were 81 (40.3%) participants who held a leadership role (e.g. CMIO, vice president [VP], director, and department chair). The percentage of leaders was higher among men than women (53.0% vs 34.1%). The top 3 (out of 27) areas of informatics expertise among men were clinical decision support, implementation, and human computer interaction; and among women were clinical decision support, implementation, and clinical research informatics. In comparison, clinical decision support, human computer interaction, and security were more frequently reported as areas of expertise by male participants, while consumer health informatics was more frequently reported by female participants. Figure 4 shows salary comparisons by years of experience. Salaries for both men and women increased with more years in the informatics profession, with the highest mean salary associated with working for 15-19 years among men and working for 10-14 years among women. There were no consistent differences in men versus women across years spent in the profession.

**Figure 4.** Annual salary by number of years working in the informatics profession stratified by gender (N = 66 males and 126 females)

The survey also requested a list of career advancement barriers. The different rankings of career barriers by gender are shown in Table 4 and rankings by strata of physician and academic status are available online (https://www.amia.org/sites/default/files/AMIA-2018-Salary-Survey-20181031.pdf). Across 5 potential career advancement barriers, on average, men reported fewer than half the number of barriers that women did (0.2 vs 0.6,
p<0.001). The #1 top career barrier for men and women was “other barriers” (i.e., work-life balance, career/life change, lack of support from family) (N=5, 7.6%) and taking time off to raise a family (N=22, 17.5%), respectively.

Qualitative analysis was performed of free-text responses to one question in the salary survey: “Are there significant life events that may have impeded your career progress?” The responses were classified according to the typology proposed by Cachon17 as personal (inherent to the individual); organizational (determined by the organization); and social (determined by sociocultural contexts in which both organization and individual are embedded). Several participants listed multiple factors – “All of the above in one way or another, and at one time or another”.

The free-text responses provide more nuance: Personal: “Two-body problem that comes from being an academic spouse”; “Special Needs Child, had to file FMLA in the past to meet child’s needs”; and “Inability to move to new city due to family commitments.” Organizational: “No family financial support during education; lack of on-the-job mentoring; starting career in areas of the country with lower salaries than where most other positions are”; “Attitudes of tenured faculty”; and “Burnout and compassion fatigue.”

Of the top 5 career barriers (Table 4), three were personal factors, and one simultaneously social and organizational in nature.

Other barriers: i.e., work-life balance, career/life change, lack of supports from family

Unadjusted Comparisons by Physician Status

On average, physicians earned $114,066 per year more than non-physicians (Table 1). Physicians had slightly fewer areas of informatics expertise than non-physicians (5.3 vs 6.0, p=0.152). Table 5 shows the top 3 areas of informatics expertise stratified by physician status. A higher proportion of physicians reported clinician decision support and implementation than non-physicians; while a higher proportion of non-physicians reported data science than physicians. Physicians reported a similar number of career barriers as non-physicians (0.5 vs 0.5, p=0.516).

Unadjusted Comparisons by Academic Status

Academics earned $37,160 per year less than non-academics (Table 1). Academics had more areas of informatics expertise than non-academics (6.1 vs 5.1, p=0.022). Table 6 shows the top 3 areas of informatics expertise stratified by academic status. A greater proportion of academics than non-academic counterparts reported clinical research informatics; while more non-academics reported standards. Academics identified a similar number of career barriers as non-academics (0.5 vs 0.5, p=0.899).

Fully Adjusted Analysis

We fitted a model to identify the factors independently associated with the zero-skewness logarithm of salary. As shown in Table 7, gender was not a statistically significant factor associated with salary and was removed from the model. The factors that were associated with higher salaries, and were statistically significant, included physician (vs non-physician), more years working as an informatics profession, full- (vs part-) time employment, a higher number of people directly reporting to participant, having a leadership position (vs non-leadership), hospital/health system (vs non-hospital/health system), expertise of consumer health informatics, and natural language processing. The factors that were associated with lower salaries, and were statistically significant, included having a combination of experience and education that was not part of informatics training, public health informatics area, and mobile health expertise. Also, “other career barriers” (i.e., work-life balance, career/life change, lack of support from family) were associated with lower salaries in the fully adjusted model. For example, the coefficient of physician was 0.312, which means if the annual salary of both physicians’ and non-physicians’ was increased by $57,012, physicians’ salary would be 1.366 times as non-physicians’ on average, after controlling for other factors. The R-squared of the model was 0.674, which means 67.4% of variance in the dependent variable (zero-skewness logarithm of salary) was explained by the factors included in the model.

In Figure 5, all plots showed that the residuals of the predictive model were normally distributed. The p-value of the skewness and kurtosis test for normality of the residuals was 0.0861, so we could not reject the hypothesis that the residuals were normally distributed.

Figure 5. Normality of residual diagnosis by residual vs. fitted plot, Q-Q plot, and histogram of the residuals
We also conducted a sensitivity analysis after excluding the outlier (extremely high salary of $750,000). All significant factors in the model remained statistically significant and estimates of predictors were in same direction, with the predictor magnitudes just slightly changed. Two more statistically significant factors were identified after excluding the outlier: education degree (higher degree associated with higher salary) and the career barrier of “Taking time off to raise a family” (barrier associated with lower salary).

Fully Adjusted Analysis by Strata of Physician, Non-Physician, Academic, and Non-Academic subgroup

We also fitted models for each subgroup and found that the statistically significant factors varied in the different models. Gender was only an independent factor associated with salary for the model among academics (N = 115). In academics, the mean salary for men was higher than the mean salary for women (β=0.302, p=0.008) after controlling for other factors. Across all models of subgroups, there were only two factors that were consistently associated with higher salary and were statistically significant: 1) more years working as an informatics professional and 2) full-time (vs part-time) employment.

DISCUSSION

To the best of our knowledge, this is the first study to report on the salaries of AMIA members. Overall the mean salary of the 201 salary survey participants was $181,774. Further, our results revealed that overall, men earned a higher salary than women on average. However, after adjusting for other factors, gender was not associated with salary in participants overall or by subgroups of academic and physician status strata, except among participants who reported an academic position, where men earned higher salaries on average. Other characteristics associated with salary may explain the differences across gender. Men (vs women) had a higher education level (doctorate level) (87.9% vs 78.6%), a higher proportion of physicians (56.1% vs 27.8%) and leaders (53.0% vs 34.1%). A lower proportion of men reported career barriers than women (22.7% vs 46.8%). These initial findings should be interpreted with caution, noting that 40.3% of participants reported that they held a higher level leadership position and may over-represent professionals who earn much more than those in non-leadership positions.

Overall, the participants in the AMIA salary survey reported a mean salary between the mean salaries reported by the 2018 HIMSS US Compensation Survey ($109,610) and that reported by the 2018 Association of Medical
Directors of Information Systems-Gartner survey for CMIO/CHIOs ($353,600).\textsuperscript{18,19} The mean salary of AMIA members is also in line with those reported by the Association of American Medical College’s Faculty Salary Report, Fiscal Year 2018 of $184,300 among MDs in the basic sciences or $145,900 among PhDs in the clinical sciences and point to the potentially lucrative nature of the biomedical informatics profession.\textsuperscript{20} On the other hand, the mean salary among academic AMIA salary survey participants ($166,618) was lower vs biomedical informatics faculty in the 2018 Association of American Medical Colleges Faculty Salary Report ($246,500).\textsuperscript{21}

Several of the differences observed in salaries among participants in our study were consistent with the HIMSS Compensation Survey.\textsuperscript{18} As in our study, in HIMSS\textsuperscript{19}, men on average earned more than women, $123,244 versus $100,477 per year, respectively. Findings from the HIMSS survey\textsuperscript{18} also suggested that salaries increased with age. In our study, we used years working in the informatics profession as a surrogate of age. We found that working for 5 years or more (versus fewer than 4 years) was associated with higher salaries and was statistically significant. However, salary increased continuously with more years worked but only among non-physicians. Unlike the HIMSS survey, where the gender salary gap widened with older age, the gender gap in our study remained relatively constant with increased years working in the biomedical informatics profession (results not shown).

Consistent with previous research, we observed that there were more barriers and different ranking of top career barriers across men and women, which may partly account for the higher salaries observed among men and higher percentage of men in leadership positions compared to women among participants overall.\textsuperscript{22,23} Whether differences in career burden due to taking time off to raise a family (#1 barrier for women) versus “other barriers” (i.e. work-life balance, career/life change, lack of support from family, #1 barrier for men) help explain the gender pay gap, as well as differences in resources available to address these barriers for men versus women, requires further research.

The findings of this study should be interpreted with caution and in the context of several limitations. First, the sample size is limited, especially for males. By comparison, the HIMSS study had 885 participants, almost 4 times the number of participants for ours, at 225. The gender ratio of women to men in this study was 2:1. Another limitation is that to protect participant identity, we did not collect sociodemographic factors such as age, race, and ethnicity. A third limitation is that in this study, we had more responses from individuals with senior or leadership-level positions than early-career individuals. For example, there were 20 full professors vs 17 assistant professors, and 81 individuals holding leadership roles vs 2 post-doctoral fellows. Very few students (N=2, 1.0%) and postdocs/fellows (N=8, 4.0%) participated in the survey. In our sample, 34% of women held leadership positions. On average, the number of women holding the most senior-level positions (such as chief-level positions) has not increased since 2015 and remains at 22%,\textsuperscript{24} even lower representation is reported for specific roles such as hospital CEOs (18% female) and deans and department chairs (16%).\textsuperscript{25} Due to the limited sample size, we did not evaluate the interaction effect between these factors and gender on salary levels.

That said, this study represents a promising start in identifying factors associated with higher salaries among informatics professionals. We intend to repeat this salary survey annually or biannually, with AMIA’s permission and assistance. We aim to increase and improve representation by reaching out to the full spectrum of informatics professionals for different genders, ages, races/ethnicities, and other characteristics where there may be gaps in compensation. Also, with a larger sample size, we will be able to take into account additional variables such as race and ethnicity and perform time-series analysis and study salary trends.

CONCLUSION

Overall, our study builds on the prior work that suggests that field of biomedical informatics may be a lucrative career choice for many in terms of salary. Gender disparity was only observed for professionals who reported an academic work setting but not in other groups (i.e. physician, non-physician, and non-academic subgroups), when specific factors, not previously considered by prior related studies, were included in the models. More years working as an informatics professional and full-time (vs part-time) employment were the only two factors that were consistently associated with higher salary across all groups and remained statistically significant. Future salary surveys of AMIA members will seek to address the limitations of the current study including small sample size and high proportion of the participants holding leadership roles, to improve representation and the generalizability of the findings and to continue to advance the biomedical informatics profession.

Abstract

In this study, we used serial heart rate variability (HRV) measures over 2 hours to improve the prediction of 30-day in-hospital mortality among septic patients in the emergency department (ED). We presented a generalizable methodology for processing and analysing HRV time series (HRVTS) data which may be noisy and incomplete. Feature sets were created from the HRVTS data of 162 patients with suspected sepsis using aggregation-based, delta-based and regression-based series-to-point transformations, and modelled over 100 random stratified splits. An optimized feature set comprising 12 selected HRVTS features performed better than baseline feature sets which only included patient demographics, vital signs and single time-point HRV measures taken at triage. This improved risk stratification approach could be used in the ED to identify high-risk septic patients for appropriate management and disposition.

Introduction

Sepsis is an increasingly recognised global problem that has a 10-20% in-hospital mortality (IHM) rate1-3. Risk stratification of septic patients in the Emergency Department (ED) may help to guide appropriate management and disposition, thereby reducing morbidity and mortality4-6. A number of clinical tools, such as the Quick Sequential Organ Failure Assessment (qSOFA), National Early Warning Score (NEWS) and Modified Early Warning Score (MEWS), have been used to risk stratify septic patients in the ED, where certain clinical information, such as laboratory investigations, are initially not available. These risk calculators rely solely on patient demographics, vital signs and clinical observations in their scoring criteria.

Several studies have reported the prognostic value of heart rate variability (HRV) parameters in septic patients presenting to the ED7,9. Septic patients have reduced sympatho-vagal balance and impaired sympathetic activity, which lead to varying degrees of cardiac autonomic dysfunction10. This can be detected by HRV analysis, a quick, non-invasive technique of evaluating the beat-to-beat variation in heart rate. HRV analyses are divided into linear and non-linear methods11. Linear methods include HRV parameters measured in time or frequency domains. Time domain HRV parameters are statistical calculations of consecutive R-R time intervals and how they correlate with each other. Frequency domain HRV parameters are based on spectral analysis. Studies have suggested that regulators of the cardiovascular system interact in a non-linear way12, 13 and HRV analysis using non-linear methods reflect these mechanisms14.

We previously demonstrated that HRV parameters measured at triage, combined with patient demographics and vital signs, can improve the prediction of 30-day IHM among septic patients in the ED compared to traditional risk stratification tools15, 16. Since sicker patients are often put on continuous electrocardiogram (ECG) monitoring in the
ED, their serial HRV measurements over time can also be derived. We postulated that HRV time series (HRVTS) may embed more prognostic information than HRV parameters derived at a single time-point, such as at triage.

To date, there has been no published study exploring the use of HRVTS for risk prediction in sepsis. Thus, in this study, we aimed to compare the performance of HRVTS over 2 hours against single time-point HRV measures at triage, in the prediction of 30-day IHM among adult septic patients in the ED setting. In addition, since serial HRV measures are seldom encountered in literature, we aimed to develop and present a generalizable methodology for processing and analysing such data which may be noisy and incomplete.

**Methods**

**Data preparation**

Ethics approval for the study was obtained from SingHealth’s Centralised Institutional Review Board (CIRB, Reference Number 2016/2858), with waiver of patient consent. Patients above 21 years old who presented to the Singapore General Hospital (SGH) ED between September 2014 and April 2016 with clinically suspected sepsis, and who met at least 2 of the 4 Systemic Inflammatory Response Syndrome (SIRS) criteria\(^1\) were included. The SIRS criteria are temperature (<36°C or >38°C), heart rate (>90 beats/min), respiratory rate (>20 breaths/min) and total white count (<4000/mm\(^3\) or >12000/mm\(^3\)).

Patient demographics (age, gender, ethnicity), first set of vital signs recorded at triage (temperature, respiratory rate, heart rate, systolic and diastolic blood pressures, and Glasgow Coma Scale (GCS) score), and outcome of interest (IHM within 30 days of ED admission) were retrieved from the hospital’s electronic medical records. Continuous one-lead ECG tracings over 2 hours in the ED were also obtained from X-Series Monitor (ZOLL Medical Corporation, Chelmsford, MA). The ECGs were split into 8 intervals of 15 minutes each and then analysed for HRV parameters using the most stable continuous 5-minute segment within each interval. 22 HRV measures in time, frequency and non-linear domains were computed for each interval. For patients whose ECGs were shorter than 2 hours or unanalysable due to non-sinus rhythm, excessive artifacts and/or ectopic beats, their data was considered missing for the relevant intervals.

To ensure data quality and to limit the amount of missing data in subsequent analysis, we only included patients with at least 7 of the 8 intervals in our final analysis (i.e. at most 1 missing interval allowed). Univariate statistical analysis was conducted to compare patients with and without outcome, as well as to compare the original and final cohorts (Kruskal-Wallis H test for continuous variables and Chi-squared test for categorical variables).

**Feature Extraction**

We created 2 baseline feature sets that did not utilize any information from the HRVTS as baselines for comparison. We then designed 3 groups of candidate feature sets (aggregation-based, delta-based and regression-based) using different methods of series-to-point transformations to encapsulate the HRVTS information. Detailed definitions of the feature sets, as well as an example of how the feature sets were calculated, are presented in Tables 1 and 2 respectively.

**Baseline feature sets:** The first baseline feature set (fs_no_HRV) contained only patient demographics and vital signs. These features are included in all subsequent feature sets. In the second baseline feature set (fs_baseline), single time-point HRV parameters generated from the first 5-minutes of ECG obtained at triage were added.

**Aggregation-based features sets:** 3 aggregation-based feature sets were constructed by taking (1) the first and last values of the HRVTS (fs_first_last), (2) the median and interquartile range (IQR) of the HRVTS (fs_med_IQR), and (3) the minimum and maximum values of the HRVTS (fs_min_max).

**Delta-based feature sets:** With the assumption that the magnitude of relative changes between neighbouring intervals were informative, we calculated (1) the first and last (fs_delta_first_last), (2) the median and IQR (fs_delta_med_IQR), and (3) the minimum and maximum (fs_delta_min_max) of the absolute differences between adjacent HRVTS measurements. Linear interpolation was used to impute missing measurements.

**Regression-based feature sets:** With the assumption that trends in the HRVTS were informative, we fitted the (1) original values (fs_reg_default), (2) absolute differences between measurements (fs_reg_delta), and (3) cumulative differences between measurements (fs_reg_cum_delta) of the HRVTS to a linear regression model.
using the ordinary least squares method. The linear coefficients and intercepts obtained were used as features to characterize the trends.

\textit{(HRVTS, heart rate variability time series; mean\textit{rr}, average width of the RR interval)}

Model Setup

Prior to modelling, all features were standardized to be between 0 to 1 by MinMaxScaler (subtracting the minimum value and then dividing by the difference between the maximum and minimum values).

We set aside 20% of the patients as test data, stratified by outcome. Within the remaining 80% of the patients, we created 100 random stratified splits, with 80% as training data and 20% as validation data in each split. We chose logistic regression with L1 regularization (LASSO) with C=1.0 as our model due to its simplicity and the interpretability of odds ratios obtained. Class imbalance was addressed by applying sample weights inversely proportional to the number of samples. We used Area Under the Receiver Operating Characteristic curve (AUC) as our performance evaluation metric.
**Feature Selection**

Each feature set was inputted separately into the logistic regression model and the median odds ratios of all non-zero coefficients obtained across 100 splits were calculated. We tested the proportion of each feature having non-zero coefficient larger than 0.5 using one-sided binomial test under Bonferroni correction.

To create an optimized feature set, the feature with the most extreme odds ratio among statistically significant ones (if any) was selected for each HRV parameter. These selected HRV features were then combined with demographic and vital sign variables significant across majority of feature sets to form an optimized feature set `fs_final_selection`.

HRV analysis was performed using Kubios HRV software version 2.2 (Kuopio, Finland)\(^\text{18}\). Statistical analysis and modelling were carried out in Python 3.6 (Python Software Foundation, Wilmington, Delaware, USA) using the statsmodel\(^\text{19}\) and scikit-learn libraries\(^\text{20}\).

**Results**

Figure 1 shows the cohort selection process. 214 patients were in the original cohort whose ECGs were split into intervals and analysed for HRV parameters. After excluding patients with more than 1 missing interval, 162 patients were included in the final cohort, of whom 31 (19.1%) met the outcome. There were no significant differences in the patient demographics, vital signs and outcome between the original and final cohorts (Table 3).

![Cohort selection flowchart](image)

**Figure 1.** Cohort selection flowchart.

Among the final cohort, 77 (47.5%) of the patients were male, with median age of 67 years (inter-quartile range, IQR 57–79). Patients who met the outcome were older (median age 76 years; IQR 68–83 years) than those who did not (median age 66 years; IQR 57–77 years). There were no significant differences in gender and ethnicity distributions between the two groups. In terms of vital signs, patients who met the outcome had higher respiratory rates, as well as lower temperatures, heart rates, systolic blood pressures and GCS scores, compared to patients who did not meet the outcome. The HRVTS of the two groups are visualised in Figure 2.

Table 4 shows the median odds ratios across all feature sets and predictor variables. Most of the features had coefficients of zero (hence odds ratio of zero) due to the L1 regularization. 12 HRV parameters (5 in time domain, 4 in frequency domain and 3 in non-linear domain) had statistically significant odds ratios and were selected into the optimized feature set `fs_final_selection` (Table 5). 3 other non-HRV variables (age, systolic blood pressure and GCS) were also statistically significant across most feature sets and added to the optimized feature set `fs_final_selection` to make a total of 15 features.

Figure 3 summarizes the median AUC of all feature sets over 100 training splits. The optimized HRVTS feature set $fs_{\text{final selection}}$ achieved the highest median AUC of 0.82, followed by the candidate feature set $fs_{\text{min max}}$ which achieved median AUC of 0.77. Both performed better than baseline feature sets which do not contain HRVTS information, namely $fs_{\text{no HRV}}$ (median AUC 0.68) and $fs_{\text{baseline}}$ (median AUC 0.70). Figure 4 compares the median Receiver Operating Characteristic (ROC) curves of these four feature sets over 100 training splits. Table 6 reports the AUC achieved on the test set by these four feature sets. $fs_{\text{final selection}}$ outperformed the rest by a significant margin, while $fs_{\text{min max}}$ did not perform well, suggesting potential overfitting with single featurization method.

**Discussion**

In this study, we used HRVTS data collected over 2 hours to improve the 30-day IHM prediction of septic patients on continuous ECG monitoring in the ED. An optimized feature set comprising 12 selected HRVTS features performed better than baseline feature sets which only included patient demographics, vital signs and single time-point HRV measures obtained at triage. This improved risk stratification could be used to inform management and disposition, such as early antibiotic therapy and ICU admission for identified high-risk patients.

While more research is needed to understand the physiological meaning and significance of each of the HRV parameters, studies have shown that HRV measures correlate with autonomic function and are predictive of adverse outcomes in septic patients. We hypothesize that higher-order dynamics and interactions in an HRVTS, including relative changes and trends over time may carry more prognostic information than the actual values of the HRV parameters themselves. This may explain why delta-based and regression-based features derived from HRVTS appear to be important risk predictors in our model.

We comprehensively explored various methods of feature engineering and selection to synthesize and make sense of the HRVTS data. In particular, our featurization method transforms a large number of data points for each patient into 15 key predictors and handles missing data. With the widespread adoption of wearable devices connected to the Internet of Things, we believe this type of high-resolution, high-volume time series data will become increasingly available. Therefore, the importance of our work lies in developing a methodology for processing and analysing HRVTS data which could be generalizable to other clinical settings and outcomes of interest, rather than in presenting a predictive model to be applied globally.

Our outcome of interest was IHM within 30 days during the same admission where the vitals and ECG were taken. Some studies did not specify a time period for mortality or if it was strictly within the same admission or not. We chose this endpoint as it is more likely to be sepsis-related compared to an out-of-hospital mortality or mortality from...
a subsequent admission. It is also more meaningful for physicians in terms of administering possible interventions such as closer monitoring and more aggressive management of high-risk patients.\\n
Our study had several limitations. Firstly, this was a single-institution study with a small sample size. Larger multi-centre prospective studies are required to validate our results. Secondly, we had included patients in our study based on clinical suspicion of sepsis and meeting at least 2 of the 4 SIRS criteria. Sepsis largely remains a clinical diagnosis and there is no gold standard to determine whether a patient is septic. Other studies have attempted to address this issue by including only patients with administered intravenous antibiotics, blood culture investigations or confirmed source of infection. We acknowledge that our cohort definition reflects suspected sepsis rather than confirmed sepsis. However, we believe this is reasonable given our eventual application in the ED where laboratory test results and confirmed diagnoses may not yet be available. In addition, while the SIRS criteria has recently been replaced with a new state of sepsis, defined as a life-threatening organ dysfunction caused by a dysregulated host response to infection, the usefulness of the SIRS criteria in diagnosis of sepsis was still emphasized by the same task force.

Thirdly, even though HRVTS can improve mortality prediction in suspected sepsis patients as shown in this study, they require more time and effort to obtain than single time-point HRV measures. Currently, we are developing a wearable device which can continuously monitor a patient’s ECG and automatically perform HRV analysis in real-time.

Fourthly, the time frame of 2 hours was chosen in this study based on the duration most patients spend in the ED while awaiting admission. Nevertheless, in our future studies, it is definitely worthwhile to explore the utility of HRVTS over a much longer period (such as 24-72 hours) and extending into the inpatient ward setting, as well as assess whether HRV-based risk predictions impact clinical management and outcomes. As continuous ECG data is inherently noisy (for example, due to patient movement or temporary disconnection), we chose to split the ECGs into 8 intervals of 15 minutes so that there is sufficient temporal window within each interval to capture a valid 5-minute segment for HRV analysis. However, this could have resulted in loss of information. Further study is needed to understand how we can better achieve granularity with noisy data.

Lastly, LASSO may arbitrarily select features from collinear groups, and further efforts should be put into interpreting the selected features and their odds ratios.

**Conclusion**

Serial HRV measurements over 2 hours can be used to improve prediction of 30-day IHM among septic patients in the ED compared to single time-point HRV measures taken at triage. This approach could be used in the ED to identify high-risk septic patients for appropriate management and disposition. In addition, the feature extraction and selection pipeline used in this paper could be applied to other short, noisy and incomplete time series data.

Abstract

Self-tracking feedback with engaging and persuasive visualizations not only helps convey data but can also affect people’s attitudes and behaviors. We investigate persuasive self-tracking feedback by augmenting data videos (DVs)—novel, engaging storytelling media. We introduce a new class of DVs, called Persuasive Data Videos (PDVs), by incorporating four persuasive elements—primary task, dialogue, system credibility, and social supports—drawn from the Persuasive System Design Model. We describe the iterative design of PDVs and a within-subjects preliminary validation to check their persuasive potential. We then assess PDVs’ feasibility using the Persuasive Potential Questionnaire in a between-subjects study comparing a PDV against a conventional DV on Amazon Mechanical Turk (N = 252). Our results indicate the feasibility of using PDVs in providing individuals’ self-tracking feedback to convey persuasive health messages, based on which we discuss opportunities for designing persuasive behavioral feedback in an engaging way.

Introduction

Self-tracking technologies such as wearable devices and mobile health apps are advancing rapidly, enabling people to collect a wide range of personal data. Compared to a large amount of research and advancements in the data collection and sensing side of self-tracking technologies, we have not seen much innovation in designing effective self-tracking feedback: existing approaches in feedback designs are limited to simple counts, graphs, stylized representations, and texture feedback. Furthermore, current feedback designs portrayed in commercial trackers often lack persuasive elements delivered in an engaging way.

Designing engaging and persuasive self-tracking feedback is important in enhancing the efficacy of self-tracking. Engaging with personal data can provide personal insights and promote self-reflection. Moreover, well-designed feedback can help people alter their self-efficacy and achieve goals. In this work, we investigate ways to design engaging and persuasive self-tracking feedback.

Data videos (DVs) are novel, popular storytelling media, which would be beneficial in presenting self-tracking data. Being recognized as one of the seven genres of narrative visualizations, data videos combine both visual and audio stimuli to promote data-driven stories in an engaging manner. They also have the capacity to guide people’s cognitive processing for the data interpretation, and thus could make self-tracking data easily digestible.

While we employ data videos to deliver easy-to-understand self-tracking feedback in an engaging way, we specifically aim to realize their persuasive potential. In creating Persuasive Data Videos (PDVs), we augment data videos with persuasive elements drawn from the Persuasive System Design (PSD) model. This model was created in response to the upsurge in the development of persuasive software applications to aid in their design and evaluation. We carefully extracted four persuasive constituents from the PSD model—primary task support, dialogue support, system credibility support, and social support—that fit the context of delivering self-tracking data.

In this paper, we aimed to answer two research questions: (1) can data videos (DVs) convey persuasive elements drawn from the PSD model (i.e., the feasibility of creating PDVs), and (2) do persuasive data videos (PDVs) demonstrate higher persuasive potential than data videos? To answer these questions, we conducted a between-subjects study on Amazon Mechanical Turk (AMT) with 252 participants. We used the Persuasive Potential Questionnaire (PPQ) to assess DV’s and PDV’s persuasive potential and individual’s susceptibility to persuasion. Our study results indicate that participants in the PDV condition recognized the persuasive elements in the video at a higher level than those in the DV condition. Moreover, PDV demonstrated higher potential to persuade than DV.
The key contributions of this paper are twofold. First, we introduce PDVs, a new class of self-tracking feedback framework that includes four elements of persuasion, carefully adopted from the PSD model. Second, we provide the evaluation of PDVs with AMT participants, demonstrating their general persuasive potential in influencing people’s attitudes.

**Self-Tracking Feedback**

Self-tracking (or self-monitoring) is an activity of recording one’s behaviors, thoughts, or feelings. Through self-tracking, people can enhance awareness, which may lead to self-discoveries and positive behavior changes. Providing effective feedback can augment such process, which is why designing effective self-tracking feedback is important for designers and researchers working in this field.

Many existing approaches in feedback design rely on text-based numerical representations, often augmented with simple visualizations. Some research on self-tracking feedback goes beyond simply presenting the collected data. For example, researchers inspired by the well-known “Framing Effects” investigated how different framing of self-tracking data (e.g., emphasizing either a positive or negative aspect of a target behavior) affects people’s perceptions and behaviors. They found that a feedback design with a particular framing could enhance self-efficacy or promote behavior change. These feedback helps people understand their current state, and furthermore, change behavior, but they are often static and lack actionable insights—a reason people may abandon self-tracking.

In this light, we aim to design persuasive and engaging self-tracking feedback. We explicitly incorporate persuasive elements and measure their persuasive potential, as we employ an engaging medium—data video—that could be appropriate to convey the summary of aggregated data.

**Persuasive System Design**

Persuasive technology concerns “computerized software or information systems designed to reinforce, change or shape attitudes or behaviors or both without using coercion or deception.” Theories and practical applications of persuasive technology have been explored in preceding decades. Such technologies span from social media apps such as Facebook that persuades its active user base to regularly upload pictures and share personal information to mobile apps designed to persuade people to lead more active lifestyles.

The Persuasive System Design (PSD) model expands the earlier work of Fogg and provides a framework to assist in the design of persuasive systems. The PSD model is composed of four persuasive categorical elements, namely (a) Primary Task Support, (b) Dialogue Support, (c) System Credibility Support, and (d) Social Support. Each of these categorical elements further contains psychological constructs known to enhance the persuasive potential of systems, which we adopt in the design of PDVs.

Also based on the PSD is the Persuasive Potential Questionnaire (PPQ), a subjective measurement tool that can aid in assessing the persuasive potential of a system. The PPQ is composed of fifteen questions grouped along three dimensions: (1) individuals’ susceptibility to persuasion which represents the degree by which an individual can be persuaded by a given feedback mechanism (IS); (2) the general persuasive potential of a system (GPP); and (3) the individual persuasive potential of the user (IPP). We build on the PSD to design our persuasive data videos and further assess their potential to persuade using the PPQ.

**Data Videos**

Data visualizations have been applied as a means to analyze and present personal data. Previous research suggests that data presentations tailored to an individual can facilitate motivation and possibly promote behavioral change. Data visualizations as a storytelling medium—data-driven storytelling or narrative visualization—have in recent years become increasingly popular among data scientists and journalists.

In particular, largely employing short animated data clips (or data-driven motion graphics), data videos appeal to a broad range of audiences as an emerging data-driven storytelling medium. When integrated with camera motion effects, such as zooming, audio stimuli, and a well designed narrative, data videos can effectively communicate data-driven facts in a short period of time. In addition, with appropriate attention cues, they can captivate and engage audiences.

We argue that data videos can further be equipped with the potential to persuade their viewers when conveying self-tracking data. The novelty of our work is in identifying those visual and narrative elements that can be integrated into data videos while offering self-tracking data feedback, and in evaluating their persuasive advantage.
Figure 1: The top row shows a regular Data Video (DV), while the bottom row shows its counterparts—the frames from a Persuasive Data Video (PDV). Each column of the bottom row represents one of the four persuasive elements we incorporated in the design of PDVs: (a) Primary Task Support; (b) Dialog Support; (c) Credibility Support; and (d) Social Support.

Persuasive Data Video

Persuasive Elements Selection

To design Persuasive Data Videos (PDVs), we carefully selected only those transferable persuasive constructs from the Persuasive System Design (PSD) framework. Transferable constructs refer to those that can be applied to a narrative structure and visual effects that make up a data video, without distracting from the core message, in our self-tracking context. Four major categorical elements from the PSD matched our criteria: (a) Primary Task Support; (b) Dialogue Support; (c) System Credibility Support, and (d) Social Support. Each of these four categories further contains specific persuasive constructs.

Below, we summarize these four categories and their constructs we applied to design persuasive data videos (Table 1).

From the Primary Task Support, we included the following constructs: Reduction, Personalization, and Simulation. These constructs are designed to encourage people in carrying out their task. For example, Figure 1-a demonstrates how we emphasized Personalization in the PDV by indicating “Your Wednesday class ends at 1:00pm. A perfect time for a walk!” with step counts visualization, whereas the DV’s message was simply set to “You are somewhat active,” while showing the same step count data.

From Dialogue Support, we included Praise, Rewards, Suggestion, Similarity, Liking, and Social Role. A system with these constructs can offer a dialogue to support a user progress toward their goals. For example, providing Praise via giving compliments such as “Great Job!” with a virtual trophy should lead people to a more positive attitude. We included messaging such as “Walk from home to the UofM. It’s 2.7 km!” as a means to support Suggestion (Figure 1-b).

From System Credibility Support, we included Trustworthiness, Expertise, Surface Credibility, Real-World Feel, Authority, Third-Party Endorsements, and Verifiability. Application of these constructs should endorse overall credibility of the system, and thus enhance persuasiveness. For example, to emphasize Surface Credibility, the narrator in our PDV was Dr. McKenzy, a hypothetical physician, who carries the persona of someone that people could trust to provide health recommendations (Figure 1-c). We also considered other representations of authority, such as to suggest the information coming from the World Health Organization or other well-known and credible sources. However, their identity was difficult to convey with a cartoon-style character, and stronger impressions could be delivered through inclusion of world-renowned experts.

Finally, from Social Support, we included Social Learning, Social Comparison, Normative Influence, Social Facilitation, Cooperation, Competition, and Recognition. Applying these constructs should motivate people via social influences. For example, in our PDV, Dr. McKenzy informs the viewer that they have 839 steps to beat Lisa (Figure 1-d). This instills a degree of Social Comparison by letting them observe their accomplishments in light of those of others.

We settled on these mappings through iterative discussion among authors, and by experimenting and considering the various visual options available in Animaker, the animated video authoring tool we used. In the next section, we describe how we realized the PDV with the self-tracking data through a preliminary validation.

**Persuasive Data Video Development**

We developed Persuasive Data Videos (PDVs) to examine whether the PSD elements described above can be properly implemented, and thus be perceived by the viewers. To ensure that the persuasive impact is the result of the persuasive elements we employed, we compared the PDV against the regular data video (DV), which was bereft of any persuasive elements. We developed the video stimuli to suit an online experiment environment (i.e., Amazon Mechanical Turk).

**Preparing the Videos.** Both the PDV and DV presented the summary of an imaginary person’s health data (i.e., Cameron, 22 years old). While the DV primarily focused on the presentation of weekly health summary data (step count, heart rate, & sleep duration), the PDV further included persuasive elements (as we detailed in the earlier section). The video structure had the following sequence of main items: An introduction showed the average number of steps taken during the week using a line graph and a bar chart. This was followed by a bar chart displaying the average number of hours slept. A line graph was then used to display the daily average heart rate during the week. And finally, a data summary of week 1 was presented and compared to recommendations (PDV: tailored recommendation, DV: generic recommendation).

We also ensured that both videos had the same length (1 min 59 sec), with the same background music, displayed data, and structure. Both videos were constructed with the same self-tracking data provided by one of the authors. The videos were created using Animaker, an online tool that allowed us to pick characters, narration styles, and animated data charts.

**Preliminary Validation.** We assessed the implementation of persuasiveness with seven HCI graduate students (all males; 22 to 41 years old), who were unfamiliar with the goal of the study and the PSD. To conduct the assessment, we generated 46 statements, two for each of the 23 constructs of the four PSD persuasive elements (Table 1) to which participants responded using a 7-point Likert scale (1 = Strongly Disagree; 7 = Strongly Agree). For example, for the Liking construct, the two statements were “The video was visually attractive.” and “Overall, the video’s look and feel have appealed to you.”
Figure 2: Subtracted perceived persuasiveness (i.e., PDV - DV) from the preliminary validation. Positive numbers indicate higher persuasive elements in PDV.

We conducted this assessment using Qualtrics. Participants first read the following preamble:

“Imagine students at the University of Monty are participating in a health program, where their health related data are tracked using their smartwatches. At the end of each week, all the students receive summaries of their data in a video format. We would like you to imagine that you are watching the weekly review of a 22 year-old student, Cameron, after his first week. Cameron is participating in the program with a few of his friends, along with many other students.”

Participants watched the PDV first and then the conventional DV, to prevent possible ceiling effect. They watched full HD (1080p) videos uploaded to YouTube. Participants were allowed to replay the video after they finished watching the entire video once, but not allowed to skip or go back. After watching a PDV, they answered the 46 questions we prepared. Subsequent to this, they watched a DV, followed by the same set of 46 question items. At the end of the session, we asked for suggestions to improve the PDV with an open ended question.

Revising the PDV: The two question items within each construct were highly correlated (Cronbach’s $\alpha > .85$). Participants showed an equal liking to both video styles, and yet, persuasive elements were successfully recognized at a higher level in the PDV than in the DV, except for the Primary Task Support (Figure 2). This result affirms that our choice of PSD elements, and further, our interpretation of these into a data video medium has the potential to persuade. However, based on the preliminary assessment results and qualitative feedback, we made three changes to the stimuli for a large-scale study (see the next section).

First, we revised PDVs not to include the Similarity construct as it involves “imitating users in some specific way,” for example, by using phrases or slang used by the user, from everyday conversation. We realized that this was not possible as we did not personalize the PDV to each viewer; and furthermore, Similarity clashed with our Trustworthiness, Credibility, and Authority representation in the PDV condition. We wished to maintain a similar degree of persuasion without losing generality for the participants in the online experiment setting. Thus, we embedded 22 persuasive aspects in the revised PDV and not 23 as used earlier. Second, we removed the heart rate data to shorten the video length to 1 min 38 sec, thus leaving the video with only step count and sleep duration data. Third, we changed the character of the persona in the DV as the viewers mistook him (a Caucasian male wearing a bandana) as a fitness coach and thus unintentionally attributed him a higher credibility. The new character was also a Caucasian male but physically larger than the previous one.

Study

To investigate whether Persuasive Data Videos have higher potential to alter lay people’s attitude than conventional data videos, we conducted a between-subjects study via Amazon Mechanical Turk (AMT). We were primarily interested in their “potential” only, as a longitudinal study would be necessary to assess their effective persuasive power over an extended time.

Procedure and Participants

After the participants read the consent form and agreed to participate, they read the following preamble:

“Imagine some people are participating in a health promotion program, where their health-related data are tracked using their smartwatches. At the end of each week, they receive summaries of their data in a video format. We would like you to imagine that you are watching the weekly review of a 22-year-old Alex, after his/her first week. Alex is participating in the health promotion program with a few of his/her friends, along with many other people.”

Subsequent to this, they watched either a PDV or a DV, and answered questions about the video and their demography. We ensured that participants could only view either a PDV or DV.

We recruited AMT workers who resided within either Canada or the US with HITs (or Human Intelligence Tasks) approval rate of 97% or above, and speak English. Participants recruited for both conditions saw the identical study description: “First, you will be asked to watch a short Video Clip (approximately 2 minutes). Subsequently, you will be asked to complete a survey asking you about your background, and experience of watching the video clip.” Altogether, 339 AMT Workers participated in this study. Following the recommendation to enhance response quality on AMT through inclusion of verifiable questions, we excluded AMT workers who did not pay careful attention to the study instructions as indicated by two gotcha questions (e.g., “How many words are in this sentence?”). Out of 339, 87 participants did not pass our two gotcha questions. This left us with 252 participants (PDV = 123; DV = 129), and their age ranged between 22 and 60 (PDV: \( M = 35.07, SD = 9.37 \); DV: \( M = 36.26, SD = 9.68 \)). In both conditions, 42% of participants were female. Participants who completed the study received 1.54 USD as a compensation, and they spent 8 mins 44 secs on average.

Questionnaire

We adapted the Persuasive Potential Questionnaire (PPQ) to match the presentation and assessment of PDVs, resulting in the 15 questions (Table 2). This allowed us to measure (1) individuals’ susceptibility to persuasion (SP: four questions), (2) the general persuasive potential of the system (GPP: three questions), and (3) the persuasive potential of the system to the individual (IPP: eight questions), using a 7-point Likert scale (1 = Strongly Disagree; 7 = Strongly Agree). We added one question to ask participants’ interest in improving their own health, and worded it as follows: “I am interested in improving my health” again on a 7-point Likert scale.
Subtracted perceived persuasiveness (i.e., PDV - DV) from the AMT study. Positive numbers indicate higher persuasive elements in PDV.

Next, to investigate whether the persuasive elements were embedded appropriately, we asked the same questions used in our prior assessment about the persuasiveness of the video. Note, two questions were used to investigate one construct in the prior validation where we found a high inter-item correlation within each construct ($r_s > .85$). However, since we added 15 PPQ question items in this study, we were concerned about participants’ potential cognitive fatigue and boredom, especially because we conducted this study using an online format. Hence, we removed the overlapping corresponding question items and made minor adjustments (rephrasing the combined question only slightly).

**Results**

First, we investigated the feasibility of creating PDVs by embedding persuasive elements (i.e., can data videos (DVs) convey persuasive elements drawn from the PSD model). Since the data was not normally distributed, we conducted non-parametric analyses. Results from Mann-Whitney U tests confirmed that participants in the PDV condition perceived all the persuasive elements at a higher level than those who were in the DV condition ($p < .05$; Figure 3).

Next, we investigated whether participants in the PDV condition perceived higher persuasive potential for attitude change than those who were in the DV condition. First, we investigated Cronbach’s alphas for all three aspects: (1) individual’s susceptibility to persuasion (SP) ($\alpha = .75$); (2) the general persuasive potential (GPP) of the system ($\alpha = .86$); and (3) the persuasive potential of the system to the individual (IPP) ($\alpha = .84$). Since all three scales were acceptable or good, we created aggregates for each of the three aspects. The results from Mann-Whitney U tests (Figure 4) showed that the video type did not have any effect on the individual’s susceptibility to persuasion ($p = .47$), indicating that participants in the PDV condition and DV condition were equally susceptible to persuasion. Next, we found that for participants’ general persuasive potential (GPP) of the system, those in the PDV condition indicated higher perceived general persuasion ($Mdn = 5.67$, $n = 123$) relative to its counterpart ($Mdn = 5.33$, $n = 129$), $U = 7520$, $z = -2.83$, $r = .18$. Finally, no significant video type effect was found for persuasive potential of the system to the individual (IPP) ($p = .30$).

**Discussion and Future Work**

**Reflecting on Study Results**

After making the necessary adjustments to our Persuasive Data Video (PDV), the manipulation check (i.e., “a measure used to determine whether the manipulation of the independent variable has had its intended effect on a participant”) indicated that the persuasive elements had the effect we expected. Furthermore, participants who watched a PDV in the AMT study perceived its higher potential to influence the general population, compared to those who watched a Data Video (DV). Altogether, we
believe that our PDV might offer beneficial feedback for applications involving attitudinal change.

Although PDVs’ potential to influence the general population (i.e., others) was perceived as higher than that of DVs, this video type difference was not found when it concerns the video’s potential to persuade oneself. This inconsistency between perceptions regarding self vs. others could be attributed to the third person effect whereby individuals normally perceive that others are more readily influenced by media than themselves.[12, 13] According to these prior works, individuals estimate being shielded from such effects but not their peers. We intend on following up with this result as it may be possible that the PDV had an unmeasured effect on its viewers. Altogether, while assessing behavior change is outside the scope of this investigation, we believe that PDVs have the potential to influence peoples’ attitude.

Overall, we attribute our outcomes to the use of the Persuasive System Design (PSD) framework. Specifically, the framework that PSD provides may have been particularly suitable for incorporating in data videos, as we did here. Unlike conventional feedback visualizations, videos allow us to spread the persuasive elements gradually, and throughout the entire viewing period. Videos also implicitly guide the viewer to those critical aspects of the data and as such can carefully control the amount of information delivered to the user. Further work is needed to examine which specific PSD elements and their video representation had higher potential to persuade.

Persuasive Feedback for Self-Tracking Data

A key strength of our approach is the use of data videos, a medium that resonate well with younger generations (including kids) who routinely consume videos. Data videos could also be delivered effectively on mobile phones, where people commonly track and view their self-tracking data. On the other hand, data videos are not suitable for delivering feedback in real-time, and thus, should be used for aggregated data that fosters reflection on past behaviors. Also, even with this engaging medium, people might get bored over time and disengage. To maintain viewers’ interest, we need to identify a desirable viewing cycle (e.g., once a day, a week, or a month) that can reveal interesting and surprising aspects about oneself, and which may depend on the data type.

In addition, even though there have been efforts on easing the process of creating data videos, it is not easy to create data videos especially with personalized recommendations. An important direction for future research would be to develop a PDV authoring tool to cover diverse contexts (e.g., productivity, finance, screen time). Such video authoring tools will enable researchers to conveniently produce personalized PDVs, which would be beneficial for conducting deployment studies.

Limitation and Next Step

Although our overall results are encouraging, we acknowledge that this study is only an initial step. Contextual limitation of this work is using the hypothetical scenario and measuring attitude rather than actual behavior. Our scenario conveyed the data of a 22 years old self-tracker, which may not be representative of AMT workers. However, because we are still at the early stage of designing effective PDV, we argue that conducting a field deployment study to measure behavioral outcomes is not the best first approach. Moreover, as demonstrated in prior works, hypothetical scenarios have been used to test a variety of feedback design contestants to identify the most effective one before running a deployment study.[11]

In this work, conducting an AMT study using a hypothetical scenario allowed us to recruit a large number of participants with relatively low cost and helped us understand the effect of persuasive elements in a brief period. Our study will help designers and researchers create engaging, persuasive data videos, which could be embedded in a self-tracking technology for a long-term
deployment study. We intend to enhance our PDVs and examine their ability to influence behavior, and plan to run a longitudinal study, for which PDVs will be tailored to each participant’s data and context. Such investigations will further advance our knowledge about new possibilities with PDVs, and will particularly be beneficial to designers of self-tracking applications.

Conclusion
We introduced Persuasive Data Video (PDV), an enhanced form of Data Video (DV) augmented with persuasive elements, for self-tracking feedback. Results from our M-Turk study were comparatively favorable toward PDV, at least indicating the potential of PDV in influencing people’s attitude. We believe that these benefits were found because of two main reasons. First, we successfully translated persuasive elements from the Persuasive System Design into our PDV. Second, related to our first point, videos may be a particularly suitable format for applying the PSD framework. Our results motivate several directions for future work in the context of designing effective self-tracking feedback, including a consideration of effective viewing cycle of PDVs, designing a PDV authoring tool that supports convenient production of personalized PDVs, as well as further studies to assess the efficacy of PDVs on people’s behavior change in a real-world context.

Engaging heart failure patients from a clinical data research network: A survey on willingness to participate in different types of research

Abstract

The willing participation of patients in clinical research is a critical element in national efforts to collect health data for precision medicine and large cohort studies. However, recruiting patients is challenging. Clinical data research networks (CDRN) have primarily been used for observational studies, but may be able to enhance recruitment efforts. We need a better understanding of patient motivation and preferences for research participation and their interest in different types of research activities, particularly among those who are already represented in CDRNs. We surveyed a heart failure patient cohort constructed from EHRs in a CDRN to assess research participation. Results showed that CDRN recruitment is feasible. Respondents were most interested in completing a one-time survey and giving a blood sample one time. They were least interested in a study about weight control that require surgery. We found statistically significant associations between race and research activity interests.

Introduction

The goal of precision medicine research is to better understand the impact of individual variability in genes, environment, and lifestyle on disease prevention and treatment. The success of this type of research is heavily dependent upon the willingness of large numbers of volunteers to join research initiatives and share their genetic, health and lifestyle data. Electronic health records (EHR) from multiple health care centers, when aggregated under a standard data model, can facilitate identification of large-scale cohorts. The establishment of clinical data research networks (CDRNs) offers an opportunity to leverage EHR resources and lower the technical and regulatory barriers for research. However, first generation CDRNs such as the Health Maintenance Organization Research Network (HMORN) Virtual Data Warehouse¹ and the U.S. Food and Drug Administration (FDA) Sentinel Initiative research network² have primarily utilized retrospective observational data from existing clinical data and did not engage participants directly.

Enrolling patients into research studies has traditionally been challenging. In fact, Williams et al. reported that insufficient accrual rate was one of the major reasons for terminated clinical trials reported in ClinicalTrials.gov database.³ In other types of research, such as studies based on surveys, which require less effort than clinical trials on the part of participants, response rates are quite low, hovering around 9% for telephone surveys.⁴ A number of studies have shown that racial and ethnic minorities in the US are less likely to express willingness to participate in a health-related studies.⁵⁻⁶ Underrepresentation of minority groups has also been identified in previous clinical trials.⁷⁻⁸ Several studies have shown that people with higher education level were more willing to participate in medical research.⁹⁻¹⁰ In addition, participants were more likely to share data via a research network if requests came from hospitals, universities, or medical groups, as they had trust in such organizations.¹¹ Thus, one concern is whether CDRNs can effectively engage diverse patients and enroll them in research studies.

The purpose of this study was to examine if a cohort of patients with heart failure identified from the EHRs of a large CDRN could be engaged to participate in new research, and to assess what type of research activities they preferred. We surveyed patients from the patient-centered SCAlable National Network for Effectiveness Research (pSCANNER) on their willingness to participate in future research. pSCANNER is a stakeholder-governed, privacy-preserving, distributed CDRN with access to EHRs across institutions and on over 30 million patients from all 50 states¹²⁻¹³ that was initially supported by the PCORNet.¹⁴ Our rationale for surveying participants was that understanding challenges from their perspectives could help CDRNs improve recruitment and retention for future studies.
Methods

In the pSCANNER network, heart failure was a condition of interest to investigators, and several future studies in this condition were planned. We first identified a cohort of patients with heart failure by running a query written against the Observational Medical Outcomes Partnership Common Data Model (OMOP) using ICD-9/ICD-10 code and the following inclusion criteria: (1) Age ≥ 18 years old; (2) Two reported diagnoses (inpatient or outpatient) related to HF (ICD-9 CM codes 398.91, 402.01, 402.11, 402.91, 404.01, 404.03, 404.11, 404.13, 404.91, 404.93, 414.8, 428.x.) between 2011 and 2016; OR one principal hospital discharge diagnosis of heart failure between 2011 to 2016, for patients not known to be deceased.

The identified participants were recruited first via e-mail (if the email address was available), using a consistent template identifying the study as conducted by pSCANNER and signed by a local investigator. A telephone outreach firm conducted phone recruitment and completion of the survey for patients for whom a valid email address was not available, or who did not respond to an email. A total of five attempts were made to contact participants. IRB approval was obtained at each of the pSCANNER sites that participated in the study: five University of California health systems (UC San Diego, UC Davis, UC Los Angeles, UC Irvine, and UC San Francisco), Veterans Administration Health System in San Diego, and the University of Southern California, Keck School of Medicine including AltaMed, a USC-partnered community clinic. For one of the sites, only in-person recruitment with paper and pencil survey collection was conducted.

The survey was developed by the PCORnet Survey Team (KK was a member), a collaborative group of investigators from multiple CDRNs participating in PCORnet. Items on the survey were intended for use by cohorts of people who were overweight/obese and by those with other common chronic conditions, such as cardiovascular disease. The items included: (1) key demographics and self-reported health status, (2) participants’ interest to participate in a variety of research activities (19 activities rated using a 3-point Likert response scale from 1=not interested to 3=very interested), and (3) preferred mode of contact for future research with yes/no response categories. The order in which each of the research activities were presented was randomized to reduce bias. The survey took approximately 5 to 7 minutes to complete. The survey was implemented in a centralized Qualtrics server and de-identified, individualized links created for each participant candidate. Participants who accessed the survey website could review the purpose of the project, the elements of consent, and the process for withdrawing from the cohort and for completing the survey. The survey responses collected by the phone interviewer were entered into Qualtrics using the unique, de-identified link. There was no time limit to the survey. All survey data were collected and stored in standardized formats under rigorous security protocols. Survey responses, including self-reported identifiers, were retained by each site’s research personnel on a password-protected secure server. Non-identifiable survey responses were attached to the pSCANNER database for individuals who responded. Direct identifiers reported on the survey (email address and phone number) were not attached to the electronic record.

All statistical analyses of data were performed in SPSS (SPSS, Chicago, IL, USA). The socio-demographics and health characteristics and mode of contact questions were summarized as numbers and percentages. Two-way analysis of variance (ANOVA) with post-hoc Tukey honest significant difference (HSD) was performed to compare the mean total scores of Research Activity Interest questions and to check for a difference between groups for two categorical demographic covariates: race and education. Statistical significance was accepted as p<0.05.

Results

Completion rates for the survey are noted in Table 1. The survey was completed by 2,444 respondents (10.2%) of the total 23,955 heart failure cohort. Of the 2,444 people who completed the survey, 68 were aged under 18 and did not meet the eligibility criteria. Therefore their survey data were excluded from further analysis, leaving 2,376 completed surveys. Table 1 shows response rates by each of the 7 pSCANNER organizations.

Table 2 summarizes the socio-demographic and health characteristics of survey respondents (n=2,376). The mean age was 63 years (SD=15.2, range 18-97) and majority were male (59%). The respondents were likely to be Caucasian (58%) and college educated (69%). About half of respondents (44%) were married at the time of completing the survey. Most of the respondents (60%) were overweight or obese (having BMI $\geq 25$) and 867 (36.5%) were diagnosed with diabetes. Among the 2,376 respondents, 756 (32.2%) indicated that they had previously participated in research.

*Rated from 1 = very inactive, 2 = a couple times a month, 3 = active most weeks, 4 = several days a week, 5 = most days
Table 3 shows participants’ interest in future research and their interests in different research activities, from 1= not interested to 3=very interested. Among the participants, the top five research activity interests were (1) completing a one-time survey or list of questions (very interested= 48.6%), (2) giving a blood sample one time (45.1%), (3) giving a blood sample that is used to study your DNA (43.6%), (4) testing a treatment given by phone or over the Internet (43.5%) and (5) completing a survey two or more times (40.4%). Participants were least interested in participating in a study about weight control that required surgery (not interested= 69.2%), a study that uses a medicine to help control weight (44.6%), and a project that involved other members in the family (42.3%).

The mean and standard deviation was calculated for each research activity to conduct a two-way ANOVA to examine the effect of race and education level on interest in research activities. There was a statistically significant association between the effects of participant race and the mean score for interest in all research activities ($F(8,2134) = 4.70, p < 0.0001$). However, no significant association was found between education and the total mean score ($F(6,2134) = 0.63, p = 0.71$).

Discussion and Lessons Learned

The design and administration of our survey demonstrated the feasibility of identifying a clinical cohort from EHRs in a large CDRN and engaging them to participate in a new research topic.

Lessons Learned for the CDRN. While the IRB protocol was identical at the sites except for site G, where only in-person survey completion was approved, there were variations in implementation that may account for the differences in the response rate. At site G, the number of completed responses was the lowest due to the need for in-person staffing to recruit respondents during clinic hours. However, the in-person engagement appears to have resulted in very high response rate. Additionally, the overall response rate of 10.2% was comparable to the other surveys of CDRN cohort that incorporated broad recruitment approaches such as unsolicited e-mails to eligible patient population.\textsuperscript{15} Site A was the first site to field the survey. At this site, all patients were emailed at the same time with the letter signed by the pSCANNER PI and a physician, but not one who was associated with Cardiology. A number of calls were received from patients questioning why they had been contacted and whether the study was a legitimate research project from that institution. Based on the experience of site A, site C revised its invitation email to be co-signed by a cardiologist and sent out emails in four batches one week apart to allow for any
adjustments needed. After the first batch, cardiology clinics at site C also received a few calls and questions during clinic visits asking about the legitimacy of the study. Hence, site C developed an informational brief about the study and distributed it to all clinic staff and physicians so that they could respond knowledgeably to any patient questions. This was distributed before the second batch of emails was sent.

Discussion among the pSCANNER team highlighted the importance of centralized coordination in accomplishing this study efficiently and effectively. First, one site tracked coordinated the project, created template invitations and letters, tracked responses and communicated with all site project managers and with the telephone survey firm. There was one contract for the survey firm that covered all sites. A different site developed and hosted the Qualtrics survey, delivering unique survey links that each site could match to their participant records. This allowed for efficient site-level tracking while allowing patient privacy to be maintained at the local site.

Patients’ willingness to participate in clinical studies is critical for advancing precision medicine research. As we learn more about patients’ attitudes and preferences toward enrolling in research, the information can be useful in designing future studies and improving patient recruitment and retention. Overall, the majority of patients in our survey showed favorable attitudes towards participating in future research studies. High interest level was shown for one-time completion of survey/questionnaire or one-time submission of a biospecimen. On the other hand, it is not surprising that respondents were less enthusiastic about participating in research that involved more invasive, higher burden processes, or research that involved family members. This is in line with other studies that investigated factors influencing clinical research participation.\textsuperscript{16,17} The high level of hypothetical participation among respondents maybe due to the fact that the respondents were already enrolled in this survey study. Also, respondents might already have established trust in research conducted by state-supported, large research universities and their academic medical centers.

While we did find a significant association between participant race and interest in all research activities, we were not able to make interpretations on each race factor and the research interests. Some studies have reported that racial/ethnic minorities tend to have reduced willingness to participate in research due to skepticism or fear toward medical research.\textsuperscript{8,18,19} On the contrary, other studies have shown that participants with minority identity showed greater willingness to participate in medical research.\textsuperscript{15,20} Prior studies have also reported that women, elderly, and minorities were consistently under-represented in cardiovascular disease (CVD) clinical trials.\textsuperscript{21-23} However, more recent online survey of 504 respondents with CVD showed that there were no significant differences in willingness to participate in clinical research based on sex.\textsuperscript{24} Further analysis documented that willingness to participate in clinical research were similar among patients with CVD and patients with other chronic conditions.\textsuperscript{24} Unlike our study which assessed participants’ willingness to participate in different types of research activities, this survey used a single-item to measure willingness to participate in clinical research. Cohort studies must be able to recruit participants who are representative of the population in order to be meaningful.

The majority of our survey respondents preferred to be contacted by research staff or their physician by personal phone call for future trial participation. This finding is similar to other studies reporting a great willingness to participate in research if asked by their own doctor.\textsuperscript{15} Although still at an early stage, using social media as a tool for clinical trial recruitment has shown some promising results in several clinical trials;\textsuperscript{25,26} even showing effectiveness in reaching historically hard-to-reach populations.\textsuperscript{27,28} Interestingly, social media was the least preferred means of contact among our survey respondents. This may be because our mean age of respondents were 63 years old and they may not embrace social media platforms as much as their younger counterparts. Future studies that assess age and cultural differences in the use of social media for recruitment tool may provide additional insights.

Several limitations must be noted. First, the survey respondents were limited to heart failure patients who were primarily treated in academic healthcare facilities in California. Thus, given geographic and cultural differences, these findings may not be generalizable to patient populations in other health settings or regions of the United States. Additionally, this was a self-report survey and therefore data regarding willingness to participate in research may be prone to social desirability biases. It is possible that participants reported higher willingness for future research participation to make a favorable impression. Furthermore, the cross-sectional design of this study makes it difficult to draw casual inferences about factors affecting respondents’ willingness to participate in research. Despite these limitations, our results suggest that CDRN infrastructure is able to support prospective enrollment of patients into future clinical studies.
Conclusion

The willing participation of patients is a critical element in ongoing national efforts to construct cohorts for precision medicine and other health research. However, enrolling and retaining patients to clinical research studies can often be challenging. This survey demonstrates that CDNs can be a source for recruiting for large study cohorts among a geographically diverse population and engaging patients into participating in future studies. Yet, identification with the local institution and investigators may be an important element in garnering patient willingness to engage in future research. Overall, most of the survey respondents showed interest in participating in future studies. The lessons learned in this CDN may be useful for other cohort studies and network-based research efforts.

Abstract

Using electronic health data to predict adverse drug reaction (ADR) incurs practical challenges, such as lack of adequate data from any single site for rare ADR detection, resource constraints on integrating data from multiple sources, and privacy concerns with creating a centralized database from person-specific, sensitive data. We introduce a federated learning framework that can learn a global ADR prediction model from distributed health data held locally at different sites. We propose two novel methods of local model aggregation to improve the predictive capability of the global model. Through comprehensive experimental evaluation using real-world health data from 1 million patients, we demonstrate the effectiveness of our proposed approach in achieving comparable performance to centralized learning and outperforming localized learning models for two types of ADRs. We also demonstrate that, for varying data distributions, our aggregation methods outperform state-of-the-art techniques, in terms of precision, recall, and accuracy.

1 Introduction

Adverse Drug Reactions (ADRs) are a major concern for medical practitioners, healthcare system, and pharmaceutical industry. As patients can experience expected and sometimes unexpected negative outcomes from taking any drug, delayed detection of ADRs can pose life-threatening risks to patients; posing considerable legal, financial, and social repercussions to the manufacturing companies and regulatory agencies. The use of medical data, such as claims and electronic health records (EHR), has become common in providing rich insights on health services and supporting ADR investigation\textsuperscript{1}. Advancements in machine learning and artificial intelligence have produced a number of analytic methods that can be applied to such high-dimensional data for the purpose of predicting adverse reactions\textsuperscript{2}. However, making timely and accurate predictions remains a challenge. Due to the distributed nature of healthcare data, obtaining a sufficiently large dataset to detect rare events requires merging data from different data silos. Analyses generated from different data sources can be conflicting or imprecise\textsuperscript{3}, necessitating methods to appropriately aggregate results.

Prior work to resolve these issues often have limitations in their approach. The Food and Drug Administration (FDA)'s self-report Adverse Event Reporting System (FAERS)\textsuperscript{4}, collects ADR data into a traditional, centralized database. A single database approach is the most straightforward way to explore ADRs, but information owned by different entities is seldom shared due to significant privacy concerns. Moreover, creating and maintaining such a large data repository incurs resource and system-level constraints, including high latency and single points of vulnerability (failure, breach). To avoid such overhead and risks, the FDA created the Sentinel system to monitor the safety of its regulated products, using a distributed data network\textsuperscript{5,6}. The network comprises multiple stakeholders, each maintaining a large claims database. Despite the distributed framework and large-scale data amassed from active participation of data partners, Sentinel has limited analytic capabilities. Limitations of other state-of-the-art systems include access to potentially small-scale, sparse, and low-quality hospital records\textsuperscript{7}. In addition, current claims-based frameworks experience a time lag between ADR instance, claim submission, adjudication, and consolidation of the claim into a database. EHR data, collected in near real-time, is therefore a promising alternative, but comes with the aforementioned quality concerns. Hence, there is an unmet need for accurate, scalable, and efficient solutions for predicting ADRs using distributed health data, that also protects the privacy of patients.

To address this challenge, we present a federated learning-based framework that permits health data to be distributed across multiple sites. Federated learning\textsuperscript{8} has brought a paradigm shift in the construction of machine learning models from distributed data sources maintained by various organizations. Under such a decentralized, collaborative learning
setting, each site contributes to the computation of a global model while simultaneously shielding its own data from leakage to distrusted third parties. Our framework allows us to train a global model based on each site’s local data, without ever moving the raw data from their respective sites. To the best of our knowledge, this is the first implementation of federated machine learning algorithms that leverages distributed electronic health data for predicting ADRs. ADR prediction itself brings significant challenges for federated learning due to the huge imbalance between the majority class of individuals who do not suffer from ADRs, and the minority class of individuals with severe ADRs. To address this issue, we propose two novel methods of aggregating model updates from the sites and compare their performance with that of the state-of-the-art alternative. To show the effectiveness of our proposed approach, we consider two use cases: (i) prediction of chronic opioid usage for patients taking opioid drugs, and (ii) prediction of extrapyramidal symptoms for patients taking antipsychotic drugs. We conduct a comprehensive experimental evaluation using real-world patient data.

The key contributions of our work include: (1) implementing federated models for ADR prediction based on three supervised learning algorithms; (2) proposing and implementing two novel methods of aggregating local model updates in a federated setup; (3) demonstrating the effectiveness of our approach in analyzing sensitive, distributed, and highly imbalanced real-world electronic health data; (4) conducting a comparative analysis to evaluate our approach against state-of-the-art alternatives; and (5) demonstrating scalability of our approach for varying number of sites, data size, and data distribution.

2 Background

The sensitive and distributed nature of electronic health information in real-world scenarios motivate the need for a mechanism that can learn from data residing in silos, while accounting for data privacy. This compels us to explore the potential and value of federated learning for ADR prediction. Federated learning enables training a global model from distributed data, without having the sites exchanging any raw sensitive data. The global model is distributed to each site, where an instance is trained locally. The updates from locally trained instances are then aggregated to improve the global model, which is shared again with the sites for another round of training. This iterative process, illustrated in Figure 1, terminates when a performance criterion is met.

Initial implementations of federated learning were intended for image classification and language modeling on mobile devices. Existing literature aims to improve the performance of deep networks in a federated setting. There is currently very limited research focusing on the application of federated learning in healthcare. Recent work noted the effectiveness of federated models in predicting hospital admissions using EHR data. However, the potential of federated learning in healthcare applications that make use of claims or EHR data for ADR prediction is yet to be explored. Moreover, the existing method of aggregating updates from local models relies on the size, rather than the inherent characteristics, of the data. This approach may not work well in healthcare applications, which often deal with skewed, sparse, and imbalanced datasets. Hence, exploring the underlying characteristics of distributed data to improve the predictive capability of the global model is also an important research direction.

Unlike the methods that focus on surveillance of all potential ADRs for a given drug, specific prediction typically employs supervised learning algorithms. Commonly used algorithms are logistic regression, random forest, decision trees, Support Vector Machine (SVM), and neural networks. Prior works on ADR prediction with machine learning methods are largely limited to centralized models, where all data are available to the researcher in a centralized data store. A majority of these works also lack evaluation on real-world datasets. For instance, distributed logistic
regression based on multi-party computation, was studied using simulated data.18

In this paper, we implement federated models based on three supervised classification algorithms: SVM, single-layer perceptron, and logistic regression, using stochastic gradient descent (SGD)-based optimization, which provides a generic approach for the algorithms to learn local models and aggregate their parameters to improve the global model and is the method currently supported by federated learning.

3 Methods

3.1 Data and cohort selection

To evaluate our approach, we used the Limited IBM MarketScan Explorys Claims-EMR Data Set (LCED). The data is procured from administrative claims and EHR data of over 1 million commercially insured patients over 5 years (2012-2017), each varying in lengths of medical activity. LCED contains patient-level features, such as demographics, diagnostic codes, outpatient prescription fills, laboratory results, and inpatient admission records. From this dataset, we defined our cohort based on the occurrences of two drug-ADR pairs during a 5 year period. Our selection was based on multiple factors: the number of patients taking the drugs of interest, the prevalence of the specific ADR of interest, and the feasibility of reliably detecting the ADR incidents using the LCED data.

Use case I: The first use case regards predicting chronic opioid usage (potential opioid use disorder) among patients who receive an opioid drug. Opioid abuse is currently one of the most pressing public health issues in the United States. The first exposure to opioids, for many who develop an abuse disorder, is a physician’s prescription to alleviate symptoms of another condition. We closely follow Zhang et al19 to construct the opioid user cohort by first identifying all patients who had one or more opioid prescriptions. We define opioid discontinuation as having 180 or more opioid-free days during one year (365 days) after the initial prescription, and chronic users of opioid as those who did not discontinue during the same period. Opioid-free day is calculated by subtracting from 365 days the sum of all subsequent opioid prescriptions’ days-supply during the year following initiation. We excluded patients who had a diagnosis of opioid use disorder, cancer, or received hospice service in the year prior to the initiation, as their chronic opioid usage was expected. After identifying a number of risk factors for chronic opioid use from the literature, we hand-generate them from the data as predictive features. Examples include age, gender, smoking and alcohol habits, diagnoses of different types of pain (spinal injury, arthritis, etc.), surgical procedures, use of psychotropic drugs, and the morphine milligram equivalent (MME) of the initial opioid prescription normalized by its days-supply.

Use case II: The second use case regards predicting incidents of extra-pyramidal symptoms (EPS), a type of motor dysfunction, from the use of antipsychotic drugs. Broad off-label use of antipsychotics is well known despite the risk for developing ADRs like EPS. Similar to the opioid cohort, we start from identifying patients who had one or more prescription for an antipsychotic. We define the incidence of EPS following antipsychotic initiation using International Classification of Diseases (ICD) Ninth and Tenth Revision diagnosis codes. Examples of patient level predictive features identified from the literature include age, gender, smoking and alcohol habits, type of the first antipsychotic (first vs. second generation), other drug use (other psychotropic drugs, drugs related to Parkinson’s Disease, etc.), comorbid diagnoses (dementia, psychiatric diagnoses, epilepsy, Parkinson’s Disease, etc.), and number of prior hospital admissions. We generate these features using the data from the one-year period prior to the initiation of antipsychotic for each patient.

Table 1: Summary of the two drug-ADR pair cohorts. SD: Standard deviation

Table 1 provides summary statistics of the two cohorts. The imbalance between the majority (non-ADR) and minority (ADR) classes was consistent with our expectation, since severe ADRs are rare with most of the drugs available on the market. Our primary analyses focus on the opioid cohort, where a better balance is achieved with a larger sample size. We examine the antipsychotic cohort as an example of small, highly imbalanced data that one can encounter frequently in the healthcare domain. The implication of severe class imbalance is discussed in the following sections.
3.2 ADR prediction model

Consider a general binary classification problem, where features, denoted by $x_k$ (for the $k^{th}$ feature), are drawn from a feature space $X$. The corresponding labels $y_k$ are drawn from the label space $Y := \{-1, 1\}$. Let the features corresponding to positive labels be denoted by $X_+$ and those corresponding to negative labels by $X_-$, that is

\[ X_+ = \{ x_k \in X : y_k = +1 \} \quad \text{and} \quad X_- = \{ x_k \in X : y_k = -1 \} \]

For any $x_k^+ \in X_+$ and $x_k^- \in X_-$, the objective of binary classification is to construct a function $f : X \rightarrow Y$ such that

\[ f(x_k^+) = +1 \quad \text{and} \quad f(x_k^-) = -1. \]

In this paper, we denote cases of ADR as labels $y_k = +1$, and cases of non-ADR as $y_k = -1$.

3.2.1 Cost-sensitive learning

Class imbalance is intrinsic to ADR prediction. Since most classification algorithms assume balanced class distributions or equal misclassification costs, they fail to represent the characteristics of imbalanced data and are more likely to classify new observations to the majority class. For ADR prediction, the cost of a false negative classification should be much higher than that of a false positive classification. Recent work on imbalanced learning can be categorized into sampling methods, cost-sensitive methods, and active learning methods. As discussed in sampling methods, such as undersampling the majority class or oversampling the minority class, either discard potentially useful data or can lead to overfitting. Since our dataset does not comprise unlabeled samples, active learning is not applicable.

Hence, to mitigate the challenge of skewed data distribution, we incorporate cost-sensitive learning, wherein we increase the cost associated with misclassifying a minority class sample. Specifically, if $C_{FN}$ and $C_{FP}$ denote the cost of a false negative and false positive in a cost matrix, respectively, then we set $C_{FN} > C_{FP}$. The magnitude of cost depends on the problem at hand and we determine their values using grid search.

3.2.2 Centralized model

For the purpose of binary classification of samples into ADR and non-ADR cases, we consider three supervised classification methods: SVM, single-layer perceptron, and logistic regression. We implemented these algorithms using scikit-learn version 0.20.2. To establish benchmark results, we first evaluate the performance of the classifiers in a centralized learning approach. This represents the scenario of gathering data from multiple sites for training a machine learning model. For each cohort, we split its entire dataset into two parts: 70% for training, and 30% for testing, where $X_{\text{train}}$ and $Y_{\text{train}}$ denote the feature and label sets for training, and $X_{\text{test}}$ and $Y_{\text{test}}$ denote the feature and label sets for testing. As the splits are stratified, the proportion of positive and negative cases in each split is the same as the entire dataset. After standardizing the features, we use 5-fold cross-validation to train the models on $X_{\text{train}}$ and $Y_{\text{train}}$, and test them on $X_{\text{test}}$. To incorporate cost-sensitive learning, we update the class_weight parameter in scikit-learn based on class frequencies.

3.2.3 Localized model

Since healthcare and biomedical data is rife with sensitive information, sharing such data across sites or transferring it to a centralized database is often restricted. In such cases, a site has to rely on its own data for predictive analytics. We consider this scenario while designing localized models for ADR prediction. We train each classifier on a site’s data, without leveraging data from other sites. Let us suppose there are $N$ sites, representing hospitals or data owners. We use horizontal partitioning to split the training data into $N$ disjoint subsets. We partition $X_{\text{train}}$ into $\{X_{\text{train}}^i\}_{i=1}^N$, where $\bigcup_{i=1}^N X_{\text{train}}^i = X_{\text{train}}$ and $X_{\text{train}}^i \cap X_{\text{train}}^j = \emptyset$, $\forall i, j \in \{1, ..., N\}$, for $i \neq j$. We follow the same logic to partition the corresponding label set $Y_{\text{train}}$ into $\{Y_{\text{train}}^i\}_{i=1}^N$. In the case of localized learning, the classifiers are trained on a single site’s data $\{X_{\text{train}}^i\}_{i=1}^N$ and $\{Y_{\text{train}}^i\}_{i=1}^N$, and tested on $X_{\text{test}}$. The limited availability of data may fail to account for detection of rare events. We consider the results obtained from the localized models for benchmark analysis with federated and centralized learning models.
3.2.4 Federated model

In this paper, we focus on classification models that can be trained using gradient descent optimization, as currently supported by federated learning. Similarly to the scenario of localized model, for $N$ sites, we randomly partition the training data into $N$ disjoint subsets of feature set $\{X_{i,\text{train}}\}_{i=1}^N$ and corresponding label set $\{Y_{i,\text{train}}\}_{i=1}^N$. Let $T$ denote the rounds of aggregating local model updates. For stochastic gradient descent, let $\eta$, $E$, and $Batch$ denote the learning rate, number of epochs, and batch based on a given batch size $B$, respectively. Let $F_i(w)$ be the local loss function of the $i^{th}$ site with respect to its model parameter $w$. As described in Section 2, a global model is shared with each site, which trains the model on its local data. During local model training, based on given $\eta$, $E$, and $Batch$, at each site, we compute average gradient $(\nabla F_i(w))$ with respect to its current model parameter $w$. We then compute weighted average to aggregate the parameter updates from the local models. The process is repeated until a convergence criterion, such as minimization of loss function, is satisfied. The process of training the global model only relies on updates from the local models, rather than raw data residing at the sites. Algorithm 1 presents the core algorithm of federated learning, where the weight $w_D^i$, used to compute weighted average, depends on the model aggregation method used. We first implement and evaluate the performance of the state-of-the-art model averaging approach, known as federated averaging. It computes a weighted average based on the fraction of data residing at each site. For this case, the weight $w_D^i$ is equal to $\frac{|D_i|}{|D|}$, where $|D_i|$ and $|D|$ denote the size of data at the $i^{th}$ site and the entire dataset, respectively. Such an approach may fail to consider the inherent characteristics of data distribution at the sites. For the use case of ADR prediction, federated averaging would not account for imbalanced data and the varying distribution of ADR cases across sites. Since such scenarios are common when dealing with real-world health data, particularly in predicting rare events, it is important to explore other aggregation approaches.

3.2.5 Aggregation of local model updates

In this paper, we propose two novel methods of aggregating local model updates. The first method is particularly designed for training data with imbalanced classes. For each site, we estimate the class ratio of its training data to assign a corresponding weight, as denoted by $w_D^i$. This would imply that sites with cases of rare events, would have higher impact when improving the global model. For the second approach, we consider loss per sample, the change in the loss function during local model training. Since a gradient descent-based method attempts to minimize the loss function, we determine its rate of convergence. This is measured by the metric epoch, which is the maximum number of passes over the training data until convergence. Based on each site’s epoch and training data size, we assign a weight, corresponding to $w_{Ep}^i$, for future aggregation. Using this approach, sites which require less training samples to reach convergence faster, will be assigned a higher weight during aggregation.

To evaluate these methods, we create a separate partition of the training data, based on the opioid cohort, to represent unequal distribution of class labels, as shown in Table 2. We do not conduct the same experiment with the antipsychotic cohort due to the limited number of minority class labels (ADR).

4 Experimental Evaluation

In this section, we present experimental results to evaluate our proposed approach. We discuss the evaluation metrics we used in this study, followed by a comparative analysis to demonstrate the effectiveness of the proposed system.

4.1 Evaluation metrics

To measure the predictive capability of the centralized, localized, and federated learning models, we compute precision, recall, and accuracy scores. As noted in prior work\textsuperscript{21,26}, precision and recall are better indicators for models
dealing with imbalanced data. We also report the runtime incurred in training the models for each setup. All experiments were run on an Intel(R) Xeon(R) E5-2683 v4 2.10 GHz CPU equipped with 16 cores and 64 GB of RAM.

2: \hspace{1cm} initialize $w_0$
3: \hspace{1cm} for $t = 1$ to $T$ do
4: \hspace{2cm} for $i = 1$ to $N$ do
5: \hspace{3cm} $w^i_{t+1} = \textsc{UPDATELOCALMODEL}(i, w_t)$
6: \hspace{2cm} $w_{t+1} = \sum_{i=1}^{N} w^i_D * w^i_{t+1}$

7: function \textsc{UPDATELOCALMODEL}(i, w)
8: \hspace{1cm} for $e = 1$ to $E$ do
9: \hspace{2cm} for $b \in \text{Batch}$ do
10: \hspace{3cm} $w = w - \eta \nabla F_i^b(w)$
11: \hspace{1cm} return $w$

For the set of experiments comparing centralized, localized, and federated learning models, we examine the observed differences in performance metrics in two ways: (a) by calculating the % relative error of federated learning and localized learning with respect to centralized learning when using federated averaging\(^9\), and (b) by testing the statistical significance of the difference using the Wilcoxon signed-rank test at 0.05 significance level.

4.2 Comparative analysis

We compare precision, recall, and accuracy of the federated learning (FL) model with two benchmark models: centralized learning (CL) and localized learning (LL). We execute the experiments 10 times for each setup. Figures 2, 3, and 4 report these metrics for the two datasets. As seen in Figure 2, SVM and perceptron yield similar scores and perform better than logistic regression. For all classifiers and datasets, federated learning exhibits comparable performance with respect to centralized learning. At the same time, due to the lack of sufficient training data, localized models do not perform well. It must be noted that the precision score for the antipsychotic data is higher than that for the opioid data. This is due to having a lower number of false positives, possibly because the former dataset is severely imbalanced with a class ratio of 1 : 65.

Figure 3 presents the recall scores of the models for the two datasets. Perceptron generated the highest recall score, followed by SVM and logistic regression. Federated learning performed as good as centralized learning, and outperformed the localized learning models. Since the implementation of cost-sensitive learning reduced the cases of false negative, even with such imbalanced data, centralized and federated learning models for SVM and perceptron achieved high recall.

Figure 4 compares the accuracy score of the three models for the given dataset. Similarly to previous observations, Perceptron and SVM perform better than logistic regression. Our federated learning approach achieves comparable and better accuracy than centralized and localized learning models, respectively.

We observe that the % relative error values from federated learning are smaller than those from localized learning (Table 3). To put the numbers into a context, a difference of 5% in recall can translate to missing 5 out of 100 ADR cases compared to using centralized learning. Higher recall is desirable given the potential cost of missing severe ADR cases, and therefore federated learning with low % relative error is preferred. Based on statistical testing, in both opioid and antipsychotic data, the performance of centralized learning and federated learning is comparable for all three metrics for all classifiers. On the other hand, the performance of localized learning is inferior compared to either centralized or federated learning for the three evaluated metrics (all p values < 0.05).

In Table 4, we report the running time (in seconds) incurred in training the models for different setups. As expected, centralized learning requires a lot of time as it involves training the models on the entire training dataset. Federated learning requires significantly less time to train the models. Localized learning models train on a subset of the data on a single round, due to which they incur the lowest running time. For both datasets, perceptron required higher running time, compared to SVM and logistic regression. Due to the considerably large scale of opioid data, it consistently required more time to train the models.

To demonstrate the scalability of federated learning models, we further measure their predictive capability, in terms of precision and recall, for a varying number of sites and data sizes. As the number of sites increases, the size of training data residing at each site proportionally decreases. Due to the imbalanced nature of the data, this has a pronounced
impact on the recall score, as evident in Figure 5. This scenario also accounts for the ability of the system to handle varying sizes of training data.

As previously discussed, we partition the opioid cohort such that the sites have a varying distribution of ADR and non-ADR cases (see class ratios in Table 2). We compare the effectiveness of our two proposed aggregation methods, in terms of precision, recall, and accuracy, with respect to default averaging (without weights) and federated averaging (based on data size). As seen in Table 5, for all evaluation metrics, our methods, particularly aggregation based on loss per sample, outperforms the state-of-the-art method of aggregation. This result implies that for skewed datasets, it is very important to consider the underlying characteristics of the data when aggregating local models.

5 Discussion

The availability of electronic health data brings countless opportunities to investigate and predict ADR, provided that the hurdles in gathering and using such data are overcome. In this work, we proposed and evaluated the use of federated
Figure 3: Comparison of recall score for centralized learning (CL), federated learning (FL), and localized learning (LL) models using SVM, perceptron, and logistic regression with (a) opioid data and (b) antipsychotic data.

Learning to address the limitations of ADR prediction frameworks based on centralized learning. We demonstrated that SVM and perceptron perform better than logistic regression with respect to precision, recall, and accuracy. Perceptron has higher recall values, making it the preferable classifier for ADR detection, where false negatives generally have more significant consequences than false positives. We also demonstrated that the performance of federated learning models is comparable to that of centralized learning, implying that a federated learning framework can be used to predict ADR without compromising the model performance, while bypassing the challenges associated with centralized learning. An important finding of our evaluation regards the quality of our proposed aggregation approach with loss to sample ratio weighting, which achieves superior performance compared to state-of-the-art federated averaging. This approach is advantageous in federated learning applications with real-world health data, where severe class imbalance is a norm, rather than an exception.

In this paper, we focused on classification algorithms that are amenable to distributed solution using gradient descent, as currently supported by the federated learning paradigm. In the future, we plan to extend our federated learning framework to other types of algorithms, such as decision trees and gradient boosting, as well as applications where large-scale distributed datasets are common and deep learning models are applicable. We will leverage other charac-

Table 5: Comparison of our proposed aggregation methods (based on class ratio and loss/sample) with respect to averaging and federated averaging methods. For SVM, perceptron (Perc), and logistic regression (LR), we report the average (standard deviation) values of precision, recall, and accuracy scores.

We will also explore potential approaches for tuning hyperparameters of the global model in a federated setup. We intend to work on approaches for privacy-preserving federated learning, which protect patients’ privacy against adversarial attacks, in addition to not exchanging raw data while training the models.

Abstract

Identifying patients at risk of deterioration in the hospital and intervening more quickly to prevent adverse events is a top patient safety priority. Early warning scores (EWS) identify at risk patients, but there is much opportunity for improvement particularly related to increasing lead time – the time from an alert trigger to adverse event (e.g., cardiac arrest, death). Our team develops healthcare process models of clinical concern (HPM-CC) and in this work has identified documentation signals that are proxies of nurses concern and can be used to predict patient risk earlier than current EWS systems that rely only on physiological data. We compared the performance of a validated EWS - the MEWS - to our novel model (MEWS-CC) comprised of MEWS criteria plus 3 proxy variables of nursing concern. MEWS-CC performed similarly to MEWS, with the added benefit of increased time from EWS trigger to event by 5-26 hours.

Introduction

Identifying preventable deterioration in the hospital setting is a patient safety priority with suboptimal outreach interventions and outcomes to date.1 While the exact estimates of preventable deaths and adverse events in the hospital setting have been debated, it is widely accepted that the numbers are much too high.2-4 Predicting a patient’s future state is a great challenge and focus of early warning score (EWS) models to identify patients at risk of deterioration in the hospital setting. EWS models predominately use vital sign abnormalities to predict cardiac arrest and death within a set time period, such as 24 or 48 hours, and overall have good predictive performance but there is insufficient evidence of positive impact on patient outcomes once implemented in the clinical setting.5,5 Many EWS studies report on the ability to predict the event at any point using the prior 24 or 48 hours, rather than the more useful clinical objective of maximizing the time from first alert trigger to event in order to enable sufficient and effective clinical intervention.5,6 Further, most studies ignore the clinically established criteria of “concern” or “worried about the patient”7 A 2014 review of EWS found that only 3 of 13 unique models included a concept of clinical concern where the clinician, typically the nurse, answered structured questions if he/she were subjectively concerned of the patient.5,7,8 In this era of big data and artificial intelligence, it is noteworthy to recall that prediction or projection of a patient state occurs routinely by clinicians in clinical practice and the predominant reason to activate a rapid response team (RRT) was the subjective criteria of “concern” before EWS criteria changes in vital sign parameters were reached.9-11 Machine learning is limited by availability of computable data. However, clinicians consume vast amounts of information during the course of clinical care that are never recorded in the electronic health record (EHR), such as by looking at or talking to a patient. The breadth of data that clinicians are exposed to and observe become information that triggers clinicians to record data in the EHR that they deemed clinically relevant and salient to the patient’s care. Therefore, the presence of recorded data itself is relevant and available to machine learning algorithms.

The most common physiological criteria used to trigger a RRT are low oxygenation, low systolic blood pressure, change in level of consciousness, or change in heart rate or respiratory rate (RR).12-14 Respiratory rate has also been shown both as the most predictive vital sign for adverse events and a variable with significant interactions with other vital signs in EWS models.15 However, delays in activation of RRTs have been attributed to overreliance on waiting for physiological criteria to be met, failure to identify deterioration, and complexities in workflow and team communication.16 Clinically intervening on delays in activation of RRTs is a priority. In this study we demonstrate a
method to measure “concern” or “worry about a patient” for use in EWS that can in turn be validated and implemented in the clinical setting.

Clinical expert intuition – or prediction of patient trajectories - is generally understood as complex decision making in which data and information are filtered and synthesized for expert pattern matching which leads to skilled judgements based on possible unconscious observations or inability to articulate the cues that guide them.\textsuperscript{16,17} Aligned with this notion of clinician decision making informed by trends to predict trajectories, one EWS study created variables that track the trend of changes in each vital signs (24hrs mean, variance, max, min) and showed that the model performed better in predicting outcomes then the models that only take into account current vital sign values.\textsuperscript{18} In clinical practice, actualizing a clinician’s predictions into shared action and plans among the care team can be a significant challenge, in part due to the difficulties experts encounter in articulating these skilled judgements and the subsequent categorization of these predictions as anecdotal in nature lacking reliability and validity. Perhaps complicating the understanding of these predictions, is the notion that “it is not that proficient nurses have internalized the rules and formulas learned during the earlier stages of skill acquisition; they are no longer using rules and formulas to guide their practice. They are now using past concrete experiences much like the researcher uses paradigms.”\textsuperscript{19}

While we acknowledge the potential for bias and flawed intuition, we posit that the clinical expert intuition paradigm holds great potential as a novel and long ignored complementary factor in predictive modeling for current rule-based EWS models.\textsuperscript{20,21} Moreover, if the bias is systematic it can be computationally measured and leveraged for information.\textsuperscript{22–25}

EHRs contain large amounts of data that are never utilized or reused for clinical or analytics purposes. EHR log files contain a vast amount of data, some of which are rarely used yet can be extracted into computable metadata patterns that model healthcare processes.\textsuperscript{22,23,26} For example, these data provide the ability to measure patterns in order placement, medication use, note frequency, and start time for discharge orders. As part of a larger National Institute of Nursing Research (NINR) funded study – the CONCERN study - our team is mining nursing notes and flowsheets for clinical data that signals nurses’ concern. Our team uses EHR metadata to compute Healthcare Process Models for Clinical Concern (HPM-CC) that can be used to model proxy signals of clinical expert intuition that a patient is not doing well with enough lead time to intervene.\textsuperscript{20,21,24,25,27} HPM-CC are generated from perceptions, interpretations, and recordings entered by clinicians (e.g., nurses, physicians), and are based on clinician decisions to observe and enter data in the EHR.\textsuperscript{20,21,24,27,28} These types of EHR utilization patterns may be misinterpreted or discarded as biased for research, but these data and their biases are rich in information that can be used to understand clinical care and may enhance predictive power.\textsuperscript{22,23} For example, we have modeled the magnitude of these documentation concern patterns in relation to the clinical outcomes of in-hospital mortality and cardiac arrest.\textsuperscript{20,21} Similar analyses by other groups have shown laboratory test timing predicts mortality.\textsuperscript{29}

What mechanisms of action might explain why HPM-CC metadata patterns are a signal of clinical concern? Clinicians rely on situational awareness to continuously prioritize – or triage - care for the patients that they are most worried or concerned about. Clinical situational awareness is gathered from objective and subjective clinical assessments and expert pattern matching. Expert pattern matching is based both on the clinicians’ prior experiences with similar patients, and comparisons to the individual patient’s baseline health status. Although clinical nurses, like all experts, struggle to articulate their clinical intuition, 37 signs and symptoms categorized into 10 general indicators have been shown to underlie nurses’ worry or concern, or intuitive knowing related to patient deterioration in the hospital setting.\textsuperscript{30} While several indicators relate to vital signs, such as change in breathing, change in circulation, rigors and change in mentation, these physiological changes also may precede changes in vital signs.\textsuperscript{30} The remaining signs and symptoms are not related to measurement of vital signs: agitation, pain, unexpected trajectory, and patient indicates feeling unwell.\textsuperscript{30} Nurses engage in two activities as core parts of nursing practice that relate to expert pattern matching that result in EHR data with these HPM-CC signals. First, nurses increase their frequency of surveillance – and subsequently frequency of documentation – for patients that fit a concerning pattern.\textsuperscript{21} Second, nurses synthesize their subjective and objective clinical assessments - otherwise buried in structured flowsheet fields - within their narrative notes and short comments associated with specific flowsheet values.\textsuperscript{21,28} In other words, the act of documenting a free-text comment in a flowsheet row provides information that the nurse likely determined an event or observation was clinically significant enough to record, since these types of data are not required data entries. Predictive modeling that is focused only on the values of structured data in EHRs will miss the healthcare processes and nursing interventions that are activated far before a patient’s vital signs are abnormal.

While nurses’ subjective feeling of worry or concern is a valuable indicator before vital signs have even changed\textsuperscript{30,31} subjective nurse observations, such as “the patient does not look well”, by their very nature do not explain what is wrong or the rationale for why a patient does not look well. This is consistent with Benner’s characterization of clinical
expert intuition being challenging to articulate.\textsuperscript{16,19} HPM-CCs that identify when nurses make these statements, their associations with other signs and symptoms, and their ability to predict outcomes can lead to a shift in how we understand and leverage clinical observational skills and clinician entered data within a patient’s chart.\textsuperscript{24,27}

In this study we evaluate the performance of a broadly used and well validated EWS – the Modified Early Warning System (MEWS)\textsuperscript{32} – compared to what we call the MEWS-CC (MEWS-Clinical Concern) model. MEWS-CC is a novel early warning system which incorporates both the patient’s physiological data from the MEWS score as well as three HPM-CC proxy signals of a nurses’ concern identified from the CONCERN study (1. frequency of respiratory rate assessment, 2. frequency of flowsheet comment entered and associated with temperature value, 3. frequency of comment entered and associated with blood saturation) (see Table 1). In our prior analyses our team identified the significance of Sp02 comments for their ability to discriminate related to outcomes of mortality and cardiac arrest.\textsuperscript{20,21} We identified that Sp02 comments were significantly more likely to be associated with a normal Sp02 measurement, while comments for blood pressure and heart rate were more likely to be associated with an abnormal heart rate or blood pressure measurement.\textsuperscript{21,28} These Sp02 comments are used by nurses to highlight when a patient’s supplemental oxygen requirements are increasing; typically, in these instances a patient’s Sp02 reading remains normal because the nurse continues to titrate the supplemental oxygen in order to keep the Sp02 reading normal for the patient. Our prior work described this phenomenon and the nurse’s intention to highlight the relationship between Sp02 and supplemental oxygen - which EHR flowsheets do a poor job of visualizing – to the physician as an indicator of deteriorating status. Additional prior work from our team also identified that the frequency of respiratory rate and temperature comments have similar significant signals associated with mortality.

MEWS, which is based solely on a patient’s physiological data, is one of the most widely used and validated EWS models.\textsuperscript{32} Given the extent of its use in practice, and as a comparator to new EWS in other literature, was the most appropriate comparator for our study. We believe that this approach will demonstrate the added benefit of modeling predictive HPM-CCs compared to the MEWS criteria alone for the combined event of (whichever occurs first): transferred to ICU, transferred to SDU, rapid response, cardiac arrest or expiration\textsuperscript{4}, as well as time to first event.

Our analysis includes a specific focus on time from first alert trigger to event by simulating a real-time prospective analytical approach, accounting for the temporal signal of each data point. Therefore, we are pursuing a shift in the goal of predictive modeling. Rather than identifying when the patient’s values indicate they are already in a risky state, our team is focused on identifying when clinicians are concerned that a patient may be entering a risky state. The difference – we believe – is affording greater lead time (trigger to event time) to effectively intervene.

\textbf{Methods}

\textit{Inclusion criteria and data collection}

Flowsheet data was queried from two separate campuses of the same hospital in Northern Manhattan, a 745-bed adult facility in an academic medical center and a 300-bed community hospital, over a two-year period (January 2015 – December 2016). To minimize variation of the patient population three types of study units were identified, general medical or surgical acute care units (ACU) (n=12), intermediate care or step-down units (SDU) (n=4) and critical or intensive care units (ICU) (n=9). We collected data for patients that met our inclusion criteria of spending more than 24 hours on a study unit and excluded those patients that were less than 18 years of age on day of admission, patients who eventually had hospice or palliative care orders written (either upon admission or at any point during their hospital visit), and patients whose hospital stay exceeded 60 days.\textsuperscript{32} We captured five physiological parameters (heart rate, blood pressure, respiratory rate, temperature and level of consciousness) and an indicator of whether a flowsheet comment was written. The content of the comment was not used in this analysis. For each flowsheet entry we also captured the patient and visit identifiers and the recorded time. Patient visit admission, discharge, and transfer data was also queried so that patient locations could be associated to each entry in the flowsheet and patient movement within the hospital could be tracked. Patients and visits were identified by unique database generated identifiers.

Order and note data were also queried to aide in the cleaning and validation of the cohort of patients experiencing our primary outcomes. The order name and time the order was written was used to determine patients with hospice and palliative care orders. Note types, time of note creation, and structured fields within notes were queried to cross validate with discharge information the cohort of patients that expired or experienced a rapid response or cardiac arrest. The structured time field within these notes aided in the validation of times of events from other data sources.

\textit{Data cleaning and validation}
Outcomes data of patient expiration, rapid response and cardiac arrest were cleaned as mentioned above by cross validating the cohort and times of events between different data sources and finally performing a chart review on 20 selected patients. To determine the transfer information of each patient, we first looked at the distinct locations that a patient had any flowsheet entry on. We then used the earliest time that a flowsheet entry occurred on each unit to look up in the admission-discharge-transfer (ADT) table when the patient was transferred to this location. This enabled us to create a cleaned cohort of patients that we knew first spent time on an ACU before an ICU or SDU (by way of flowsheet entries) and the times that the patient transferred (by way of ADT entries). Ignoring this method and only focusing on ADT information resulted in patients that had transfer information but were never actually transferred. This method was validated through patient chart review.

Vital sign information was stripped of extraneous text so that they included only numbers consistent with possible physiological criteria for each measurement. To determine the level of consciousness for the MEWS score, one nursing expert mapped the top 95% of distinct structured and free text entries to the concepts ‘Alert’, ‘Reacting to Voice’, ‘Reacting to Pain’, and ‘Unresponsive’. These mappings were independently validated by a second nursing expert.

Table 1. MEWS criteria (blue), clinical concern criteria (yellow), MEWS-CC (MEWS-Clinical Concern) criteria (green)

Data analysis

Our data set was reduced to only include those visits that began on one of our 12 acute care units, as opposed to patients that were in an ICU or SDU prior to their ACU stay. We felt that this more accurately defined the visits that we were considering as unanticipated transfer to ICU or SDU. Upon review of the data and chart reviews, we did not feel that the hospital trajectory of a patient admitted to an ICU unit, transferred to an ACU and then transferred back to the ICU should be considered the same as a patient who began on an ACU and then transferred to the ICU.

The endpoints for our data set were discharged alive (no outcome) and the combined event of transferred to ICU, transferred to SDU, rapid response, cardiac arrest or expiration (primary outcome). The time for the primary outcome was the first time at least one of the sub-outcomes occurred.

The MEWS model and the MEWS-CC models (TABLE 1) were implemented in our sample data. The three additional clinician documentation pattern data points from the CONCERN study were: the number of respiratory rates entered.
(not considering the value, just that a respiration rate was entered), the number of SpO2 comments written, and the number of temperature comments written. These variables were selected based on our team’s preliminary analysis focused on patient mortality which indicates a strong signal using longitudinal logistic and hazard regressions with time-varying covariates. The scoring criteria displayed in Table 1 for each of these variables were naively selected based on inspection of the probability mass functions (pmf) for the number of respirations entered, SpO2 comments, and temperature comments. An estimate of the pmf for number of respirations entered in a 24 hour period was generated via a histogram, for patients admitted on an equivalent, but not included, ACU. The estimate showed a mode at 5 and approximately 50% of the mass to the left of 6, approximately 80% to the left of 11, and approximately 98% to the left of 21. For temperature and SpO2 comments, thresholds 1 and 2 corresponded to approximately the 98th and 99th percentiles, respectively. It will be the purpose of future work to analytically derive optimal thresholds for all of our covariates, however this work shows that positive results can be obtained by including crude estimates for clinician documentation frequencies.

As with many EWS models, the scoring system displayed in Table 1 is used to calculate a total score for which there is a threshold chosen that any patient with a score above that threshold is considered at risk and any patient below that threshold is considered low risk. MEWS, as a broadly used and validated score, has a widely accepted threshold of > 4 which we used for the MEWS in our analysis. However, we also ran the MEWS analysis for additional thresholds (0 to >9) to confirm any improved performance at other thresholds in our data set. Give that our new model MEWS-CC does not have established thresholds we computed performance measures for a series of different thresholds in order to understand which resulted in the best performance.

While our data set is retrospective, these two models were implemented using a simulated real-time approach – at each data point both models would update their scores as though a clinician had just entered this new data point in real time. This was done to provide an accurate baseline for our comparator, MEWS, as well as output an accurate time that both models would send alarms if implemented in real-time today. Since we know each patient visits’ endpoint, we could then compute time of the alarm to the time of the endpoint.

Finally, we ran the MEWS model alone and compared it to the MEWS-CC model to determine the change in predictive power. We approached the evaluation of the EWS models based on a previous study conducted by Umstead et al. 201633, since this approach includes both evaluation of predictive accuracy and evaluation of time from alert trigger to event (lead time). Based on Umscheid et al. 2016 we identified the following four metrics to describe differences in performance between the two models33 for the thresholds described above: 1. Area Under the Receiver Operating Curve (AUC); 2. Positive Predictive Value (PPV); 3. Negative Predictive Value (NPV); 4. Lead time i.e. how early the model was able to identify the adverse event before it happened (evaluation of time from alert trigger to event).

Results

A total of 44,581 unique patients (64,822 hospital admission encounters) were included in our initial data set. After applying inclusion and exclusion criteria our final data set was comprised of 28,394 unique patients (38,885 encounters). (See Table 2.)

Table 3 provides the performance metrics for each model, including 4 different thresholds of scores for the MEWS-CC model. The MEWS model, using the standard threshold of 4, had the following performance in our data set: PPV = 0.2642, NPV = 0.9247 with a median of 13 hours from trigger to event. The MEWS-CC threshold of 5 was most similar in performance to the MEWS with: PPV = 0.2348 and NPV = 0.926. The meaning of the false positive rate in this is complex. It describes the number of patients that were predicted to have one of our outcomes (transferred to ICU, transferred to SDU, rapid response, cardiac arrest or expiration) but did not. While the alert trigger was a false positive, it is possible that these patients may have had indicators of concern and been in a risky state that was mitigated by clinical intervention. Therefore, we interpret the true positive rates in Table 3 as at minimum the patients who experienced an outcome and we should be concern about.

Table 3 also displays the lead times for each model and threshold to allow for evaluation of the amount of time a clinician is afforded to intervene for an at risk patient after the EWS alert triggers. The lead time of the MEWS was 13 hours. The lead time for the MEWS-CC model was 39 hours (threshold > 3), 32.5 hours (threshold > 4), 24 hours (threshold > 5), and 18 hours (threshold > 6). Therefore, using a threshold of > 3 for the MEWS-CC model, there was an additional 26 hours, or greater than one full day, for clinicians to act and intervene on a patient with an alerted risky state. At the threshold of > 5 for the MEWS-CC model there was an additional 11 hours of lead time, equivalent to.
almost 1 nursing shift, for clinicians to act and intervene. MEWS was also run for additional thresholds and each time the two models had comparable performance, the MEWS-CC had a greater lead time. The MEWS-CC threshold of >3 contributed to a much higher false positive rate than MEWS-CC threshold of >5. The complexity of this false positive rate is assumed to include patients that were never at risk, but also patients that were at risk but did not experience a bad outcome due to early identification and clinical intervention or other unknown reasons.

Figure 1 displays the Receiver Operating Curves (ROCs) for MEWS and MEWS-CC Models and calculation of the AUC. The AUC for the MEWS model was 0.61. The AUC for the MEWS-CC model was 0.65. There was similar performance of AUC between the MEWS and MEWS-CC at a threshold of >5.

Discussion

Our implementation of a simple rule, based on frequencies of one vital sign entry and two vital sign comments, resulted in a model with equivalent performance to the MEWS that triggered alarms 5-26 hours (depending on selected threshold) before the first MEWS alarm. We emphasize that this approach was identified without using machine learning, but rather based on nursing subject matter expert knowledge of documentation and practice patterns for selection of variables that are a signal of nursing expert concern about a deteriorating patient. The ability to trigger an alert a full clinical shift (12 hours) or day earlier (24 hours) is clinically significant. For example, the clinical priority in order to prevent death for sepsis patients is early intervention which is dependent on early identification.\(^{34,35}\) It is plausible that nurses’ temperature comment documentation relates to the prominent campaigns in recent years to increase awareness and identification of sepsis.\(^{36,37}\)

Other studies have also identified EWS models with equivalent or slightly better performance than MEWS, such as Churpek et al. who used a machine learning approach, but - like many studies - did not report lead time.\(^{15}\) Importantly, we note that our team is approaching EWS modeling from a different paradigm of both data types (metadata patterns) and data temporality (simulated real-time prospective analysis). In our interpretation, a lack of reported lead time is ultimately incomplete for an EWS given that from a clinical perspective, slightly better accuracy of prediction without improvement in lead time offers limited opportunity to change patient treatment plan and trajectory. However, it is possible that combining newer EWS models that have improved accuracy, such as Churpek et al. (or other models derived from a machine learning approach), with our HPM-CC variables as used in MEWS-CC model could result in better performance and lead time that is both statistically and clinically significant. Further, our HPM-CC modeling approach is not a black box approach. In addition to validation of predictive power, our team is engaging in usability studies to understand the best approach to communicate predictions that are based on EHR metadata to busy clinicians to improve understanding of patient risky states and drive appropriate follow-up.

The complexity of the meaning of the false positive rates is critical to understand and account for given our aim to predict patients that are entering a risky state based on clinician concern. Further research is needed to understand if there were patients in our false positive group who avoided a bad outcome due to clinician identification of concern and early intervention - and if so it would appear that our data accurately detected that concern, but our study was not designed to detect early intervention. These false positive complexities are true of the MEWS group as well. Future
work should focus on discriminating between these types of clinical process characteristics in EWS studies. Similarly, other EWS studies have discussed differences between the choice of study endpoints in light of the fact that EWS impact on clinical outcomes is controversial.

Our analysis also included one difference in criteria that was not used in the published MEWS validation studies: patients that were admitted first to an ICU or SDU are excluded. This is a possible explanation of why we found a slightly lower MEWS AUC than reported elsewhere. In other words, patients that were admitted to the ICU and then transfer to ACU may be more likely to transfer back to ICU then a patient that was admitted first to an ACU. Both cohorts should be studied in future work. In the future, it would also be interesting to consider adding into an early warning system the indicator if a patient has ever been to the ICU and measure any EWS performance changes.

Our findings raise the question: if the documented nursing practice patterns - defined by our team as a proxy of nurses’ concern - are statistically significant early predictors why are these patients not adequately receiving early intervention once the nurse that documented those data is concerned? Clinical care teams and clinical workflows in the inpatient setting have complexities that have been shown to contribute to suboptimal communication paths and the efficient achievement of shared situational awareness among the members of the care team\textsuperscript{28,36,38–40} As discussed in the introduction, nurses’ expert concern is not always able to be well articulated with references to physiological changes to back up that concern, as typically desired by members of the medical team. This lack of a shared mental model of a patient’s state, combined with competing needs and priorities of other patients, contributes to delays in a shared situational awareness of a patient’s decline and delays in interventional care and procedures to save that patient. This is a challenging team situation in which the physician is typically not physically present at the patient’s bedside and able to observe the same subtle changes in the patient's condition that the nurse is responding to in our data. EHRs can help fill gaps in shared situational awareness for clinicians who are remote - not on site - but only for data types that are clinically well understood and recorded in the EHR. The metadata we processed in our study are not data types that are taught, referenced, or used in the course of clinical care. However, as mentioned, our team is investigating how these significant data points can be translated into an interpretable score by all members of the care team in order to increase shared situational awareness, even for clinicians that are viewing data remotely, to enable early intervention.

Our identification of respiratory rate as a significant signal for patient deterioration aligns with prior work describing oxygenation status and change in respiratory rate as one of the most common physiological criteria used to trigger a RRT\textsuperscript{12–14}, as well as Churpek et al., who identified respiratory rate as a predictive feature with significant vital sign interactions.\textsuperscript{15} From a clinical process perspective, respiratory rate is different from other vital signs in that, with the exception of ventilated ICU patients, it is typically manually measured. The nurse counts a patient’s respirations for a full minute. All other vital signs (blood pressure, heart rate, temperature) and related physiological measures (SpO\textsubscript{2}) are measured using a machine. However, in reality the manual process of counting a patient’s respirations for a full minute is typically not done in practice because an experienced nurse (and even most novice nurses) can typically identify a patient with abnormally high or low respirations upon initial visual observation. This practice results in nurses documenting respiratory rates less frequently in practice than other types of vital signs; we posit that beyond recording that a patient’s respirations were normal occasionally throughout a nursing shift, documentation of this vital sign may only occur when a patient’s respiratory rate is observed to be abnormal. Conversely, other vital signs require a specific machine measurement, rather than an “eyeball visual observation” and in clinical practice it is not common to take a machine measurement without recording it in the chart. However, an “eyeball visual observation” that a patient’s breathing looks ok – while likely performing other patient care activities - may not always be recorded in the chart. This difference in how, when, and why a physiological measure is performed and recorded in the EHR is important to understand when analyzing flowsheet data for EWS modeling because it impacts the information signals, including frequency of measurement and subsequently missing data. We also point to a potentially similar pattern of missing data in the clinical observation level of consciousness. It is possible that nurses document this selectively for patients for which it is more clinically relevant due to disease process (neurological) or clinical setting (ICUs). As stated previously, our past work identified the significance of SpO\textsubscript{2} comments for their ability to discriminate related to outcomes of mortality and cardiac arrest and that a comment is more likely to be associated to an abnormal SpO\textsubscript{2} value\textsuperscript{20,21} Our findings indicate that there may be similar clinical processes that factor into a nurse deciding to enter a respiratory rate value, SpO\textsubscript{2} comment, and perhaps temperature comments as well.

EHRs have been criticized for leading to information overload at the point of care. Yet, the vast amount of EHR information available can be extracted into computable metadata patterns that model healthcare processes and when synthesized can provide insights into clinical care patterns and associated outcomes. We believe that surfacing select patterns at the point of care could be a potential approach to overcoming information overload and supporting clinical
expert decision making by the entire care team. The findings from this study indicate the potential of HPM-CCs to enhance the lead time for triggering EWS and providing care teams with greater insight into patient’s risky states and ability to effectively intervene.

**Limitations**

The findings presented in this study are from two hospital sites part of one hospital system and require validation in other hospital data sets. To increase generalizability of our findings we used a well-validated EWS – the MEWS. We found overall similar performance of the MEWS in our data set as reported elsewhere in the literature, lending confidence in the data used in this study. It is important to note that the three selected HPM-CC variables are based on our team’s work to date which is not exhaustive of all nursing concern signals and additional significant variables may be identified from our data set as our work continues. We therefore position this evaluation as a use case to demonstrate the potential methods for enhancing EWS, rather than a validated and conclusive finding. Finally, the high level of missing data for the level of consciousness MEWS feature may have influenced the performance of the model, yet this is an evaluation of performance in using real clinical data, and handling missing data could be considered an inherent part of model performance in the clinical setting.

**Conclusion**

Unfortunately, there remain high rates of preventable deterioration in the hospital setting.2-4 Timely identification of patient deterioration is a modifiable factor that can change the trajectory of a patient’s status and outcome. We identified three variables from HPM-CC metadata patterns of nursing documentation as proxies of nurses’ concern that were able to increase the time from EWS trigger to event for patients in our data set. This is a noteworthy finding with direct links to potential clinical interventions, such as clinical decision support alerting and care team dashboards displaying patient risk status. Future work should confirm the best HPM-CC factors and thresholds to combine with EWS and validate these predictive models in at other sites.

A Sociotechnical Multiple Perspectives Approach to the Use of Medical Scribes: A Deeper Dive into the Scribe-Provider Interaction

¹Oregon Health & Science University, Portland, OR USA

Abstract

Because of increased electronic health record use, many organizations are hiring medical scribes as a way to alleviate provider burnout and increase clinical efficiency. The providers and scribes have unique relationships and thus, this study’s purpose was to examine the scribe-provider interaction/relationship through the perspectives of scribes, providers, and administrators utilizing qualitative research techniques. Participants included 81 clinicians (30 providers, 27 scribes, and 24 administrators) across five sites. Analysis of the scribe-provider interaction data generated six subthemes: characteristics of an ideal scribe, characteristics of a good provider, provider variability, quality of the scribe-provider relationship, negative side of the scribe-provider relationship, and evaluation and supervision of scribes. Future research should focus on additional facets of the scribe-provider relationship including optimal ergonomic considerations to allow for scribes and providers to work together harmoniously.

Introduction

The use of electronic health records (EHRs) in the United States has increased dramatically over the past decade due to the Health Information Technology for Economic and Clinical Health (HITECH) Act¹. Subsequent to the adoption of EHRs, unintended consequences like over-documentation² have occurred due in large part to regulatory mandates of documentation and documentation system inefficiencies. One way that organizations address physician dissatisfaction associated with the EHR and documentation is by hiring medical scribes. Mishra, Kiang, and Grant define medical scribes as “paraprofessionals who transcribe clinic visit information into the EHRs in real time under physician supervision³(p1468).” Prior research has demonstrated that the use of medical scribes lowered the documentation time for physicians³ and increased the time and quality of provider and patient interactions³,⁴. According to one study, medical scribes also “reduce the [provider’s] burden of record keeping and order entry⁵(p277).” Despite the documented benefits, concerns have been identified such as functional creep of scribe duties and the stifling of further development of EHR usability⁶.

Few comprehensive studies have analyzed the interaction of providers and scribes within the context of the sociotechnical environment in which they operate. Yan and colleagues⁴ conducted a seminal study that used qualitative research methods to investigate the role of clinical scribes through the lenses of providers, scribes, and patients in primary care. They described three themes: documentation, patient care, and teamwork (the scribe-provider interaction). They found that from the documentation perspective, the scribes captured information in real time and increased the amount of perceived detail in the providers’ notes. From the patient perspective, the patients perceived that provider spent more time focused on them and less time focused on the EHR by utilizing a medical scribe. From the teamwork perspective, high levels of communication and trust were important characteristics for both scribes and providers. Scribes also valued providers who were willing to teach. While this study had interesting findings, it only investigated primary care settings.

Sattler and colleagues conducted a one-year qualitative longitudinal study investigating four primary care providers and two scribes at one family care practice to learn more about the scribe-provider workflow and relationship⁷. They sent out surveys to the providers after each day and ultimately generated 11 themes, “which were further categorized under four domains: clinical operations, joy of practice, quality of care, and patient experience⁷(p51).” Regarding clinical operations, it was revealed that scribes lowered the amount of time providers spent writing notes. Surrounding the joy of practice, one physician said it was, “So fun to have a ‘partner in crime’ and to spend the day together⁷(p52)!” Another provider said that, “It’s also important to note that it is really fun having [the scribe] to work with. She is a friend now and a colleague⁷(p53).” In relation to quality of care, the study demonstrated that the scribes learned provider preferences and included more details than the providers did in their notes. The results surrounding patient experience revealed that the providers were able to spend more quality time with their patients and notice nonverbal communication they could have missed without the scribe in the exam rooms. The study had important limitations,
including that it only investigated a single primary care clinic, had a small sample size (four providers and two scribes) and did not survey scribes.

Neither of these previously mentioned studies used a sociotechnical model as a framework for studying medical scribes. One of the more popular sociotechnical models is the eight dimensions of sociotechnical model for health information technology. This model shows how all eight dimensions work together to help understand complicated healthcare entities.

The goal of the overall study was to use a sociotechnical model as a framework for studying scribes and the EHR in urgent care, emergency departments, and primary care settings across five organizations. The primary goal of the present study was to further expand knowledge of scribe-provider interactions and describe this relationship dynamic in-depth by analyzing what we discovered through interviews and observations from providers, scribes, and administrators. The overall purpose of this work was to investigate the climate of medical scribes in various practice settings and use this information to develop a set of simulation activities based on identified and needed competencies.

**Methods**

**Settings:** We used purposive sampling and selected our sites based on (a) the diversity of geographical location (b) size of clinics/hospitals, (c) whether the hospital/clinic was academic or community based, (d) EHR vendor, and (e) whether the scribes were hired through an internal program or a scribe company.

From October 2017 through January 2019, we conducted five site visits across the United States to hospitals and clinics in multiple geographic settings. The sites included teaching hospitals, community health systems, and outpatient clinics representing a wide range of sizes. Most clinics/hospitals were using the Epic system. However, one had recently switched from Cerner to Epic and one used AllScripts. We were interested in studying various scribing models; therefore, we visited one site that used virtual medical assistants (MAs) and nurses as medical scribes. Two of our sites used a traditional third party scribe company to hire scribes, which entailed hiring pre-professional scribes that were typically pre-health students. One of our sites had a homegrown scribe program where the hospital created their own pre-professional scribe company to hire and train scribes; the scribes were typically pre-health students. One of our sites used a scribe company that was closely tied to the academic hospital to hire pre-professional scribes; these scribes were typically college students with pre-health backgrounds.

**Data gathering:** We used the Rapid Assessment Process (RAP) model to construct our methodology. RAP uses a rapid qualitative and ethnographic approach to aggregate and process data in a timely manner. RAP helps establish ethnographic validity by using triangulation. Triangulation is “the use of several different researchers, the use of multiple perspectives to interpret a single set of data, and the use of multiple methods to study a single problem.” During the site visits we triangulated by using different researchers and methodologies.

We used qualitative research methods including observations in the hospitals/clinics to collect our data where researchers created field notes which are “usually handwritten notes that are done as the data is being collected.” We also used semi-structured audio-recorded interviews, which allowed the participants to answer questions on our interview guide, but they could also expand on topics or discuss ideas that were not mentioned in the interview guide. The team included ten researchers with multidisciplinary backgrounds including clinical, informatics, scribe vendor industry, and methodological expertise. Two trained researchers worked in pairs conducting the interviews. One person was the lead interviewer ensuring all questions on the interview guide were answered while the assistant interviewer asked follow up questions and made sure that the recorders were functioning properly.

To gather a holistic view, we took a sociotechnical approach to study medical scribes based on the eight dimensions of sociotechnical model for health information technology. During interviews and observations, we looked at the (a) hardware and software computing infrastructure, (b) clinical content, (c) human computer interface, (d) people, (e) workflow and communication, (f) internal organizational policies, procedures, and culture, (g) external rules regulation, and pressures, and (h) system measurement and monitoring. We used the eight dimensions of sociotechnical model for health information technology to study medical scribes. We investigated hardware and software computing infrastructure during our observations where we watched providers and scribes interact with the EHR. Through observations and interviews, we learned more about clinical content by hearing what vocabulary the scribes could add to the note. We observed human computer interface by watching the scribes interact with the EHRs. For people, we interviewed them and learned how the EHR made them feel and what kind of training they were provided to learn how to navigate the EHR. For workflow and communication, it was pertinent that we observed the
scribes’ workflow and see how they communicate with their providers. For a couple of the site visits, we were able to look at different organizations’ policies and procedures when it came to what scribes can and cannot do during a patient visit. It was pertinent that we investigated external rules, regulations, and pressures as well; we did by looking at the Joint Commission’s policies on medical scribing. Lastly, we looked at system measurements and monitoring through interviews and observations; we would ask how the scribes were monitored; all the organizations handled monitoring differently. We gathered data until we reached saturation, meaning until we were seeing and hearing the same things repeatedly.

Analysis: Using NVivo 11, we coded our transcriptions and iteratively conducted a theme analysis using a grounded theory approach. We began our coding process by using a dyad system to conduct a line by line analysis of the field notes and transcripts to identify repeated concepts, which we turned into codes. Once we created the codebook, we were able to use that to code our field notes and transcripts. Most of the transcripts and field notes were coded using dyad pairs consisting of the research team members who all had different backgrounds and allowed for a multidisciplinary approach. The team met often to discuss results and report findings, which is a form of member checking and helps validate the results. We used the codes we found in the transcripts and field notes to develop the themes and subthemes. Overall, we had ten coders who helped code the transcripts and field notes.

The study was approved by the Institutional Review Board (IRB) at the Oregon Health & Science University. IRB review and/or official determinations (if a site did not have an IRB, it had other mechanisms for reviewing our protocol) were also obtained from all sites.

Results

We visited five site visits across the United States with varying differences (see Table 1).

Table 1. Site visit demographics.
During our site visits, we interviewed a total of 81 clinicians (30 providers, 27 scribes, and 24 administrators) for a total of 47 hours of recorded audio. Physician interviews ranged from 9 minutes to 58 minutes; scribe interviews ranged from 11 minutes to 65 minutes; administrator interviews ranged from 21 minutes to 80 minutes. Most interviews took place in person, but one interview took place over the phone. It is important to note that nine of our interviews had only one interviewer instead of two due to members of the research team needing to be in other interviews or observing.

We observed at five sites, which included 12 clinics. Specifically, there were two Urgent Care Clinics, two Ear, Nose and Throat (ENT) Clinics, three Family Medicine Clinics, three Emergency Departments (EDs), one Pediatric Cardiology Department, and one Sports Medicine Department. We spent a total of 80 hours observing.

Through this research we discovered ten majors themes (see Figure 1).

**Figure 1.** Themes of sociotechnical research on medical scribes.

We have previously described ten themes emanating directly from our data, but this paper will focus on the scribe-provider interaction theme. The *scribe-provider interaction* theme is crucial in explaining how the provider and scribe work together effectively and how their relationship could improve. Through qualitative analysis, we found that this general theme included six subthemes: characteristics of an ideal scribe (knowledge/characteristics all exceptional scribes should possess), characteristics of a good provider (knowledge/characteristics all exceptional providers/scribe-users should possess), provider variability (how providers differ and the impact these differences have on scribes), quality of relationship (the benefits of the scribe and provider relationship), negative relationship (the negative aspects of the scribe and provider relationship), and evaluation and supervision of the scribes (what level of evaluation/supervision the scribes receive from the providers) (Figure 2).

**Characteristics of an Ideal Scribe**

During the interviews and observations, scribes, providers, and administrators offered descriptions of characteristics they felt scribes should exhibit and key knowledge a scribe should possess. One of the most commonly occurring characteristics was excellent communication. An ideal scribe can communicate openly with the provider and “ask a few questions” to clarify things. One scribe said that, “The more communication you have with your provider... the better it is for everyone.” The same scribe further went on to state that scribes are, “in a healthcare system and communication is the only way to get things done right. You can’t expect people just to read your mind.” With the unique dynamic between a provider and the scribe, the scribes need to be willing to communicate their needs. As a
provider explained, “one of the hallmarks of a great scribe too is speaking up for yourself. We are moving so fast in clinic that I feel like a good scribe will [ask questions or]...stop me so they can fill in the note.” Scribes also need to be able to handle criticism and feedback too. As one scribe stated, “Your provider is going to give you criticisms, and we talk about ways to kind of turn that into a positive rather than negative.”

It is important for scribes to be flexible/adaptable as well. Many of the scribes we interviewed and observed worked with multiple providers and in multiple clinics/specialties; they had to adapt quickly to the provider’s preferences and department differences. One administrator said that scribes “aren’t the one that’s leading the pace or direction of this investigation. [They] are along for the ride and sort of adjusting the entire time.” Because they have to adapt to situations quickly, being able to handle pressure is critical. In reference to one urgent care clinic, a scribe stated that, “getting flustered, easily, isn’t going to work well in this atmosphere.”

An ideal scribe should have some sort of medical/healthcare background (e.g., current pre-medical student, prior work as another healthcare professional [MA, CNA]). Due to the fast-paced environment of scribing, knowledge of medical terminology (including anatomy and physiology) was mentioned multiple times as something scribes need to know well. Otherwise, a scribe might be inefficient if they struggle with terminology.

Professionalism, not only in appearance, but also in interactions towards patients and providers is key for scribes to be successful. As one scribe mentioned, a scribe needs to be “a fly on the wall, because [patients] are going through hard things and it’s hard enough to talk about [it] to one person, let alone one person and their helper in the corner...so just being respectful.” A provider told us she “wanted the scribe to be a fly on the wall, to melt into the corner, to not be a part of the conversation, to be an observer.” One site uses remote scribes to achieve this idea of “fly on the wall.” The scribes talk to the providers through audio only, with no video recording, which allows for the patients and providers to talk freely without the scribe physically present.

Scribes need to be able to type quickly with accurate spelling and grammar, and possess strong technology/computer skills (e.g., knowing how to navigate EHR). Scribes have been called the provider’s, “peripheral brain” because, “The scribe is [their] go-between the medical information being recorded and the scribe is also interacting with the [provider in] a way so [they] can interact with the patient in the best way possible.”

A scribe needs to be intelligent and a “quick learner.” One provider mentioned that pre-professional scribes “are just sponges, and they are so smart and so good at learning.”

Lastly, scribes, especially pre-professional scribes, must have a passion for medicine. As one scribe noted, scribes need to “be interested in medicine... that doesn’t mean being pre-med or pre-PA or whatever it may be, just having a genuine interest in learning everything about medicine.” A few people we interviewed and observed stated that having

---

**Figure 2.** Subthemes of the scribe-provider interaction theme.
a passion for medicine ties in to motivation. One provider said, “I think a scribe who didn’t have an interest in medicine, I think, for obvious reasons, wouldn’t be motivated to learn the [medical] lingo necessarily.”

One scribe told us that her “motivation and interest in one day being a doctor” helps her be a great scribe. Another scribe said that the most important thing about being a scribe is that “you need to be motivated and actually enjoy medicine.” This scribe further went on to say that when he became a scribe he told himself that he wanted to become a PA “so everything that [he] was learning [he] was retaining.”

Characteristics of a Good Provider

Scribes, providers, and administrators often listed characteristics they felt providers/scribe users should have. Like an ideal scribe, a good provider is able to communicate effectively. One scribe mentioned that, “The more that a physician’s willing to communicate, the more smoothly that the day goes.” Another scribe noted, “It can get a little frustrating when they’re not communicating with you, or when they’re just doing their thing, and they pretend you’re not there.”

The scribes also want to work with providers who are willing to clarify exam findings and are clear about what they want in their note. One administrator told us that “the scribe’s role is purely… to do documentation under explicit direction and so an ideal provider is someone who realizes this and is very vocal and is able to think out loud.” A few scribes mentioned that they like it when a provider says the exam findings aloud during the exam, which allows them to be more efficient with their notes.

Staying organized is another key characteristic of a good provider; a scribe said that if the providers “are disorganized... it puts [them] behind because [they] cannot obtain the information that [the scribe] need[s] from them.”

One administrator said scribes “grow based on their feedback” from physicians, so scribes also want a provider who is willing to provide them with feedback, even if it is negative, so they can improve.

One of the most reoccurring characteristics of a good scribe user is one who is willing to teach. When talking about trying to find providers to use scribes, one administrator said that they “look for that doctor that has that teaching heart.” During an observation, one researcher noted that one provider was a “natural teacher, so he love[d] answering [the scribe’s questions] and explaining medicine to [the scribe].” A scribe stated that he thought the providers “[knew] scribing [was] not always the most exciting job. And so they [did] their best to help make it educational for [the scribes] and make it a good experience.”

Another scribe said that “being willing to teach your scribe [is important]. Like, we can only learn so much on our own. We can do all this research at home; but if you talk us through things, we’re not going to forget it, you know, when we’re seeing the flu or strep throat. And, you’re like, okay, this is what’s going to be. This is how we’re going to treat this. These are the generic symptoms for this. If they take the time, I feel like they put out what they put in. So, if they want to be our teacher, they’re going to get better charts out of it.”

A good provider must be willing “to give up a certain amount of control” when it comes to specific word usage in a note. One administrator said that, “A lot of [the providers] have a hard time [letting go of control of the note] and they need every word to be literally what they would have written.” They need to be able to “be comfortable with some degree of variation in the phrasing” of sentences.

One provider said that “some [providers he] knows are so meticulous and so detail oriented that everything has to be perfect... [he] thinks that people have to be flexible” when it comes to the note. The providers must review the scribes’ notes, but letting go of small structural changes or latitude changes in phraseology could allow the providers to review charts quickly.

Finally, a provider must have patience “because sometimes [the providers] forget that it is a human working the computer” and because “not every scribe is perfect on their first shift.” Scribes are an investment; as one provider said, “the more we invest in them the faster they learn and the better they get. So, it’s really on us to improve them.”

Provider Variability

Each provider is unique. As one researcher noted during observations, “the scribes usually said there were a variety of personalities and some were easier to deal with than others, but they like the variety.” This was the case for most
of the sites. At every site, we observed that scribes had profiles that were specific to each provider and included provider preferences, templates, smart phrases/macros, general information on the specific clinical workflow, and common terminology. It is key for the scribes to be able to adapt to the provider’s variability.

One scribe summarized this: “Every provider is different and knowing the preferences before you walk in, you will have a better shift. If you walk in not knowing who you are working with or the preferences, I think it is going to be a rough shift... I have to come in maybe 15 minutes early and set up more macros than I would normally, or ask them more questions or be ready to type paragraphs on paragraphs on the HPI because they are so in-depth, versus other ones that are more laid back.” Maintaining profiles with provider preferences was especially useful for scribes who worked across specialties with multiple providers throughout any given week. Because providers have different preferences in their notes, a few sites have tried to improve this process as much as possible by creating a standardized note template for scribes to use across all providers.

Quality of Scribe-Provider Relationship

The scribe and provider have a unique relationship; as summarized by a scribe, “there are very few people in the clinic, if anybody, who spends as much time with the provider as the scribe does.” Because of the amount of time spent together, setting up a functional relationship between the scribe and provider is critical. The providers want to be “able to bond with [their] scribes” and the scribes want that relationship too. The scribe and provider must have a good rapport and work together as a team, despite the power dynamic. An administrator stated, “of course, there’s a hierarchy here but also, [the providers] are relying on [the scribes].” Another provider stated, “It is crucial to that relationship that the physician view the scribe as someone who’s a key member of the team.” As one provider noted, having a stronger overall relationship with his scribes led to a higher “quality of note that results as a consequence.”

Trust is a key component to this relationship dynamic as well. One administrator summarized, “if you don’t have that trust set up, you are [out of luck]. Because that is the foundation of scribing.” Typically, the longer a scribe is with a provider, the higher the level of trust can develop. Almost like a dating website, matching the scribes and providers is a key component to forming a high quality relationship. Scribe companies must determine what the provider’s personality is as well as the department’s culture, and try to find a scribe who will mesh well with the entire healthcare team. When the scribe-provider relationship is well formed, one provider noted that “we leave happy [at the end of the day]. We leave with a smile on [our] face.”

An administrator provided an example of how one scribe had been with the same provider for the past five years and the provider “loves her. She’s part of the family. [The provider] is not going to quit. He’s going to work forever”. If a solid relationship formed, the scribe can often predict the provider’s next move and anticipate what questions the provider will ask their patients. One provider told us that the scribes “are not transcriptionists at all... they’re pulling out things and dropping down things, and managing things, and gathering information from other sources for us. They’re doing stuff that I don’t feel competent to do. And I always tell them at the end of the day, thanks... we both do what we do best, and we, both complement each other.”

Negative Side of Scribe-Provider Relationship

While there are many positives to the scribe and provider relationship, during our site visits we also noted potential negative issues. One issue that was identified in multiple sites was the lack of provider revisions of scribed documentation prior to sign off. One administrator stated that she “would guess a lot of the doctors, once they feel really comfortable with a scribe they do a quick review if they are being good [as in, being thorough]. But some of them may just sign and that’s where you get into the risk.” Another administrator mentioned that he “thinks that [providers] get kind of lax when they have had a scribe for a while... [and] read through [the note] but maybe just a lot quicker.”

A different administrator mentioned that she saw scribes “writing pretty junky notes... and the doctors were just signing them. Not reading, just sign, sign, sign, sign.” Another provider stated that “if I know my scribe is accurate almost all the time, then I can more quickly review the note and sign it off.” Most of the providers are aware of the importance of reviewing, though. As one provider stated, “it is our responsibility ultimately to edit that note.”

Despite efforts to match scribe and providers carefully, mismatches of clashing personalities sometimes occurred. For example, two administrators told us about a mismatch between the scribe and provider based on political preferences. One provider stated that, “Sometimes the scribe’s personality doesn’t work out and it does not mean they’re a bad scribe or there’s something done wrong.” Mismatches were also common because the provider and scribe had
communication issues. One scribe talked about how they “rely on [the provider] to communicate... ‘cause if they’re not then it’s not gonna be a good work environment for either of [them].”

Departmental mismatches occurred as well. As one provider stated, “There’s some scribes that’ll come to us from another department where it’s an endocrinology visit and that person spends an hour-and-a-half with each individual patient and they see ten patients or whatever a day. That person has a hard time getting fast at Urgent Care type visits because you’re seeing people fast.” Mismatches also occurred because the providers lacked patience with their scribes who were new/inexperienced or slower. A few of the organizations try to alleviate mismatches between the scribe and provider by moving scribes to different departments that best match their personality and workflow.

The provider’s overreliance on scribes is another negative aspect that can lead to loss of productivity. Providers can become over-dependent on their scribes to write notes and navigate the EHR. Another provider mentioned the cognitive impact scribes have. He told us that “when he writes or types [the notes] himself, it goes into his brain and memory better. He finds himself asking the scribe to look things up that normally he would have remembered [if he had written the note himself].”

Another common negative was failing to make the scribe feel like part of the clinical team. Despite the efforts, the scribes sometimes felt like they were at the “bottom of the totem pole” when it came to working with the providers. While scribes are supposed to be part of the team with the provider, sometimes the providers asked the scribes to do tasks beyond their scope and the scribes complied. One administrator said that he has seen smaller clinics where “the providers are having the scribes log in as them and sign orders.”

Boundary issues may also occur. One administrator said that “scribes are bright, enthusiastic young people and they form personal relationships with the department and the physicians. Sometimes there are boundary issues with scribes.” This administrator said she has seen “things like scribes housesitting for [providers], scribes running errands for [providers], scribes doing nice things for doctors in expectation that will give them a better shot at a good letter [of recommendation].” With the power dynamic, it is the organization and provider’s responsibility to be clear and set boundaries.

Evaluation and Supervision of Scribes

An overarching theme we observed was the lack of standardization of evaluation and supervision of scribes. The evaluation and supervision of scribes seemed to vary not only between sites but also between individual providers within the same organization. A few of the scribe-provider pairs reviewed the notes after each patient, others reviewed notes together at the end of the day, and others providers reviewed the scribe’s notes on their own time away from the scribe. Each provider varied in the amount of feedback offered to the scribe. Occasionally providers offered regular feedback, which seemed to be valued by the scribes. However, not all providers offered much feedback. When this lack of feedback occurred, a couple of the scribes said that they learned to look back at past notes and see where changes were made, then they could adjust their notes in the future for that provider and learn from their mistakes. The scribes, however, do not have the clinical/medical background that the providers have to understand why these changes were made.

Trust plays a large role in the time providers spend evaluating scribes. As the provider’s trust increases, the amount of time reviewing notes and evaluating scribe performance decreases. One provider told us that “you see, you know, 25-30 patients and that, you know, three or four shifts a week, I can’t pore through everything. So, I pretty much trust my scribe on the history, the physical, the review of systems.” A scribe mentioned that “over time, providers start to trust you and know what you’re writing. And, obviously, I didn’t go to med school for 12 years, so I could have some errors in them, in my notes that I guess could be reviewed a little bit more in-depth... I guess the provider just kind of assumes that you know what you’re writing.”

The processes for scribe evaluation varied between study sites as well. Several of the sites had an informal process for evaluating a scribe’s performance. Typically, in these cases, the scribe management team would observe the scribe and offer remedial training if a provider had complained. The evaluation was more reactionary than proactive. Other sites had a more proactive approach to evaluating scribes. These sites had quarterly/monthly formal audits that took place where the scribe management team would audit a random selection of the scribes’ notes using specific grading criteria (e.g., did the chart get closed in a timely manner, did the scribe add their attestation). The scribe management team allowed the providers to “get a chance to evaluate the quality of scribe documentation as a part of the audit process.”
One of the scribes who audits the organization’s charts said that she “sends surveys to the providers each month, and [they’ll] rate them on... overall attitude, efficiency in charting, and so that’s their opportunity to... voice their concerns.” At the end of the quarter/month, the scribes would receive a document “about what [they] did right...[and] what [they] did wrong.” One scribe said that these monthly audits were “the way that most people learn.”

Discussion

This study is unique in its analysis of the scribe-provider interaction, and identification of components that make for a strong scribe and provider relationship. While there were overarching themes, we learned that there is great variability in what it takes for the scribe and provider to have a successful relationship. Every site did things in a slightly different way from the others; there was no observed standardization in how the scribe-provider interaction took place. Seeing the extent of variability between individual provider’s preferences and how organizations addressed this issue was fascinating. Some standardized providers’ notes as much as possible while other organizations asked scribes to keep track of different provider preferences.

This study found similar results to Yan and colleagues⁴; we saw that trust and communication are important characteristics for both scribes and providers. Furthermore, we also saw that providers need to be willing to teach their scribes and scribes need to have the necessary medical knowledge to write a note. The current study also expands on Yan and colleagues’ research. Their research specifically targeted primary care; we included urgent care and emergency departments as well as primary care in our study to show a more global picture of the scribe-provider interaction. We also observed the camaraderie between the providers and scribes noted in Sattler and colleagues’ research⁷. Their research focused on primary care providers, where our study branched beyond primary care. They also had a small sample size that focused only on the physicians’ responses and we conducted interviews with 81 individuals (scribes, providers, and administrators).

The current study does have limitations. First, since we saw wide variation in scope and use of scribes in clinical practice during our site visit, we suspect that the results of this study cannot be generalized since we expect the degree of variability to be widespread in all areas of scribe use. Second, all of the sites we visited volunteered to participate in the study, which could skew data or allow for bias. It would be beneficial if future studies investigated what the best ergonomics are for making the scribe-provider interaction more efficient. Through observations, we noted that the layout of the exam rooms could sometimes hinder how well a scribe could document the patient-provider interaction and there is very little research on ergonomics in regards to the scribe-provider relationship. Finally, determining best practices for scribes and providers/scribe users is key for making the relationship function. Future research should determine the best practices necessary to optimize this domain.

Conclusion

If scribes are to efficiently and safely assist providers in generating documentation using the EHR, the relationship between scribe and provider pairs need to be a constructive one. The scribe and provider need to be matched well in order for this relationship to blossom. The providers must supervise and evaluate their scribes’ performance as well. It is just as important that providers learn to be good scribe users as it is that scribes learn to do their job well. Providers who use scribes need training about how to use scribes most effectively. An important aspect of using them effectively is to continuously and deliberately promote positive relationships with them.

Abstract

Logistic regression (LR) is widely used in clinical prediction because it is simple to deploy and easy to interpret. Nevertheless, being a linear model, LR has limited expressive capability and often has unsatisfactory performance. Generalized additive models (GAMs) extend the linear model with transformations of input features, though feature interaction is not allowed for all GAM variants. In this paper, we propose a factored generalized additive model (F-GAM) to preserve the model interpretability for targeted features while allowing a rich model for interaction with features fixed within the individual. We evaluate F-GAM on prediction of two targets, postoperative acute kidney injury and acute respiratory failure, from a single-center database. We find superior model performance of F-GAM in terms of AUPRC and AUROC compared to several other GAM implementations, random forests, support vector machine, and a deep neural network. We find that the model interpretability is good with results with high face validity.

Introduction

Patients undergoing surgery and anesthesia experience external stresses that place them at risk for numerous complications, including acute kidney injury and acute respiratory failure. One of the roles of the anesthesia clinician is to regulate the patient’s physiology to minimize these risks. Logistic regression-based models for predicting postoperative acute kidney injury1–3 and acute respiratory failure4–6 have been developed by multiple groups. Linear models offer a high degree of transparency regarding which features drive the output, but they are inherently limited in their flexibility, which limits their predictive accuracy. Various machine learning (ML) models have been proposed to solve these clinical prediction tasks with greater accuracy. Classifiers for acute kidney injury have been described in postoperative7 and non-surgical hospitalized patients8, 9. Although these ML models outperform logistic regression, they are not frequently used in clinical practice in part due to their lack of interpretability.

An interpretable model must provide predictions that are both accountable and actionable. An accountable model provides information about which features are contributing to the output prediction. This information can include feature importance and feature interactions. An actionable model provides guidance regarding how to modify the input features so that the post-intervention features will lead to the desired output.

Interpreting ML models is an extremely active field10–12. Incorporating interpretability constraints directly into the structure of the model and using post-hoc interpretation methods are two of the main directions13. Most existing work focuses on accountability. Che et al14 transfer the DNN’s knowledge to gradient boosting trees (GBT) using knowledge distillation and interpret feature importance through measures of variable importance designed for GBT. Another work15 visualizes the region of interest through class activation maps. Ge et al.16 feed features extracted from recurrent neural networks into a logistic regression model for prediction, where importance of the transformed features can be directly read off. Neural networks with attention-like mechanisms are also popular to visualize the features which contribute the most to a classifier for a particular case11. A smaller number of techniques address the actionability requirement. An early work17 proposed an integer linear programming method to extract actionable knowledge from a random forest. Gardner et al. proposed a label changing method by searching semantically meaningful changes to an image under its manifold space18. As far as we know, little work has been done on addressing accountability and actionability at the same time in the clinical area.

An extension to generalized linear models, generalized additive models (GAMs), can address accountability and actionability simultaneously. Examples includes LR, density based logistic regression19 (DLR), generalized additive
neural networks (GANN), and deep embedding logistic regression (DELR). LR assumes a fixed (up to a parameter) monotonic relationship between each feature and the outcome probability, limiting its flexibility and predictive performance. GAMs loosen these assumptions by inferring a transformation of the inputs with the full flexibility of non-parametric or parametric methods. For example, DLR transforms each feature through a kernel estimator, and our recently proposed DELR performs feature-wise nonlinear transformation using neural networks. GANN, which used a single hidden layer, can be treated as a special case of DELR, which used multi-layer DNNs. Despite the increased flexibility, with suitable constraints we can extract accountability and actionability from GAMs. Given an input example, GAMs allow us to calculate the contribution of each feature to that example’s predicted value. Feature contribution curves can be drawn to provide actionable directions on the optimal change and magnitude of improvement for each numeric feature. However, only when all the features are conditionally independent (given the label) can GAMs model the true distribution of data. Feature interactions are not allowed in GAMs, restricting their performance in dealing with complex datasets. In addition, GAMs have the undesirable property of treating static and time-varying features equally. For example, demographic characteristics such as age, gender, and height are not possible to change. On the other hand, it is possible to deliver interventions that modify a patient’s vital signs during surgery.

To address these problems, we propose a variation of GAMs that splits features into time-varying (or targeted) features and static features. F-GAM fits a context-based scaling for each time-varying factor based on the static factors, substantially increasing its flexibility compared to models which require the effect of a feature to be the same for all examples, but retains the ability to derive personalized feature-effect curves. F-GAM retains the full flexibility of a DNN for the effect of static features and DNN-based flexibility for the transformation of time-varying factors. We implement F-GAM as an end-to-end trained model with minimal hyper-parameters. In extreme cases where there are no static features available, F-GAM reduces to DELR. If there are no time-varying features, F-GAM becomes a DNN. We empirically validate the accuracy performance of F-GAM with existing ML models, including other GAMs and demonstrate the interpretability of F-GAM through a case study on predicting acute kidney injury.

**Background and Notation**

**Notation**

Operating room data contains both preoperative data such as demographic information and intraoperative data such as vital signs and medications administered. Given a patient \( i \), pre-op data \( x_i^S \in \mathcal{R}^{D_1} \) collected before the surgery are treated as static feature vectors while intra-op data represented as \( x_i^{TV} \in \mathcal{R}^{D_2} \) can be modified in real time. Together, we use \( x_i = [x_i^S, x_i^{TV}] \in \mathcal{R}^D \) to denote input features and \( y_i \in \{0, 1\} \) to represent the binary outcomes.

Our examples are binary classification, but the extension to multi-class classification is straightforward with a final softmax transformation and appropriate loss function.

**Generalized Additive Models**

A generalized additive model (GAM) is an ensemble of \( D \) univariate functions, where \( D \) is the number of features. We use \( x_j \) and \( y \) to denote the \( j \)th dimension of input \( x \) and class label, respectively. The output of each univariate function, denoted as \( f_i(x_j) \) is a real number. We can write the GAM structure as

\[
g(E(y)) = \beta_0 + f_1(x_1) + f_2(x_2) + \cdots + f_D(x_D),
\]

where the function \( g \) is the link function, bounding the range of right hand side value of Eq.1, and \( E(y) \) is the expected value of the label conditional on \( x \). Constraints on \( f_k \) such as smoothness or degrees of freedom regularize the estimation problem to decrease out-of-sample loss. With a little abuse of notations, we use \( F(x) \) to denote \( E(y|x) \) throughout this paper for ease of presentation. By inverting the link function, the GAM has the form,

\[
F(x) = g^{-1}[\beta_0 + f_1(x_1) + f_2(x_2) + \cdots + f_D(x_D)],
\]

where the model output is controlled by the sum of each univariate function. GAM assumes all the features of input \( x_i \) are making contributions independently. Interpreting a GAM is straightforward as the marginal impact of a specific feature does not rely on the rest of features; we are able to know the importance of a feature by plotting its corresponding univariate function or calculating its variance over the sample. Actionable changes can be made based the shape of each \( f_k(x_k) \).
Figure 1: Overall architecture of F-GAM. Each circle denotes a scalar. Upper left part is feature mapping module. Every time-varying feature is fed to its own deep and narrow neural network (DNNN) separately. Weight learning module, which is shown in upper right part takes static features as input and calculates feature weights. Note that bias learning module is not plotted in this figure for simplicity.

Logistic regression is a special case of GAM by choosing logit function \( g(x) = \ln \frac{x}{1-x} \) as the link function and setting \( f_k(x_k) \) to be \( w_k x_k \) yielding

\[
F(x) = \sigma(w_0 + w_1 x_1 + w_2 x_2 + \cdots + w_D x_D),
\]

(3)

where the sigmoid function \( \sigma(x) = \frac{1}{1+\exp(-x)} \) is the inverse form of the logit function. LR assumes a monotonic relationship between the final output \( F(x) \) and input features due to the linear function \( f_k \). However, this condition doesn’t hold in many cases, such as the relationship between ICU transfer rate and age.

**Methods - Model Algorithm**

In this section, we propose a factored generalized additive model (F-GAM) framework in which interactions between time-varying features and static features are allowed. The overall model has the form

\[
F(x) = \sigma \left[ \sum_{t=1}^{D_2} w_t(x^S) f_t(x^TV) + w_0(x^S) \right]
\]

(4)

In F-GAM, \( w_t \) is no longer a constant weight parameter, but the output of a DNN that accepts the static feature vector as input and estimates the weight of \( t \)th time-varying feature for each case. The feature-wise nonlinear transformation functions \( f_t, t = 1, 2, \ldots D_2 \) are jointly estimated. \( w_0 \) is a bias / intercept term that also depends only on the static features. In our operative examples, \( w_0 \) represents the estimate of risk before any intra-operative data becomes available as long as the input features have been appropriately centered.

F-GAM can be decomposed into four different modules: time-varying feature mapping module, feature weights learning module, bias term learning module and logistic/softmax regression module. We display the F-GAM architecture in Figure 1.

**Time-varying feature mapping module**

In traditional GAMS, the ability of the univariate function \( f_k \) to approximate the unknown transformation plays a crucial role in model performance. We choose to use deep and narrow neural networks (DNNN)\(^2\) for the nonlinear feature embedding. Being a universal approximator, a DNNN is able learn complex patterns automatically. The general tools for regularizing neural networks are immediately available to control overfitting without the difficult-to-understand
smoothness or degree-of-freedom constraints of other GAM transformations. Each time-varying feature is fed into a DNNN with distinct parameters; however, several hyperparameters (depth, width, dropout, training stopping time) are shared across $t$ to avoid having to search over a large hyperparameter space. The shared architectural parameters also tend to prevent over-fitting of just a few features (data not shown). A learnable look-up table (categorical embedding) is attached before a DNN for categorical features. In our examples, all time-varying features are quantitative or ordinal rather than categorical.

**Feature weights learning module**

Rather than applying fixed weights for the input features, we use nonlinear functions $w_t$ to adjust the feature weight dynamically. The nonlinear function should have the following two properties. First, the nonlinear function should not increase the number of parameters dramatically. Second, the nonlinear function should be able to handle both numerical features and categorical ones. Thus, we choose to use deep neural networks as the nonlinear functions. Rather than assigning each $w_t$ a standalone DNN as we did for $f_t$, all the weight-learning functions are estimated with a common DNN except the last layer. With this multi-task setup, we are able to exploit the shared structure of the data to reduce the effective number of parameters. Joint predictions of $w_t$ also allow the module to dynamically choose between potentially correlated $x_t^M$ to emphasize, meaning that $w_t$ represents both the relevance and precision of $f_t$ in the given context. For the second property, we use categorical embedding. When there are no static features, $w_t$ is a constant per time-varying feature and F-GAM reduces to DELR. That is to say, DELR is a special case of our model.

**Bias term learning module**

In order to increase expressiveness of the final model, we add a bias term based on the static features. Again, we use a DNN to model the bias term. This DNN is appended to the penultimate layer of the feature weights module to reduce redundancy. When there are no time-varying features, only the bias term controls the final output. In this case, F-GAM simplifies to a deep neural network.

**Logistic/softmax regression module**

With all the transformed features and weights ready, we apply the dot product operation to the time-varying feature mapping and the learned weights. After adding the bias term $w_0$, a sigmoid function $\sigma$ is used to model the positive rate given input data.

Our F-GAM is trained end-to-end by minimizing the cross entropy loss between true label distribution and prediction distribution. We also apply weight decay and an early stopping strategy to avoid over-fitting. The code is available at https://github.com/nostringattached/FGAM.

**Methods - Experiments**

**Data Sources**

Models were trained and validated using a dataset obtained from a single academic medical center (Barnes Jewish Hospital, St. Louis, Missouri). All adult patients who received surgery with anesthesia between June 2012 and August 2016 were eligible for inclusion. Due to the limited incidence of acute respiratory failure among patients who were not admitted to the intensive care unit (ICU) after surgery, prediction of this complication was limited to patients admitted to the ICU after surgery.

Acute kidney injury and acute respiratory failure were the two complications that were used as targets in the experimental models. Per Kidney Disease: Improving Global Outcomes (KDIGO) criteria, acute kidney injury was defined as an increase in the serum creatinine value by $>0.3$ mg/dL or $>50\%$ within 48 hours, compared to the preoperative value\(^23\). Acute kidney injury was undefined if the patient was receiving dialysis before surgery. The preoperative creatinine was the most recent value available before surgery, but no more than 30 days before surgery. Acute respiratory failure was defined as mechanical ventilation for $>48$ hours after surgery or reintubation within 48 hours. Acute respiratory failure was undefined if the patient was receiving mechanical ventilation before surgery, if the patient had a second surgery within 48 hours, or if the patient died within 48 hours.

Baseline demographic characteristics, comorbid health conditions, and preoperative laboratory values were retrieved
from the electronic medical record. The total doses of commonly used medications (including intravenous fluids, blood pressure-raising and -lowering agents, sedatives, pain medications, and nephrotoxic antibiotics) were also retrieved. The full list of features included in the analysis is shown in Table 1.

Table 1: Features included in the model.

| Demographic Characteristics | Age, Height, Weight, Ideal body weight, Body mass index, Sex, Race, Charlson Comorbidity Index, Functional capacity, American Society of Anesthesiologists physical status, Surgery type |
| Comorbid Conditions | Hypertension, Coronary artery disease, Prior myocardial infarction, Congestive heart failure, Diastolic function, Left ventricular ejection fraction, Aortic stenosis, Atrial fibrillation, Pacemaker, Prior stroke, Peripheral artery disease, Deep venous thrombosis, Pulmonary embolism, Diabetes mellitus, Outpatient insulin use, Chronic kidney disease, Ongoing dialysis, Pulmonary hypertension, Chronic obstructive pulmonary disease, Asthma, Obstructive sleep apnea, Cirrhosis, Cancer, Gastro-esophageal reflux, Anemia, Coombs positive, Dementia, Ever-smoker |
| Preop Vital Signs | Systolic blood pressure, Diastolic blood pressure, Pulse oximeter, Heart rate |
| Preop Labs | Albumin, Alanine phosphatase, Creatinine, Glucose, Hematocrit, Partial thromboplastin time, Potassium, Sodium, Urea Nitrogen, White blood cells |
| Intraoperative Time Series | Mean arterial pressure, Systolic blood pressure, Diastolic blood pressure, Heart rate, Pulse oximeter, Temperature, Respiratory rate, Tidal volume, Peak inspiratory pressure, Positive end-expiratory pressure, Fraction inspired oxygen, End-tidal carbon dioxide, End-tidal anesthetic concentration |
| Intraoperative Meds and Fluids | Albumin, Amiodarone, Crystalloid (lactated ringers + normal saline), Dobutamine, Ephedrine, Epinephrine, Fentanyl, Furosemide, Gentamicin, Hydromorphine, Midazolam, Nicardipine, Norepinephrine, Packed red blood cells, Phenylephrine, Propofol, Remifentanil, Vancomycin, Vasopressin, Other blood products |

For intraoperative time series features, summary measures were derived. For each feature, the mean, standard deviation, maximum, and minimum over the entire surgery were calculated. The maximum pulse oximeter reading was omitted due to ceiling effects, while minimum peak inspiratory pressure and minimum tidal volume were omitted due to expected lack of clinical significance. In addition, the fraction of surgery with extreme values of certain parameters were also calculated, using multiple cutoff values. These included duration of low mean arterial pressure (<55, <60, or <65 mmHg), high heart rate (>100, >110, or >120 beats per min), low heart rate (<60, <55, or <50 beats per min), low temperature (<36 or <35.5 °C), low pulse oximeter (<90 or <85%), high exhaled carbon dioxide (>50 mmHg), low exhaled carbon dioxide (<30 mmHg), high peak inspiratory pressure (>30 mmHg), and high tidal volume (>10 mL per kg). Lung compliance was also calculated as final tidal volume divided by final peak inspiratory pressure.

Experimental Technique

For each of the two target outcomes, F-GAM was compared to four baseline models (decision tree [DT], random forest [RF], support vector machine [SVM], and deep neural network [DNN]) and to three GAMs (logistic regression [LR], gradient boosting decision stumps [GBDS] and deep embedding logistic regression [DELR]). Note that density based logistic regression (DLR) was not included as it did not finish training in 24 hours. Each model was trained using a 70% random sample of the dataset. 10% of the dataset was selected as a validation set for hyper-parameter tuning and performance was tested on the remaining 20% of the dataset. Model performance was quantified using area under the receiver operating characteristic curve (AUROC) and area under the precision-recall curve (AUPRC). We calculate two-sided 95% confidence intervals for each measure using the statistical analysis method given by Hanley and McNeil.

Results

The dataset included 111,890 patients. Of these patients, 5,018 were excluded from the acute kidney injury model because they were receiving dialysis before surgery or because no postoperative creatinine value was available. Of the remaining 106,872 patients, 6,472 (6.1%) experienced acute kidney injury. Of the original 111,890 patients, 89,688 were excluded from the acute respiratory failure model because they were not admitted to the intensive care unit, while 6,578 were excluded due to preoperative mechanical ventilation or one of the other exclusion criteria. Of the remaining 15,624 patients, 489 (3.1%) experienced acute respiratory failure.

Performance of the models is shown in Table 2, while the receiver-operating characteristic and precision-recall curves are shown in Figure 2. For both outcomes, F-GAM provided the highest AUROC and the highest AUPRC. DT and RF are excluded from Figure 2 for readability purposes.

Figure 3 demonstrates how the contribution $w_t(x^S)f_t(x_t^{TV})$ to the predicted risk of acute kidney injury changes at different values $x_t^{TV}$ of four representative time-varying features in two randomly selected patients. Each panel assumes that all other time-varying features remain constant. Points that are higher on the vertical axis represent a larger contribution to the predicted probability.

Discussion

Our experimental results demonstrate that F-GAM outperforms other methods with respect to accuracy on this task while also offering the benefits of accountability and actionability. All of the models tended to perform better for kidney injury than for respiratory failure, which is likely related to the higher incidence of kidney injury in our dataset and the larger sample size used for this outcome (106,872 versus 15,624). The pure deep neural network didn’t perform as well in our dataset, likely because it is very easy to overfit despite traditional regularization methods such as learning rate decay and weight decay being applied. The random forest model had performance characteristics that were most similar to F-GAM, but F-GAM would be preferable over the random forest because F-GAM offers interpretability, while the random forest does not.
Figure 2: ROC curve and precision recall curve (PRC) of different models predicting acute kidney injury and acute respiratory failure. LR = logistic regression, SVM = support vector machine, GBDS = gradient boosting decision stumps, DNN = deep neural network, DELR = deep embedding logistic regression, F-GAM = factored generalized additive model.

Figure 3 demonstrates how predictions generated by F-GAM can be used to guide intraoperative management. For example, the lower-left panel shows that an increase in maximum heart rate from 100 bpm to 110 bpm appears to be associated with an increased risk for acute kidney injury, because the graph has a steep positive slope in this region. On the other hand, an increase from 80 bpm to 90 bpm is not associated with increased risk, because the graph has a flat slope in this region. Multiplication times the scalar $w(x^3)$ allows the curve to expand or shrink vertically depending on the baseline characteristics and other health conditions of an individual patient. Thus an increase in maximum heart rate from 100 bpm to 110 bpm appears to be associated with increased risk both in a healthy patient (blue curve) and in a very ill patient (orange curve), but the increase in risk (i.e., the slope) is much greater for the very ill patient. This observation fits the anesthesia clinician’s intuition.

The anesthesia clinician should not assume that the associations reported by this model indicate that elevated heart rate causes acute kidney injury. Nor should the clinician assume that blindly giving a medication that lowers the heart rate will decrease the patient’s risk for acute kidney injury. On the contrary, increased heart rate is often a sign of an underlying problem, such as dehydration. The underlying problem, not the fast heart rate, is what increases the risk for acute kidney injury. It is the clinician’s job to identify the underlying problem and correct it.

The upper-left panel provides another example of a scenario where the reported correlation should not be assumed.
Figure 3: Contribution of each feature to the predicted probability of acute kidney injury as a function of feature value. Each panel assumes that all other dynamic features are held constant. The blue curve shows the feature contributions in a 57-year-old healthy female (who ultimately did not have AKI), while the orange curve shows the feature contributions in a 49-year-old female with hypertension, chronic kidney disease, and cirrhosis of the liver (who did have AKI).

to indicate causation. The graph shows a negative slope as the cumulative dose of phenylephrine (a medication that raises blood pressure) increases from 0 to 100 mcg/kg. This suggests that administration of low doses of phenylephrine might decrease the risk of acute kidney injury (if all other features remain constant). This example demonstrates one of the limitations of any factorized model structure; it is unlikely that large doses of phenylephrine decrease the risk of acute kidney injury in and of itself, but it is well supported in the anesthesia literature that untreated low blood pressure increases acute kidney injury risk. Additionally, zero or very low doses of phenylephrine (a weaker first line drug) may represent immediate escalation to stronger vasopressor such as norephinephrine, which increases risk.

In regions where the curve is relatively flat, observing a different value for that feature will have minimal impact on the predicted probability of the target. This can be seen in the left portion of the upper-right panel. Static features (such as age) may also be important (and our model accounts for these effects through the presence of static features in the weights $w_t(x^S)$ and in the bias term), but these features by definition are non-modifiable and change neither when intraoperative problems occur nor when the problems are corrected.

When F-GAM predicts a high probability of an adverse outcome such as acute kidney injury, the time-varying features contributing the most to that prediction are those with the highest current values of $w_t(x^S)f_t(x^TV)$. Curves similar to those shown in Figure 3 can be shown to the clinicians in real time during surgery. When a clinician enters the room to provide assistance with a patient who triggered a high-risk alert, these curves can help the clinician quickly determine what features are important in this particular case. This saves time that would otherwise be spent reviewing all the vital signs and other data. In an environment with as much real-time data as an operating room, streamlining data review is a major advantage, particularly if the clinician coming to provide assistance is otherwise unfamiliar with the patient. Ideally, the clinician will identify the underlying diagnosis sooner and deliver treatment sooner, if treatment is
Conclusion

In this paper, we have described a novel Factored Generalized Additive Model (F-GAM) and demonstrated its use in predicting postoperative acute kidney injury and acute respiratory failure in a historical cohort of patients receiving surgery with anesthesia. F-GAM allows for interactions between static and time-varying input features while retaining the qualities of accountability and actionability. Our model outperformed baseline models and other GAMs in predicting both of the complications tested, and the graphical displays of risk indicated associations that have face validity to an anesthesia clinician. Next steps include application of this technique to other outcomes and prospective deployment of these models for prediction of complications.

Implementation of Real-Time Electronic Clinical Decision Support for Emergency Department Patients with Pneumonia Across a Healthcare System

Nathan C. Dean MD, Caroline G. Vines MD, Jenna Rubin RN, Dave S. Collingridge PhD, Mark Mankivsky, Raj Srivastava MD MPH, Barbara E. Jones MD, Kathryn G. Kuttler PhD, Missy Walker MD, Nathan Jenson DO, Brandon J. Webb MD, Todd L. Allen MD, Peter J. Haug MD

Abstract:
A real-time electronic CDS for pneumonia (ePNa) identifies possible pneumonia patients, measures severity and antimicrobial resistance risk, and then recommends disposition, antibiotics, and microbiology studies. Use is voluntary, and clinicians may modify treatment recommendations. ePNa was associated with lower mortality in emergency department (ED) patients versus usual care (Annals EM 66:511). We adapted ePNa for the Cerner EHR, and implemented it across Intermountain Healthcare EDs (Utah, USA) throughout 2018. We introduced ePNa through didactic, interactive presentations to ED clinicians; follow-up visits identified barriers and facilitators to use. Email reminded clinicians and answered questions. Hospital admitting clinicians encouraged ePNa use to smooth care transitions. Audit-and-feedback measured utilization, showing variations from best practice when ePNa and associated electronic order sets were not used. Use was initially low, but gradually increased especially at larger hospitals. A user-friendly interface, frequent reminders, audit-and-feedback, a user survey, a nurse educator, and local physician champions are additive towards implementation success.

Introduction/Background
Pneumonia is an acute infection of the lungs that fills alveoli with inflammatory cells and fluid, making it difficult to breathe, take in oxygen, and expel carbon dioxide. Pneumonia is the eighth leading cause of death in the United States, with more than six million cases annually, one million hospitalizations, and costs over 7 billion dollars for inpatient treatment alone. However, pneumonia care varies dramatically across healthcare providers and institutions. 

Pneumonia treatment is neither straightforward nor simple. When a patient is suspected of having pneumonia, clinicians must (1) assess symptoms and clinical findings and determine whether pneumonia is likely compared to another diagnosis, (2) identify the most appropriate site for treatment, (3) determine whether the bacteria causing the infection is likely to be resistant to commonly prescribed antibiotics, and then select the appropriate antibiotic. Correctly performing these tasks is critical for patient safety but given the complexity of these questions and the fundamental limitations of human decision-making, too often care varies from best practice. For example, without pneumonia clinical decision support (CDS), a provider might discharge a patient home on oral antibiotics instead of arranging for hospital admission to provide needed 24/7 nursing care, electronic monitoring and intravenous antibiotics. Studies have demonstrated variability in rates of hospital admission between different institutions, and two-fold variability in rate of hospitalization between physicians in a single emergency department (ED).

Well-established scientific guidelines exist for pneumonia treatment, but they are underused. Decades of research, quality improvement, and policy work led to the development, deployment, and validation of pneumonia treatment guidelines; most recently, the Infectious Disease Society of America (IDSA) and the American Thoracic Society (ATS) 2007 pneumonia treatment guideline. Guidelines are intended to help clinicians accurately diagnose pneumonia, determine the most appropriate treatment setting, and deliver the most effective treatment. The 2007 guideline was the primary knowledge base behind our real-time, electronic pneumonia CDS tool (ePNa).

Effectively deployed pneumonia CDS should standardize treatment and improve patient safety. Paper-based clinical decision support improves pneumonia treatment, but not enough to fully optimize it. Informed by the 1993 ATS pneumonia treatment guideline, our team deployed a pneumonia treatment CDS tool across Intermountain Healthcare (Utah, USA) starting in 1995 using paper-based flow charts and standardized written order sets. This intervention was associated with reduced mortality for pneumonia patients. Although the results showed effectiveness, the paper-based CDS pneumonia tool did not integrate well into clinical workflow, making widespread adoption difficult. Building on this early work, our team integrated guideline recommendations and best available evidence to develop
ePNa for the Intermountain Healthcare (Intermountain) electronic health record (EHR). ePNa extracts real-time data from the EHR to guide diagnosis, risk stratification, and treatment.

**Favorable Clinical Outcome Data**

ePNa operating in Intermountain’s legacy EHR was deployed in four Salt Lake Valley EDs beginning in May 2011, and during 2012 was used by ED physicians in 63% of pneumonia patients. We reported results of a quasi-experimental implementation study of ePNa in the four EDs compared with three similar Intermountain hospitals along Utah’s urban corridor that served as usual care, concurrent controls. All-cause, 30-day mortality among patients with community-acquired pneumonia where ePNa was available was significantly lower compared to three usual care hospitals (OR: 0.53; 95% CI: 0.28 to 0.99). Unadjusted mortality was 7.8% in usual care hospitals versus 5.2% in the ePNa hospitals. During a baseline year prior to ePNa implementation, mortality of pneumonia patients was similar between the 7 hospitals. Patients with higher severity illness were more likely to be admitted to ePNa hospitals for treatment versus control hospitals where more of those patients were sent home. Patients in the ePNa hospitals were more likely to receive guideline recommended antibiotics.

**Goals**

Based on the value of ePNa demonstrated in the four Salt Lake Valley EDs, the Intermountain Office of Research funded a large-scale effort to develop and deploy ePNa for Intermountain’s version of the newly installed Cerner EHR (iCentra) across all 22 Intermountain hospitals. The deployment of ePNa was designed and conducted in step-wise fashion according to a prespecified implementation trial (ClinicalTrials.gov Identifier: NCT03358342). Our goals were:

1. Adapt ePNa from its legacy version to function well in iCentra. To accomplish this, we wanted to learn from clinician user observations, conduct a formal survey, and incorporate their suggestions to continuously improve ePNa function.
2. Achieve 80% ED physician utilization of ePNa in patients diagnosed with pneumonia at Intermountain hospitals. We targeted 80% rather than 100% use because of diagnostic uncertainty during ED patient care, and to be realistic considering ePNa’s “opt in” design.
3. Identify effective methods of implementing CDS for EDs, including barriers and facilitators.
4. Measure processes of care and clinical outcomes associated with implementation of ePNa after trial completion.

**Description of ePNa**

ePNa is an innovative, real-time electronic CDS tool for pneumonia treatment in the ED. No comparable tools have been described in published literature. It is unique in having been deployed and utilized by ED clinicians with published favorable clinical outcome data.

ePNa logic incorporates the Five Rights Framework. (Table 1) ePNa integrates a pneumonia detection system with a management tool that delivers the right information to ED clinicians caring for patients with suspected pneumonia. Its detection system helps identify ED patients who might have pneumonia based on their presenting symptoms, physical exam, laboratory and radiographic findings. The clinical management system of ePNa evaluates each patient’s severity of illness to recommend (1) which patient disposition (outpatient care, inpatient ward care, or the intensive care unit) is the safest setting for pneumonia treatment, (2) which antibiotics should be prescribed, and (3) which microbiology studies (e.g., blood culture) are warranted. Patients with lower severity diseases treated at home have been shown to be more satisfied with their care and to return to work and/or usual activities more rapidly compared with similar severity patients admitted to the hospital. Direct cost of care is 20 times higher for comparable patients admitted to the hospital versus those treated at home. However, more severely ill patients are more safely treated by direct admission to a hospital ward or intensive care unit.

Table 1: ePNa and the Five Rights Framework of Decision Support
effectively communicated. Ideally, initial ED treatment comprises best practice that is smoothly transitioned and continued in the hospital. However, if the inpatient team makes different treatment decisions based on individual clinician variability rather than patient-centered illness features, there is discontinuity of care and potential for patient harm. Similarly, patients returning for follow-up a day or two following their initial ED encounter are often seen by a different clinician. Standardizing clinical practice facilitates continuity of care by different providers.

**Technical description of ePNa**

ePNa consists of a pneumonia detection system combined with a management tool seamlessly integrated into usual ED physician workflow through a single user interface.

**Detection system**
The ePNa detection system is embedded in the iCentra decision support environment. It leverages tools designed to run prediction and classification algorithms in a clinical setting. It operates by consuming a stream of 40 clinical data elements captured from the EHR during ED patient care (Figure 1). The ePNa screening framework uses a natural language processing (NLP) subsystem to identify information in free-text reports to determine the presence of pneumonia. The detection system relies on a probabilistic Bayesian network to calculate likelihood of pneumonia.

When the combination of data results in a probability of pneumonia ≥ 40%, ePNa alerts the clinician using asynchronous messaging. At this point, the clinician can launch the tool, but may opt out if the patient is not believed to have pneumonia. Physicians may identify patients with a calculated risk of < 40% estimated pneumonia likelihood and still activate the management tool. The 40% threshold yields a 50% positive predictive value of the pneumonia alert, thereby decreasing “alert fatigue” and limiting negative impact on the ED clinical environment. After confirmation of pneumonia, ePNa takes the clinician through risk-stratification and recommends patient disposition and treatment. Physicians may also directly launch the management portion of ePNa without an alert, utilized when calculated pneumonia probability is < 40%.

**ePNa objectively calculates severity of illness for each patient with pneumonia.**

1) Estimates 30-day mortality risk using an electronic version of a validated severity score (eCURB). The 5 elements are patient age, initial systolic blood pressure, initial respiratory rate, altered mental status, and blood urea nitrogen level.

2) Calculates the patient’s ability to oxygenate arterial blood compared to the fraction of inspired oxygen (PaO2/FiO2) from measured percutaneous oxygen saturation (SpO2).

3) Gathers electronically the 9 minor criteria for severe pneumonia (IDSA/ATS 2007), summed into an ordinal score.

4) Identifies patients with an associated pleural effusion by NLP of the chest imaging report

ePNa then recommends (1) patient disposition, (2) antibiotic therapy, and (3) suggested microbiology tests appropriate to the patient’s condition. It displays the data in a form suitable for physician review. The physician can alter tool recommendations based on individualized clinical judgment.

**Site of care - outpatient, hospital ward, or intensive care unit**

Patients with eCURB-predicted mortality ≥ 5%, PaO2/FiO2 < 280 mm Hg adjusted for altitude, or significant pleural effusion are recommended for hospital admission in accordance with previously validated criteria. Patients with ≥
3 severe Community Acquired Pneumonia (CAP) minor criteria, or PaO2/FiO2 < 120 mm Hg are recommended for direct admission to the intensive care unit. (figure 2) Severity information is displayed to the ED physician with the site of care recommendation. The open loop design of ePNa allows the physician to accept or reject this recommendation; if rejected, the physician is asked to provide a reason from a pre-populated pick list or to add free text. This functionality allows real-time learning from the use of the tool.20

Identification of patients with risk factors for antibiotic resistant bacterial pathogens
Drug Resistance In Pneumonia (DRIP) is a 10 factor ordinal score that measures risk for antibiotic resistant bacterial pathogens developed at Intermountain and externally validated.21 In 2014, ePNa was updated to electronically calculate DRIP and incorporate its results into antibiotic treatment recommendations. This operation involves the following:

1. Searches the longitudinal EHR for hospitalization ≥48 hours within the previous 60 days and matches facility name and addresses for skilled nursing homes, rehabilitation facilities, and long-term acute care facilities. It also searches International Classification of Diseases codes version 10 (ICD-10) indicative of chronic obstructive pulmonary disease, diabetes, chronic heart failure, and active cancer.
2. Extracts previous microbiology results for Methicillin-resistant Staphylococcus aureus and Pseudomonas aeruginosa.
3. Searches electronic prescribing records for antibiotic use within the prior three months or use of gastric acid reducing medications.
4. Applies NLP to ED chest imaging reports to identify presence of a feeding tube, a measure of functional status.
5. Asks the ED physician to confirm that the patient is ambulatory (versus chair/bed bound).

Figure 3 shows the user interface for determining the DRIP score. Physicians click on the right-sided box to add or delete risk factors if there is information not present in the electronic health record (e.g. a visitor to Utah without
Diagnostic testing recommended by ePNa

Patients admitted to the Intensive Care Unit are recommended for two blood cultures, urine antigen tests for *Streptococcus pneumoniae* and *Legionella pneumoniae*, nasal swab for *Methicillin resistant Staphylococcus aureus* and viral respiratory pathogens by Polymerase Chain Reaction, and a tracheal aspirate for semi-quantitative culture if newly intubated. The same battery of studies is recommended for patients with a DRIP score >3 being admitted to a hospital ward.

Adaptation of ePNa for iCentra

Beginning in 2016, Intermountain changed over from its legacy EHR to iCentra. Beginning in January 2017, ePNa was reprogrammed and adapted to operate within iCentra. Beta testing began in the 4 Salt Lake Valley EDs in July 2017. After implementation in a 5th ED in November 2017 identified additional issues with functionality requiring reprogramming, a successful re-launch began in January 2018 across the remaining Intermountain Hospitals.

The iCentra version of ePNa retained a “P” alert on the ED electronic tracking board (LaunchPoint), but the one-click launch functionality of the legacy version could not be replicated. Three “clicks” from the physician user are needed to launch ePNa in the iCentra version, but then ePNa functions easily once initiated. The iCentra version of ePNa features a direct link to Computerized Physician Order Entry that was not available in the legacy EHR. As the last step of ePNa, the clinician launches one of 6 pneumonia order sets (2 outpatient, 2 hospital ward, 2 intensive care unit, each with a low risk/high risk for antibiotic resistant pathogens version). ePNa iCentra also contains drug allergy information linked to the order entry set, functionality not available in the legacy EHR.

Automatic loading of ePNa output into clinician ED and admission notes. ePNa’s calculated percent likelihood of pneumonia, the severity calculations (eCURB, PaO2/FiO2, and severe CAP criteria), and the DRIP score are automatically loaded into clinician documentation under a sectional heading of “Clinical Decision Support.” In addition, ePNa’s recommendation for site of care, whether the ED physician agreed with its recommendations, plus any additional ED physician comments, are automatically loaded in ED and admission notes.
**Implementation of ePNa across Intermountain**

Intermountain operates hospitals in small, rural locations (often staffed by family practice physicians) as well as large, tertiary care medical centers in urban regions that use a board-certified emergency medicine staffing model. After achieving acceptable tool functionality in January 2018, we began implementing ePNa into 6 geographic clusters of Intermountain Hospital ED’s at approximately 2-month intervals. We began with larger hospitals, with the later implementation sites being smaller rural hospitals.

**Methods of CDS implementation**

1) **Front line provider education:** ED physicians, Advanced Practice Clinicians, ED nurses, admitting hospital and critical care physicians first received didactic, customized and interactive presentations prior to ePNa launch. Emergency departments were the focus for implementation since if ePNa isn't run in the ED, it is less likely to be started after hospital admission. Emergency department 'buy-in' is key and promotes continuity of care between providers throughout the hospital stay.

2) **Nurse educator engagement:** Multiple follow up visits by the ED nurse educator (JR) began after ePNa launch at each site.

3) **Physician champions:** We identified physician champions in every ED to teach and encourage their peers to adopt ePNa into routine care of pneumonia patients. The largest ED physician group identified thirteen members as super users available to answer questions and promote utilization while working in the ED.

4) **Feedback to improve the CDS tool:** Physician champions provided a voice for feedback and insights to functionality of their location. Individual providers also gave feedback to the nurse educator during her visits. Follow up group meetings were conducted with physicians from the ePNa team, answering questions and concerns from providers.

5) **Email reminders:** Reminders and answers to frequently asked questions were sent to providers.

6) **Audit and feedback:** Repeated audits of ePNa use were fed back to providers along with issues involving pneumonia patient care where ePNa had not been used. Audits that included the physician provider and patient encounter identifiers were made available to all providers at each ED, engendering discussion and provider accountability. We observed the largest increases in ePNa utilization after audit results were openly shared by local champions/ED leadership, leading to discussion among providers.

7) **Admitting hospital physicians “encourage” the routine use of ePNa by ED physicians and increase patient safety by facilitating transitions of care from the ED to the hospital.** ED physicians frequently comment that ePNa structures and supports their conversations with admitting physicians.

**Rate of ePNa uptake**

Despite published favorable outcome data, ED physicians were initially slow to adopt the iCentra ePNa, judging its value by the user interface and subjective assessment of its impact on their individual clinical care. This adoption pattern was more pronounced outside of Salt Lake Valley (where clinicians had used the legacy version of ePNa). Audits were conducted over time to measure uptake and use of the tool. These audits showed variations from best practice in about half of pneumonia patients when ePNa was not used, or when the associated computerized order set was not also used. Six audits were performed during 2018 (Figure 4). Hospital clusters where ePNa was launched earlier in 2018 have more measurements than later clusters. Each audit spanned 2 to 4 weeks (longer at smaller hospitals to increase the number of patients), ranging between 4 and 30 cases per facility depending on the interval and facility ED case volume. Patients were initially identified by ICD-10 codes for pneumonia, or for sepsis and acute respiratory failure with pneumonia present as a secondary diagnosis. Physicians (ND, CV, NJ, MW) individually reviewed each case to verify ED physician diagnosis of pneumonia, excluding those where the physician diagnosis was not pneumonia, e.g. aspiration pneumonitis. Figure 4 illustrates the percent utilization of ePNa by hospital over the 6 audits.
Results of emergency department physician survey.
A REDCAP confidential survey of ED physicians was conducted in December 2018. Survey details have been previously published. The response rate of completed surveys was 53%, or 90 of 169 invited physicians. We used Principal Component Analysis followed by Reliability testing to group like questions together. Figure 5 illustrates respondents’ opinions about how well ePNa helps with clinical decision-making. The mean score on component 1 is 3.6 (SD=0.79). Response options ranged from strongly disagree (1) to strongly agree (5) with a neutral rating corresponding to (3), a mean of 3.6 indicates that the majority of respondents hold favorable opinions about how well ePNa helps their clinical decision-making. However, responses regarding decision support with diagnosing pneumonia revealed that most respondents felt ePNa does not help. Respondents’ opinions of the “P” alert system (component 2) resulted in a mean score of 3.1 (SD=1.3). A mean of 3.1 is approximately in the center of the scale. However, scores are spread out across the response scale, indicating that respondents...
have diverse opinions on how well the alert system works.

The median response to questions about how much time ePNa requires is 3.0 (IQR=2) (Figure 6). This median is in the center of the scale, suggesting that respondents are split over how much time it takes to use ePNa.

The median response for “ePNa is free from technical problems” is 2.0 (IQR=1.0), Figure 7. A median of 2.0 is on the disagree side of the scale, suggesting that most respondents feel that ePNa does have technical problems.

With the mean responses to components 1 and 2 being below 4.0 (agree), progress can be made in improving respondents’ perceptions toward ePNa. The comments on improving ePNa support this conclusion. Removing bugs and glitches and adding new functionality will likely enhance perceptions of ePNa.

There were a few strong, negative comments about ePNa. However, these comments were balanced by an equal number of strong, positive comments. People with strong, negative opinions may never be persuaded that ePNa is effective and usable no matter how well it works, or that CDS is needed. However, in this survey the majority of respondents believe that ePNa is slightly above average in quality, and those opinions may improve with enhancements to the interface and functionality of ePNa. Efforts on improving perception and utilization should focus on clinicians who are amenable to adopting CDS into their clinical care.

Two survey comments from clinicians represent several similar comments and illustrate current limitations of ePNa.

“The tool often gives recommendations that are inappropriate and potentially dangerous. I’ve had it recommend outpatient therapy for patients who need the ICU and vice versa.” ePNa requires accurate, real-time data to calculate severity of illness which drive disposition recommendations. The nurse educator has emphasized to ED nurses the importance of charting SpO2 on room air (for calculating PaO2/FiO2), and confusion (oriented to person, place, and time or not; key components of both eCURB and the severe CAP criteria). For example, a patient brought in by ambulance may have had a room air SpO2 of 60% measured by prehospital medics and placed on high flow oxygen by mask, resulting in a saturation of 99% on arrival to the ED. Only the latter might be available to ePNa, but PaO2/FiO2 is not accurately calculated from high SpO2.
Uncharted data are considered normal by all severity systems, yet if confusion is present and not charted, ePNa might give a “dangerous” recommendation. ePNa requires timely, accurate entry of patient data, yet the frequently busy and occasionally chaotic ED environment can make accurate CDS function difficult. ePNa is open loop CDS which cannot anticipate every clinical scenario, thus the treating physician must do what he/she feels is safe and appropriate for the individual pneumonia patient.

Another illustrative comment: “Better alert system. A dedicated care pathway column would make the user interface and inter-operability much improved”. The screening algorithm was not updated for iCentra ePNa, and due to technical limitations, the single click for launching ePNa featured in the legacy version could not be carried over. This presented an early barrier to use and adoption of ePNa. We are now re-deriving the screening tool for iCentra and plan a pop-up dialog box to launch the program with a single click once ePNa identifies a patient with ≥ 40% likelihood of pneumonia.

Summary and Conclusions

ePNa is an innovative electronic CDS tool for ED patients with pneumonia. Published outcome data demonstrated reduced mortality and appropriate hospital admission of high severity patients with pneumonia. A long-term goal of the current study is to demonstrate similar results across the large and small, urban and rural Intermountain Hospitals. However, the huge challenge of broad adoption by ED physicians must occur first.

Adaptation of ePNa into iCentra allowed implementation across all Intermountain hospitals. In this paper, we have described our implementation process, reported ePNa usage during 2018, and results of our ED physician survey. Physician utilization has been higher in larger, urban medical centers with longer exposure to ePNa. Recurring personal and electronic feedback/reminders from the ePNa team is increasing its use across Intermountain. Improvements in the pneumonia detection component and improving the user interface that launches ePNa are underway, as identified by ED physician users and described above. More work to improve charting of critical data elements by ED nurses will increase tool accuracy and use of ePNa. We hope to eventually export ePNa outside of Intermountain to determine its generalizability among different pneumonia populations and providers with different diagnosis and treatment patterns. These efforts will benefit from the lessons learned during the implementation of ePNa at Intermountain.

Abstract

Precision health's more individualized molecular approach will enrich our understanding of disease etiology and patient outcomes. Universal implementation of precision health will not be feasible, however, until there is much greater automation of processes related to genomic data transmission, transformation, and interpretation. In this paper, we describe a framework for genomic data flow developed by the Clinical Informatics Work Group of the NIH National Human Genome Research Institute (NHGRI) IGNITE Network consortium. We subsequently report the results of a genomic data flow survey administered to sites funded by NIH-NHGRI for large scale genomic medicine implementations. Finally, we discuss insights and challenges identified through these survey results as they relate to both the current and a desirable future state of genomic data flow.

Introduction

Precision health's more individualized molecular approach will enrich our understanding of disease etiology and patient outcomes.1 Individuals receiving treatment within healthcare systems will ultimately be characterized by multiple methods, including genomics, epigenomics, metabolomics, and proteomics.1

Acquiring and interpreting these new data sources are now possible because of the decreasing costs of molecular testing, development of large-scale biologic databases, and computational tools that facilitate analysis of large data sets.1 Genetic sequencing in particular is on the verge of becoming a routine part of clinical care.2 However, major challenges to routine use persist. Variant interpretation and reporting is currently extraordinarily complex and time-intensive.3 Genomic lab instrument interoperability with clinical information systems is hindered by a lack of adopted health IT standards.3 Finally, clinical decision support (CDS) necessary for clinicians to understand the significance of all clinically important variants is not widely implemented. At every step, from the point of raw data being generated by the genomics instrument to CDS at the point of care, the delivery of genomic data will require markedly improved automation.

This manuscript focuses on the current status of genomic data transmission, transformation, and interpretation (flow) from instrument to point of care. Specifically, we describe a framework for genomic data flow developed by the Clinical Informatics Work Group (CIWG) of NIH-NHGRI's "Implementing genomics in practice" (IGNITE) Network. We subsequently report the results of a related survey administered to sites funded by NIH-NHGRI for large scale genomic medicine implementations. Finally, we discuss insights and challenges identified through these survey results as they relate to both the current and a desirable future state of genomic data flow.

Methods
Over the course of several months and through a series of meetings, members of IGNITE's CIWG committee developed a draft framework for genomic data flow informed by their own institutional experiences and the medical literature. This draft framework was presented to the full IGNITE consortia and refined based on further feedback.

Members of the CIWG Committee subsequently developed a RedCap survey that corresponded closely to components of the draft framework. For purposes of our survey, we focused on germline molecular testing, but we anticipate that many aspects would be generalizable to somatic molecular testing. Given our primary goal of refining a genomic data flow framework, we chose to survey institutions with well-developed advanced genomic molecular testing laboratories. To this end, we invited survey respondents from institutions that had been funded by NIH-NHGRI as part of the IGNITE and Electronic Medical Records and Genomics (eMERGE) consortia to implement large scale genomic medicine implementations. Surveys were conducted from May 2018 to February 2019.

In the following discussion, we illustrate aspects of the data architecture using two important examples of genomic molecular testing, whole genome sequencing (WGS) and pharmacogenetics (PGx).

Results

Development of a genomic data flow framework. The final proposed framework for genomic data flow is depicted in figure 1. For the sake of simplicity, in the descriptions of the components of figure 1, we will refer only to the number (e.g., "component #2") rather than a full description (e.g., "refer to component #2 of figure 1").

In figure 1, genomic data generally flows left to right. Genomic instrument results from the institution's own laboratory are processed and transformed by a bio-informatics pipeline (component #4). All identified variant results for a patient (component #7) are stored for at least the life of that patient, and separately, interpretative annotations for those results are stored (component #8). For purposes of electronic health record (EHR) performance, clinically actionable subsets of variant data (component #10) and the corresponding interpretative annotations (component #11) are stored, which are available through the EHR (component #13) and for CDS (component #12).

For pathology reporting and reasons discussed below, we distinguish between automatically-generated portions of a draft report (component #5) and the final report completed by the laboratory's genetics expert (component #6). A genome variant knowledge base (component #3) is required in machine-readable form for purposes of the bio-informatics pipeline and automatically-generated portions of a draft report, as well as in human-readable form for the genetics expert. Discrete results and annotations data from an external genomics laboratory (component #1) flow into the full variant (component #7) and interpretative annotations (component #8) databases, while the external pathology report would flow through the pathology reporting system (component #6) and into the EHR (component #13). Finally, processes would allow for ongoing re-interpretation of results as genomic knowledge evolves (component #9) and genomics results would be shared with the patient through a patient portal (component #14). These framework components are discussed more fully below.
Genomic laboratory instrument (internal and external testing). Genomics laboratory instruments rely on a variety of underlying laboratory techniques (e.g., DNA arrays, DNA sequencing, real-time quantitative polymerase-chain-reaction). Such testing is performed in a variety of clinical contexts e.g., prenatal testing or determining predisposition to cancer). For purposes of this paper, our focus begins with the raw data generated by the instruments for genomic tests performed both internally within the institution's laboratory (component #2) and at an external laboratory (component #1).

In the case of WGS, raw data typically consist of fluorescent, chemiluminescent, or electrical current signals. These are transformed into sequential base calls using platform-specific algorithms. The resultant FASTQ file can contain the results for millions of short DNA sequences. It is this FASTQ file that provides the source input for platform-independent software processing, as discussed below in the bio-informatics pipeline section.

These sequence reads are appropriately associated with metadata that describe the methods and technologies used to produce those results. In the case of WGS, such metadata commonly include sequencing quality scores. These quality scores are important for interpretation given that they reflect the statistical confidence that a given base call is correct.

Many genomics laboratory instruments were not designed to work in a clinical networked environment. There is need for both greater interoperability and implementation of standards. To such ends, the HL7 Clinical Genomics Work Group recommends a transcoding process, whereby genomic data are transformed from bio-informatics format into healthcare IT data standards. They also describe an alternative approach where genomic data are encapsulated in healthcare standards.

Bio-informatics pipeline. As described in Leipzig et al.’s review of bio-informatic pipeline frameworks, a bio-informatics pipeline invariably involves the shepherding of files through a series of transformations. These pipelines have evolved into frameworks that accommodate integration of user-defined tools, definition of both serial and parallel steps, complex dependencies, and varied data file types.

In the case of WGS, the source input for a platform-independent bio-informatics pipeline is commonly in the form of a FASTQ file, which can contain millions of short DNA sequences. Through the pipeline, these short sequences are aligned to a human genome reference sequence. Through comparison to the reference sequence, variants for an individual are also determined ("called"). Variants can include single nucleotide variants, insertions/deletions, and copy number variants. Identified variants are prioritized, and then annotated with respect to the clinical relevance of those particular variants. Throughout the process, the data are transformed into successively smaller file formats, such as FASTQ, BAM, SAM, and finally VCF. Pipeline processing for WGS is frequently time-intensive. Both open source and proprietary software is available for these transformations (e.g., GATK, SAMtools, Atlas2).

From an abstract level, pipeline processing for PGx genotyping is similar, insofar as variants are called, prioritized, and annotated for clinical relevance. PGx pipelines commonly rely on translation tables. Such tables relate diplotype results (e.g., CYP2C19 *2/*2) to drug related phenotypes (e.g., poor metabolizer) and CDS recommendations (e.g., "Increased risk for reduced response to clopidogrel. Consider alternative drug").

Such prioritization and curation of variants have become immensely more challenging as a result of WGS and its large number of associated variants. For example, the typical human genome has more than 4 million variants. As noted by Kohane et al., the burden of false-positive incidental findings in WGS "threatens current capabilities to deliver clinical-grade whole-genome clinical interpretation."

Genomics pathology report with interpretation (automatically generated and final). The quality of final genomics pathology reports is a key determinant of the effectiveness of genetic medicine, with high-quality reports concisely explaining both the variants identified in a patient and their clinical relevance. Producing these reports is also labor-intensive and expensive.

While the actual sequencing is getting more affordable and higher quality, efficient interpretation is lagging. In one study of the clinical implications of WGS, Dewey et. al found that curation of the 90 to 127 genetic variants found in
each participant required a median of 54 minutes per genetic variant\textsuperscript{17} (i.e., presumably approximately 100 hours of interpretation by genetic experts per sequenced participant).

Given our belief that this level of intensity for manual curation for WGS would not accommodate universal WGS testing, we distinguish between the automatically-generated portions of a draft pathology report (component #5) and the final pathology report completed by the laboratory's genetics expert (#6). Over time, and out of necessity, we anticipate that the automatically-generated portions of the report will become more complete and valid. Through interfacing to the EHR, it also seems likely that such automatically-generated reports will incorporate an increasing amount of patient-specific clinical context (including family history). While it may never prove completely possible due to inherent complexity, the goal would arguably be for valid WGS results to require no more manual expert curation than is currently associated with complete blood count (CBC) results.

\textit{Genomic variant knowledge base.} A genome variant knowledge base (component #3) is required in machine-readable or computable form for purposes of the bio-informatics pipeline and automatically-generated portions of a draft pathology report. A human-readable form is required for the genetics expert who is completing the pathology report. Such a genomic variant knowledge base could also be employed for purposes of CDS logic (e.g., if variant patterns for particular conditions are coupled to actionable recommendations).\textsuperscript{18}

Common variant knowledge bases include the Database of Single Nucleotide Polymorphisms (dbSNP) Online Mendelian Inheritance in Man (OMIM), and ClinVar.

\textit{Full variant database with meta-data and a separate interpretative annotation database.} Given that germline genomic results are applicable for the life of an individual, and the recognized clinical significance of those results will change as a result of evolving knowledge, a full genome database consisting of all variants and metadata requires long term storage.\textsuperscript{18} Long term storage of a full variant database including metadata (component #7), and a separate interpretative annotation database (component #8) is consistent with at least three of Masys et al.'s desiderata: (1) maintain separation of primary molecular observations from the clinical interpretations of those data, (2) maintain linkage of molecular observations to the laboratory methods used to generate them, and (3) anticipate fundamental changes in the understanding of human molecular variation.\textsuperscript{5}

Given nascent EHR support for genomic data, and the large size of many of these full variant files (e.g., a FASTQ file can be 250 gigabytes for WGS\textsuperscript{12}), these databases typically exist outside of an institution's EHR. Rapid retrieval and analysis of such full genomic data is challenging for the typical EHR database system and could be expected to lead to performance issues.\textsuperscript{19} While such files can be compressed, Masys et al. have emphasized the importance of lossless data compression with the ability to produce a fully accurate copy of the original sequence.\textsuperscript{5}

\textit{Clinically relevant subset of variant database and separate interpretative annotation database.} Similar to the case of the full variant database and their interpretations, and consistent with Masys et al.'s desiderata,\textsuperscript{5} our proposed framework separates the subset of clinically relevant variants (component #10) from their interpretative annotations (component #11).

Recommendations for storage of a clinically actionable subset of variants are based on the fact that "the amount of molecular sequence data that currently has demonstrated clinical significance is a tiny fraction of the full genome and proteome, and it is neither computationally feasible nor desirable to query or analyze one's entire genome in real time to support healthcare-related decisions."\textsuperscript{5} Such a clinically actionable subset would be accessible to the EHR and CDS.

Such clinically relevant subsets of variant information seem to be commonly stored in the EHR problem list as a form of work-around for ensuring that clinicians are aware of the clinically actionable variant information for a patient, and for driving CDS.\textsuperscript{13,20} As EHR vendors improve their systems' ability to incorporate discrete genomic data, similar to how patient drug allergy information is not typically embedded in problem lists, it is likely that variant data will be both displayed to clinicians and available to CDS in non-problem list sections of the EHR.
Ongoing re-interpretation of individuals’ genomic results as knowledge evolves. Germline genetic results have lifelong ramifications for individuals. While an individual’s germline genomics is expected to remain immutable, the clinical significance of that individual’s identified variants will change dramatically over the foreseeable future as a result of ongoing intense genomics research. Need for corresponding ongoing re-interpretation of genetic results (component #9) makes a compelling case for standards-based, structured (computable) electronic reports.8 Both the pathology reports and discrete data that drive CDS will require updating.

As described by Aronson et al., the GenelInsight Suite was specifically designed to accommodate this need for ongoing re-interpretation.16 It relies on a centralized genetic knowledgebase and a highly flexible report-generation tool. A single action by a geneticist updates both future reports and generates alerts for clinicians treating patients. Automatically-generated draft reports and user-defined templates save geneticist time. Clinical alerts are driven off of changes to the genetic knowledge base.

EHR with integrated CDS. As of 2013, there were over 2500 clinical genetic tests available to clinicians.21 Even more overwhelming, the average human genome contains over 4 million variants. The full vision of precision health and genomics (and metabolomics, proteomics, etc) will not be realized in the absence of robust computerized CDS. Until such time as every variant for every person is stored and accessible, precision health will require both pre-test CDS (triggered when a clinician takes an action that should be informed by a genetic assessment but there is no record of such) and post-test CDS (alerts triggered when an action is taken that may be contraindicated by a patient’s genetic profile).22

Given current health care infrastructure, the most straightforward method for robust genomics CDS at the point of care on a widespread basis would currently be to leverage existing EHRs (component #13) with integrated CDS (#12) – potentially in the form of CDS web services. Welch et. al have similarly argued that a CDS architecture would appropriately primarily rely on EHR capabilities that are either currently supported or likely to be supported in the near future.18

Patient portal. The patient is a central stakeholder with respect to precision health. It has been hypothesized that modules incorporated into the patient portal may substitute for or lessen the burden of genetic counseling.23 Patient portal applications and sharing of results may also increase patients’ participation in their own care.23 For such purposes, both discrete and final report data would be appropriately shared with the patient through a secure patient portal (component #14).

Survey results

Genomic laboratory instrument (internal testing). 86% (6/7) of survey respondents reported that their site performs CLIA-certified germline molecular testing internally. Table 1 lists the types of CLIA-certified germline molecular testing internally performed at these six sites. Table 2 reports the clinical contexts for which internal germline molecular testing occurs at these 6 sites. In all cases, reports related to internal molecular testing are available for clinician review within the EHR.

60% (3/5) of sites reported that these reports are stored as PDFs in the EHR, while 20% (1/5) reported storage in the structured XML-based Clinical Document Architecture (CDA) format and 20% (1/5) reported storage in a proprietary format. In the case of pharmacogenomics testing, 75% (3/4) of sites reported that discrete genetic results are transmitted from the laboratory instrument to the EHR.

Discrete genetic results are transmitted much less frequently from the instrument to the EHR in other clinical contexts: 0% (0/1) of testing for genetic cancer predisposition, 0% (0/5) of perinatal genetic disorder testing, 25% (1/4) of bone marrow and organ transplant testing, and 0% (0/3) metabolic and vascular disease marker testing.
Genomic laboratory instrument (external testing). 100% (7/7) of survey respondents reported that their site sends at least a portion of their germline molecular tests to an external CLIA-certified laboratory. Table 2 reports the clinical contexts for which such external germline molecular testing occurs at these 7 sites. In all cases, these external reports are available for clinician review in the EHR, almost exclusively either as a PDF or scanned image. The exception was one site that stored their externally-provided pharmacogenomics report in structured CDA format.

For most types of external testing, the results of external germline molecular testing are stored only as a report in the EHR. In the case of external pharmacogenomics testing, discrete genetic data are stored as a result of external pharmacogenomics testing at 40% (2/5) of sites. In the case of external determination of genetic predisposition to cancer, discrete data are stored at 17% (1/6) of sites. No discrete genetic data are stored as a result of genetic disorders tested perinatally, bone marrow and organ transplants, to detect metabolic and vascular disease markers, or testing for neurodevelopmental disorders.

Bio-informatics pipeline. 86% (6/7) of sites support a computer-based genomics data pipeline platform. Among these six sites, pipelines are employed for genotyping (83%) and sequencing (67%). The most common reason for supporting a computer-based pipeline among these 6 sites is for purposes of pharmacogenomics (83% of sites). Internal personnel maintain these pipelines at all six sites. 50% (3/6) employ an open source pipeline framework, 33% (2/6) employ a commercial framework, and 67% (4/6) employ custom scripting. 50% (3/6) utilize PGx translation tables.

Respondents noted challenges related to these pipelines, including (1) the need to upload the pharmacogenomics phenotype information into the EHR as a discrete field, (2) updating and maintaining the underlying data related to newer medical literature, and (3) non-conformity of different methods of variant calling.

For the six sites that perform internal germline molecular testing, structured variant data is stored outside of the genomics instrument at 67% (4/6) of sites. In all such cases, these structured variant data are stored external to the EHR. For 75% (3/4) of sites, annotations are stored with the structured variant information. For 50% (2/4) of sites, a subset of the variants are available to the EHR (e.g., through entry into the patient's problem list). There are no sites where all variants are accessible within the EHR.

Genomics pathology report with interpretation (automatically generated and final). 100% (6/6) of sites that perform internal germline molecular testing create interpretative reports. 83% (5/6) of sites automatically generate a portion of the results (e.g., variant calls) on this report. 100% (6/6) automatically generate a portion of the interpretation (e.g., phenotype for PGx variants) on this report. Genetics experts utilize templates to create these reports at 100% (6/6) of sites.

Genomic variant knowledge base. Genetic experts at these six sites rely on Pubmed (100% of sites), PharmGKB (83% of sites), dbSNP (83% of sites), CPIC guidelines (83% of sites), laboratory-maintained resources (67% of sites), OMIM (67% of sites), RefSeq (67% of sites), GeneTests (33% of sites), and other resources (33% of sites). 67% (4/6) of sites noted time-consuming aspects associated with interpretation, including (1) NGS with multiple variants can "easily take 4-8 hours of manual effort," (2) integration of pharmacogenetic test results with other clinical factors, and (3) rare variants and variants with incomplete penetrance require extensive curation.

Ongoing re-interpretation of individuals' genomic results as knowledge evolves. 86% (6 of 7) of institutions reported updating prior interpretations as a result of new variant knowledge. At these 6 sites, such updates have been "triggered" by clinician request (50% of sites), patient request (17% of sites), and as part of a scheduled review process (33% of sites). Updates have originated from the internal laboratory (100% of sites), as well as the external laboratory (50% of sites).
Efforts to update prior interpretations have included updating of interpretive reports (83% of sites), updating of stored annotations (83% of sites), notifying ordering providers about reinterpretation (67% of sites), and notifying patients about reinterpretation (50%).

14% (1/7) of sites have policies in place related to updating prior interpretations as new knowledge emerges.

**EHR with integrated CDS.** 71% (5/7) of sites reported implementing genomics-based clinical decision support within its EHR (both the inpatient and outpatient settings in all cases).

Among these five sites, 100% implemented CDS to recommend treatment based on genetic results, 80% implemented order sets that include genetic testing, 40% implemented CDS to recommend genetic testing triggered by particular orders, and 40% implemented genomics test order templates.

All of these sites implement genomics CDS using their institution's EHRs CDS infrastructure, but one site also employs an external CDS infrastructure.

**Patient portal.** 57% (4/7) of sites report the sharing of genomic reports through a patient portal, while 29% (2/7) report mailing reports to the patient.

**Survey results and the proposed data flow framework**

We believe the survey results validate our proposed data flow framework (figure 1). Participating institutions implement most of the framework components. These institutions also contend with a number of data flow challenges, such as time-consuming manual curation and incomplete discrete data transmission.

The primary framework component that did not appear to be widely implemented, but we believe should remain in the framework, is a systematic process for re-interpreting genomic discrete and pathology reports that remains in step with evolving knowledge. We attribute this finding to the fact that there are currently no trivial automatic methods of performing this task. There is simply too much manual curation required to re-create final reports and interpretative annotations on all previously sequenced patients on a scheduled basis for the life of a patient.

While all sites create final pathology reports and ensure that these results are shared with the ordering providers (in compliance with CLIA requirements), discrete results are less consistently transmitted to downstream systems. This was particularly the case with external laboratory results. Many reports are also stored in PDF format, rather than structured CDA format. Incomplete population of the EHR with both discrete results and structured reports has potential adverse ramifications for CDS. At least some sites rely on entry of variant results into the EHR problem list as a work-around.

We found that all sites automatically generate portions of their draft reports and employ templates. Most sites rely exclusively on their EHR's integrated CDS system to implement CDS.

**Conclusions**

Widespread implementation of precision health will not be feasible in the absence of significant advancements in the automation and standardization of genomic transmission, transformation, and interpretation from instrument to point of care. There is critical need for increased automation of genomic pathology reporting, improved transmission of full discrete variant results and metadata in standardized format to downstream systems, improved methods to store clinically actionable genomic data in EHRs, improved methods to automatically update genomic results for the lifetime of a patient as genomic knowledge evolves, and improved methods to create, maintain, and share comprehensive genomic CDS logic among institutions.

The results of our survey appear to validate our proposed genomic data flow framework. We anticipate that explicit definition of a genomic data flow framework can facilitate discussion of much-needed improvements. Participating survey respondents, arguably leaders in the field of clinical genomics as evidenced by their funding for large scale genomic implementation, are still challenged by current limitations of genomic instruments, bioinformatics pipelines, genomic variant knowledge bases, lab information systems, and EHRs.

Facilitating Analysis of Publicly Available ChIP-Seq Data for Integrative Studies

Avantika R. Diwadkar, MS1, Mengyuan Kan, PhD1, Blanca E. Himes, PhD1
1Department of Biostatistics, Epidemiology and Informatics, University of Pennsylvania, Philadelphia, PA, US

Abstract
ChIP-Seq, a technique that allows for quantification of DNA sequences bound by transcription factors or histones, has been widely used to characterize genome-wide DNA-protein binding at baseline and induced by specific exposures. Integrating results of multiple ChIP-Seq datasets is a convenient approach to identify robust DNA-protein binding sites and determine their cell-type specificity. We developed brocade, a computational pipeline for reproducible analysis of publicly available ChIP-Seq data that creates R markdown reports containing information on datasets downloaded, quality control metrics, and differential binding results. Glucocorticoids are commonly used anti-inflammatory drugs with tissue-specific effects that are not fully understood. We demonstrate the utility of brocade via the analysis of five ChIP-Seq datasets involving glucocorticoid receptor (GR), a transcription factor that mediates glucocorticoid response, to identify cell type-specific and shared GR binding sites across the five cell types. Our results show that brocade facilitates analysis of individual ChIP-Seq datasets and comparative studies involving multiple datasets.

Introduction
Transcription factors play a key role in the regulation of gene expression and the re-organization of chromatin by binding to specific genomic loci in a cell type-specific manner1, 2. Chromatin immunoprecipitation sequencing (ChIP-Seq) is a popular genomic approach to identify binding sites in the genome for a protein of interest3. The technique involves reverse cross-linking of a protein of interest to DNA, followed by fragmentation, immunoprecipitation and parallel sequencing, which permits identification of DNA sequences bound by transcription factors or histones across the genome4. ChIP-Seq has been widely used, with over 40,000 ChIP-Seq assays of various DNA-binding proteins available in public repositories, such as the Gene Expression Omnibus (GEO) and Sequence Read Archive (SRA)5. The availability of these datasets enables researchers to explore novel questions related to transcriptional response by comparing results of multiple ChIP-Seq datasets.

Analysis of ChIP-Seq data is a multi-step process that includes obtaining quality control measures, mapping of sequencing reads to a reference genome, peak calling, performing differential binding analysis, annotating sites, and identifying motifs6. Several specialized informatics tools have been developed to perform these tasks7. The ENCODE project produced many ChIP-Seq datasets along with published standards and guidelines that recommend use of biological replicates, specific antibody and input control characteristics, and uniform processing pipelines to analyze ChIP-Seq data of different protein classes8, 9. For example, to determine whether transcription factor binding sites are associated with corresponding gene transcription, it is recommended that ChIP-Seq experiments include measures of RNA polymerase II (RNAP2) occupancy along with the transcription factor of interest10. In the absence of RNAP2 ChIP-Seq data, genome-wide gene expression results derived from microarray or RNA-Seq studies with similar treatment conditions as the ChIP-Seq study of interest can be used to link transcription factor binding sites with transcriptomic changes.

Software tools to analyze ChIP-Seq data include the R packages chipseq11 and CSAR12, which perform binding site identification based on aligned data obtained via command-line tools, while Homer13, seqMINER14, and Sole-Search15 are popular tools that focus solely on aspects of downstream analysis. Pipelines that combine existing informatics tools to perform comprehensive ChIP-Seq analyses include ChiLin16 and the ENCODE pipeline (https://github.com/ENCODE-DCC/chip-seq-pipeline2), which consist of Python scripts that integrate steps for sequence data mapping, peak calling, and differential binding analysis (only available in ChiLin). The Galaxy-based platforms Cistrome17 and Nebula18 are similar cloud-based options, but their computational speed and customization of commands are comparatively limited. None of the existing pipelines, however, facilitate analysis of publicly available ChIP-Seq data via automated retrieval of raw sequencing files and phenotype information from public
repositories. Thus, there is a need for an end-to-end ChIP-Seq data analysis pipeline that includes direct access to the growing resource of public datasets in a sophisticated yet straightforward manner.

Here, we present brocade, an efficient and customizable ChIP-Seq data analysis pipeline that can be used to analyze publicly available ChIP-Seq data. To demonstrate the utility of brocade, we applied it to study the tissue-specificity of the glucocorticoid receptor (GR). Glucocorticoids are anti-inflammatory drugs commonly used to treat diseases such as asthma\(^1\). At a cellular level, glucocorticoids act by diffusing across the cell membrane and binding to GRs that then translocate to cell nuclei and modulate transcription of various genes in a tissue-dependent fashion\(^2\), including the upregulation of anti-inflammatory genes\(^3\). Although glucocorticoids are known to directly modulate gene transcription via GR binding to glucocorticoid response elements (GREs) and other transcription factors, the cell-specificity of GR-mediated gene transcription is not fully understood. We used brocade to analyze five publicly available GR ChIP-Seq datasets corresponding to five cell types to identify cell type-specific direct transcription targets of the GR.

**Methods**

*Reproducible Analysis of ChIP-Seq Data*

We created brocade, a set of Python scripts that generate bash and R markdown scripts that invoke various functions to facilitate the nearly automated analysis of any ChIP-Seq dataset, with human decision-making required for key steps such as selection of relevant phenotype data (Figure 1). A high-performance computing (HPC) environment is required to run the pipeline efficiently; bash scripts generated by brocade are currently in Platform Load Sharing Facility (LSF) format, a common workload management platform used in IBM clusters. Bash scripts are submitted to an HPC environment to perform GEO/SRA file downloads, read alignment and mapping, peak calling, quality control and differential binding analysis. The data download step can be skipped if a user would like to analyze local ChIP-Seq files. R markdown scripts produced by brocade are used to generate three html reports that (1) describe publicly downloaded datasets, (2) provide quality control metrics, and (3) report differential binding analysis results. Full instructions and code are available on GitHub at [https://github.com/HimesGroup/brocade](https://github.com/HimesGroup/brocade) (individual Python scripts are in the `pipeline_scripts/` directory; R markdown template files are in the `template_files/` directory). We keep separate Python scripts for each of these steps rather than consolidating them into a master script because user input is required at key points during analysis. Additionally, separating steps allows users to more easily understand and customize scripts to suit their needs.

![Figure 1. Steps followed by brocade to analyze ChIP-Seq data along with corresponding R packages (in bold) and other software used.](image-url)

372
Publicly Available Data Download and Phenotype Preparation. Brocade downloads ChIP-Seq raw sequence data in fastq format by retrieving files from an ftp address corresponding to a user-provided GEO accession number using the SRAdb R package. A phenotype file is generated based on information extracted from the phenoData object of the GSE Matrix file that users must confirm is appropriate for desired analyses. Alternatively, users can provide their own fastq and phenotype files.

Read Alignment, Peak Calling, and Quality Control. Adapters, if specified, are trimmed using Trimmomatic22 and overall quality control metrics of fastq files are obtained using FastQC23. Trimmed reads are aligned to the reference genome (currently hg38) using BWA24. Bamtools25 is used to count and summarize the number of mapped reads, while Picard Tools26 is used to compute the insert size of paired-end libraries. Aligned read files are converted to bigwig format, which can be uploaded to the UCSC Genome Browser for peak visualization. DNA-protein binding sites are identified using MACS226 where broad or narrow peak calling is assigned to histone modifications as needed.

Differential Binding and Peak Annotation. Differential binding analysis is performed with the R package DiffBind27, which has built-in functions to retrieve read counts by Rsamtools and GenomicAlignments, and uses DESeq2 to compare binding differences between conditions of interest (e.g., treatment vs. control vehicle)28. The Benjamini-Hochberg method is used to adjust for multiple comparisons and calculate adjusted p-values (q-values). Binding sites are annotated with ChIPseeker29 and binding motif identification is performed with Homer13 and visualized with the R package seqLogo.

Primary GR-Mediated Transcriptomic Changes

ChIP-Seq Datasets. Publicly available ChIP-Seq datasets that measured GR-binding induced by glucocorticoid exposure were obtained from GEO/SRA by searching for the term “glucocorticoid receptor” with Homo sapiens selected as organism. To identify genes with active transcription in/near GR binding sites, we utilized RNAP2 ChIP-Seq datasets provided with GR ChIP-Seq datasets when possible. For GR ChIP-Seq datasets with no available RNAP2 ChIP-Seq profiles, we sought microarray datasets obtained for equivalent cell types under similar treatment conditions in GEO. We utilized brocade to analyze the GR and RNAP2 ChIP-Seq datasets and identify differential binding sites for samples exposed to glucocorticoids vs. control. GR and RNAP2 binding sites were considered to be significantly changed by glucocorticoids if q-values were <0.05. Differential gene expression results for microarray samples were obtained using RAVED (https://github.com/HimesGroup/raved)30. Genes were considered to be significantly differentially expressed with glucocorticoid exposure if q-values were <0.05.

Identification of Shared and Cell Type-Specific Primary GR Target Genes. We defined primary GR target genes as those genes with a GR-binding site within ±20 kb distance of the gene’s transcription start site (TSS), while also having either (1) an RNAP2-binding site within ±3kb of the gene’s TSS (i.e. promoter region), or (2) a significant differential expression result in the corresponding microarray dataset. We identified shared and cell type-specific primary GR target genes by comparing results obtained across all available cell types.

Results

Overview of Brocade Reports

Brocade output html reports include quality control checks and a summary of annotated binding sites for each study of interest. The quality control report has tables and plots illustrating the summary read counts, percentage of mapped and unmapped reads (Figure 2A) and a principal component analysis (PCA) plot based on mapped reads per sample. The differential binding report provides volcano plots (Figure 2B), a PCA plot based on differential binding results, heatmaps, and boxplots of log2 normalized counts (Figure 2C) for significant binding sites identified (i.e., those with q-value <0.05). The report includes select plots from the R package ChIPseeker: frequency of read counts within ±3 kb of the TSS (Figure 2D) and distribution of binding site distance relative to TSS (Figure 2E), as well as sequence logos of top motifs (Figure 2F).

Publicly Available ChIP-Seq Datasets

Our GEO/SRA search yielded glucocorticoid response ChIP-Seq datasets with dexamethasone exposure for five cell types: airway smooth muscle, bronchial epithelial (Beas-2B), adenocarcinomic alveolar basal epithelial (A549), and (2) a differential control, are trimmed using Trimmomatic.
acute lymphoblastic leukemia (RS4;11) and lymphoblastoid (Table 1). RNAP2 ChIP-Seq profiles were available for the three structural cell types (i.e., airway smooth muscle, Beas-2B and A549). We used gene expression microarray datasets GSE71615 (10nM dexamethasone, 24 hr) and GSE44248 (1000nM dexamethasone, 8 hr) for the RS4;11 and lymphoblastoid cells, respectively. Following analysis of ChIP-Seq datasets with brocade, we retained all significant differential binding sites (q-value < 0.05) for the three structural cell types. For the RS4;11 and lymphoblastoid cell datasets, we retained glucocorticoid-induced GR-binding sites with log2-fold change ≥1, as the RS4;11 dataset lacked replicates and no significant GR-binding sites (q-value <0.05) were identified for the lymphoblastoid cell line. Significant genes (q-value <0.05) from the microarray differential expression analysis were also retained.

ChIP-Seq Results

We found 39,328 differential GR-binding sites for airway smooth muscle, 20,620 for Beas-2B, 7,818 for A549, 5,113 for RS4;11 and 999 for lymphoblastoid cell line, which corresponded to 6,421, 4,130, 2,297, 1,391, and 137 gene targets, respectively. Most differential GR-binding sites lied beyond 20kb of TSSs (Figure 3A), with a correspondingly large proportion of GR-binding sites located in intronic and distal intergenic regions (Figure 3B). Compared to the large number of GR-binding sites, only 3,220, 1,845, and 2,173 differential RNAP2-binding sites were identified for airway smooth muscle, Beas-2B, and A549, respectively. 8,449 differentially expressed genes for RS4;11, and 262 for lymphoblastoid cell line were identified. Thus, the number of primary GR target genes, based...
on overlap of GR-binding-associated genes with evidence of active transcription (i.e., RNAP2 bound genes or differentially expressed genes obtained via microarray), was 710 for airway smooth muscle, 405 for Beas-2B, 249 for A549, 685 for RS4;11, and 1 for lymphoblastoid cell line (Figure 3C).

**Figure 3.** Characteristics of GR-binding sites for each cell type. (A) Number of GR binding sites within and beyond 20kb of TSS of annotated genes. (B) Proportion of GR binding sites according to type of genomic region. (C) Genes with GR-binding that have (green) vs. do not have (blue) active transcription in response to glucocorticoid exposure as determined by RNAP2 or microarray results. ASM: airway smooth muscle; Beas-2B: airway epithelial cells; A549: adenocarcinomic alveolar epithelial cells; RS4;11: acute lymphoblastic leukemia cells; LCL: lymphoblastoid cell lines.

**Shared and Cell Type-Specific Primary GR Target Genes**

The majority of primary GR target genes were cell type-specific, consistent with our previous transcriptomic findings for genes that were differentially expressed in response to glucocorticoid exposure (Figure 4)\(^{30}\). Because the lymphoblastoid cells only had one primary GR target gene (C16orf87) that did not overlap with the primary GR target genes of any of the other cell types, its results were excluded from Figure 4. Twelve primary GR gene targets, (i.e., FKBPs, MAP3K6, ST3GAL4, IRAK3, NFKBIA, IER2, STX10, ZFP36, TIPARP, IGF2BP3, NBN, DECR1) were shared across airway smooth muscle, Beas-2B, A549 and RS4;11, which included the well-known glucocorticoid-responsive gene FKBPs and IRAK3, a gene that is highly expressed in response to glucocorticoid exposure in airway smooth muscle\(^{36, 37}\) and whose variants have been associated with asthma in European populations\(^{38, 39}\). Thirty-eight additional genes were shared across structural cells, including the known glucocorticoid-responsive genes PER1\(^{36, 37}\), CEBPD\(^{36, 37}\), and DUSP1\(^{36, 37, 40}\). Although Beas-2B and A549 originate from bronchial epithelium, Beas-2B and airway smooth muscle shared more primary GR target genes than Beas-2B and A549 (195 vs. 90).

**Figure 4.** Overlap of primary GR target genes among four cell types.
To confirm shared and cell type-specific results of some primary GR target genes at the level of mapped reads, we checked plots of bigwig files created by brocade. Specifically, we confirmed that there was differential GR-binding induced by glucocorticoids in three cell types for FKBP5 and CRISPLD2, a gene known to be differentially expressed in response to glucocorticoid exposure in airway smooth muscle.\textsuperscript{36, 37} FKBP5 had 4 significant differential GR-binding sites in airway smooth muscle, 6 in Beas-2B, and 6 in A549 (Figure 5A), while CRISPLD2, had 5 in airway smooth muscle, 4 in Beas-2B, and one in A549 (Figure 5B). Differential RNAP2-binding sites for FKBP5 were observed in all cell types (Figure 5A), whereas for CRISPLD2, they were only observed in airway smooth muscle cells after glucocorticoid exposure (Figure 5B).

To confirm that ChIP-Seq results were consistent with transcriptomic results more broadly, we obtained gene expression data for each gene available in our web application REALGAR\textsuperscript{41}, and confirmed that FKBP5 was differentially expressed with glucocorticoid exposure vs. control in all three cell types, while CRISPLD2 was differentially expressed only in airway smooth muscle.

**Figure 5.** Differential GR- and RNAP2-binding sites near genes (A) FKBP5 and (B) CRISPLD2 in airway smooth muscle, Beas-2B, and A549 cells treated with dexamethasone (green) and control vehicle (orange). Asterisk (*) indicates most significant GR or RNAP2 binding site.
Discussion

With the growing interest in leveraging publicly available data, we present brocade, a pipeline that facilitates automated ChIP-Seq data analysis spanning data download from GEO/SRA to differential binding site identification and annotation. As integration of multiple datasets relies on having accurate and consistently obtained results for individual studies, brocade was designed to streamline and standardize ChIP-Seq data analysis. It produces well-documented yet concise html reports that are easily customizable to allow users to include alternative methods. Although brocade is nearly automatic, researchers are required to manually inspect quality control metrics and plots to identify sample outliers and define phenotypes of interest prior to performing differential binding analyses. To maximize use of all publicly available ChIP-Seq datasets, brocade can process standard ChIP-Seq experimental designs that include input DNA and biological replicates to control for genomic artifacts and individual sample variation, respectively1, but also datasets that lack such controls.

There is no consensus on how to assign a specific GR-binding site to a potential gene target on a genomic scale, especially when GR-binding occurs distant to TSS regions. The majority of GR-binding sites have been found to be outside of promoter regions but enriched within 100kb of glucocorticoid-responsive genes42. We restricted our definition of GR-binding sites to include those within 20kb of a target gene’s TSS, a plausible distance that is used in many studies31, 32 and one supported by the fact that among the hundreds of primary target genes we identified, many were well-known glucocorticoid-responsive genes. However, we may have excluded GR bindings that occur in distal enhancers, as the ability to accurately link distal binding events to transcriptional regulation is limited42.

Previous studies have compared protein-DNA binding regions across cell types to identify shared and unique transcription factor binding sites1-43. However, transcription factor binding events alone do not guarantee their role in mediating gene transcription. To identify GR-binding sites that were more likely to mediate glucocorticoid-induced gene transcription, we combined GR-binding site data with evidence of gene transcription provided by RNAP2-binding or differential gene expression results. Previous studies identified glucocorticoid-responsive genes such as FKBP5 across multiple cell types, and PER1 and CRISPLD2 as specific to airway smooth muscle36, 37. Our results found that the transcriptional response of CRISPLD2 to glucocorticoids occurs via promoter-proximal GR binding and is specific to airway smooth muscle, but these cell type-specific findings require further experimental validation. Future studies could compare DNA sequences of the GR-binding sites identified in CRISPLD2 or other genes to determine whether shared and cell type-specific transcriptomic changes involve direct GR binding to GREs or GR-tethering to transcription factors.

Ideally, ChIP-Seq experiments include controls such as RNAP2 ChIP-Seq that help to determine whether transcriptional response accompanies transcription factor binding, but some ChIP-Seq studies use gene expression changes measured by microarray or RNA-Seq as a proxy for changes in transcriptomic activity10. Our results were limited by the design of individual experiments, including different assays used to infer active transcription of genes (i.e., RNAP2 ChIP-Seq for airway smooth muscle, Beas-2B, and A549; microarray for RS4;11 and lymphoblastoid cell line), which likely introduced bias. Other limitations when comparing results across cell types are the heterogeneous dosages of dexamethasone administered, and the fact that one dataset lacked any replicates, which decreases the reliability of its results. Nonetheless, comparison of the GR ChIP-Seq datasets yielded promising results that stand to improve as more publicly available data is generated.

Future versions of brocade will include automated approaches to identify and process publicly available datasets using phenotypes and meta-data extracted from GEO/SRA entries and linked publications to increase its automaticity. For example, for datasets without RNAP2 ChIP-Seq, an automated search through GEO/SRA could identify an appropriately matched gene expression dataset. Future versions of brocade will also include analysis of more recent DNA-protein binding techniques such as ATAC-Seq, DNase-Seq, and STARR-Seq, as these become more widely used.

Conclusion

We developed brocade, a reproducible ChIP-Seq analysis pipeline, that facilitates analysis of publicly available datasets in GEO/SRA. We applied brocade to explore the cell-type specificity of primary GR target genes in five cell types (i.e., airway smooth muscle, Beas-2B, A549, RS4;11, lymphoblastoid). Most primary GR target genes showed cell type-specific activity (e.g., CRISPLD2), but twelve genes were shared across four cell types (e.g., FKBP5). These results indicate potential cell-specific mechanisms of glucocorticoid action that can be explored in future studies.

Abstract
We present a systemic approach to devise and deploy Privacy Preserving Record Linkage (PPRL) systems using asymmetric key cryptography and illustrate the strengths of such an approach. With our approach, the security implications of sharing a common secret salt across the network may be avoided, allowing the local participating sites to use private keys along with the current cryptographic hashes to maximally secure their own data. In addition, the final ciphertext tokens are compatible with those used by existing record linkage modules, allowing seamless integration with the existing PPRL infrastructures for downstream analysis. Finally, study-specific hash production requires action only by the central party. The main intuition for this work is derived from how asymmetric key approaches have enabled internet-scale applications. We demonstrate that such a design, where the local sites no longer need special-purpose software, affords greater flexibility and scalability for large scale multi-site linkage studies.

Introduction
Privacy preserving data sharing for collaborative research across different organizations has recently become a significant challenge in healthcare research\textsuperscript{1}. Data in electronic health records for a single patient may be spread across a number of different healthcare providers. After the patient visits different hospitals and clinics, their electronic health records are registered at the respective data repositories. Harnessing such disjoint information is crucial for establishing a complete longitudinal picture of the patient’s treatment history, assessing the patient’s comprehensive health condition, and improving overall healthcare quality. Complete datasets could be assembled by linking these disparate records; however, doing so directly requires matching certain patient records and may put patient’s privacy at significant risk. Relevant laws and regulations also restrict the sharing of protected health information (PHI) without prior consents from patients. Thus, secure and efficient technologies for privacy preserving record linkage (PPRL)\textsuperscript{2,3,4} are needed to strike the perfect balance between accurate data linkage and privacy protection.

To date, the predominant approach for PPRL is to use cryptographic hashing, such as the SHA-2 family algorithms\textsuperscript{5,6} to conceal PHI. Such a cryptographic hash method is suitable here because it performs a cryptographic transformation, after which the sensitive patient information is converted into hashes—a kind of ciphertext virtually indiscernible from random text strings. Another key property of such hashing algorithms is they work effectively as one-way functions, where the ciphertext (hashes) can be efficiently generated from plaintext but reverting back to plaintext is practically impossible. These two key properties ensure that sensitive identifying information is protected after the hash function is applied. Because the hash function is also deterministic, the same identifying data elements are always transformed to be the same hashes. As a result, the original patient data is de-identified into anonymized tokens and may then be transmitted outside the institution boundary for linkage analysis studies. Such techniques have been deployed in several multi-site network as the principle PPRL approach. Several clinical data research networks (CDRNs)\textsuperscript{7,8,9} funded by the national Patient-Centered Clinical Research Institute (PCORI)\textsuperscript{10,11} serve as prominent examples. Within these research networks, the cryptographic hashes are first generated at different local institutions to de-identify the records, and then submitted to a trusted central party where a designated honest broker performs the tasks of record linkage and deduplication.

Because protecting patient privacy is paramount, it is important to ensure the PPRL systems achieve high security standards. In principle, properly implemented hash functions (such as SHA-256 and SHA-512) constitute a noninvertible function. That is, one cannot reverse engineer the hashing transformation to reveal the identifying data elements. However, a well-known attack against it is the so-called “dictionary attack”, where an attacker uses pre-computed tables to recover the plaintext. For example, if some possible contents are known to be contained in the inputs to the hashing function (such as name, date of birth, etc.), an attacker can construct rainbow lookup tables by producing hashes from the complete set of potentially valid input values. To reduce such security risks, a common approach is to use a “salt,” a random text string added to the original input text. Using a salt renders building the lookup table practically impossible because the attacker does not know what the salt looks like. For PPRL systems relying on cryptographic hash functions, one common salt needs to be used and shared with all participating sites\textsuperscript{12}. This raises security concerns because, if an attacker obtains the salt, a dictionary attack is again possible. Because the salt is common, this security risk applies to all the participants. Therefore, protecting the common salt is essential to
the security of hash-based PPRL systems. It is also worth noting that such security concerns apply whenever a common secret is used, including the “passwords” in PPRL systems using bloom filters.

To meet such challenges, proper security measures for safeguarding the secret salt have been developed. Typically, the secret salt needs to be securely transmitted to the local hosts where the hashing will take place. These hosts have specifications that meet HIPPA security standards, and only authorized employees in the covered entities have access to them. Such an approach becomes unwieldy when the network gets large, however, because all participating sites need first to obtain institutional approval and then securely obtain the hashing application. It becomes especially problematic in a situation where large-scale projects are conducted across networks that adopt different PPRL software products, since now the different vendors need to agree on which common secret salt to use, to disseminate it, and to ensure all parties involved are in compliance with the security protocol. This inevitably leads to technical and policy challenges related to salt distribution and management. Such challenges may vary for different research networks, but they likely always will exist and present significant hurdles for scaling up the PPRL solution across a growing number of networks. As PCORI are planning to carry out large scale and across network linkage, more efficient solutions are needed to mitigate such challenges.

The question then arises: “Can we design an approach to completely eliminate the security implications of sharing a common secret?” In this paper, we describe a novel approach to conduct privacy preserving record linkage using asymmetric key cryptography. With asymmetric keys, the problem of deploying a common secret salt is eliminated because keys are unique for each local institution. Instead of receiving a common salt, local sites instead use their own private keys for encryption and securely transfer their individual public keys to the central party. Critically, the final ciphertext produced remains resistant to cryptanalysis and known attacks. An important additional benefit for the approach is that it allows the PPRL system to scale up more easily, as will be demonstrated below.

Here we highlight the key requirements for such a system. In the method section, we describe how our system, dubbed “PPRL-Plus,” fulfills each of these requirements.

   A. Enable asymmetric key encryption such that local sites use their own secret keys to encrypt their own data, thus eliminating the need for a common secret salt.
   B. Apply strong cryptographic primitives that are sufficiently secure, such as the existing SHA-2 hashing methods and asymmetric key encryption primitives.
   C. Allow easy integration into existing PPRL infrastructures by ensuring outputs remain compatible with existing record linkage tools.
   D. Produce record identifiers in ciphertext that are still resistant to cryptanalysis and known (e.g., dictionary or rainbow table) attacks.

**Method**

In cryptography there are essentially two prevailing paradigms: symmetric key cryptography and asymmetric key cryptography. In symmetric key systems, the same key is used both for encryption and decryption, whereas in asymmetric key systems different keys are applied. One significant advantage for asymmetric key system is only sharing of the public key is required, unlike in symmetric cryptography in which the entire secret key needs to be shared. The common salt approach currently used in PPRL systems is analogous to symmetric key encryption because the same secret (salt) is shared among the local sites in advance, leading to the security concerns and management burdens discussed above. The main focus in our work is to enhance the existing PPRL systems with asymmetric key encryption in order to eliminate the need to use a network wide common secret, while ensuring encryption is sufficiently secure.

The most important applications for asymmetric cryptography include key exchange and digital signatures. Our main intuition derives from digital signatures and given the scope of this paper we are going to skip describing key exchange. In digital signatures, the sender first signs the plaintext message \( m \) using its private key and forwards the encrypted message to the receiver. The receiver then decrypts the message using the sender’s public key in order to verify the authenticity of the message that it actually originated from the sender. One common approach here is to perform a cryptographic transformation first by hashing the plaintext \( m \) and then signing the hash \( h(m) \) using the sender’s private key. The receiver then recovers the hashed message \( h(m) \) using the sender’s public key for verification purposes. In the context of PPRL, \( m \) corresponds to the patient identifying data and \( h(m) \) the hashes produced for record linkage.
Here we briefly go over the well-known RSA algorithm\(^\text{16}\) to illustrate the digital signature process. The first step in RSA algorithm is key generation, where a \{private, public\} key pair is generated as follows:

1. Choose two large primes \( p \) and \( q \) of similar magnitude.
2. Calculate \( N = p \times q \). (\( N \) will be the modulus.)
3. \( \varphi(N) = (p - 1) \times (q - 1) \). (This is the Euler toient function.)
4. Find \( e \), such that \( \gcd(e, N) = 1 \). (\( e \) is the public key.)
5. Find \( d \), such that \( d \times e \equiv 1 \mod \varphi(N) \). (\( d \) is the private key.)

During the signing process, a hashing function is first applied to obtain the hash \( h(m) \) for the plaintext \( m \). The digital signature is then calculated using the private key \( d \) as \[ \text{signature} = (h(m))^d \mod N. \] The signature is sent to the receiver along with \( h(m) \), which is also typically encrypted. The receiver may then verify the signature by comparing the value of \( (\text{signature}^e \mod N) \) to \( h(m) \). (In practice, the hash value \( h(m) \) is subsequently processed according to padding and encoding schemes as specified in standards like PKCS\(^\text{17}\) or OAEP\(^\text{18}\).)

Note that a given signature also constitutes an encrypted (and hashed) message, provided the \( h(m) \) is sent for comparison purposes. But the message is encrypted with a private key and decrypted with a public key, the opposite of what is done in the RSA key exchange algorithm proper. The message is hashed for performance reasons and also to prevent “existential forgeries,” a known security problem with RSA signatures. The receiver is able to verify the signature because the following holds true for properly generated key pairs \{\( e, d \)\} and any non-negative integer \( k \):

\[
(h(m)^d)^e = h(m)^{de} = h(m)^k \varphi(N) + 1 = (h(m)^\varphi(N))^k \times h(m) = h(m)(1)^k = h(m) \mod N
\]  

(1)

Note the digital signature not only uses asymmetric key cryptography but also makes use of a hash function, so it already contains those key components required in our proposed PPRL-Plus system. However, closer scrutiny reveals the last requirement D is not satisfied. The reason is that in the end the hash \( h(m) \) is recovered, unlike in the existing PPRL solutions, where the salt has been mixed in to produce \( h(salt||m) \). Since unsalted hashes are susceptible to dictionary attack, the requirement is not met yet.

The fundamental transformation scheme we want to perform may be illustrated using the following simple example:

Alice: “abc” \( \xrightarrow{\text{PrivateKey}^a} \) “foo” \( \xrightarrow{\text{PublicKey}^a} \) “xyz”  
Bob: “abc” \( \xrightarrow{\text{PrivateKey}^b} \) “bar” \( \xrightarrow{\text{PublicKey}^b} \) “xyz”

where “xyz” \( \neq \) “abc” in both cases.

Here Alice and Bob both hold “abc,” which they each transform into different ciphertext tokens (denoted as “foo” and “bar” respectively) at their local sites using private key encryption. These different tokens are transferred to the central party, where they are subsequently transformed into the same final ciphertext tokens (denoted as “xyz”) using the appropriate public keys. The crucial requirement for this transformation scheme is that reversing the final ciphertext back to the original text must be infeasible (denoted as “xyz” \( \neq \) “abc”). If we apply standard RSA digital signatures, the final tokens will be equal to the original \( h(m) \) value “abc,” which is what is needed. Security concerns arise (in the context of PPRL) if the final ciphertext can be easily reversed back to \( h(m) \), because when \( h(m) \) does not utilize the secret salt, it is susceptible to attack.

To address this, we present a novel method for key generation, based on RSA, to produce asymmetric key pairs that satisfy special mathematical properties. We couple this with a second component: a compression algorithm to produce de-identified tokens suitable for the existing record linkage software modules. More specifically, these ciphertext tokens not only have the same format (such as the commonly used hexdigest format), but also the same cryptographic properties of the regular hashes. We call a ciphertext token containing such properties a pseudo-hash. The first component (Algorithm 1) is executed at the local sites, while the second (Algorithm 2) is executed by the central trusted party to generate tokens for linkage analysis.

The PPRL-Plus key generation algorithm follows:

1. Let \( |N_2| \) be the size of modulus \( N \) in binary. (Default value: 2048.)
2. Let \( |h(m)|_2 \) be the size of the hash in binary. (Default value: 256, when SHA-256 in use.)
3. Choose \( 1 < r < \frac{|N_2|}{|h(m)|_2} \). (Default value: 7.)
4. Execute steps 1 through 3 of RSA Key Generation.
5. Find the key pair \( \{d', e'\} \), where \( d' \times e' = r \mod \varphi(N) \).
6. \( d' \) is the private key, and \( e' \) is the “protected” key.

**Algorithm 1.** Modified key generation for PPRL-Plus. The subscripts “2” here denote the binary format.

In this algorithm, we introduce a new integer parameter \( r \), such that the binary width of \( h(m)^r \) is guaranteed to be less than that of \( N \) (the same as RSA key size). This holds when the size of \( h(m)^r \) in binary is at least \(|h(m)|_2\) bits less than that of \( N \) in binary. For example, in the algorithm above where the default SHA-256 hashing function is used, the hashes \( h(m) \) will be exactly 256 bits, using the default value of \( 7 \) for \( r \), \( h(m)^r \) will be at most \( 256 \times 7 = 1792 \) bits wide, which is guaranteed to be smaller than the modulus \( N \), a 2048-bit integer. Hence, the following holds true.

\[
(h(m)^{d'} e')^e = h(m)^{d' \times e'} = h(m)^{\varphi(N) \times k + r} = (h(m)^{\varphi(N)})^k \times h(m)^r = h(m)^r \mod N
\]

(2)

The above transformation corresponds to the original RSA verification algorithm. The main difference is that with the set of key pairs \( \{d', e'\} \), the original hash \( h(m) \) is transformed into \( h(m)^r \). The signing produces hash signatures \( h(m)^d \mod N \) and it takes place at the sender just as in the original digital signature procedure. Using properly constructed one-way compression function \( \gamma(h) \), it can be subsequently converted into a pseudo-hash \( h(m)^r \) that satisfy requirement D, as the following:

\[
\gamma(h(m)^r) = h(m)', \text{ where } h(m)' \neq h(m) \text{ and } |h(m)|_2 = |h(m)|_2.
\]

(3)

Here, the following key property must hold for \( \gamma(h) \): it takes an input whose binary size is approximately \( r \) times the binary size of the original hash \( h(m) \), and outputs a pseudo-hash whose binary size is exactly the same as \( h(m) \). For example, in our default setting where the original hash is produced by SHA-256 and \( r = 7 \), \( \gamma(h) \) takes input that is approximately 1792 bits long and outputs a pseudo-hash that is exactly 256 bits long, which is conveniently the same width as a SHA-256 hash value to be consumed by the existing hash matching modules. In most PPRL applications, the hashes are processed into the corresponding hexadecimal format using a digest function. For example, if SHA-256 is used, the outputs will be strings contain 64 hexadecimal characters. In our implementation, we take a number of randomly selected 256-bit blocks from \( h(m)^r \) and iteratively apply them as XOR stream ciphers. Due to the pseudo-randomness of the hash function in \( h(m) \), each 256-bit blocks randomly selected from the binary form of \( h(m)^r \) can be treated as a pseudo-random number, hence as a stream cipher. More formally, the compression algorithm can be described as follows:

<table>
<thead>
<tr>
<th><strong>Input</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td>( h(m)</td>
</tr>
<tr>
<td>( s : ) seed for random number generator (RNG)</td>
</tr>
<tr>
<td>( k : ) number of times XOR stream ciphers applied</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th><strong>Output</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td>( h(m)}_{16} : ) pseudo-hash in hexadecimal format</td>
</tr>
</tbody>
</table>

\[
\text{RNG} \leftarrow s \\
\text{index} \leftarrow \text{RNG}(|h(m)|_2) \\
\text{size} \leftarrow |h(m)|_2 \\
\text{block} \leftarrow h(m)\}_{index: \text{index} + \text{size}, \text{circular}} \\
\text{repeat } k \text{ times:} \\
\text{index} \leftarrow \text{RNG}(|h(m)|_2) \\
\text{stream} \leftarrow h(m)\}_{index: \text{index} + \text{size}, \text{circular}} \\
\text{block} \leftarrow \text{block} \oplus \text{stream} \\
\text{h(m)}_{16} \leftarrow \text{hexdigest(block)}
\]

**Algorithm 2.** Pseudo-hash compression algorithm. The subscripts denote binary or hexadecimal formats.

In this algorithm, the block size is defined as the standard hash size in binary. For example, if SHA-256 is used, the block size will be 256. The starting block index is randomly selected by a random number generator (RNG) from a range of integers up to the binary width of \( h(m)^r \), and indices are implemented as a circular array, such that the entire
range of \( h(m) \) may be utilized. Using a fixed value for the seed, the sequence of integers generated for the block indices are guaranteed to be the same every time the above algorithm runs. The seed is an important security parameter and must be kept secure. After the initial block is selected, the XOR stream cipher is repeatedly applied \( k \) times. Note that \( k \) must be chosen carefully. To satisfy requirement D, it must be infeasible to recover \( h(m) \) via \( h(m)^r \). It is crucial to ensure cryptanalysis of pseudo-hash output \( h(m)^r \) generated via Algorithm 2 cannot reveal \( h(m)^r \). Fortunately, without prior knowledge of how random indices are chosen, the probability of finding all correct stream ciphers can be estimated as follows (assuming \( r = 7, \) and \( |h(m)|_2 = 256 \) for SHA-256):

\[
\prod_{i=1}^{k} \frac{1}{|h(m)|_2} \leq \left( \frac{1}{256 \times (r-1)} \right)^k = \left( \frac{1}{2^{8 \times \log(20)}} \right)^k < \left( \frac{1}{2^{10.5}} \right)^k < \frac{1}{2^{512}} \quad \text{when } k = 50.
\]

Therefore, when we choose \( k \) appropriately, such probability is even smaller than finding a collision for a SHA-512 hash. In the above equation, where \( k \) is set to 50, an intruder has no reasonable way to invert the pseudo-hash output \( h(m)^r \) back to \( h(m) \), and then proceed to recover \( h(m) \). As a general guideline, \( k \) should be determined by the parameter \( r \) and the block size \( |h(m)|_2 \). Using such \( k \), enough random blocks are sampled from \( h(m)^r \) to ensure the chance that any parts of it were never passed through the XOR stream cipher would be very low. Specifically, using our default values \( (r = 7, k = 50 \text{ and SHA-256}), \) the probability that a given bit is never chosen is \( \prod_{i=1}^{k} P_i \cong \left( \frac{1}{2^{10.5}} \right)^k < 0.05\% \). Note that approximately 6 out of 7 bits within \( h(m)^r \) won’t be chosen as a part of the XOR stream cipher for each round.

Here we complete the discussions for the main algorithmic methods in PPRL-Plus system. The new key generation algorithm is a slight modification based on the widely used open standards of RSA key generation, and it not only offers the local sites the preferred private keys for encryption, but also does not require use of a common secret salt. Compared to existing PPRL systems in which all the participating parties needs to have special software to retrieve the salt and to produce the hashes, only the central trusted party needs one piece of additional software to run the pseudo-hash compression algorithm. Because it does not require the efforts to coordinate and disseminate the salt, this promises to be a more scalable solution to incorporate a large number of participating sites to perform intra-network record linkage studies. In the next section, we discuss how we have operationalized the different algorithmic components in a research data network setting, where we simulate a multi-site study. Notice such mode of operations also applies in multi-site studies that span several different research networks.

**Results**

In this section, we first explain how to deploy the key generation algorithm (Algorithm 1). The default value for \( r \) in the original RSA key generation algorithm should be 1 as always, the PPRL-Plus key generation algorithm can be achieved by using a new value for \( r \) in the product of \( d \) and \( e \mod \varphi(N) \) (as shown in step 5 of Algorithm 1). Using a good quality open source project, such an algorithm can be implemented quite easily. In our experiment, we set the default values for \( r \) to 7 as demonstrated above. New key pairs were generated around one second on desktop hardware.

![Figure 1. Key generation and hash signature generation workflow.](image-url)
Notice the key pairs in our discussion here are only meant to be used in the PPRL applications to encrypt the hashes. They are not the same as the regular RSA keys of the host server. To differentiate these keys, we call them PPRL-Plus keys. Once the key pair is generated, the private key \( d \) is used to encrypt the hashes created from the cryptographic hash algorithms (such as SHA-512 or SHA-256). This step corresponds to generating \( h(m)^d \mod N \). Here we leverage the security primitive that finding the modular root of an arbitrary number (hash signature) is infeasible when the key size is large enough. In our implementation the key size of 2048 bits is used according to the NIST recommendation\(^\text{19}\).

Notice the secret salt is no longer required when creating the hashes because the security for the hashes is now protected by the private key to which only the local site has access. The resulting hash signatures not only apply a cryptographic hash algorithm to de-identify the PHI, but also are sufficiently protected by the site’s own private key. Hence, they can be transmitted outside the institutional boundary to a file repository hosted by a central party for downstream analysis.

One major issue that needs to be addressed here is that we need to enhance the security measures with respect to the supposedly public key component \( e \). In regular RSA key generation, the public key \( e \) may be shared with impunity. This is expressly not the case for the method we describe here. If somehow an intruder obtains the private hash signatures \( h(m)^d \mod N \), the known value of \( e \) can be used to derive \( h(m)^e \), which can be mapped to \( h(m) \) for dictionary attacks. We thus call the \( e \) component a protected key in the PPRL-Plus system, as compared to public key in the regular RSA application. The resulting key \( e \) is then encoded in PEM format and securely forwarded to a central party when requested, as indicated in Figure 1.

![Figure 1. Pseudo-hash generation workflow.](image)

The pseudo-hash compression and the subsequent data distribution workflow is illustrated in Figure 2. In order to produce hashes suitable for linkage, the following actions are performed. A signature repository is populated with encrypted data from the various local institutions. The trusted party (also referred to as the honest broker) uses the pseudo-hash compression engine to process the data received from the various local institutions. As needed, protected keys are retrieved from the local sites and the hash signature files from signature repositories. The honest broker plays a coordinating role throughout this execution phase. During execution, the engine picks a fixed seed to ensure the XOR stream ciphers are obtained from the same set of blocks within \( h(m)^y \). Therefore, the same \( h(m)^e \) values from different local institutions are be compressed to the same pseudo-hashes \( h(m)^e \) for the down-stream linkage. During execution, details that have significant security implications (namely, the seed and the protected keys) reside only in the host machine’s memory. These data are never written to disk. Furthermore, they are properly scrubbed from
memory at the earliest opportunity. Notice that the private hash signatures $h(m)^d \ mod \ N$ by itself is sufficiently secure as long as the private key $d$ meets the standard size requirement.

Since all the submitted data needs to be processed by the compression engine, it is necessary that the compression algorithm offers acceptable speed performance. In our experiment, we implement the pseudo-hash compression algorithm using Python version 3.7.3, and we observe a simulated average speed of 0.4 millisecond per record using an Intel i7 8th generation processor. This translates to approximately 7 minutes to generate one million pseudo-hashes using a single-threaded application. Given this performance, we are convinced the compression algorithm is efficient enough to generate study-specific pseudo-hashes for multiple studies. On the other hand, we observe the average simulated speed to generate the private hash signatures is about 21 milliseconds, which translates to approximately 6 hours for 1 million private hash signatures. This is primarily due to the security requirement to use a sufficiently large private key. While such performance speed appears slow, it might actually be considered acceptable in practice, because the private hash signatures need only be generated once at each local site. In addition, such a performance issue may be addressed easily using parallel processing or hardware acceleration.

In large-scale data research networks where multiple studies are carried out, it is common to create hashes that may only be used for individual projects. This is necessary to comply with various data governance policies. In current PPRL systems, hashes created for one particular study may not match with hashes created for other protocols. Therefore, study-specific hashes must be generated using different secret salts, and all local sites need to run the hashing application as many times as there are studies requiring their site-specific hashes. This becomes unwieldy as the scale of the data research network grows larger, and more studies are in demand. Note that in PPRL-Plus, if a different seed is used in the compression algorithm, a different set of XOR stream ciphers will be obtained, and different pseudo-hashes will be generated. However, the pseudo-hashes created even with a different seed will still match if they originate from the same $m$ and $h(m)$. Such characteristics ensure pseudo-hashes are only capable of linking records under one study and cannot be used for linkage to other studies, assuming a different seed is used for each study. Moreover, since pseudo-hash generation is performed at an outside entity, the local institutions no longer need to re-generate linkage hash tokens for different studies. Thus, PPRL-Plus provides better scalability for conducting multiple concurrent projects. The resulting study-specific pseudo-hash tokens are further transferred to different study teams for downstream analysis, as illustrated in Figure 2.

**Discussion**

In the following table we compare our proposed PPRL-Plus system to the prevailing PPRL security measures. As we have explained previously, the main advantage for PPRL-Plus is to achieve the goal of using site-specific private keys for encryption. In order to produce the site-specific private hash signatures $h(m)^d \ mod \ N$, first hashes are calculated using the standard SHA-2 family functions. The hashing functions required such as SHA-256 or SHA-512 come with modern programming language and database applications and can be easily applied. Second, only slight modification to the open source RSA key generation library is required to change the remainder value from the default 1 to $r$. Third, the private hash signatures $h(m)^d \ mod \ N$ may be calculated efficiently. Fast implementations for the modular exponentiation function required in the third step are also available, such as the $\text{pow()}$ function from Python’s standard build-in library. Therefore, it is straightforward for participating sites to adopt this approach locally to create private hash signatures without using special-purpose vendor software.

Note that in regular digital signatures, padding and encoding schemes such as PKCS or OAEP are applied to prevent malleability attacks. However, in the context of PPRL, the main security threat is not about altering ciphertext.
Therefore, we may skip such padding schemes. If such padding is required, it is necessary to use a smaller value for the remainder \( r \), such that the conditions in equation (2) in the method section still hold. The resulting private hash signature is secure in its own right and may be transmitted securely outside the institutional boundary, as long as the key size is sufficiently large. Currently the NIST recommendation for the key size is 2048 bits. Guaranteed by the demonstrated security of the RSA formulation, the hash signatures \( h(m)^d \ mod \ N \) saved in the signature repository by themselves are resistant to cryptanalysis. Armed only with these signatures, intruders have no way to recover the original \( h(m) \). If a private hash signature were exposed, the relevant local site need only produce a new key pair, regenerate the private hash signatures, and permanently delete the old key pairs. Following such a recovery procedure, normal operations may be resumed. Because different local sites use different key pairs, the impact on any individual security instance is confined to a particular local institution. On the contrary, in common salt-based PPRL systems, the compromise of any individual institution may have broader impact.

Also note that while executing the pseudo-hash compression algorithm, the value of \( h(m)^r \) for the unsalted hash \( h(m) \) is present in the memory of the host machine. Since \( r \) is employed as a common public parameter, one can easily replace \( h(m) \) with \( h(m)^r \) in a dictionary table. Therefore, carrying out a cryptanalysis attack using \( h(m)^r \) is just as easy as using \( h(m) \). The seed for the random number generator also persists in memory, albeit for short period of time, posing another potential risk by possibly revealing how the XOR stream ciphers are applied. It is therefore very important to ensure the security of the host machine where the pseudo-hash compression engine runs, and to flush the memory completely as soon as these sensitive data are no longer required.

To eliminate such vulnerability completely, we seek a method to achieve the fundamental transformation scheme presented in page 3 without using resorting to intermediary processing that may reveal the original hash \( h(m) \) or any of its derivable forms. In future work, we will be seeking a function with suitable mathematical properties that can directly transform the private hash signatures into pseudo-hash tokens that are not practically reversible to the original hash values.

**Conclusion**

In this paper, we have demonstrated a novel framework to carry out privacy preserving record linkage for multi-site studies using asymmetric key cryptography. The main advantage of our approach is greater scalability by eliminating the need for pre-disseminating a common secret to participating sites. Our inspiration is derived from how asymmetric keys have helped scale up secure Internet applications. We have provided an overarching demonstration of how to design, implement, and deploy a PPRL system based on asymmetric keys. This work is still in its early stages, and we are working to identify functions with better mathematical properties to meet the fundamental transformation requirements.

Abstract

Opioid addiction in the United States has come to national attention as opioid overdose (OD) related deaths have risen at alarming rates. Combating opioid epidemic becomes a high priority for not only governments but also healthcare providers. This depends on critical knowledge to understand the risk of opioid overdose of patients. In this paper, we present our work on building machine learning based prediction models to predict opioid overdose of patients based on the history of patients’ electronic health records (EHR). We performed two studies using New York State claims data (SPARCS) with 440,000 patients and Cerner’s Health Facts database with 110,000 patients. Our experiments demonstrated that EHR based prediction can achieve best recall with random forest method (precision: 95.3%, recall: 85.7%, F1 score: 90.3%), best precision with deep learning (precision: 99.2%, recall: 77.8%, F1 score: 87.2%). We also discovered that clinical events are among critical features for the predictions.

Introduction

The United States is experiencing an epidemic of opioid related deaths due to the misuse and abuse of opioids, including both prescribed pain relievers and illegal drugs such as heroin and synthetic fentanyl. According to Han1, 91.8 million (37.8%) civilian non-institutionalized adults in the US used prescription opioids in 2015. Among them, 11.5 million (4.7%) misused them and 1.9 million (0.8%) had a use disorder. Between 2005 and 2014 OD-related hospitalizations and emergency room visits increased 64% and 99% respectively.2 According to Scholl L3, drug overdoses resulted in 70,237 deaths during 2017, and 47,600 (67.8%) of them involved opioids.

Improving current clinical practices can potentially reduce the risks of opioid misuse or overdose. For example, CDC4 has provided recommendations for prescribing opioids for chronic pain care on opioid prescription for primary care clinicians. The joint commission also provided new and revised pain assessment and management standards for accredited hospitals. Clinical decision support systems (CDSS) can provide medical advice through integrating a patient’s EHR data for inference, which holds high potential for improving clinical decisions and clinical practices. For instance, using EHR data to help physicians provide better care in opioid use disorder is proposed5, which depends on understanding the past history of patients and using pre-defined rules for the decision support. It is particularly important to predict and identify patients at risk for opioid toxicity in time for optimal clinical interventions, such as reducing opioid dosage or suggesting alternative options for chronic pain management.

CDSS is made possible with the adoption of EHR, which has increased dramatically with the introduction of the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009. Besides EHR data managed by healthcare providers, large scale EHR data are also made available through government open data initiatives, such as claims data from the New York State Statewide Planning and Research Cooperative System (SPARCS).7 In addition, commercial EHR vendors often provide large scale de-identified EHR data for research purposes; for example, Cerner’s Health Facts is a large multi-institutional de-identified database derived from EHRs and administrative systems.

Traditional machine learning has been widely explored and discussed in previous work8,9,10,11. Recently, deep learning methods are gaining popularity in EHR based predictive modeling. For instance, Rajkomar et al. performed a large scale deep learning-based study with high prediction accuracy using EHR data in multiple medical events prediction12. Another study employed a fully connected deep neural network to suggest candidates for palliative care.13 Recurrent neural networks (RNN) are also applied to take advantage of patient’s background information for prediction of clinical events12,14,15,16. For example, one study explored the application of RNN for chronic disease prediction using medical notes17. Our recent work has applied fully connected networks for predicting diseases and improving coding18,19. For opioid related application, Che20 followed a deep learning based method to classify opioid patients into opioid-
dependent and long-term users. Ellis used machine learning classifiers to predict the likelihood of patients having substance dependence 21.

In this paper, we built multiple prediction models for predicting the risk of opioid poisoning in the future using patients’ history from claims data and EHR data respectively, and examined most important features for such predictions. We leveraged large scale databases to identify features that are commonly associated with opioid poisoning, while minimizing irrelevant features. We used the medical records of a patient for the prediction, including demographic information and past medical history including diagnoses, laboratory results, medications and related clinical events. Both traditional machine learning algorithms and deep learning methods were studied in our research. Our results demonstrated that with comprehensive EHR data such as Health Facts, our models provided highly promising prediction results: we were able to generate a best recall using Random Forest based method (precision: 95.3%, recall: 85.7%, F1: 90.3%, AUC: 95.1%), and best precision and Area Under the ROC Curve (AUC) with Neural Networks (precision: 99.2%, recall: 77.8%, F1: 87.2%, AUC: 95.4%). We also discovered that clinical event features play critical roles in the prediction.

Methods

Data Sources

We extracted inpatient EHR data from two clinical databases, SPARCS and Health Facts, as our data sources. 

SPARCS Inpatient Data. We used hospital discharge data from New York State SPARCS7 database. New York State requires any New York State healthcare facility (Article 28 licensed) certified to provide inpatient services, ambulatory surgery services, emergency department services or outpatient services to submit data to SPARCS. The purpose of SPARCS is to create a statewide dataset for providing high quality medical care by serving as an information source.

Cerner’s Health Facts Inpatient Data. We also utilized Cerner’s Health Facts as another data source for our studies. Health Facts includes de-identified EHR data from over 600 participating Cerner client hospitals and clinics in the United States. In addition to encounters, diagnoses, procedures and patients’ demographics that are typically available in claims data, Health Facts also includes medication dosage and administration information, vital signs, laboratory test orders and results, surgical case information, other clinical observations, and health systems attributes22.

Diagnosis Codes for Data Extraction

All patients were classified into two groups, namely opioid overdose patients and other patients. Opioid overdose patients are defined as those who received at least one opioid related diagnosis code in their medical records. For those patients who have not been diagnosed with those codes, we took them as negative (non-opioid poisoned) patients.

The opioid poisoning related diagnosis codes are a collection of ICD-9 codes and ICD-10 codes (starting from October 1, 2015) for poisonings by opiates, opium, heroin, methadone, and other related narcotics. According to Moore23, the selected ICD-9 codes include 965.0 (Poisoning; Opiates and Related Narcotics), 965.00 (Poisoning; Opium/alkaloids, unspecified), 965.01 (Poisoning; Heroin), 965.02 (Poisoning; Methadone), 965.09 (Poisoning; Other opiates and related narcotics), E85.00 (Accidental Poisoning; Heroin), E85.01 (Accidental Poisoning; Methadone), 97.01 (Poisoning; Opiate antagonists) and E85.02 (Accidental Poisoning; Other Opiates and Related Narcotics), selected ICD-10 codes include T40.4 (Poisoning; other synthetic narcotics), T40.0 (Poisoning; opium), T40.1 (Poisoning; heroin), T40.2 (Poisoning; other opioids), T40.3 (Poisoning; methadone), T40.6 (Poisoning; narcotics), all of the codes and their descendant codes.

Although we don’t know if those negative patients will get opioid overdose in the future, we can take their status of opioid poisoning in the last visit as the future we want to predict. We can say that they have low risk of opioid poisoning in near future. Then we can use all the information of visits before last one as features for prediction.

Study Datasets

We built two independent study datasets for SPARCS and Health Facts respectively. We extracted records from January 13, 2005 to December 25, 2016 from SPARCS. We selected patients with at least one historic encounter before first opioid poisoned related diagnosis. We randomly chose 40,000 positive (opioid poisoned) patients. As the dataset would be highly imbalanced by having all non-opioid related patients, we chose 400,000 negative patients without a history of opioid poisoning.

For Health Facts database, we extracted records from January 8, 2000 to December 29, 2017. The selection of patients is similar to SPARCS data, but we further filtered patients and retained those who had at least one hospital visit with
a clinical event record to help in evaluating the importance of clinical events. We used 110,000 patients from Health Facts, with 10,000 positive ones and 100,000 negative ones.

**Features.** Information useful to predict future opioid overdose includes diagnosis codes, procedure codes, medications, clinical events and demographic information. Since SPARCS and Health Facts are very different datasets, the features from each dataset vary significantly.

Diagnosis codes specify diseases, symptoms, poisoning for patients, and the history of diseases are critical information for predicting the future. Due to the large space of ICD codes, in order to prevent influence of too many unrelated or biased features, we filtered the diagnosis codes based on their frequency of co-occurrence with opioid poisoning, or their frequency appeared in the history of opioid poisoned patients. For reliability, we removed all opioid poisoning related diagnosis codes to prevent the model from directly getting results from the related codes. Diagnosis codes are used for both SPARCS and Health Facts datasets.

Procedure codes are specific surgical, medical or diagnostic interventions received by patients. Procedure codes are extracted for both datasets.

Medications are recorded by NDC codes, which is available in Health Facts dataset only. Preprocessing medication codes followed the same procedures as diagnosis codes and procedure codes. After filtering, only 10% of them are selected in the feature space. As dosage and duration of medications can be important, they are added to the features space using medication codes. For a specific medication, we measured the time period that the patient took it and the total dosage the patient took during the period, and had them added to the feature space. Quantity of dosage is measured in according unit in the database, to illustrate it, liquid dosage such as Toradol IV/VM (ketorolac) is measured in tubes, solid dosage such as Pepcid (famotidine) is measured in tablets, and duration is measured in minutes.

Clinical events are related symptoms, procedures, and personal situations that are not formally classified into any codes above, which is available in Health Facts dataset only. Some of them are identified as clinical events in Health Facts, for instance, the pain level of patients, smoke history, height, weight, and travel information. Since 79.21% of hospitals in Health Facts have clinical event records, they can be helpful for most hospitals for prediction.

Demographic information such as age, gender and race are added to the feature space as well to improve the prediction. Since they are relevant to a patient’s social-economic status, we included it in the feature space in SPARCS dataset.

**Feature Selection and Normalization**

While there is a large number of codes from diagnosis, procedures and medications, many of them are not useful for prediction. Gathering all codes would also create a gigantic feature space that would then result in very slow training process. Therefore, we filtered the features to compress the feature space. For each feature category, we ranked all codes by their frequencies of occurrence in the history of patients with opioid poisoning. We kept the top 10% features in each category in the feature space. Note that Health Facts has more comprehensive features than SPARCS. The numbers of features selected are summarized in Table 1.

**Table 1. Summary of selected features for prediction in study datasets.**

For opioid poisoning patients, we used features from visits before they were diagnosed with opioid poisoning for the first time. We took advantage of all visits before the last one for non-opioid poisoning patients, features in all of those visits will be used for prediction. Their status of opioid poisoning in the last visit is the target we want to predict.

For ages, we segmented them into multiple age groups according to the ages of last visit: the first age group is 0-5, followed by every 10 years. This can accelerate the training process with minimal impact on the performance. For categorical features, for example, race and payment methods, One-Hot encoding method was applied to encode those features. Figure 1 illustrates how One-Hot Encoding is implemented for sources of payments. For Patient 1, a code [1,1,0,0,0,0,0] will be generated.

Figure 1. An Illustration of the One-Hot Encoding on Sources of Payment.

We used a binary representation for diagnosis codes, procedure codes, medication codes and clinical events. If one of these features is detected from a patient’s history, the feature value is 1, otherwise the value is 0. Other features, such as medication dosage quantity and duration, clinical events of numeric values such as blood pressure, height, pain score, are assigned with numeric value and are measured in according units in the database, for instance, height measured in centimeters, blood pressure measured in mm[Hg]. The feature preprocessing is illustrated in Figure 2.

Figure 2. Example of feature preprocessing or the prediction models.

**Prediction Methods**

The goal of this study is to predict opioid poisoning of patients in the future using existing EHR data. We built our prediction models with multiple machine learning methods. Traditional machine learning methods such as decision tree and random forest have been proved effective in many health data analytics applications. Recently, deep learning methods have been widely used due to the capability of handling large number of features. Since there are a large number of features in our studies, we decided to take advantage of deep learning methods as well and compared that with traditional methods.

**Traditional Machine Learning Methods.** We utilized methods including random forest, decision tree and logistic regression in our work, which have proven effective for EHR data-based prediction tasks. In the experiments,
we kept most settings and parameters with default values, and adjusted some of them to fit our tasks. In practice, for clinical decision support, identifying all patients with high opioid poisoning risk is desired, thus between high precision and recall rates, the high recall rate in the prediction model can be more critical. In logistic regression, we employed l2 regularization as the penalization and liblinear as the optimizing algorithm. Both random forest and decision tree models took Gini impurity as the criterion to split data in training, which will be further discussed for feature importance calculation below. Furthermore, there is no tree depth limit for either random forest or decision tree model. We assigned a 10 times higher weight to positive cases than negative cases for all three methods during the training phase in order to achieve a higher F1 score, which can potentially solve the problem that the dataset is imbalanced.

**Deep Learning Methods.** Deep neural networks have been proven effective in many healthcare prediction applications\(^\text{13, 14, 16, 20, 27}\). We implemented a fully connected neural network based model. Our model is composed of three fully connected layers, two dropout layers and one output layer. First two fully connected layers are each followed by a dropout layer and then followed again by one more fully connected layer, which is connected to the output layer. We set the dimension of first two fully connected layers as 512 and third fully connected layer as 8. Since this is a binary classification task, the dimension of the last layer is one. A dropout layer follows a fully connected layer to prevent overfit - it will randomly drop out a portion of outputs from previous fully connected layer at each training epoch. We set the portion or namely dropout rate as 20%. The framework of our neural network is illustrated in Figure 3.

![Figure 3. The framework of the neural network designed for the prediction model.](image)

A rectified linear unit (ReLU) function is used as the non-linear transformation function for each hidden layer. We chose ReLU for preventing vanishing gradient and sparse activation problems, and improving computation efficiency\(^\text{28}\). A sigmoid function is applied in the last layer. We learned the parameters by optimizing binary cross-entropy loss function. To minimize the loss function, Adam optimization algorithm was selected. Adam is an optimization algorithm can replace classical stochastic gradient descent procedure to update network weights iterative, it has advantages in computation efficiency and little memory requirement for it combines the best property of adaptive gradient algorithm and root mean square propagation\(^\text{29}\).

**Implementation.** In our experiment, the implementation environment is the Python programming language (2.7). Traditional machine learning methods are implemented with Python scikit-learn package\(^\text{30}\). Deep learning is implemented with Python Tensorflow\(^\text{31}\) and Python Keras\(^\text{32}\). Other used libraries include Python Numpy and Python Pandas. The training was performed on an NVIDIA Tesla V100 (16GB RAM).

**Results**

**Prediction Results Analysis**

In our experiments, for both SPARCS and Health Facts datasets, we randomly took 90% of positive and negative patients as training set and rest as test set. To be specific, 360,000 negative patients and 36,000 positive patients as training set, while 40,000 negative patients and 4,000 positive patients as test set, for SPARCS dataset. 90,000 negative patients and 9,000 positive patients as training set, while 10,000 negative patients and 1,000 positive patients as test set, for Health Facts dataset.
To comprehensively evaluate performance of models, we calculated all common metrics including accuracy, precision, recall, F1 score and AUC. As the dataset is imbalanced, accuracy and AUC can be misleading. As we stated in the previous section, recall is a critical factor for the prediction models. The F1 score is a measurement considering both precision and recall, so it is an aggregated assessment of the overall prediction performance. We compared traditional methods and deep learning method for two datasets respectively. The results are shown in Table 2. The best results for each metric category are highlighted in bold.

</tbody>
</table>

Results demonstrated our models are capable of classifying opioid poisoning very well. We can achieve an F1 score of 79.27% for SPARCS (by deep learning) and 90.30% for Health Facts (by random forest). For precision, the best performance we can achieve is through deep learning: 97.07% for SPARCS and 99.23% for Health Facts, indicating the ability of models to identify only opioid poisoned patients. For recall, we can achieve 71.68% for SPARCS and 85.70% for Health Facts respectively for the best case, indicating the ability to find all the opioid poisoned patients in the dataset. The best AUC score we can achieve is 94.94% for SPARCS and 95.41% for Health Facts respectively.

For the SPARCS dataset, which comes with a smaller number of features, deep learning generates the best F1 score and a comparable AUC score with random forest. For Health Facts, which has more comprehensive features, random forest has the best F1 score, and deep learning generates the best AUC score.

**Feature Analysis**

It is vital to understand the importance of different features in the models, to support researchers or clinicians to exploit potential causes or trajectories of diseases. Based on our best traditional method random forest, we generated top most important features for both datasets in Table 3 and 4 respectively. The rank and feature category are also shown in the tables. Random forest calculates the importance of each feature by using Gini importance\(^1\). It is defined as the total decrease in node Gini impurity index weighted by the probability of reaching that node averaged over all decision trees of the ensemble. Gini impurity index is defined as:

\[
G = \sum_{i=1}^{n_c} n_c p_i (1 - p_i)
\]

where \(n_c\) is the number of classes, \(p_i\) is the ratio of this class, and \(G\) is the Gini impurity index. Random forest is an ensemble of decision trees. For every input sample, each decision tree will decide the path from root to leaf node for it, and the leaf will tell if the case is positive or negative. Then the model will ensemble the results of all decision trees to decide the final result.

In every node of the decision tree, there is a feature to decide the path after the node. So for each node, samples left for each class are different, and the Gini impurity index will be different. Then we have Gini importance as:

\[
I = G_{\text{parent}} - G_{\text{split1}} - G_{\text{split2}}
\]

\(G_{\text{parent}}\) is the Gini impurity index of the parent node, \(G_{\text{split1}}\) and \(G_{\text{split2}}\) are the Gini impurity indexes for two child nodes. Finally, the weighted summation of Gini importance of all nodes for one feature in all decision trees will be the final importance of that feature.

For New York State SPARCS data, most important features are diagnosis codes. The top feature is “Sedative, hypnotic or anxiolytic dependence, continuous” (ICD-9 code 304.11, approximately mapped to ICD-10 code F13.20 “Sedative,
hypnotic or anxiolytic dependence, uncomplicated”). These disorders result from the non-medical use of medications known as sedatives, hypnotics, and anxiolytics. The second top feature is relevant to Hepatitis C (ICD-9 code 070.70 or ICD-10 code B19.20), which is commonly transmitted by needles shared among those who inject drugs non-medically34. The third top feature “other alteration of consciousness”. Common underlying causes of decreased consciousness includes drugs, alcohol, substance abuse, certain medical conditions, epilepsy, low blood sugar, etc. Note that marijuana misuse (“cannabis abuse, unspecified”) ranks top 4. There are multiple top features relevant to chronic pain (“other chronic pain”, “chronic pain syndrome”, “lumbago”). Injury from car accidents or third-degree burn are also among the top 20 features.

The Health Facts database has much richer features compared to SPARCS data. It includes many clinical events and medications in addition to diagnoses and procedures. Interestingly, basic measurements such as heart rate (Pulse, Heart Rate, Pulse Posterior Tibial Right, or Pulse Dorsalis Pedis Left) and respiratory rate are among top predicting features, as taking too much of opioid can lead to a slow heart rate and difficulty maintaining breathing. Temperature, pain scale, history of fall, and BMI are also among the top 20 features.

Table 5 summarizes the aggregated importance of each category of features on contributing to the prediction. For SPARCS, diagnosis dominates the contribution, and the procedure follows. Demographic information also contributes to the prediction. For Health Facts, the descending order of importance of the predictor categories is clinical events, diagnosis, medications, procedure and demographic information.

Experiment on Using Primary Data only for the Prediction

Since diagnosis codes are secondary data for billing purposes, we were interested in studying the performance with only primary data. We took the Health Facts dataset and removed all diagnosis codes and then built the same models. Table 6 shows the result before and after removing diagnosis features. By removing the diagnosis data, we could still achieve a good performance on prediction with similar results. Random Forest achieves slightly higher AUC without diagnosis codes.

Discussion

Data and evidence based studies hold high potential for studying the problem of opioid epidemic in the U.S. With the wide availability of Electronic Health Records, predictive modeling provides a powerful approach to automatically predict the risks of opioid overdoses. Compared to previous related work, for example Che et al. try to classify opioid overdose patients into short and long term users, our work is to identify potential opioid overdose patients among all patients. To our best knowledge, this is the first work on machine learning based opioid overdose prediction with large scale EHR data. Instead of limiting the method to a specific model, we proposed multiple models and compared their performance.
While claims data such as SPARCS has limited information, our experiments demonstrate that they can still achieve reasonable prediction results. More comprehensive EHR data such as Health Facts has richer information and thus can achieve very promising results. Our methods can achieve best recall with the random forest method (precision: 95.3%, recall: 85.7%, F1 score: 90.3% and AUC: 95.11%), and best precision with deep learning (precision: 99.2%, recall: 77.8%, F1 score: 87.2% and AUC: 95.41%).

The analysis of features also provides interesting findings. For example, in SPARCS-based claims data, Hepatitis C is an indicator of potential non-medical opioid use, as Hepatitis C infection is frequently infected due to the sharing of needles and syringes for drug use. Marijuana misuse, tobacco use and alcohol are also linked to opioid overdose. Chronic pain management and treatment of acute pain can lead to opioid overdose. With more comprehensive EHR data, we find many clinical events such as measurements of heart beat, respiratory rate and pain scale that can help the prediction, and the clinical events dominates the contribution for prediction. By removing secondary data such as diagnosis codes, we find that our model can still achieve comparable performance. Our study also demonstrates that demographic information and sources of payments are helpful factors for the prediction.

One important information source that could enhance our models is clinical notes, which are missing from datasets in this study. In our future work, we will include clinical notes by applying natural language processing technologies. Another limitation of our method is that we did not employ any specific imputation method to deal with the missing value problem. To include more features with many missing values, we will employ different imputation methods. Besides, for convenience in this work, we took all patients that has not been diagnosed as opioid overdose as negative patients, but actually we don’t know about their future, we will try to apply more reasonable way to identify positive and negative patients. For the deep learning models, we currently have a relatively simpler architecture which does not take advantage of the temporal factors of the data and visits. We will explore RNN method and combine both outpatient and inpatient visits for future studies.

Conclusion

The opioid epidemic has become a national emergency for public health in the United States. Identifying patients of high risk of opioid overdose can provide smarter and safer clinical decisions for treatment, and potentially improve current clinical practices for pain management. Our studies on machine learning based predictive models for opioid overdose prediction show promising results with both claims data and comprehensive EHR data. It demonstrates that an AI based approach, if implemented at clinical side, can achieve automated prediction with high accuracy, and provide an opportunity for AI assisted prediction to support healthcare providers to combat opioid crisis.

Abstract

Social and behavioral determinants of health (SBDH) are environmental and behavioral factors that impede disease self-management and can exacerbate clinical conditions. While recent research in the informatics community has focused on building systems that can automatically infer SBDH from the patient record, it is unclear how such determinants change over time. This study analyzes the longitudinal characteristics of 4 common SBDH as expressed in the patient record and compares the rates of change among distinct SBDH. In addition, manual review of patient notes was undertaken to establish whether changes in patient SBDH status reflected legitimate changes in patient status or rather potential data quality issues. Our findings suggest that a patient’s SBDH status is liable to change over time and that some changes reflect poor social history taking by clinicians.

Introduction

Social and behavioral determinants of health (SBDH) are environmental and behavioral factors such as unstable housing and substance use disorders that often impede disease self-management and can lead to or exacerbate existing comorbid conditions. Due to the established impact of SBDH on health outcomes for persons living with chronic disease, health systems are increasingly attuned to these determinants and the clinically meaningful information they provide. However, evidence suggests that providers often struggle to retrieve information related to SBDH, and that those providers who are unaware of SBDH provide worse quality care.

Integrating SBDH data into electronic health records (EHRs) has generated widespread interest among health systems and healthcare providers. The informatics community has focused on three approaches to integrating SBDH into EHRs: expanding data collection to include structured data elements representing SBDH, associating community-level SBDH information with individual patients, and using information extraction and Natural Language Processing (NLP) methods to identify patient-level SBDH information contained in clinical documentation. SBDH such as smoking status, substance abuse, and homelessness have been the focus of recent NLP approaches, looking for identifying these at the encounter level, but have to date achieved modest-yet promising performance. However, there has been little work so far on characterizing a patient’s SBDH status beyond a single encounter.

It is unlikely that a patient’s documented SBDH status is invariably consistent with the patient’s true state. Patients are often hesitant to disclose sensitive information such as sexual orientation and substance use to healthcare providers, and may be less likely to share sensitive information with non-physician providers. In addition, the quality of social history taking by clinicians is variable, and providers are liable to make incorrect assumptions about their patient’s health. As a result, a patient’s SBDH status recorded in the patient record may reflect inaccuracies attributable to phenomena inherent to clinical documentation of sensitive information.

There is little knowledge of how social and behavioral determinants of health as expressed in patient records change through time. While it has been established that an individual’s SBDH may change across the life course, it is unclear whether the information in EHRs accurately represent such changes. To our knowledge, the only relevant study that examined changes in SBDH documentation was conducted by Bejan et. al. in 2017, which observed cyclic transitions between the at-risk and homeless categories among homeless patients, and less frequent transitions among individuals with stable housing. In this paper, we conduct a longitudinal analysis of multiple SBDH as expressed in the patient record and attempt to answer several important questions. First, we assess whether SBDH change through time and
estimate their respective rates of change. Second, we conduct a survival analysis to examine the timescale of these changes. Third, we employ both quantitative and qualitative methods to examine potential data qualities issues related to SBDH.

**Dataset**

In this section, we describe the methods used to curate and analyze a longitudinal gold-standard corpus of clinical notes. A protocol for manual annotation of clinical notes was developed and followed by multiple rounds of annotation. The study described herein was approved by the Institutional Review Board at CUIMC and patient informed consent was waived due to the retrospective nature of the study.

**Development of Annotation Guidelines for SBDH**

Two physicians experienced in the prevention and treatment of HIV reviewed the biomedical literature to identify social and behavioral determinants that increased an individual’s risk for acquiring HIV. 29 individuals risk factors were selected and included sexual orientation, housing status, alcohol use and drug use which are the focus of the study described herein.

We obtained document-level annotations for the aforementioned SBDH domains and risk factors and thus considered all SBDH as binary variables. Annotators were instructed to review the entire length of each clinical document and label the presence of both the high-level domain and granular SBDH label. For example, the phrase “patient denies alcohol use” would be result in a positive label for the high-level SBDH domain ‘alcohol use documented’ but a negative label for ‘active alcohol use’. The annotation guide can be downloaded at [https://github.com/danieljfeller/SBDSH](https://github.com/danieljfeller/SBDSH).

**Creation of Gold-Standard Corpus for Longitudinal Analysis**

A corpus of clinical notes was obtained from the clinical data warehouse at Columbia University Irving Medical Center (CUIMC), a large academic medical center in New York City. For this study, we obtained all individual notes associated with 32 randomly sampled individuals with HIV who received care at CUIMC. The study cohort was characterized by analyzing structured demographic data extracted from the EHR system at CUIMC. Additional details on this cohort are described elsewhere.

Annotation was conducted by 1 physician and 2 medical students who were instructed to manually review every clinical document included in the patient record. An initial set of 3 longitudinal patient records were collaboratively coded by all annotators for training purposes; 76 notes were annotated by each of the 3 reviews and a Kappa of 0.736 was observed across all SBDH labels. Throughout the annotation process, annotators relied on the guidelines described above.

**Creation of Gold-Standard Corpus for Data Quality Analysis**

We collected a larger gold-standard corpus for analyzing data quality of SBDH documentation. In contrast to the longitudinal corpus described above, we included in this cohort HIV+ individuals associated with only a portion of their clinical notes annotated and required only that individuals had 2 or more notes with SBDH documentation. These notes were annotated for the purposes of a previous study.

**Methods**

The analysis described herein focused on 4 SBDH; sexual orientation, housing status, alcohol use and drug use. Encounters with confirmed documentation of SBDH were isolated and analyzed to examine changes in a patient’s SBDH status. and potential data quality issues. We then manually reviewed pairs of notes authored on the same-day with conflicting documentation to identify possible sources of data quality issues related to SBDH.

**SBDH Preprocessing**

A distinct dataset was created for each SBDH of interest and included only notes where the respective high-level SBDH was documented. For example, to be included in the analysis of ‘drug use’ status, it was necessary that a note discuss drug use (even if drug use was a negative label, as in “no history of substance use”). This way, all notes in that SBDH dataset had explicit discussion of that SBDH and either positive or negative findings for that SBDH. Notes that did not discuss the SBDH were not included; absence of a certain SBDH in a clinical note most often reflects the fact that this domain was not discussed by patient and provider, rather than evidence that the patient is a negative case.
Survival Analysis

To assess the rate of change in SBDH status, we simply parameterized each annotated document using sequence time (e.g., visit\_time\_1, visit\_time\_2, etc. where visit\_time\_i represents the time between the first and i\textsuperscript{th} visit in the longitudinal record of a patient) and estimated the likelihood that a patient at visit\_i would transition to a different state (e.g., ‘never used alcohol’ to ‘actively using alcohol’), as documented within the documentation at the next visit. This analysis was conducted using the corpus generated by a comprehensive annotation of the entire longitudinal record of the 32 HIV+ individuals in our cohort.

We used survival analysis to analyze the expected duration of time associated with changes in patient SBDH status. Observation periods were established between adjacent notes in a patient’s longitudinal history and time was measured in days. An event was defined as any change in SBDH status observed in the subsequent note. Observations were (right) censored when the subsequent note was observed with the same SBDH status as observed in the preceding (index) note. A survival function was estimated for each SBDH using the Kaplan-Meier estimate and can be interpreted as the fraction of clinical notes observed at time \( T \) with an observed change in SBDH status documented in the subsequent note:

\[
\hat{S}(t) = \prod_{t_i \leq t} \left( 1 - \frac{d_i}{n_i} \right)
\]

where \( d_i \) is the number of notes with subsequent SBDH changes at time \( t_i \) and \( n_i \) is the number notes not associated with any subsequent SBDH change (and who have not yet been censored) at time \( t_i \).

Quantitative Analysis of Data Quality

In order to assess data quality in SBDH documentation, we used a larger cohort of patients who were required only to have multiple notes manually annotated. Using the parameterization of sequence time described above, we considered illegitimate transitions to be those that were chronologically impossible; for example, a patient could be documented as having ‘never used alcohol’ subsequent to being documented as ‘actively using alcohol’.

In addition, we identified same-day conflicts in SBDH documentation by isolating clinical notes that were written on the same day by distinct providers. Similar to previous analyses, we required that all notes under consideration have confirmed documentation of the relevant high-level SBDH domain. Same-day conflicts were defined as observed discrepancies in SBDH status (e.g., documentation of “no active alcohol use” and “active alcohol use”).

Qualitative Analysis of Data Quality

We manually reviewed 20 note pairs that exhibited same-day conflicts in patient SBDH status with the goal of developing an understanding of the sources of data quality problems. 5 note pairs were gathered from each of the four SBDH analyzed herein. The sources of data quality issues were identified using a set of annotation guidelines we created for this analysis. Data quality issues reflected 1) inappropriate use of copy & paste if content was duplicated across notes of the same type, 2) an inaccurate problem list if outdated information contained in structured clinical data was automatically inserted into narrative free-text, 3) variable history taking wherein the note with positive documentation contained significantly more information regarding SBDH compared to the note with negative documentation (e.g. provider documents a minimal social history and does not inquire about specific substances, for example”), 4) a patient hesitant to disclose sensitive information when it was clear that both notes contained a detailed social history but that the patient gave conflicting answers across the notes, and 5) the use of a standard note template which automatically inserted negative and formulaic documentation of SBDH status.

Results

Cohort Characteristics

3273 clinical documents associated with 32 HIV+ individuals were manually annotated and included in the longitudinal corpus. All available clinical notes associated with these patients was annotated with a range of 11 to 473 notes per patients (median 50, mean 102). The longitudinal histories of patients in this analysis were of variable lengths and ranged from 196 days to 3146 days; the mean longitudinal history was 997 days and the median was 772 days.
75% of individuals were male (24) and the average age was 46 years with a standard deviation of 13.5 years. Race and ethnicity information was missing for a majority of the cohort, but 8 patients were documented as African American, 7 as Caucasian Hispanic, 2 as Caucasian non-Hispanic, and 1 as Asian.

The larger cohort used in the data quality analysis included 366 individuals with multiple annotated notes (4294 notes total). All available clinical notes associated with these patients was annotated with a range of 2 to 473 notes per patients (median 2, mean 11). The longitudinal histories of patients in this analysis were of variable lengths and ranged from 0 days to 3146 days; the mean longitudinal history was 469 days and the median was 174 days. 60.3% of individuals were male (221) and the average age was 53 years with a standard deviation of 12.2 years. Race and ethnicity information was missing for a majority of the cohort, but 71 patients were documented as African American, 58 as Caucasian Hispanic, 30 as Caucasian non-Hispanic, and 1 as Asian.

### Longitudinal Changes in SBDH

A state diagram illustrating changes of documentation status for alcohol use computed across the cohort of 366 individuals is presented in Figure 1, across 1077 pairs of consecutive notes.

Many patients in the longitudinal cohort of 32 individuals were observed to have temporal changes among all SBDH analyzed. Alcohol status was most likely to change across subsequent notes (23.3%), followed by drug use (10.4%), drug use (8.7%), and sexual orientation (1.1%). A chi-square goodness of fit test found a significant difference in these proportions ($\chi^2: 29.2, p < 0.001$).

A Kaplan-Meier plot that presents the 365-day survival function of the 4 SBDH analyzed in this study in presented in Figure 2. The y-axis represents the proportion of notes without changes in SBDH documentation, and the x-axis represents the number of days between each subsequent note. 365-day transition rates for housing status, drug use, and alcohol use were 39.6%, 30.6%, and 36.3%, respectively. The 365-day transition rate for sexual orientation was 6.9%.

### Data Quality in SBDH Documentation

While most of the transitions in SBDH status looked sensible, we observed illegitimate transitions in SBDH status as shown in Figure 1. Among 353 notes documenting patient SBDH status as ‘active alcohol use, 43 were followed by documentation of ‘never used alcohol’ (12.2%). Moreover, among 165 notes documented that the patient had ‘historical alcohol use’, 26 were followed by documentation of ‘never used alcohol’ (15.7%).

We also observed same-day conflicts in patient SBDH status. For instance, 23.2% of 56 same-day note pairs with alcohol status documented had conflicting indications of alcohol use, 21.2% of 52 same-day note pairs had conflicting indications of substance use, 6.8% of 44 same-day note pairs had conflicting indications of patient housing status, and 8.0% of 25 same-day note pairs had conflicting of sexual orientation. We also observed conflicts in SBDH documentation within a 7-day period. 12.6% of annotated notes associated with the same patient had conflicting
indications of alcohol use (N = 230). In addition, 14.3% of notes describing drug use exhibited the same changes (N = 265), as did 7.6% of notes describing housing status (N=198). 1.6% of notes with sexual orientation documentation exhibited same-week conflicts (N = 127).

Manual review of 20 same-day conflicts in SBDH revealed multiple sources of poor data quality with incomplete social history taking by clinicians being most common. Among the 20 manually reviewed note pairs with same-day conflicts in SBDH, 14 (70%) conflicts reflected variable quality of social history taking by clinicians, wherein the note with positive documentation contained significantly more detailed information regarding SBDH compared to the note with negative documentation. The majority of such instances entailed particularly brief social histories that may have reflected inaccurate assumptions and/or limited social history taking by healthcare providers. 2 note pairs exhibited evidence of an inaccurate problem list, wherein note content automatically generated from the patient’s EHR problem list conflicted with information contained in narrative free-text. 2 note pairs exhibited evidence that a patient was hesitant to disclose SBDH, as it was clear that both notes contained a detailed social history but that the patient gave conflicting answers across the notes. 1 note pair conflict reflected the use of a standard note template, which automatically declared negative SBDH status.

Discussion

The findings of this study suggest that social and behavioral determinant of health as expressed in the patient record exhibit changes over time. Our longitudinal analysis of 4 distinct risk-factors suggests that a patient’s SBDH status should be treated as a shifting, mutable variable in electronic systems. We also provide evidence that some changes in SBDH documentation reflect data quality issues and not actual changes in the patient state.

We present the first comprehensive longitudinal analysis of multiple SBDH as expressed in patient records. Four distinct SBDH were examined throughout the course of 32 patient records and exhibited varying rates of change. A patient’s recorded alcohol status was most likely to change, as 23.3% of adjacent encounters with documentation of alcohol use contained conflicting information. This may reflect the high prevalence of heavy episodic drinking among persons living with HIV, which has resulted in calls for repeated assessments of alcohol consumption in this population.\textsuperscript{30,31} While documentation of substance abuse and housing status were less likely to change compared to alcohol use, these SBDH exhibited changes across as much as 10% of adjacent encounters. Epidemiological studies suggest that these SBDH are likely to change; most individuals who are considered with unstable housing experience only transient periods of homelessness\textsuperscript{37}, and many HIV+ persons with substance abuse disorder engage in episodic
rather than sustained use.\textsuperscript{32,33} These findings suggest that automated approaches to inferring SBDH should not treat these variables as fixed patient characteristics and thus should reevaluate a patient’s SBDH status on a regular basis.

In contrast to alcohol use, substance abuse, and housing status, a patient’s recorded sexual orientation was unlikely to change, as 1.1% of adjacent encounters with documentation of sexual orientation contained conflicting information. This rate reflects the infrequent changes in sexual orientation observed among persons experiencing stigma and discrimination.\textsuperscript{34} This findings suggest that distinct SBDH are likely to change at different rates and thus may be reevaluated on different time scales.

Multiple findings indicated that some changes in patient SBDH status reflected data quality issues and not legitimate changes in the patient state. We observed a high frequency of implausible longitudinal changes in patient SBDH status, wherein a patient transitioned from an active status (e.g. active alcohol use) to having no history of active status (e.g. no history of alcohol use). In addition, we observed same-day conflicts in patient’s documented SBDH status. Our manual review of these discrepancies observed that most conflicts reflected the variable nature of social history taking. It has been established that some healthcare providers are reluctant to discuss sensitive issues with their patients, thereby limiting their ability to take a comprehensive social history.\textsuperscript{35} The implication of these data quality issues is that any attempt to characterize a patient’s SBDH status should not merely reflect the most recent documentation. Decision support systems that aggregate multiple instances of SBDH documentation may provide a more faithful representation of a patient’s SBDH status compared to data collected during a single encounter. Information retrieval and classification methods should utilize observation windows that leverage only recent EHR data\textsuperscript{36,37}, or weight decay techniques that model the decreasing relevance of data elements to computational phenotypes.\textsuperscript{38,39}

Future research should conduct a more comprehensive analysis by annotating all notes associated with a large corpus and use techniques such as mutual information to assess how the predictability of future SBDH status relative to existing documentation changes with time.\textsuperscript{40} Such an analysis would open the possibility for techniques that could accurately model the relevance of social and behavioral determinants of health documentation.\textsuperscript{41,42} In addition, more research is needed to better estimate the likelihood that changes in SBDH documentation reflect true changes in the patient state versus documentation errors. This could be accomplished by obtaining additional sources of data such as validated psychometric instruments or laboratory tests indicative of substance abuse.

Limitations

First, our methods did not enable us to quantify the proportion of SBDH changes that reflected true changes in the patient state and the proportion that reflected documentation errors. A key limitation of this study is our inability to estimate whether a patient’s SBDH status is accurate and note that obtaining this information is likely not possible using clinical notes alone. Second, while our annotators achieved a relatively high inter-rater reliability, there were likely some erroneous annotations and thus some temporal changes in SBDH status may reflect annotation errors rather than changes in documented SBDH status. Third, our findings were generated by analyzing data from a specific patient cohort treated at a single institution. The high prevalence of SBDH within the study cohort may have resulted in a higher frequency of SBDH changes.

Conclusion

Social and behavioral determinants of health as documented in the patient record are subject to change through time. Future approaches to automated inference of SBDH from EHRs should consider the fluid nature of these variables and the impact of data quality on their methods and results.

Abstract

We consider the task of producing a useful clustering of healthcare providers from their clinical action signature—their drug, procedure, and billing codes. Because high-dimensional sparse count vectors are challenging to cluster, we develop a novel autoencoder framework to address this task. Our solution creates a low-dimensional embedded representation of the high-dimensional space that preserves angular relationships and assigns examples to clusters while optimizing the quality of this clustering. Our method is able to find a better clustering than under a two-step alternative, e.g., projected K means/medoids, where a representation is learned and then clustering is applied to the representation. We demonstrate our method’s characteristics through quantitative and qualitative analysis of real and simulated data, including in several real-world healthcare case studies. Finally, we develop a tool to enhance exploratory analysis of providers based on their clinical behaviors.

Introduction

Exploratory analysis and visualization of health data are central to the advancement of clinical care. Clinical data are naturally high-dimensional and sparse because most medical concepts are not applicable to most individuals. For example, any individual physician performs a small subset of procedures, and any patient fills prescriptions for a small subset of medications. Our work seeks to provide effective representations of these settings by producing useful clusterings of high-dimensional sparse count data. Our focus is in the analysis of large-scale healthcare data arising from claims and health records databases, where we are interested in clustering patients or providers based on the number of time each billing code, procedure code, or drug prescription is observed.

Similarity between sparse, high-dimensional points is typically better measured through angular distances like cosine similarity rather than euclidean distance. As a result, many standard clustering methods will perform poorly in these tasks, and clustering algorithms in lower-dimensional representations have been developed to address this problem. For example, one popular approach adopts a two-step process: (a) learn a low-dimensional representation, (b) apply clustering over the low-dimensional representation, which is illustrated by the exemplar of principal components analysis (PCA) to find a low-dimensional representation followed by k-means to cluster points based on this representation\textsuperscript{1}. A variety of deep learning methods have also been used to find a low dimensional representation in the first step\textsuperscript{2}. For example, Tian et al.\textsuperscript{3} use stacked autoencoders to learn a representation, followed by k-means. Similarly, Trigeorgis et al.\textsuperscript{4} define a deep non-negative matrix factorization and use the representation thus learned to cluster data with k-means.

A major drawback of this two-step process is that the representation learned in the first step is not necessarily well suited to producing a clustering in the second step. For example, autoencoding is designed to minimize reconstruction loss, and a representation that minimizes reconstruction loss is not guaranteed – or even particularly likely – to map points to a meaningful clusterable space.

To address this issue, several methods have been defined that integrate both steps – reconstruction learning and clustering – in a single deep learning framework. This enables the representation to be informed by the clustering, not just by its ability to reconstruct data, and thus creates the possibility of finding both a more clusterable representation and a better clustering. For example, Xie et al.\textsuperscript{5} add a centroid-based soft clustering criterion to an autoencoder backbone and iteratively refine the autoencoder’s parameters so as to improve the quality of the clustering. Similarly, Yang et al.\textsuperscript{6} define a method that integrates an autoencoding deep neural network and a k-means clustering loss, and fits this model with an alternating stochastic gradient descent algorithm.
While these approaches show excellent performance on certain types of data, e.g. imaging, they are not well-suited to sparse count data. This is primarily due to their dependence on autoencoding with euclidean distances for representation learning. Even with additional constraints to encourage the representation to be well-clusterable, the autoencoders may not retain angular information relevant to a representation for high-dimensional sparse data. The use of centroid-based clustering compounds this problem because the identification of an appropriate centroid location may not be representative of any member of the cluster.

We argue that, instead of a centroid-based approach, an angular-based clustering is better suited for high-dimensional sparse data and that, therefore, an angular-based representation should be adopted. This representation constraint motivates our development of a novel clustering approach that embeds the representation on the surface of a hypersphere, where the angular distance from the axes or poles naturally provides cluster membership. While several support vector clustering algorithms have the option to incorporate angular distance into the kernel defining an embedded space\textsuperscript{7,8}, these methods do not preserve angular representation during clustering (instead the embedding is transformed into a graph), and these methods have not been shown to be scalable to the large sample sizes present in our applications.

**Our contribution.** We propose a method that learns a low-dimensional embedding with geometric constraints that enables simultaneous representation learning and cluster determination. We propose an architecture that simultaneously (1) optimizes signature reconstruction in an autoencoding framework, (2) embeds the signature on a low-dimensional hypersphere surface, and (3) assigns examples to clusters in a soft clustering by angular similarity. We further provide the following options. To account for the setting the case where we have expert knowledge about co-cluster membership, we provide a placeholder for an accessory loss to encode this information during optimization. The degree to which each component is prioritized can be adjusted by the user to enable enhanced exploratory analysis. To efficiently compare clusterings with different numbers of clusters, we also build our framework with a fixed hypersphere representation tied to lower-dimensional clustering hyperspheres.

We demonstrate our method’s characteristics and its advantages over previous work in simulations, and we illustrate the value of this approach through several case studies: provider characterization from Medicare claims and imaging characterization by radiology notes. We demonstrate the utility of our method with an informatics tool that characterizes providers based on their procedure and prescription signature in Medicare claims.

**Method**

We first describe the method and architecture with respect to inputs and outputs, then describe the distances and losses necessary for learning the representations, and finally specify customizations and implementation parameter choices.

Consider our input of a sparse count matrix $M$ with $N$ rows and $K$ columns. We are interested in clustering over rows (providers) and columns (prescriptions and procedures). We will consider clustering across rows and columns separately. First, we construct an autoencoder consisting of an encoder $\Psi_1$ and a decoder $\Psi_2$. For a row of matrix $M$, define the hidden representation $h$ of size $H$ such that $\Psi_1(x) = h$ and $M$ as the reconstruction given by $\hat{M} = [\Psi_2 \circ \Psi_1(x), \forall x \in M]$. Define $\Psi_3$ as the function transformation for the clustering module that takes as input $h$ and outputs cluster membership probabilities $c$, a non-negative vector of size $C$ that sums to 1: $\Psi_3(h) = c$. Figure 1 illustrates the framework for the neural network.

Next we define our losses which encode our desire to create a representation that maintains pairwise distances while endowing an angular distance for clustering. Unlike support vector clustering that uses all pairwise distances with complexity $O(N^2)$, our method uses pairwise batch distances $O(B^2)$ with batch size $B$, which alleviates the computational bottleneck when $N$ is large. Specifically, we propose to learn a hidden representation $h = \{h^c, h^||\}$ given by angle $h^c$ and norm $h^||$, such that the distance measure between examples in $M$ is approximately preserved in the angle $h^c$. To achieve this, we define batch pairwise similarity and its loss $L_{h^c, O}$ as a penalization to the autoencoder loss as follows. Define $h_B$ and $\hat{M}_B$ the representation and reconstructions for a batch of examples with sizes $B \times \{\cdot\}$ for $H$ and $M$ respectively. Let $\delta(x_i, x_j)$ be the pairwise distance measure.

Define $\delta_B$ the batch distance measure, i.e. $\delta_B(\{x_1, \ldots, x_B\}) = [\delta(x_i, x_j)]_{ij} \forall i, j \in \{1, \ldots, B\}$. Then, $L_{h^c, O} = \frac{1}{B} ||\delta_B(h^c_B) - \delta_B(\hat{M}_B)||_2^2$ captures the differences between the pairwise distances in $h^c_B$ and $\hat{M}_B$. 

409
Figure 1: Autoencoder with clustering module. Nodes are Input (I), Output (O), Hidden (H), and Cluster (C). H and O are constrained by a batch distance measure; we use cosine similarity for sparse count data. H \( h^* \) and C are constrained by batch cosine similarity that ties the angular representation to the cluster probability. See details in the text. The layers and connectivity are shown in the Table on the right. LReLU: leaky rectified linear unit

While \( L_{h^*O} \) encourages matching distances in \( h^* \) and \( M \), two vectors in \( h \) could have the same angle but different embedding locations, i.e., different \( h||\cdot|| \). Note this could be problematic because the hidden vectors are used to learn cluster membership probabilities \( c \), and different embedding locations mapping to the same cluster probability vector could induce unwanted within-cluster heterogeneity. To encourage approximate injectivity, we introduce the loss \( L_{|||\cdot|||} = 1 \) that penalizes hidden representations away from the surface of the unit norm hypersphere. We could enforce this as a hard constraint, however, the ability to violate the constraint may facilitate alignment of the embedded representation angle with that of the output space.

Now we leverage the angular embedding property of the hidden representation. The key is to note that for a probability vector that sums to 1, its element-wise square root vector has unit norm and can be interpreted as an angle. Therefore, like the previous loss, we can match the angular representation of \( c^\frac{1}{2} \) to that of \( h^* \) with batch cosine similarity.

Define \( c_B = \Psi_3(h_B) \) the batch of probability vectors indicating cluster membership. Note that the cosine similarities of rows of \( c_B^\frac{1}{2} \) are non-negative and we are not interested in incurring loss due to differences between 0 and negative cosine similarities. We define \( L_{c,h^*} = \frac{1}{B} ||\delta_B(c_B^\frac{1}{2}) - \max(\delta_B(h_B^*), 0)||^2_2 \).

We consider additional loss terms to assist customizable representation learning. First, we introduce an entropy loss term to encourage cluster probabilities to be spread across more than one cluster. This encourages large clusters with overlap to spread across multiple clusters to reveal subgroup characteristics and enables injecting belief about characteristics of the clustering. For optimization, it encourages exploration in cluster membership and could help avoid local optima.

Second and optionally, the framework can use accessory information to inform the clustering. Our primary framework encodes a single hidden representation for clustering, but does allow for specifying multiple numbers of clusters \( C \). In place of a single softmax, the terminal layer \( C \) can be a concatenation of possible numbers of clusters, e.g. \( \{2, 3, \ldots, 100\} \), where the softmax is applied to nodes corresponding to each of the possible numbers. Therefore, one can provide a cluster assignment of size \( C_{out} \) that informs the hidden representation and request a more or less granular clustering \( C_{out} \). Unlike hierarchical clustering, this extension produces a multiarchy.

Thus, our overall objective function is \( \sum_i \lambda_i L_i \) for \( L_i \in \{L_{M,M}, L_{c,h^*}, L_{h^*O}, L_{||h^*||=1}, L_{entropy}, L_{C_{out}}\} \). Unless otherwise specified, we set \( \lambda_i \) respectively: \( \lambda_i \in \{1, 1, 10^{-1}, 10^{-1}, 10^{-4}, 0\} \).

Finally, we describe our particular implementation choices, and suggest the reader to refer to the autoencoder frame-
Table 1: Quantitative evaluation on simulated data, relative to the true cluster labels. Data are generated as described in the text, with baseline parameters set at centroids=25, samples=1000, dims=1000, sod=0.01, explode=10000, and varied in each dataset as indicated. Data are clustered using our method (Sphere), and the closest neural embedding clustering techniques DCN, SAE+KM, and DEC. The best score is in boldface.

work shown in Figure 1. In pre-processing we log transform each element using the function $f(x) = \log(1 + x)$ to prevent overemphasis of common events in the angular representation. We use cosine similarity for our distance measure between $h$ and $\hat{M}$ and between $h$ and $c$ as it is a natural distance representation for sparse count data. In the architecture, the permute-pool layer copies the tensor $P$ times, permutes the values, and performs max-pooling over the $P$ dimension with size 3 and stride 2. In our experiments we set $B = 128$, $P = 4$, and $H = 128$. We set $C$ to be twice the desired number of centroids, and in post-processing we iteratively merge the clusters identified based on maximum pairwise cluster distances.

Results

We evaluate our method on real and simulated data. Our results on simulated data show (1) that our method produces superior clusterings than other recently proposed deep clustering methods in this setting, and (2) how different components of our method affect the results of the method. Our case study evaluations on three real-world healthcare data show (1) the quality of our method’s clustering results, (2) the breadth of applicability of this method in a real-world context, and (3) the method’s scalability on large real-world data.

Quantitative evaluation

First, on simulated data generated to share properties of our target healthcare applications, we show that our method typically finds a clustering that, under several measures, is more similar to the ground truth labels from the simulation than competing methods are.

We generate data as follows. Centroids are sampled from a multivariate normal $\mathcal{N}(0, I)$ and normalized onto the unit sphere. We generate an equal number of samples for each centroid by adding noise distributed according to $\mathcal{N}(0, \sigma^2 I)$. Then we translate these points away from the origin by multiplying each point by an “explosion” factor $\kappa$ drawn from a random uniform on $[1, \kappa]$. The purpose of this step is to make the data more similar to that in our
healthcare applications, where patients and providers often have varying, i.e., non-constant, norm of total encounter counts.

Thus, the simulation is parameterized by the number of centroids, the number of dimensions, the explode factor, the number of samples, and the standard deviation of the noise. We set each parameter to a baseline level and vary one at a time to test our algorithm.

**Comparison to other methods.** We cluster the data using our hypersphere clustering method (“Sphere”), as well as three leading deep clustering frameworks that are similar to our method in combining autoencoders and clustering criteria: Stacked Autoencoder plus K-means (SAE+KM)\(^3\), Deep Embedded Clustering (DEC)\(^5\), and Deep Clustering Network (DCN)\(^6\). We evaluate results of these clustering methods using the Adjusted Rand Index (ARI) relative to the ground truth labels from the simulation.

Results are shown in Table 1. Our method produces better clusterings than the other methods on all six simulated datasets, as measured by ARI. Of note, the two-step SAE+KM method performs approximately as well as the integrated DCN and DEC methods on this data. This suggests that merely integrating clustering and representation learning into a single framework is not enough on its own to produce a good clustering; rather, it is also essential in this context for the representation to capture the relevant geometry of the data, as our method does.

**Comparison to variants of our method.** Next, we compare our method to variants of our method. These variants are created by omitting different components of the method one at a time, and thus, this evaluation demonstrates the importance of each component.

In the first variant (“Encoder”), we remove the decoder from the framework. Doing so results in worse clustering performance on all six datasets. The possible limitation of decoder removal is that it no longer needs to preserve the information in the input because the network does not need to reconstruct the input.

In the second variant (“HKM”), we run k-means in the hidden, embedded space our method constructs, instead of using our method’s clustering module. The embedded space is not designed to work well with k-means, and in fact, is constrained to have similar geometry to the original space, where k-means performs poorly. Likely for this reason, the HKM variant performs worse than our method on all datasets.

In the third variant (“Clu-t-SNE”), we substitute a t-SNE manifold constraint for \(L_{h=O}\), with the exception that to conform with the overall architecture of our method, instead of computing all \(O(N^2)\) pairwise distances, we define the KL-loss based on \(O(B^2)\) batch pairwise distances. This variant slightly outperforms our method when sample size is small (“samples=100”), but otherwise performs worse than our method.

The final variant (“Monotonic”) adds a constraint to our method rather than removing a component. Specifically, motivated by autoregressive flow literature\(^9\), we apply positive weight constraints and strictly monotonic activations (already present) to our network to get a autoregressive network. This variant outperforms ours in one case, but otherwise achieves equal or worse performance.

**Case study: Biclustering healthcare providers, prescriptions, and procedures with Medicare data**

The quantitative results in the previous section show that our method performs quite well on simulated data that we constructed to have properties of real-world high-dimensional sparse count healthcare data. In this section, we complement these quantitative results with a case study of provider characterization from procedure and prescriptions claims in Center for Medicare and Medicaid Services (CMS) Part D data. We compare our method’s results to those obtained by k-means, and use our method to explore the clusters identified.

**Objectives and Data.** The purpose of this case study is to cluster healthcare providers, prescriptions, and procedures based on data obtained from CMS claims, with the ultimate objective to gain insights on providers’ patterns of care based on this clustering, as well as on groupings of prescription and procedure use. To that end, we obtained Medicare Provider Utilization and Payment Data: Part D Prescriber Summary Table CY2015\(^10\), which tabulates all prescriptions and procedures given under the Medicare Part D program in 2015 in the United States. This data consists of approximately \(10^9\) providers, \(10^4\) procedures, and \(10^3\) drugs. We used our method and k-means to separately
Figure 2: Provider clustering by (a) hypersphere clustering, (b) k-means. Each column corresponds to a cluster and each row a specialty (only the most common ones are shown). We display the top three specialties associated with providers in that cluster, and order the axes according to number of providers and size of cluster. Relative to K-means, hypersphere clustering provides clusters with more diversity in top three specialties.

Comparison to k-means. The clusterings formed by our method and by k-means, each with 20 clusters, are shown in Figure 2, where the top three specialties within the identified clusters are visualized. The full list of included specialists per cluster is shown in the Appendix. On examination of these results, our method produces qualitatively better clusters than k-means does. For example, our clustering consistently includes a larger fraction of specialists in specialist clusters, e.g., Emergency Medicine (20k, Cluster 39), Dentist (85k, Cluster 25), and Psychiatry (21k, Cluster 38). Our clustering, unlike k-means, also identifies clean obstetrics and hematology oncology clusters. Although k-means identifies a cardiology and interventional cardiology cluster that our method does not initially identify, our method identified this cluster and merged it (Cardiology (18k), Nurse Prac (3k), Internal Medicine (2k)) into the internal medicine cluster (Cluster 38) in post-processing.

Our method also provides insight in regard to providers in specialties that are not as common. For example, our method’s urology cluster also includes a large fraction of the radiation oncologists in our dataset (see Appendix).
Figure 3: Left: histogram of nurse practitioner counts by cluster. Cluster names are given by clinical assessment of top 10 prescriptions. Right: t-SNE representation of 2000 randomly selected nurse practitioners. Cluster membership is indicated by color, and the axes are the dimensions of the t-SNE embedding.

detailed assessment of this cluster, we found that urology medications tamsulosin and finasteride were most commonly prescribed in this cluster and that radiation oncologists most commonly prescribed tamsulosin, followed by hydrocodone/acetaminophen and dexamethasone, possibly for prevention and treatment of complications of radiation therapy. Our clustering identified radiation oncologists and urologists as being similar according to the drugs they commonly prescribe, a finding that would not be identified through the use of a standard ontology alone.

To investigate our method’s biclustering (clustering on dimensions of provider and prescriptions), we investigated three questions: (1) does the clustering provide insight into how nurse practitioners provide care, (2) similarly, can we differentiate among family practice and internal medicine doctor subtypes, and (3) is the pain management cluster identifying commonality in opioid prescribing despite provider membership to many specialties?

Nurse practitioners. Nurse practitioners (NPs) tend to provide care in care units defined by medical specialties and subspecialties, but the CMS does not provide characteristics at that granularity. To characterize the type of care they provide, we can investigate their membership to identified clusters. Figure 3 (left) shows the breakdown of membership across clusters. We pulled the top 10 prescriptions administered by NP cluster members, as defined by mean log(1+·), and used our clinical expertise to characterize the care provided. Evidently, the NPs do cluster based on prescription behavior along lines of medical specialties. The top 10 medications for each cluster are provided in the Appendix. To empirically demonstrate the variation in the NP clustering, Figure 3 (right) shows a t-SNE(cos) plot of a random subset of 2000 NPs to illustrate their similarity (manifold distance) alongside their cluster membership (color). This demonstrates that the method does provide cluster separation and could be used to select NPs based on approximate specialization for future investigation.

Family practice and internal medicine. Similar to nurse practitioners, the specialty titles “family practice” and “internal medicine” are underdifferentiated. To investigate these providers’ prescription patterns, we inspected the FP/IM predominating clusters for differences. Figure 4(a) shows the breakdown of the providers across clusters, with labels corresponding to average care descriptions of the members in those groups. We selected three of the clusters that roughly corresponded to IM emphasis cardiology (IMC), IM emphasis infectious disease (IMID), and FP emphasis infectious disease (FPID). We compared the three clusters by listing the three prescriptions with the largest mean log(1+·) difference in prescribing.

- Compared to FPID providers, IMC providers prescribed more general IM medication (“levothyroxine”, “atorvastatin”, “lisinopril”) and fewer antibiotics (“levofloxacin”, “amoxicillin-clavulanate”, “azithromycin”).
- Compared to IMID providers, IMC providers prescribed more general internal medicine medication
Figure 4: Left: histogram of FP and IM provider counts by cluster. Cluster names given by clinical assessment of top 10 prescriptions. Right: snapshot of tool showing cluster membership for a selected physician, demo at http://4e46.net/docproc/.

{“atorvastatin”, “levothyroxine”, “lisinopril”} and fewer outpatient antibiotics {“clindamycin”, “amoxicillin”, “doxycycline”}.

- Compared to FPID, IMID providers prescribed stronger community-acquired pneumonia antibiotics {“levofloxacin”, “azithromycin”, “amoxicillin-clavulanate”} and fewer older and narrow-spectrum antibiotics and community care medications {“clindamycin”, “amoxicillin”, “ranitidine”}.

Pain management. Table 3 contains, by specialty, the top three medications prescribed by providers in the pain management cluster. The clustering demonstrates that, irrespective of the specialty, these providers prescribe large quantities of various opioids, including oxycodone, hydrocodone, morphine, fentanyl and others. We also compared the opioid-prescribing cluster against the other two clusters containing over 100 pain management specialty providers by listing the three prescriptions with the largest mean log(1 + ·) difference.

- Compared to the first cluster, the opioid-prescribing cluster prescribed more {“oxycodone”, “morphine”, “gabapentin”} and less {“celphalexin”, “prednisone”, “tramadol”}.

- Compared to the second cluster, the opioid-prescribing cluster prescribed more {“oxycodone”, “morphine”, “gabapentin”} and less {“ibuprofen”, “acetaminophen with codeine”, “azithromycin”}.

We developed a tool at http://4e46.net/docproc/ to facilitate learning about providers, their commonalities and memberships based on the their procedure and prescription signature in Medicare Part D claims data. This tool is illustrated in Figure 4 (right). An interested user can search by provider, cluster, or specialty to better understand group characteristics as well as the signature of practice for individual practitioners.

Other Case Studies

We also carried out several additional case studies. These case studies (1) demonstrate flexibility of the method with respect to number of desired clusters, (2) demonstrate the ability of our method to work well on real-world datasets across domains including text.

Single-representation multiple clustering. To illustrate single-representation multiple clustering, we run the simulation variant with 100 samples and 10 clusters, with samples 0-9 in cluster 0, 10-19 in cluster 1, and so on. Figure 5

Figure 5: Left: multiple clustering outputs ($C = 2$ to $C = 20$) from a single representation, with y-axis indicating samples ordered by ground truth cluster membership each of size 10, and x-axis indicating the number of clusters found divided by the number available to the algorithm, and color indicating cluster membership within column. Right: Top three radiology descriptions per cluster (first seven) with procedure counts based on MIMIC radiology notes. Illustrates the predicted cluster assignments for different $C$ along the x axis, with colors for a given $C$ determining co-cluster membership and with colors for different $C$ learned to be close to the previous cluster color but far from other cluster colors. The figure demonstrates recovery of the ground truth clusters (10 of them) and also provides clusterings identified when $C \neq 10$, noting that the algorithm may elect to place 0 members in a cluster if the data warrants it.
Characterizing radiology notes. In our final case study, we sought to organize a large collection of radiology notes based on the notes’ contents, for individuals with critical care needs. We used de-identified radiology notes from MIMIC III v1.4, a natural language processing pipeline, and a bag of words representation to cluster radiology notes. The note descriptions provided are specific in some senses, e.g. anatomical: "X-ray of left foot 4th digit, two views", but nonspecific in other senses, e.g. by indication: “CT chest w/o contrast” for cardiac, pulmonary, or gastrointestinal disease, or something else? After stop word removal, stemming, and lemmatization, the bag-of-word representation resulted in a sparse matrix of size: 522,279 notes by 275,263 unique word tokens. We performed clustering with 30 clusters. The result was a meaningful clustering, with for example, top members of distinct clusters including: kidney ultrasounds, infant radiographs, and abdominal ultrasounds. The cluster list is shown in Figure 5 (right).

Conclusion
In this paper, we defined a deep clustering method to address this task of clustering high-dimensional sparse count data, as often arises in analysis of healthcare data and other fields. To do so, we described an autoencoder architecture that takes into account not just image recovery and clustering quality, but also geometric relationships in the data. We demonstrated that this approach works well through quantitative comparisons with other methods, as well as through detailed case studies on real healthcare data, including the development of an informatics tool that enables exploratory analysis of providers based on their clinical behaviors.

Abstract
In this paper, we report on the development of an analytical model and a decision support tool for meeting the complex challenge of scheduling dialysis patients. The tool has two optimization objectives: First, waiting times for the start of the dialysis after the patients' arrivals must be minimized. Second, the minimization of lateness after the scheduled finish time, which is relevant for transport services, are pursued. We model the problem as a mathematical program considering clinical pathways, a limited number of nurses managing the patients, and dialysis stations. Furthermore, information about patients' drop-off and pick-up time windows at/from the dialysis unit are considered. We develop a platform in Microsoft Excel and implement the analytical model using an Open Source optimization solver. A case study from a dialysis unit in the UK shows that a user can compute a schedule efficiently and the results provide useful information for patients, caregivers, clinicians and transport services.

Introduction
Recent research has reported an increasing prevalence of chronic kidney disease worldwide1. Patients who are in the end stage of chronic kidney disease (ESRD) rely on dialysis treatments to survive. Hemodialysis is a common approach to manage the condition. It is typically performed in a clinical setting three times a week for several hours, where the patient is connected to a machine via a vascular access. Patients seeking treatment in dialysis units have individual characteristics which can be distinguished on a variety of metrics such as blood flow rate, dialysate flow rate and composition, volume of fluid to be removed and size of dialyzer. Regular laboratory tests of the patient’s blood help the physicians to determine a suitable treatment plan. Patients may have many preferences, including the desire for short treatment times and preferred starting times during the day. Dialysis facilities, on the contrary, pursue planning the treatment efficiently by optimizing resource utilization for the best patient outcomes. Patient scheduling which is done in dialysis units world-wide, can be defined as assigning patients to scarce resources and time slots to maximize some objective2.

In this paper, we develop an analytical approach to deliver a patient-centric scheduling platform for dialysis patients. Individual patients' characteristics are taken into account, such as the patient’s clinical pathway, alongside the consideration of the availability of scarce resources that are required. We formulate the scheduling problem as a mathematical program which includes the scheduling decisions around the patients’ availability time windows. Using Microsoft Excel, a manager of a dialysis unit can specify parameters in our tool. The manager selects the waiting time objective and obtains feasible solutions based on the objective function and constraints which are implemented using the Open Source solver back-end of our tool. In doing so, patient schedules can be obtained effectively and efficiently such that waiting-times for patients can be minimized. Finally, the optimal schedules can be shared with patients, caregivers, clinicians and transport services.

The remainder of this paper is structured as follows. In the next section, we provide an overview of related patient scheduling work followed by the presentation of the analytical model, demonstration of the platform and discussion, and conclusions.
Related Work

Patient scheduling is the process of assigning individual patients and/or patients’ activities to time and/or healthcare resources on the operational decision level. In contrast, appointment scheduling defines a blueprint of patients’ appointments on a tactical level. While some reviews focus exclusively on patient scheduling, appointment scheduling problems have been reviewed by several authors. In this section, we position our paper in the relevant patient scheduling literature and focus on patient-related objectives as shown in Table 1.

Table 1: Patient-related objectives

The table reveals that most of the research focus has been on one single patient-related objective which is the minimization of patient waiting times which is similar to the objective of the collaborating dialysis unit. The difference of our work is, however, that we consider patient waiting times which occur before the start of the treatment and after the end of the treatment.

The analytical approach proposed in this paper can be categorized into and differentiated from the literature on patient scheduling as follows. One relevant paper focuses on hemodialysis scheduling but on a tactical decision level. The authors schedule patients’ treatments across several days and not within a day as we do. Furthermore, we provide a decision support tool that allows managers to accommodate patient availability and schedule patients more efficiently. In another relevant paper, therapy jobs are scheduled hospital-wide. The difference to our work is, again, that we provide a decision support tool that is based on an Open Source solver as compared to a commercial solver. Using Microsoft Excel and Open Source software increases the usability in the National Health Service because most of the computers have Microsoft Excel pre-installed, users are familiar with it and the Open Source package can be downloaded free and installed as a plugin. Another difference is that dialysis stations are considered as a scarce resource and patients’ clinical pathways consist of a setup, dialysis and a finish activity as our next section will reveal.

An Analytical Model

In what follows, we will introduce the parameters for our analytical model, the decision variables, objective function and constraints. Finally, an example schedule is given.

Parameters

Planning horizon, patients and activities

Let \( T := \{1, 2, \ldots, T\} \) be the set of 15-minute slots with planning horizon \( T \). In practice, we start the day at 7:00am and finish it at 11:00pm so that the planning horizon comes up to \( T = 64 \) periods enumerated using the set \( T := \{1, 2, \ldots, 64\} \). Dialysis patients are denoted by set \( \mathcal{P} \). \( A \) denotes the set of all clinical activities to be scheduled and \( A_p \subseteq A \) denotes the subset of activities for patient \( p \in \mathcal{P} \).

Hospital resources, capacity and demand

Nurses and stations have a capacity \( R_{nurse}^t \) and \( R_{station}^t \), respectively, in period \( t \in T \). For example, \( R_{nurse}^t = 1 \) means that 1 nurse is available between 7:00am and 7:15am. The demand of activity \( i \in A \) on nurses and stations is denoted by \( r_{nurse}^i \) and \( r_{station}^i \), respectively. This parameter will be used in the clinical pathways which are introduced next.
Clinical pathways

In our model, clinical pathways represent standardized, typically evidence-based health care processes as defined by van De Klundert et al. \(^{40}\). For more definitions and a literature review on clinical pathway modelling, see Aspland et al. \(^{41}\). We depict the clinical pathway of a patient as an activity-on-node graph in which the set of nodes represents the clinical activities. Weighted arcs represent minimum time lags between clinical activities and we write the activities’ capacity requirements below the nodes, see the legend in Figure 1.

Consider, for example, patients’ set of dialysis activities which are the setup, dialysis and the finish activity, depicted by \(\sigma_p, \delta_p,\) and \(\phi_p\), respectively shown in Figure 1. \(r_{\text{nurse}}^p = 1\) means that the patients’ setup activity requires 1 nurse who is busy with the patient setting her up on the dialysis machine.

Let \(E\) denote the set of all minimum time lags between clinical activities. A minimum time lag \((i, j) \in E\) of weight \(d^\text{min}_{i,j} \in \mathbb{Z}_{\geq 0}\) stipulates that activity \(j\) has to be scheduled at least \(d^\text{min}_{i,j}\) periods later than activity \(i\). Given the graph \((A, E)\), the earliest and latest start of activities, denoted by \(E_i\) and \(L_i\), respectively can be calculated using longest path methods (see, for example, \(^{42}\)). Let \(W_i := \{E_i, E_i + 1, \ldots, L_i\}\) denote the time window of activity \(i\). Once we have calculated the latest time slot \(L_{\phi_p}\) in which the dialysis activities can be scheduled, the index of the last period can be calculated by \(T = \max L_i\). Table 2 provides an overview of all parameters and decision variables. The latter will be introduced next.

*Figure 1: Clinical pathways for two dialysis patients*

</tr>
</tbody>
</table>
Decision variables

We use binary activity-to-period assignment variables, a concept which has been used successfully in other scheduling literature, see\textsuperscript{43}. Accordingly,

\[
x_{i,t} = \begin{cases} 
1, & \text{if clinical activity } i \in A \text{ starts in period } t \in W_i \\
0, & \text{otherwise}.
\end{cases}
\]

Objective function

Having introduced all necessary parameters and decision variables, the objective functions are given by Equations (1) and (2).

\[
\begin{align*}
\text{Minimize } & z = \max_{p \in P} \sum_{t \in W_p} t \cdot x_{\sigma_p,t} \\
\text{Minimize } & z = \max_{p \in P} \sum_{t \in W_p} t \cdot x_{\phi_p,t}
\end{align*}
\]

Objective function (1) minimizes the maximum waiting time for patients to start the dialysis session as follows: Each patient \( p \) has a time window to start the session which is defined for the individual’s dialysis start activity \( \sigma_p \) (see the patients’ clinical pathways shown in Figure 1). Now, one decision variable \( x_{\sigma_p,t} \) is equal to 1, we multiply the time point \( t \) which leads to the scheduled start times across all patients. Now, the maximum value of this start time vector is minimized. Similarly, for objective function (2), we minimize the maximum scheduled finish time of the treatments.

Constraints

In what follows, we add constraints to our model which we break down by clinical pathways, nurse and machine constraints.

Clinical pathways, nurse and machine constraints

Constraints (3) use the information from the clinical pathways defined earlier and ensure that minimum time lags between all consecutive activities are guaranteed.

\[
\sum_{t \in W_j} t \cdot x_{j,t} \geq \sum_{t \in W_i} t \cdot x_{i,t} + \delta_{i,j}^{\min} \quad \forall p \in \mathcal{P}, (i, j) \in \mathcal{E}_p
\]

Nurse constraints (4) ensure that the demand for nurses does not exceed the nurse capacity.
\[
\sum_{i \in A} \sum_{t \in W_i} r_{i,nurse}^{\min(L_i,t)} \sum_{\tau = \max(E_i,t-p_i)+1}^{\min(L_i,t)} x_{i,\tau} \leq R_{t,nurse}^{nurse} \quad \forall t \in T
\] (4)

Constraints (5) ensure that the demand for the stations does not exceed the station capacity.

\[
\sum_{i \in A} \sum_{t \in W_i} r_{i,station}^{\min(L_i,t)} \sum_{\tau = \max(E_i,t-p_i)+1}^{\min(L_i,t)} x_{i,\tau} \leq R_{t,station}^{station} \quad \forall t \in T
\] (5)

Constraints (6) ensure that each activity is scheduled exactly once.

\[
\sum_{t \in W_i} x_{i,t} = 1 \quad \forall i \in A
\] (6)

Variable definitions and their domains are given by (7).

\[
x_{i,t} \in \{0, 1\} \quad \forall i \in A, t \in W_i
\] (7)

**Example**

Table 3 shows a station and nurse allocation example based on the clinical pathways defined in Figure 1. “–” means that the variables are not defined in these periods because they are outside the activities’ time windows. We assume that the processing times of the patients’ start activities are 1, the finish activities require two time periods and the durations of the dialysis (\(\delta_p\)) take 4 and 1 period for patients 1 and 2 respectively. Naturally, the durations are longer in reality as the next section will reveal.

<table>

<td>1</td>
</tr>
<tr>
<td>(\sum_{i \in A} \sum_{t \in W_i} r_{i,nurse}^{\min(L_i,t)} \sum_{\tau = \max(E_i,t-p_i)+1}^{\min(L_i,t)} x_{i,\tau})</td>
<td>1</td>
<td>2</td>
<td>2</td>
<td>2</td>
<td>2</td>
<td>2</td>
<td>1</td>
</tr>
</tbody>
</table>

The example reveals that the first activity is scheduled in period \(t = 1\) which means that the nurse is allocated in the same period. In the next period \((t = 2)\) the second patient’s first activity \((\sigma_2, \text{see Figure 1})\) is scheduled which allocates the nurse in the second period \((t = 2)\) as can be seen in the second to last row. In period \(t = 3\), the nurse is not assigned to tasks that involve the connection and disconnection of patients to/from machines.
The last row shows the demand profile for the capacity requirement from the dialysis stations. As can be seen, one station is allocated in period $t = 1$, followed by an allocation of two stations in periods $t = 2, 3, \ldots, 6$. As only one patient is on the station at period $t = 7$, the demand profile goes down to 1.

**Decision Support Tool**

We created a decision support tool in Microsoft Excel. The tool is broken down into a parameters tab which is shown in Figure 2, the solver tab shown in Figure 3, and a solution tab shown in Figure 4.

Figure 2 shows the user interface where the manager can input each patient, along with their treatment duration and arrival time on the left-hand side. Sometimes, a station may be unavailable because of maintenance operations going on for the dialysis machine. Accordingly, the user can parametrize the station availability by using the “station availability table” on the right-hand side. The nurses’ availability and the cleaning time for the machines can also be inputted.

**Figure 2:** Parameters for scheduling the patients in the Dialysis Unit. All patients’ names are synthetic.

In Figure 3, the user can choose which objective function they wish to optimize when solving the scheduling problem. As mentioned in the modelling section, we have two patient lateness objectives, the first being the time they wait after arrival before starting their treatment, and the latter being the time a relative, Welsh ambulance or a private taxi service has to wait for the treatment to finish. Once the user selects the objective function, OpenSolver will use the inputted values and constraints to create a schedule which is then displayed to the clinician using metrics such as activity start times and lateness.
Figure 3: Solving the problem of scheduling the patients in the Dialysis Unit

Figure 4 shows the output of the tool in a Gantt chart. For each station, we can see which patients have been scheduled at time \( t \). The black bars relate to the patients’ start activity \( \sigma_p \) and finish activity \( \phi_p \) (introduced in Figure 1). Recall that these activities require nurses in addition to the stations. The coloured bars relate to activity \( \delta_p \), where only the station is required for the actual dialysis activity \( \delta_p \).

Discussion

In several workshops we discussed the usability and acceptability of the platform with managers from the National Health Service. One major feedback to improve the usability of the platform was that we have to link our tool with the clinical information system which operates on a separate database. However, using an ODBC connection, we will be able to link Microsoft Excel with the patient data in the collaborating dialysis unit.

The usage of our platform will have several implications and benefits for different stakeholders: Using our tool, patients can be communicated an expected dialysis start time which may reduce perceived waiting time. Nurses will be able to plan their breaks during the day which is very difficult at the moment because of the workload imposed by the unfavorable schedules: Currently, nurses struggle to take breaks during midday because patients who started the treatments in the morning finish at midday and need to be taken care of. In parallel, new patients who arrive at midday have to be setup on the machines and delays may impose overtime at the end of the nurses’ shifts. Another benefit of our structured approach is that transport services and patients’ caregivers can be informed about the scheduled dialysis.
finish times. Using information about the patients’ home addresses, transport services may aggregate trips for patients and provide more efficient services.

The mathematical model has been formulated as a deterministic problem which means that uncertainty is not taken into account at this stage. Uncertainty may happen in patients’ no shows, late arrivals and uncertain dialysis durations. Using information from the past, however, machine learning algorithms may be used to accurately predict no-shows which then can be incorporated into our tool. Alternatively, a rolling-horizon procedure may be used to take into account variation during the execution of the schedule.46

Conclusions

In this paper we have presented an analytical model and a decision support tool for the problem of scheduling dialysis patients in a dialysis unit in the UK. One objective is to minimize the maximum waiting time for patients to start the dialysis session. The second objective minimizes the maximum scheduled finish time of all treatments. In doing so, the model avoids nurses’ overtime at the end of the day. Using data from a hospital we demonstrated the effectiveness of our approach and showed the solution output using a Gantt chart. This helps the dialysis unit to find out the optimal sequence of patients on the different dialysis stations.

Future work will include further patient related objective functions including patient preferences, clinician guidelines and targets, and also taking into account resource-related measures such as utilization maximization. Furthermore, we will evaluate the importance of each of the different objectives and incorporate the result into a multi-criteria optimization approach. Also, our aim is to quantify the effectiveness of the approach in practice.

Acknowledgments

This research was supported by the Welsh Health Hack 2017 in collaboration with the Welsh Government, Bevan Commission, ABCi and the Wales Deanery. Additional funding was received from the Bevan Commission’s Health Technology Exemplar scheme. Also, the Data Innovation Research Institute at Cardiff University provided Seedcorn Funding to support the project and to facilitate new collaborations.

Engaging Pharmacists to Crowdsourced a Fine-grained Medication Risk Scale: An Initial Measurement Study Using Paired Comparisons of Medications

Allen J. Flynn, PharmD, PhD, Greg Farris, BS, George Meng, MSEE, Jack Allan, Sara Kurosu, Natalie Lampa, Koki Sasagawa, BS
Medical School, University of Michigan, Ann Arbor, MI

Abstract

A coarse classification of medications into two risk categories, one for high-risk medications and one for all others, allows people to focus safety improvement work on medications that carry the highest risks of harm. However, such coarse categorization does not distinguish the relative risk of harm for the majority of medications. To begin to develop a more fine-grained measurement scale for the relative risk of harm spanning many medications, we performed an experiment with 18 practicing pharmacists. Each pharmacist-participant made 210 paired comparisons of 21 commonly prescribed medications to reveal a subjective scale of perceived medication worrisomeness (PMW). Statistical analyses of their collective judgments of medication pairs differentiated five levels of PMW. This study illuminates one path towards a fine-grained medication risk scale based on PMW. It also shows how the method of paired comparisons can be used to remotely crowdsourced expert knowledge in support of learning health systems.

Introduction

Current approaches to medication safety typically focus on mitigating risks from using high-alert medications. According to the Institute for Safe Medication Practices (ISMP), a high-alert medication is “a drug that bears a heightened risk of causing significant patient harm when it is used in error”\(^1,2\). Based on evidence about medication errors and adverse drug events, ISMP enumerates individual high-alert medications. One example is promethazine injection, which has a low pH and therefore causes severe injuries in cases of extravasation\(^3\). ISMP also specifies that certain therapeutic drug classes are comprised only of high-alert medications, e.g., the opioid therapeutic drug class\(^4\).

It is useful to develop policies and procedures for handling high-alert medications like promethazine and opioids\(^4\). Pharmacists often lead efforts to develop such policies and procedures within provider organizations\(^5\). However, the current binary approach to medication risk categorization, where medications are classified either as high-alert or NOT high-alert, is too coarse to meet growing risk assessment needs in practice. With only these two risk categories, it is impossible to assess the relative risk of harm (RRH) of a specific medication in comparison to others. Also, the current two-category approach to risk categorization is not suitable for determining the composite relative risk of harm (cRRH) of a list of prescribed medications comprising a patient medication regimen. However, multiple studies suggest that relative risk scores for individual prescriptions and whole medication regimens are needed in practice to direct attention to potential problems and to allocate provider effort in more optimal ways\(^6–8\).

The broadest goal of this work is to improve medication safety systematically by first developing and then applying a reliable, valid, and fine-grained measurement scale to accurately indicate to prescribers and patients the RRH for every prescribed medication. In the absence of such a scale, pharmacists are devising makeshift scoring tools within electronic health record systems (EHRs) to try and identify patients at the greatest risk for adverse drug events\(^9\). This paper reports an initial experiment to realize a new approach to creating a fine-grained medication RRH measurement scale. We show that a crowdsourced scale can be built using paired comparisons and remote knowledge acquisition.

Background and Significance

Besides scoring the relative risk of individual prescriptions and whole medication regimens, there are a growing number of other uses for a reliable, numeric RRH measurement scale for medications\(^9\). For example, to safely and incrementally implement artificial intelligence (AI) in pharmacy practice, to uphold safety there is a need to initiate AI solutions in a limited way beginning with those medications with a low or very low RRH\(^10,11\). Also, with a more fine-grained medication RRH scale, it would be possible to use risk scores arising from applying the scale as inputs to try and improve many holistic patient risk models, such as hospital readmission risk models\(^12\).

Ideally, large quantities of accurate and current data about the actual harm caused by medications would be used to derive a reliable and valid measure of RRH for all medications. Unfortunately, high-quality medication error and adverse drug event data are not available in sufficient quantities to build a comprehensive RRH measurement scale in this way. Estimates indicate that less than 20 percent of actual medication errors and near misses are reported\(^13\). Such
sparse and incomplete data only support the identification of the most harmful, high-alert medications. This paper explores the feasibility of constructing a fine-grained medication RRH measurement scale with data about perceived medication worrisomeness (PMW) collected from practicing pharmacists using the method of paired comparisons.

There are several reasons to believe that pharmacists may develop an expert sense of the relative risk of harm for a wide range of medications as they practice pharmacy. First, pharmacists are accountable for therapeutic and other outcomes stemming from the use of a vast array of drugs. Second, pharmacists’ interest in understanding the full breadth of the medication armamentarium distinguishes their practice from specialty medical and nursing practices. Third, pharmacists often develop risk-based medication safety policies and guidelines and apply them in practice. Fourth, pharmacists are exposed to adverse drug events, likely adding to their insight about medication risks.

If pharmacists do develop a sense of RRH of medications through practice, then the method of paired comparisons could offer an efficient and effective way to acquire this expert knowledge from them. The analytic method of using paired comparisons has at least a 90-year history. Paired comparisons are used in many scientific fields to establish reliable and valid rating scales. The method of paired comparisons is especially useful when no natural measurement scale is available, which is the case for a scale to measure the RRH of many medications. For this study, we chose to infer RRH from perceived medication worrisomeness (PMW) while recognizing that the RRH of medications is most likely a complex multidimensional concept deserving of further, more detailed examination.

The method of paired comparisons provides a way to rank multiple items. Via experiments, paired comparisons enable us to estimate the probabilities of true ratings of multiple items along a continuum of interest. First, the set of all pairs of items are defined, then participants are asked to judge items against one another head-to-head in a manner that reveals a subjective continuum. Once these judgments are made, the paired comparison data provided by participants can be fit to specialized linear models, like the Bradley-Terry model.

In the Bradley-Terry model, paired comparison data are represented in terms of initial probability estimates where

\[
\text{Probability (item } i > \text{ item } j) = \frac{\alpha_i}{\alpha_i + \alpha_j},
\]

\(i \neq j\) and \(\alpha_i\) and \(\alpha_j\) are positive-valued parameters associated with items \(i\) and \(j\), for each of the paired comparisons. These data are then combined for an entire experiment and fitted to a hyperbolic secant probability distribution function. By fitting these data this way, researchers can compute maximum likelihood estimates of the true probability of each item’s performance, along with a corresponding degree of uncertainty. In light of their uncertainties, the maximum likelihood estimates of the true probabilities can then be rank ordered on a single continuum of interest.

We designed and executed a paired comparison experiment. It involved repeated paired comparisons of perceived medication worrisomeness made by pharmacists. We did this to demonstrate, in a preliminary way, the feasibility of using this type of experiment to reveal a comprehensive, fine-grained RRH scale for medications by remotely crowdsourcing pharmacists’ expert knowledge of medication concerns using a novel online data collection tool.

Medications generally have different risk profiles. It follows that we must manage the risk of harm from medications on a medication-specific basis. We recognize that in many but not all cases, patient-specific factors mediate or moderate the RRH of medications. However, just as we think of the likelihood of medication side effects for all people, we believe it is reasonable and equally necessary to focus on the general risks of harm from medications for everyone.

To better allocate limited clinician resources and mitigate the risk of harm from using medications, a fine-grained measure of the RRH of prescribed medications is needed. To our knowledge, a broadly conceived, reliable, valid, fine-grained measure of RRH for medications does not exist. This study is significant because it begins to address this unmet need in a rigorous, systematic way. We report an initial step towards a comprehensive measure for assessing whether various prescribed medications have RRHs that are very low, low, moderate, high, or very high. To improve safety and spare provider work-time, we hope that in the future such a measure will direct people’s attention toward a wider array of significant medication risks and away from other insignificant medication issues.

Research Questions

For this study, we investigated three research questions. The first two questions, RQ1 and RQ2, represent tests of the major hypothesis proposed by Bradley and Terry for all paired comparison experiments. To answer RQ1 and RQ2, we test whether or not statistically significant differences from random selection exist to rank medications on a subjective scale of perceived medication worrisomeness. The third question, RQ3, addresses how to scale-up an experiment like this one to achieve a comprehensive fine-grained RRH scale for hundreds of medications.
**RQ1.** To what degree do a group of practicing pharmacists collectively perceive differences in worrisomeness among single medications in a collection of 21 commonly prescribed medications?

**RQ2.** To what degree do a group of practicing pharmacists collectively indicate differences in worrisomeness among individual therapeutic categories of medications in a collection of 7 common therapeutic categories?

**RQ3.** What are some key requirements for using the method of paired comparisons to crowdsource a comprehensive relative risk of harm scale spanning hundreds of medications?

**Methods**

We begin with a relevant but fictional worked example of our analytic method which comes primarily from the work of Bradley and Terry\textsuperscript{17,18}. After the worked example, we describe more details of our specific experimental methods.

**Worked Example of the Analytic Method of Paired Comparisons Applied to Fictitious Medication Comparisons**

Consider the following fictional experiment where perceived medication worrisomeness (PMW) for 4 medication items is examined using the method of paired comparisons. The 4 medications are aspirin, acetaminophen, ibuprofen, and ketorolac. They are non-opioid analgesics with varying risk profiles\textsuperscript{21}. The set of all pairs of these 4 medications has a cardinality of \(\binom{4}{2}\), or six. These six pairings appear in rows 1 to 6, columns II and III, of Table 1 below.

Now, imagine that 20 pharmacists compare the six pairs of medications in Table 1 head-to-head by indicating, independently for each pair, which medication in the pair would cause them to worry most for a patient who takes it. From these 20 repetitions, assume the fictional but realistic data shown in columns IV and V of Table 1 arise. The data in the first-row show that 8 fictitious pharmacists perceived aspirin (1\textsuperscript{st} in pair) to be more worrisome than acetaminophen while 12 other pharmacists perceived acetaminophen (2\textsuperscript{nd} in pair) to be more worrisome than aspirin.

With the data in Columns IV and V of Table 1, Equation 1 above can be used to generate estimates of the true probabilities describing how pharmacists perceive the relative worrisomeness of medications in each pair. Then, by fitting the data in Columns IV and V to an appropriate statistical model, it is possible to test whether or not any of these six medications differ from one another in overall perceived medication worrisomeness (PMW).

To rank order the four medications, \(M_1 \ldots M_4\), for PMW after arriving at parameter estimates with standard errors for each one, the data in Table 1, columns IV and V can be fitted to a statistical model for combining paired comparison data. One commonly used model for this comes from Bradley and Terry\textsuperscript{17,18}. Here is an expression of their model in the context of this worked example:

\[
\text{logit} \left[ \text{Probability} \left( M_i \text{ is more worrisome than } M_j \right) \right] = \lambda_i - \lambda_j ,
\]

where \(\lambda_i = \log(\alpha_i)\) for all \(i\), and \(\lambda_j = \log(\alpha_j)\) for all \(j\), for the entire experiment. Assuming all comparisons are independent, parameters \(\{\lambda_i, \lambda_j\}\) for the overall PMW of each medication can be estimated by maximum likelihood.

To estimate the parameters \(\lambda_1, \ldots, \lambda_4\), which correspond to \(M_1, \ldots, M_4\), a system of two maximum likelihood equations can be solved iteratively\textsuperscript{17}. To solve these equations, we used the BradleyTerry2 package for the R statistical computing platform\textsuperscript{19}. What results from this model-fitting procedure are maximum likelihood estimates (MLEs) with standard errors (SEs) for the PMW of aspirin, ibuprofen, and ketorolac. The MLE and SE for acetaminophen set to zero by convention (Table 2, Columns II and III). In Column V of Table 2, we then use Firth and de Menezes method of calculating quasi-standard errors for these MLEs to allow statistical inferences to be made about the degree of difference in PMW between contrasting pairs of medications\textsuperscript{22}.

Generating results like the fictional results in Table 2 above is a goal of this study. At this point, we have completed our review of a fictitious worked example detailing the analytic and statistical methods for this study.

Medication and Therapeutic Category Selection

For this study, we used the two criteria listed directly below to select a total of 21 medications for comparison. The five medications marked with a diamond (♦) are designated as high-alert medications by ISMP.

1. Each medication appears on the Top 200 most commonly prescribed drugs list for 201823
2. Each medication is a member of one of these seven therapeutic drug categories or drug classes
   a. Antibiotics (amoxicillin, azithromycin, ciprofloxacin)
   b. Anticoagulants (apixaban♦, rivaroxaban♦, warfarin♦)
   c. Antidepressants (amitriptyline, citalopram, sertraline)
   d. Antidiabetics (glyburide♦, liraglutide, metformin♦)
   e. Antihypertensives (amlodipine, lisinopril, losartan)
   f. Benzodiazepines (alprazolam, clonazepam, lorazepam)
   g. Non-steroidal anti-inflammatories (aspirin, ibuprofen, naproxen)

To reach our complement of 21 medications, those that are listed above in parentheses, we selected three medications from seven different therapeutic drug categories. Only very commonly prescribed medications were included in an effort to ensure that pharmacists would be very familiar with all 21 medications. Settling on 21 as the total number of medications gave rise to a total of \( \binom{21}{2} \) or 210 pairs of medications for comparison by each pharmacist-participant. To show that this number of comparisons is workable, we ran several tests and confirmed that pharmacist-participants can comfortably make 210 paired medication comparisons in less than an hour.

We intentionally included medications for acute problems (e.g., antibiotics) and others for chronic diseases (e.g., antihypertensives). We included controlled substances (i.e., benzodiazepines) and non-controlled substances. Most of the medications come in oral tablets or capsules, but we added one injectable medication (liraglutide). Also, we included concerning medications associated with many adverse drug events (e.g., anticoagulants24) but also generally safe over-the-counter medications (non-steroidal anti-inflammatory drugs called NSAIDs).

Rationale for Not Permitting Ties When Pharmacist-Participants Make Paired Comparisons

We did not permit pharmacist-participants to declare ties in PMW when making paired comparisons. Our rationale for not permitting ties is based on the assumption that no two medications have precisely the same risk profile or carry an identical risk of harm. To check this assumption, we collected timestamps for each paired comparison choice made serially by pharmacist-participants and used this timestamp information to look for any paired comparisons that were difficult or very difficult for the majority of pharmacist-participants to make.

Determination of the Number of Pharmacist-Participants to Recruit

Using the method for estimating experiment size from the second edition of David’s 1988 textbook on paired comparisons (p. 109)25, we sought to determine an appropriate number of pharmacist-participants to recruit. Recall that we have a fixed number of 21 medication items (or treatments, t) to be compared and ranked. David indicates that, for \( t=21 \), to ensure at least a predetermined probability of 0.95 for the selection of the medication perceived to be most worrisome, assuming a minimum parameter difference of between 0.1 and 0.15 between the medication perceived to be most worrisome and the next most worrisome medication(s), 10 to 20 subjects must make all 210 paired comparisons. On this basis, we sought to recruit between 10 and 20 pharmacist-participants for this study.
Recruitment of Pharmacist-Participants

For this study, we recruited pharmacist-participants who met the following two inclusion criteria.

1. The pharmacist-participant is licensed and registered to practice pharmacy in at least one U.S. state
2. As part of their current work role, the pharmacist-participant performs some direct patient care duties

To recruit pharmacist-participants who met the two criteria above, we executed two non-probability sampling strategies. Our primary recruitment strategy was referral or snowball sampling. We sent invitation messages by e-mail to 20 hospital, ambulatory care, and community pharmacists asking them to participate and to invite other pharmacists they know to participate. We deliberately sent these messages to individuals in several states, including Michigan, Ohio, Indiana, Illinois, and Connecticut. Our secondary recruitment strategy was to advertise on the Michigan Pharmacists Association’s public LinkedIn account. We posted three paid messages inviting pharmacists to participate. When pharmacists responded, we shared more information, including a consent form, and offered them a $50 gift card in exchange for an hour of their time spent as a study participant.

Design, Development, and Testing of CrowdSort – An Online Paired Comparison Data Collection Tool

For this study, we developed an online web application tool, or web app, to collect paired comparison data from remote pharmacists (Figure 1). We call this web app CrowdSort because it enables people to participate in sorting or ranking using the method of paired comparisons. With CrowdSort, we collected data when participants joined us remotely from their worksites around the U.S. for individually-scheduled, hour-long conference calls.

CrowdSort’s source code is available at github.com/kgrid-demos/crowdsort. Three team members led CrowdSort development (AF, GM, JA). For the front end, several team members (JA, SK, NL, KS) used HTML, CSS, Vue.js, and JavaScript to establish CrowdSort’s user interface. For the back end, three team members (GF, GM, SK) deployed CrowdSort on a cloud server at Heroku (heroku.com) and then used the mLab Heroku add-on to establish a persistent connection to a database operating on the Heroku platform. Once deployed in this way, the CrowdSort web app posted each paired comparison to our cloud database with a date and timestamp. Three team members (AF, JA, KS) developed and cross-checked two software tools for transforming the raw paired comparison data into a format suitable for analysis using the BradleyTerry2 package for the R statistical computing platform.

We designed CrowdSort’s user interface so that it would be simple to use. Our user interface design process began by examining the user interfaces of the comparison-making websites either.io and rrrather.com. With the designs of these two existing websites in mind, we created CrowdSort’s similar user interface (Figure 1).

For users to complete each paired comparison using CrowdSort, they simply click on one of the two text options appearing in the two onscreen boxes (Figure 1). These two boxes, highlighted by a shadow effect, are the chief feature of this user interface. For that reason, they have different colors and appear in the middle of the screen.

Figure 1. View of CrowdSort web application for making paired comparisons online with a web browser
As an example of a paired comparison, in Figure 1 above, a single comparison is portrayed between the antibiotic ciprofloxacin in the blue box on the left and the antidiabetic drug metformin in the brown box on the right.

After the user clicks on one box or the other to make their choice, a new pair of medications is displayed until all 210 paired comparisons have been made. This first version of CrowdSort, which is accessible online at crowdsort.herokuapp.com, is designed NOT to allow users to indicate ties in perceived medication worrisomeness.

To mitigate order effects, whenever a web browser reloads CrowdSort, both the order of the 210 pairs and their left-right position onscreen are randomly shuffled. To mitigate effects of using colors to distinguish the two onscreen boxes visually, we chose the colors brown and blue because they are NOT safety related colors, like red, orange, yellow, or green. The two colors also randomly shift between left and right as the user makes paired comparisons.

To test CrowdSort, four research team members worked to develop, document, and run tests of this system, uncovering and fixing software defects in the process (JA, SK, NL, KS). Then, to confirm CrowdSort was ready to support remote data collection, we conducted two trial runs with University of Michigan student pharmacists. Because these two trial runs were both successful, data collection activities commenced.

Prompt to elicit pharmacists’ thoughts about perceived medication worrisomeness

For this study, we gave careful consideration to the prompt and instructions for pharmacist-participants who performed the comparisons of 210 pairs of medications. We prompted them to select which medication in each pair would cause them to worry more than the other if the medication was indicated and prescribed for one of their patients (Figure 1). This prompt was devised to elicit pharmacists’ initial reactions to each pair of medications in a way that does not suggest a correct answer. As much as possible, we wanted to avoid having the task of making comparisons feel like taking a test or exam. We deliberately avoided the term “risk” in the prompt because, unlike “worry”, which is subjective, “risk” could elicit objective or legalistic meanings in the minds of participants. We assume that the concepts of perceived medication worrisomeness and perceived medication risk are closely and positively correlated.

Results

This section begins with several overall results followed by results which address each research question, RQ1-RQ3.

A total of 18 pharmacist-participants from seven different states were recruited for this study. Eight men and 10 women were included. Seven pharmacist-participants were community pharmacists and 11 were hospital pharmacists. All 18 pharmacist-participants completed the data collection process by using the CrowdSort web app to perform 210 paired comparisons. Their work resulted in a dataset with 3,780 paired comparisons of PMW, including 360 comparisons for each of the 21 medications. After removing all comparisons of drugs in the same therapeutic category, we found that pharmacist-participants indirectly made 3,402 paired comparisons of the seven therapeutic categories listed above.

We analyzed the time required for pharmacist-participants to make 210 paired medication comparisons with the CrowdSort web app. On average, they completed this task in 16 ± 8 minutes (Range: 9 to 41 minutes). To detect whether some comparisons might have been more difficult than others, we used the timestamps for each comparison to look for paired comparisons that required pharmacist-participants three or five times more than their average comparison-making interval. No pairing required significantly more time than average for the majority of participants.

RQ1. To what degree do a group of practicing pharmacists collectively perceive differences in worrisomeness among single medications in a collection of 21 commonly prescribed medications?

Results relevant to answering RQ1 are illustrated and summarized in Figure 2 below. We found that our small crowd of 18 practicing pharmacists collectively perceive significant differences in perceived medication worrisomeness (PMW) among the 21 medications compared. The anticoagulant warfarin is perceived as most worrisome overall. It was judged more worrisome in 346/360 (96%) of its head-to-head pairings. The hypertension medication amlodipine and the antibiotic amoxicillin were least worrisome overall. These two medications were judged more worrisome in only 48/360 (13%) and 58/360 (16%) of their head-to-head pairings, respectively. Using quasi standard errors to enable medication-by-medication comparisons, our results reveal five emerging PMW groups (Figure 2). Between the groups of medications perceived to be least worrisome and most worrisome, three intermediate groups can be seen.

As noted, warfarin♦, which is marked with a diamond because it is an ISMP high-alert medication, has the highest estimated PMW. Next, in the High Intermediate group, two other high-alert anticoagulants, apixaban♦ and rivaroxaban♦, appear (Figure 2). The Intermediate group includes all 3 benzodiazepines (alprazolam, clonazepam, lorazepam), an antidepressant (amitriptyline), an antibiotic (ciprofloxacin), and a high-alert antidiabetic (glyburide♦).
Figure 2. PMW estimates with Quasi Standard Errors for 21 medications abbreviated on the X-axis. Diamonds (♦) indicate ISMP high-alert medications. Select estimates are noted. Percentages are the empirical proportion of pairings when amiodipine, amoxicillin and warfarin were judged more worrisome.

The Low Intermediate group includes all 3 NSAIDS (aspirin, ibuprofen, naproxen), an antibiotic (azithromycin), two antidepressants (citalopram, sertraline), two antidiabetic drugs (liraglutide, metforminic), and two antihypertensives (lisinopril, losartan). Finally, amoxicillin and amiodipine have the lowest estimated PMW scores (Figure 2).

We assessed goodness of fit and found that our medication paired comparison data fit the Bradley-Terry model well. To do this, we computed standardized residuals for each of the 210 paired comparisons. Upon inspection, we found the distribution of these residuals to be platykurtic and slightly skewed compared to the normal distribution (Kurtosis = 2; Skewness = 0.25; W/S = 7.5, n=210). Besides, we found that 171 of 210 (81%) of the fitted probabilities fit within less than one standard deviation from the Standardized Residual Mean (SRM), while 35 (17%) fell between 1 and 2 standard deviations of the SRM and four (2%) fell beyond 2 standard deviations from the SRM.

RQ2. To what degree do a group of practicing pharmacists collectively indicate differences in worrisomeness among individual therapeutic categories of medications in a collection of 7 common therapeutic categories?

Results relevant to this question are illustrated and summarized in Figure 3 below. By making 210 paired comparisons of medications associated with the seven therapeutic categories, participant-pharmacists indirectly indicated that significant differences exist in their minds regarding the relative worrisomeness of these therapeutic drug categories.

As shown below in Figure 3, we infer from the paired comparison data for medications that the therapeutic category of medications perceived to be most worrisome is the anticoagulants category. Pharmacist-participants indicated the anticoagulant in a pair was more worrisome than medications from all other classes 93% of the time. The therapeutic category evidently perceived to be least worrisome was antihypertensives. Pharmacist-participants indicated that the antihypertensive medication in a pair was more worrisome than medications from other therapeutic classes only 21% of the time. Using quasi standard errors to enable category-by-category comparisons, our results reveal a total of four distinct, emerging groups of inferred therapeutic category worrisomeness (ITCW).

As a class, anticoagulants have the highest estimated PMW. Next, in the High Intermediate group, the benzodiazepine therapeutic category appears by itself (Figure 3). The Low Intermediate group includes antibiotics, antidepressants, antidiabetics, and NSAIDs. The least worrisome therapeutic category in these results is the antihypertensives category.

We assessed goodness of fit and found that our inferred paired comparison data for the seven therapeutic categories fit the Bradley-Terry model moderately well. To check goodness of fit we computed standardized residuals for the (2) or 21 comparisons. Upon inspection, we found the distribution of this low number of 21 residuals to be very platykurtic and a little skewed compared to the normal distribution (Kurtosis = 0.2; Skewness = -0.5; W/S = 3.9, n=21). However, we also found that all 21 of the fitted probability values from using the Bradley-Terry model for the paired comparisons for the therapeutic categories fit within less than one standard deviation from the Standardized Residual Mean (SRM).
RQ3. What are some key requirements for using the method of paired comparisons to crowdsource a comprehensive relative risk of harm scale spanning hundreds of medications?

By doing this study, we learned about three sets of requirements that must be met to scale up paired comparison experiments with the CrowdSort web app to achieve large-scale crowdsourcing of expert knowledge by this method.

Access Requirements

The first set of requirements that must be met are access requirements. The first version of the CrowdSort web app surfaced several access issues which we overcame. However, CrowdSort is currently not accessible enough to be used for a large-scale experiment. Future versions of the CrowdSort web app need to enable paired comparison data collection on most web browsers and not only on the Google Chrome web browser that we used. Also, to scale up the use of CrowdSort, it needs to be upgraded to a responsive design that can be accessed on various devices including smart phones, tablets, laptops, and desktop computers. Furthermore, CrowdSort must be secured using a secure sockets layer (SSL) certificate. Also, CrowdSort must be made accessible to multiple simultaneous users.

Authorization Requirements

The second set of requirements relate to user authorization. For this study, we collected background information and made inquiries to ensure that every participant was a licensed pharmacist working in a role with patient care duties. Because we collected data remotely but synchronously during live video conference calls we could manually authorize pharmacists to participate. To expand the use of CrowdSort, a more robust and scalable method of validating user credentials is required. We are presently exploring options for automating the user authorization process.

Paired Comparison Task Division Requirements

The third set of requirements are intrinsic to the method of paired comparisons. To develop a fine-grained RRH scale for the majority commonly used medications requires 300 to 400 medications to be compared. Therefore, the number of head-to-head comparisons that must be made would range from 44,850 to 79,800. So many thousands of paired comparisons are far too many for individual pharmacists to complete them all. Instead, we are exploring ways to divide this sizeable comparison-making task up amongst a large number of pharmacist-participants, such as the cyclic paired comparison experiment designs described by David25.

Discussion

We began with a goal of demonstrating the feasibility of crowdsourcing a fine-grained scale for measuring the RRH of many medications. We confirmed that the method of paired comparisons can be used to acquire expert judgments about perceived medication worrisomeness remotely from a diverse group of practicing pharmacists. We are encouraged by the finding that our participants could complete 210 head-to-head medication comparisons in an
average of 16 minutes. This is evidence that, with effective software and incentives, the approach we have taken could scale up to support a large crowdsourcing program to estimate RRH for hundreds of medications.

In terms of granularity, our results for PMW (Figure 2) and for ITCW (Figure 3) demonstrate that it is possible to rank medications into multiple risk-informed PMW categories. By systematically probing pharmacists’ mental models of medication worrisomeness, we found statistically meaningful differentiation among five groups of medications and four groups of therapeutic drug classes. Perhaps more compelling is that these credible results came from engaging just 18 pharmacists. We hypothesize that more groups of medications will emerge on the PMW scale as additional paired comparison data enable more precise estimates. Besides, we did not seek to find definite lower or upper bounds for PMW. More work is needed to determine which medications are perceived to be least and most worrisome of all.

Our PMW scale has four different levels containing high-alert medications (Figure 2). Also, PMW does NOT consistently align with the distinction between prescription-only (i.e., Legend) versus over-the-counter (OTC) drugs. In our results, two Legend medications, amlodipine and amoxicillin, had the lowest PMW estimates. Meanwhile, three OTC medications – aspirin, ibuprofen (Motrin), and naproxen (Aleve) – had remarkably higher PMW estimates than amlodipine and amoxicillin. We did not ask the pharmacist-participants why they perceive two Legend medications to be less worrisome than three OTC drugs. It could be that, taken together, the relatively wide therapeutic windows of amoxicillin and amlodipine, the typically short duration of amoxicillin use, and the fact that amlodipine (Norvasc) is generally well tolerated, all led to these two medications being ranked least worrisome of the 21 in the study set.

It is clear that the 18 pharmacist-participants perceived anticoagulants to be the most worrisome of the study set, especially warfarin. The finding of high PMW and ITCW for anticoagulants may reflect nationwide safety problems with serious but avoidable bleeding events caused by warfarin and other anticoagulants. These findings suggest that a prescription for any oral anticoagulant may raise a mental warning flag in the minds of practicing pharmacists.

This study pertains to our prior published work examining how pharmacists currently develop medication-related risk scores and patient medication regimen complexity scores. Presently, many attempts to develop medication risk and complexity scores are localized at single organizations and involve assigning points to a small number of concerning medications, often with the most points going to those medications with the narrowest therapeutic windows. Few of these locally-devised medication-related scoring mechanisms have been validated. In contrast, our approach is to develop and validate a rigorous, comprehensive RRH scale for medications by combining the judgments of pharmacists from many organizations using the method of paired comparisons. In this manner, we seek to develop a robust, comprehensive, reliable, and valid RRH scale for assessing prescriptions and whole medication regimens.

More generally, this study highlights a potential role for the paired comparisons method in large-scale knowledge acquisition for learning health systems. To be fully successful, we believe learning health systems will need methods and mechanisms like CrowdSort to routinely and methodically source expertise from human practice on a grand scale. The new knowledge that results from crowdsourcing will need to be carefully tested and curated to make it useful.

**Limitations**

This study is limited in a variety of ways. First and foremost, a single experiment with 18 pharmacist-participants does not allow us to generalize our findings about the worrisomeness of medications in any meaningful way. We plan to do future work to expand, validate, and test the impact of these findings. Another limitation is that we only included 21 medications yet 300 to 400 medications need to be rank-ordered in terms of RRH to arrive at a useful measurement instrument. Finally, we were unable to include participant interviews in this study and so we cannot explain the logic of our pharmacist-participants with respect to the task of comparing the worrisomeness of medications head-to-head.

**Conclusion**

By engaging 18 practicing pharmacists from around the United States in a paired comparison experiment, we ascertained their individual and collective judgments about the perceived medication worrisomeness of 21 commonly prescribed medications. We performed data collection remotely using a web application developed for this study called CrowdSort. We found the pharmacists in our sample perceive the relative worrisomeness of medications in a systematic way giving rise to five distinct groupings of medications. This result shows it is feasible to group medications into multiple risk-related categories, transcending the binary categories of high-alert and NOT high-alert that we use in practice today. Further, we showed that some therapeutic categories are more worrisome than others in the minds of our pharmacist-participants. In preparation for future work, we identified several key requirements for scaling up this initial experiment. This study demonstrates the feasibility of developing a comprehensive fine-grained measure of the relative risk of harm by crowdsourcing expert knowledge from pharmacists.
Acknowledgements

We thank our pharmacist-participants. We are grateful to pharmacist Bruce Chaffee for motivating this work. We thank Rachel Kuo and Melanie Johnson for helping us test the Crowdsort web app. For guidance on our statistical approach, we thank Kerby Shedden and Corey Lester. For their general help in preparation for this experiment, we recognize and thank Betty Chaffee, Peter Boisvert, Charles P. Friedman, Nate Gittlen, and Brooke Raths.

The Use of Inter-terminology Maps for the Creation and Maintenance of Value Sets

Kin Wah Fung¹, MD, MS, MA; Julia Xu¹, MD, PhD; Sigfried Gold¹, MFA, MA

¹National Library of Medicine, National Institutes of Health, Bethesda, MD

tkwfung@nlm.nih.gov|xujc@mail.nlm.nih.gov|sigfried@sigfried.org

Abstract

Value sets are essential in activities such as electronic clinical quality measures (eCQM) and patient cohort definition. Creation and maintenance of value sets is labor intensive and error prone. Our method aims to use existing inter-terminology maps to improve the quality of value sets that are defined in more than one terminology. For 197 eCQM value sets defined in SNOMED CT plus ICD-9-CM and/or ICD-10-CM, the map-generated codes showed good overlap with the value set codes. Manual review showed that some new codes identified by mapping should probably be included in the value sets. This could potentially augment the ICD-9-CM codes by 45% (1.5 codes), ICD-10-CM codes by 25% (1.8 codes) and SNOMED CT codes by up to 42% (4.8 codes) per value set on average. The mapping between SNOMED CT and ICD-10-PCS did not perform as well because of the granularity discrepancy in the map.

Introduction

A value set is typically a list of codes taken from a biomedical terminology that collectively defines the scope of a clinical concept. Value sets can be used to identify patient cohorts, measurement criteria for clinical quality improvement, allowable values for a data element (in a survey instrument or the electronic health record), among other uses. One important function of value sets is to ensure that health information from disparate sources are interoperable, whether to support collective data analytics or continuity of patient care. Towards this goal, value set codes are often derived from commonly used clinical terminology standards such as SNOMED CT, ICD code sets (ICD-9-CM, ICD-10-CM and ICD-10-PCS), LOINC and RxNorm.

Value sets play a crucial but often unappreciated and unnoticed role in the capture, use, and analysis of clinical information. Of all the professionals who interact with and rely on value sets in their work with health records, a small fraction is likely to know what a value set is, even in the informatics community, which has a deep, foundational appreciation for the role of standardized terminologies in the complex ecosystem of medical care and health sciences.

Creation of value sets is a labor-intensive process that usually involves subject matter experts working with terminologists to identify codes to include (and exclude) for a particular use case. Maintenance of value sets is essential to keep them up-to-date, since terminologies do evolve over time. The burden of curation is even bigger for value sets that are defined by more than one terminology because the same clinical information can be encoded by different code systems e.g., SNOMED CT and ICD-10-CM for diagnosis. Previous studies have investigated automated methods to assist the authoring and quality assurance of value sets, making use of information such as the hierarchical structure of terminologies and the semantic types of the codes.¹⁻³ This study describes a novel approach of using existing inter-terminology maps to improve the quality of multi-terminology value sets. In an earlier study, we have shown that published maps between ICD-9-CM and ICD-10-CM can help in the translation of codes in value sets.⁴

High quality and up-to-date value sets will generally increase their re-use and utility.⁵ This paper concentrates on one domain where value set reuse is assured by mandate and incentive: as parts of eCQM (electronic clinical quality measures).⁶ The Centers for Medicare & Medicaid Services (CMS) use eCQM in a variety of quality reporting and value-based purchasing programs. The main advantage of electronic quality measurement is that the burden of manual chart pulling, data extraction and reporting can be much reduced. In addition, there is reduced lag time from documentation to reporting and potential access to real time data for quality measurement.

The National Library of Medicine (NLM) in collaboration with the Office of the National Coordinator for Health Information Technology (ONC) and CMS runs the Value Set Authority Center (VSAC), a repository, website, and set
of application programming interfaces (APIs) for public value sets created by external parties. The VSAC does not create value set content but provides tools for value set authors to create and maintain their value sets. Through the VSAC, users can download all official, up-to-date versions of eCQM value sets. VSAC also hosts value sets from other sources, such as the HL7 C-CDA (Consolidated Clinical Document Architecture) and CMS Core Clinical Data Elements and Hybrid Measures.

**Methods**

We downloaded all the eCQM value sets from the VSAC website. Among the eCQM value sets, we identified those that were defined using more than one terminology. One of the terminologies had to be SNOMED CT, and the other could be one or more of ICD-9-CM, ICD-10-CM and ICD-10-PCS. ICD-9-CM included both diagnosis and procedure codes. We excluded the ICD-9-CM procedure codes, which were used in only a small number (2 out of 140) of value sets with ICD-9-CM codes. In addition to the lists of codes, the download file also contained metadata about the value set, including the value set OID, value set name, version and purpose. The purpose described the clinical focus, data element scope, inclusion and exclusion criteria. However, the purpose was not always filled in.

Figure 1. Overall schema of study

---

**Generation of the reference inter-terminology maps**

1. **SNOMED CT and ICD-9-CM map**

   To generate the map between SNOMED CT and ICD-9-CM, we combined two sources of mappings. The first was the ICD-9-CM Diagnostic Codes to SNOMED CT Map published by NLM. The purpose of this map is to facilitate translation of ICD-9-CM codes to SNOMED CT. Even though the U.S. moved from ICD-9-CM to ICD-10-CM in 2015, many existing electronic health record systems still contain clinical information encoded in ICD-9-CM. To facilitate migration to SNOMED CT as the primary clinical terminology for patient health problems (diseases and conditions), it is desirable that the legacy ICD-9-CM data be translated to SNOMED CT. This map is updated yearly to synchronize with the latest version of SNOMED CT. This map is divided into two parts: the one-to-one and one-to-many maps. From both parts, we extracted pairs of SNOMED CT and ICD-9-CM codes into our map. The second source of mappings was the SNOMED CT to ICD-9-CM map published by SNOMED International. The original goal of this map was to facilitate the generation of ICD-9-CM codes from SNOMED CT-encoded clinical information. Since most countries using ICD-9-CM have moved to ICD-10-CM, SNOMED International stopped the maintenance of this map in 2016. We retrieved the last version of this map through the MRMAP table in the UMLS (2016AA version). We harvested pairs of SNOMED CT and ICD-9-CM codes from this map, excluding SNOMED CT concepts that have become inactive since the last update of the map. The combined set of code pairs formed our **SCT-I9 Map**.
2. SNOMED CT and ICD-10-CM map

We used the SNOMED CT to ICD-10-CM map published by NLM. This is a rule-based map that maps all SNOMED CT concept from three hierarchies (Clinical finding, Event and Situation with explicit context) to ICD-10-CM. The map is rule-based to cater for the ICD-10-CM coding rules, which sometimes stipulate that the same disease be coded differently according to patient age, gender and co-morbidities. For example, the SNOMED CT concept Failure to gain weight (36440009) may be coded to ICD-10-CM codes Adult failure to thrive (R62.7), Failure to thrive in newborn (P92.6) or Failure to thrive (child) (R62.51) depending on age. In the NLM map, there is always a default map target that is used when no additional information is available. For our study, we harvested all pairs of SNOMED CT and their default ICD-10-CM map targets to create our SCT-I10 Map.

3. SNOMED CT and ICD-10-PCS map

For mapping between SNOMED CT and ICD-10-PCS, we used the mappings contained in the vocabulary resource of the OHDSI Consortium (Observational Health Data Sciences and Informatics). The purpose of the OHDSI vocabulary is to enable transparent and consistent content across disparate observational databases to support efficient and reproducible research. The mappings are expressed as ‘is a’ relationships between an ICD-10-PCS code and a SNOMED CT concept. For example, the ICD-10-PCS code Bypass Cerebral Ventricule to Intestine with Synthetic Substitute, Open Approach (00160J5) is a Ventriculostomy (63933000) in SNOMED CT. We harvested all the pairs of SNOMED CT and ICD-10-PCS codes linked by ‘is a’ to form our SCT-PCS Map.

Identification of map-generated code lists for each value set using the reference maps

For each value set, we used the reference maps to find mappings for the original value set codes in each terminology. We called the codes found by mapping the “map-generated codes”. We used the reference maps in either direction. For example, if the value set contained SNOMED CT, ICD-9-CM and ICD-10-CM codes, we would generate the following four lists of map-generated codes

- **I9-from-SCT codes** - ICD-9-CM codes identified based on the original SNOMED CT codes in the value set mapped through the SCT-I9 Map
- **I10-from-SCT codes** - ICD-10-CM codes identified based on the original SNOMED CT codes in the value set mapped through the SCT-I10 Map
- **SCT-from-I9 codes** – SNOMED CT codes identified based on the original ICD-9-CM codes in the value set mapped through the SCT-I9 Map
- **SCT-from-I10 codes** – SNOMED CT codes identified based on the original ICD-10-CM codes in the value set and mapped through the SCT-I10 Map

Evaluation of the map-generated codes

For each value set, we evaluated the map-generated codes in two aspects. First, we wanted to know how closely the map-generated codes resembled the original value set codes. Second, we wanted to know whether the map-generated codes could help to identify codes that should have been included in the value set. The evaluation was done as follows:

1. **Jaccard similarity coefficient**

   We used the Jaccard coefficient as an indicator of the similarity between the original value set codes and the map-generated codes for each terminology of each value set. The Jaccard coefficient was defined as the number of codes common to both the original and map-generated code lists divided by the number of codes in the union of the two lists. The Jaccard coefficient generally reflects the degree of overlap between two lists of items in which the number of items can be different. As an example, for a value set with SNOMED CT, ICD-9-CM and ICD-10-CM codes, we would generate four Jaccard scores between:
   a. original ICD-9-CM and I9-from-SCT codes
   b. original ICD-10-CM and I10-from-SCT codes
   c. original SNOMED CT and SCT-from-I9 codes
   d. original SNOMED CT and SCT-from-I10 codes
2. Manual review
   We performed manual review of all the codes found by mapping that were not present among the original codes in a value set. For practical purposes, we limited our review to cases in which the total number of codes (both map-generated and original) for the pair of terminologies in focus was less than 100. The reviewer judged whether the new code found by the map was:
   a. Exact match – the map-generated code matched exactly the meaning of one of the original codes in the value set. The map-generated code should probably be included in the value set.
   b. Approximate match, candidate – the map-generated code was similar in meaning to at least one original code in the value set, and should be considered as a candidate for addition to the value set. We judged the suitability of inclusion based on the stated purpose of the value set and the inclusion criteria, if explicitly stated. Otherwise, we would rely on the name of the value set and other codes in the value set to make our judgment.
   c. Approximate match, not a candidate – the map-generated code was similar in meaning to at least one original code in the value set, but was not considered a candidate for addition due to the inclusion and exclusion criteria, if explicitly stated.
   d. Not a match – the map-generated code did not match any of the original value set codes.

   In interpreting the review results, we assumed that all codes in a terminology that were within the scope of the value set (as judged by the name, accompanying documentation and the original value set codes) should be included in the value set. We assumed that there was no exclusion for certain special kind of codes (e.g., unspecified codes) unless explicitly stated. We assumed that the code list in one terminology in a value set could be used independently from other code lists in a different terminology. Finally, we also assumed that map-generated codes that did not fall within the scope of the value set and did not match any of the original value set codes should not be included in the value set.

Results

The value sets

We downloaded 715 eCQM value sets (version September 2018) from VSAC of which 221 contained SNOMED CT and one or more of the other target terminologies. Table 1 shows the combination of terminologies in these value sets.

Number of value sets with this terminology: 221

*2 value sets using ICD-9-CM procedure codes excluded from study

Among the 221 value sets, only 83 (38%) had explicitly stated purpose, scope, inclusion and exclusion criteria.

In the following section, we present our findings according to the pair of terminologies covered by the reference maps that we created.
1. SNOMED CT and ICD-9-CM map

The SCT-I9 Map we created could provide mapping to 89,043 SNOMED CT concepts, which represented 72% of concepts in the three relevant hierarchies (Clinical finding, Event and Situation with special context). On the ICD-9-CM side, it covered 13,014 (89%) diagnostic ICD-9-CM codes.

Table 2 summarizes the results of using the SCT-I9 Map to generate candidate value set codes. The map was able to suggest some codes in almost all the value sets in either direction of mapping. For the map-generated codes, 62% of the ICD-9-CM codes and 53% of SNOMED CT codes already existed in the value set. For each value set, we measured the similarity between the original codes in the value set and the map-generated codes for the same terminology by calculating the Jaccard coefficient. The average of the Jaccard coefficients for ICD-9-CM and SNOMED CT was 0.5 and 0.38 respectively. We manually reviewed all the map-generated codes that were not among the original value set codes, limiting to value sets with 100 codes or less. We reviewed a total of 305 ICD-9-CM and 789 SNOMED CT codes from 89 value sets.

For the map-generated ICD-9-CM codes, 33% of the codes not present in the original value set were found to be exact matches to another code in the value set. For example, in the Optic Neuritis value set, the ICD-9-CM code *Meningococcal optic neuritis (036.81)* was found by mapping but not in the original value set. However, the SNOMED CT code *Meningococcal optic neuritis (73431005)* was in the original value set. A further 16% of the map-generated ICD-9-CM codes were approximate matches and could be considered candidates for addition. For example, in the Uveitis value set, the ICD-9-CM code *Syphilitic uveitis, unspecified (091.50)* was found by mapping but not in the original value set. This code should probably be added to the value set since it also contained the SNOMED CT code *Uveitis due to secondary syphilis (186854007)*. Overall, 50% of the reviewed ICD-9-CM codes did not match any of the value set codes.

For the map-generated SNOMED CT codes, 4% of the codes not present in the original value set were found to be exact matches. For example, in the Hypotension value set, the SNOMED CT code *Orthostatic hypotension (28651003)* was found by mapping but not in the original value set. However, the ICD-9-CM code *Orthostatic hypotension (458.0)*
was in the original value set. Almost half (45%) of the map-generated SNOMED CT codes were approximate matches and candidates for addition. For example, in the Bradycardia value set, the SNOMED CT code Symptomatic sinus bradycardia (444605001) was found by mapping but missing from the value set. This code should be considered a candidate to be added to the value set since it also contained the SNOMED CT code Severe sinus bradycardia (49044005). A small number of codes (2%) were approximate matches but not considered candidates for addition. This number could be artificially low because only a third of all value sets had explicitly stated purpose, inclusion and exclusion criteria, which were needed to determine if a code belonged to this category. For example, in the Lupus value set, the SNOMED CT code Systemic lupus erythematosus in remission (698694005) was an approximate match but not a candidate because the exclusion criteria explicitly excluded “systemic lupus erythematosus in childhood or in remission”. Overall, 48% of the reviewed SNOMED CT codes did not match any of the value set codes.

The unmatched codes generally belonged to two types. The first type was mapped-generated codes based on a part of a composite term that was not relevant to the value set. For example, the Lupus value set contained the SNOMED CT code Pericarditis co-occurrent and due to systemic lupus erythematosus (25380002), which was mapped to the ICD-9-CM code Other acute pericarditis (420.99) that was outside the scope of the value set. The second type was related to the “Not Elsewhere Classified” (residual or catch-all) codes in ICD-9-CM. For example, the Bradycardia value set contained the ICD-9-CM code Other specified cardiac dysrhythmias (427.89) which was mapped to many SNOMED CT codes, including Sinus tachycardia (11092001) that were not within the scope of the value set.

2. SNOMED CT and ICD-10-CM map

The SCT-I10 Map we created could provide mapping to 110,184 SNOMED CT concepts, which represented 89% of concepts in the three relevant hierarchies (Clinical finding, Event and Situation with special context). On the ICD-10-CM side, it covered 30,576 (43%) ICD-10-CM codes.

| Jaccard score: macro-average (median) | 0.3 (0.2) |
| Manual review: |
| Value sets reviewed | 112 |
| Original codes in value sets | 806 ICD-10-CM codes |
| Map-generated codes reviewed | 547 ICD-10-CM codes |
| Exact match (%) | 136 (25%) |
| Approximate match, candidate (%) | 127 (23%) |
| Approximate match, not candidate (%) | 0 (0%) |
| Not a match (%) | 284 (52%) |

Table 3 summarizes the results of using the SCT-I10 Map to generate candidate value set codes. The map was able to suggest some ICD-10-CM and SNOMED CT codes in 98% and 89% of the value sets respectively. For the map-
generated codes, 59% of the ICD-10-CM codes and 37% of SNOMED CT codes already existed in the value set. The macro-average of the Jaccard coefficients for ICD-10-CM and SNOMED CT was 0.3 and 0.32 respectively.

We reviewed 547 ICD-10-CM and 1,124 SNOMED CT codes (from 112 and 96 value sets) that were not present in the original value sets. For the map-generated ICD-10-CM codes, 25% of the codes were found to be exact matches to another code in the value set. For example, in the *Chlamydia* value set, the ICD-10-CM code *Chlamydial peritonitis (A74.81)* was found by mapping but not in the value set. However, the SNOMED CT code *Chlamydial peritonitis (197172005)* was in the original value set. A further 23% of the map-generated ICD-10-CM codes were approximate matches and could be considered candidates for addition. For example, in the *Breastfeeding* value set, the ICD-10-CM code *Hypogalactia (O92.4)* was found by mapping but not in the value set. This code should be considered for addition to the value set since it also contained the ICD-10-CM code *Suppressed lactation (O92.5)*. Overall, 52% of the reviewed ICD-10-CM codes did not match any of the value set codes.

For the map-generated SNOMED CT codes, 5% of the codes not present among the original value set codes were found to be exact matches. For example, in the *Rubella* value set, the SNOMED CT code *Rubella meningitis (1092351000119107)* was found by mapping but not in the value set. However, the ICD-10-CM code *Rubella meningitis (B06.02)* was in the value set. Almost three-quarter (72%) of the map-generated SNOMED CT codes were approximate matches and candidates for addition. For example, in the *Proteinuria* value set, the SNOMED CT code *Microalbuminuria due to type 1 diabetes mellitus (18521000119106)* was found by mapping but missing from the value set. This code should be considered a candidate to be added to the value set since it also contained the SNOMED CT code *Microalbuminuria (312975006)*. A small number of codes (0.4%) were approximate matches but not candidates for addition. For example, in the *Chronic Malnutrition* value set, the SNOMED CT code *Progressive encephalopathy with severe infantile anorexia (715794009)* was an approximate match but not considered a candidate because of the exclusion criteria “all diagnosis codes for feeding disorders of infancy or childhood”. Overall, 23% of the reviewed SNOMED CT codes did not match any of the value set codes.

The unmatched codes could generally be attributed to the same reasons as for the SCT-I9 Map (see above).

3. **SNOMED CT and ICD-10-PCS map**

The SCT-PCS Map we created could provide mapping to 4,563 SNOMED CT concepts, which represented 8% of concepts in the Procedure hierarchy. On the ICD-10-PCS side, it covered 40,378 (51%) ICD-10-PCS codes.

Table 4 summarizes the results of using the SCT-PCS Map to generate candidate value set codes. The map was able to suggest some ICD-10-PCS codes in 83% of the value sets, and some SNOMED CT codes in all value sets. For the map-generated codes, 47% of the ICD-10-PCS codes and 34% of SNOMED CT codes already existed in the value set. The macro-average of the Jaccard coefficients for ICD-10-PCS and SNOMED CT was 0.38 and 0.08 respectively.

We reviewed a total of 99 ICD-10-PCS and 48 SNOMED CT codes (from 8 and 12 value sets) that were not present in the original value sets. For the map-generated ICD-10-PCS codes, 15% were approximate matches and could be considered candidates for addition. For example, in the *Hip Fracture Surgery* value set, the ICD-10-PCS code *Repair Right Hip Joint, Percutaneous Endoscopic Approach (0SQ94ZZ)* was found by mapping but not in the original value set. This code should be considered for addition to the value set since it also contained the ICD-10-PCS code *Repair Right Hip Joint, Open Approach (0SQ90ZZ)*. The remaining 85% of the reviewed ICD-10-PCS codes did not match any of the value set codes.

For the map-generated SNOMED CT codes, 19% of the codes not present in the original value set were found to be approximate matches and candidates for addition. For example, in the *BH Outpatient Psychotherapy* value set, the SNOMED CT code *Individual psychotherapy (18512000)* was found by mapping but missing from the value set. This code could be considered a candidate to be added to the value set which also contained the SNOMED CT code *Group psychotherapy (76168009)*. The remaining 81% of the reviewed SNOMED CT codes did not match any of the value set codes.

Most of the unmatched codes were related to the fact that the majority of the SNOMED CT codes in the SCT_PCS Map were broader than any of the value set codes (see Discussion).

**Discussion**

Value sets are useful resources and help to ensure the validity and comparability of data collected for various purposes. However, the creation and maintenance of value sets is a non-trivial process. Terminologies are constantly updated to reflect advance in biomedical science and changes in coding rules. While it is relatively straightforward to identify codes that have become obsolete when a terminology is updated, it is more difficult to identify new codes that should be included in a value set. In medical classifications like ICD-9-CM or ICD-10-CM, due to the requirement of a single (as opposed to a poly-) hierarchy, new codes related to the same condition are sometimes added to a different branch from the existing codes (e.g., in ICD-9-CM, hypertension in pregnancy is put under the chapter Complications of pregnancy, childbirth and puerperium), making them more liable to be missed by the value set editors. If value sets are not properly maintained, their quality will deteriorate over time, with deleterious effects on the validity of the data generated using these value sets. The impact can range from inaccurate calculation of payments to providers due to errors in electronic clinical quality reporting, to missing patients from a research cohort due to an omitted code.

Our study shows that existing inter-terminology maps can be useful adjuncts for the creation and maintenance of value sets that involve more than one terminology. Take the example of mapping between SNOMED CT and ICD-9-CM. There are 138 eCQM value sets that are defined by both of these terminologies. The overlap between the original value set codes and map-generated codes is considerable judging from the Jaccard scores (0.5 and 0.38 for ICD-9-CM and SNOMED CT respectively). This lends support to the general validity of our method that a significant portion of the original value set codes can be found by inter-terminology mapping. More importantly, mapping also uncovers a significant number of codes that are potentially missed by the value set curators. Based on our review, the exact matches are almost certainly missed codes that should be added. We think that a considerable portion of the approximate matches should probably be added as well. If we assume that all the exact matches and half of the approximate match candidate codes are indeed added to the value sets, the SCT-19 Map would augment the 87 value sets by a total of 127 ICD-9-CM codes (1.5 codes per value set). This represents a 45% increase to the 284 original ICD-9-CM codes in these value sets. (Table 2) By similar assumptions, the SNOMED CT codes in these value sets would be augmented by 21% (2.4 codes per value set) on average. Similarly, the SCT-110 Map will augment the ICD-
10-CM codes by 25% (1.8 codes per value set) and SNOMED CT codes by 42% (4.8 codes per value set) on average. (Table 3)

The results for the SCT-PCS Map are less satisfactory. The overlap between the map-generated codes and the value set codes is on the low side, especially in the ICD-10-PCS to SNOMED CT direction. Manual review did not find any exact matches. This is not surprising considering the differences between SNOMED CT and ICD-10-PCS. ICD-10-PCS codes are generally more granular and contain information (e.g., surgical approach, use of devices and procedure intent) that is not captured in SNOMED CT concepts. Therefore, it is unusual to find an exact match between the two terminologies. The main purpose of the mappings in the OHDSI vocabulary is to support data aggregation and analytics. Many of the SNOMED CT concepts in the map are very general (e.g., Procedure on skin (118718002)), whereas value sets tend to use more specific SNOMED CT concepts. Moreover, the mappings in the OHDSI vocabulary are generated algorithmically with limited human review, unlike the other mapping resources used in this study that are all manually validated. It is possible that the performance of the SCT-PCS Map can be improved by propagating the mappings of the broader SNOMED CT concept to their descendants. We shall explore this option in future.

Use of inter-terminology maps in the creation and maintenance of value sets is likely to improve their quality (e.g., reducing missing codes) and reduce the curation time and effort. All the maps used in this study are in the public domain and regularly updated by the owners (except for the SNOMED CT to ICD-9-CM map from SNOMED International). To be useful, the codes suggested by the maps should have high accuracy (i.e. high signal-to-noise ratio). In our study, the proportion of map-generated new ICD-9-CM, ICD-10-CM and SNOMED CT codes that are either exact or approximate candidate matches are 49%, 48%, and from 49% (mapped from ICD-9-CM) to 77% (mapped from ICD-10-CM) respectively. (Tables 2 and 3) The suggestions based on the SNOMED CT to ICD-10-PCS map are not as useful. In actual implementation, how to present the map-suggested codes to the value set editors in a dynamic and efficient way is an important consideration. We hope to explore this issue in our future research. A potential refinement of our method is to use multiple routes of mapping to hone in on the most promising codes. For example, if a value set contains SNOMED CT, ICD-9-CM and ICD-10-CM codes (the most common type in our study), the SNOMED CT codes generated from the ICD-9-CM and ICD-10-CM maps can be used for mutual validation.

The VSAC has become the de facto home for dissemination of value sets for various purposes. It is also an authoring platform for value sets. The recent addition of the ability to create intensional value sets is likely to reduce the burden of value set curation. Instead of enumerating the codes in a value set (extensional value set), an intensional value set specifies the rule for inclusion of codes. An example will be using the expression ‘377.3-’ instead of a list of ICD-9-CM codes (‘377.30’, ‘377.31’, ‘377.32’, ‘377.33’, ‘377.34’, ‘377.39’) to represent the value set of Optic neuritis. When a terminology is updated, it is expected that the intensional definition will pick up new codes automatically, provided that they are subsumed by the same parent codes. However, this is more likely to be true in a multi-hierarchical terminology like SNOMED CT. How useful it is for single-hierarchy terminologies like ICD-9-CM and ICD-10-CM remains to be seen. Another observation in our study is that only 38% of the eCQM value sets have explicitly stated purpose and inclusion/exclusion criteria. This kind of information is essential for users to understand the scope of a value set and determine whether it fits their use case. Without this information, the users can only guess by the name of the value set and the codes it contains. For reliable re-use of value sets, it is essential that value set authors provide the necessary value set metadata and documentation.

We recognize the following limitations in our study. The study only focused on the eCQM value sets that are defined in more than one terminology. The results may not be generalizable to other value sets. We only studied maps between four terminologies, albeit that they are among the most commonly used in value sets. We found significant performance difference among different terminologies. Whether this method is applicable to other terminologies remains to be seen. All manual review of the map-generated codes was done by one author (JX) and not independently validated. We only reviewed value sets with 100 codes or less.
Conclusion

Inter-terminology maps can potentially be used to assist human curators in the creation and maintenance of value sets that are defined by multiple terminologies. The map-generated codes showed good overlap with the original value set codes, lending support to the validity of the method. For value sets using SNOMED CT in combination with ICD-9-CM and/or ICD-10-CM, the map-generated codes could potentially augment the ICD-9-CM codes by 45% (1.5 codes per value set), ICD-10-CM codes by 25% (1.8 codes per value set) and SNOMED CT codes by up to 42% (4.8 codes per value set) on average. The map between SNOMED CT and ICD-10-PCS did not work as well, probably due to the big difference in granularity between the terminologies and the inexact nature of the source mappings.

Abstract

Diabetes is a manageable chronic condition that contributes significantly to the global health burden of diseases and mandates a global collective effort to create an effective solution. This paper describes a community diabetes care pathway built upon a Strengths-Oriented Global Health Informatics Framework and an interdisciplinary standardized terminology, the Omaha System, along with a related translational process to disseminate best practices in diabetes care in China. This project demonstrates a novel strengths-oriented collaborative approach to disseminate best practices of diabetes management in global health communities and offers a potential to bring person-centered coordinated care to multi-levels of engagement that generate actionable and measurable results. Such collaboration opens a continued dialogue in the discourse for constructing global health informatics principles and practice to reduce the burden of diseases around the world.

Introduction

As one of the four priority noncommunicable diseases (NCDs), diabetes contributes significantly to the global health burden of diseases, reflective of a surge in associated risk factors such as obesity in the general population globally.1 Diabetes was a direct cause of death for an estimated 1.6 million people in 2016.2 As a major global health issue, diabetes in China is now becoming the world’s biggest epidemic.3 With the estimated 11 percent population suffering diabetes,4 China has the most diabetes cases worldwide. In company with its strong economic growth, pressing needs have emerged to promote diabetes care in China. To address this increasing health challenge and reduce the burden of diabetes around the globe, commitments among nations have been sought for the development of a collective consensus as well as investment in creating affordable, cost-effective interventions based on the best available science.1

Global health informatics can be used as an effective vehicle to promote what is defined by global health as improving health and health equity for all people worldwide5 via dissemination of best global health informatics practices and principles and support of an exchange forum of global health experiences and expertise.6 This new global social space not only strengthens connections around the world but also cultivates locality and regionality through globalization.7 Multi-partnerships through global efforts have been implemented in the past to improve diabetic care in China based on a Share-Care Community Model.8 Community-based care has been given a global focus on the initiation of best community practices through the employment of the standardized language, the Omaha System, by the Omaha System Community of Practice.9 This paper describes the creation of an open source diabetes care pathway for community care based on a Strengths-Oriented Global Health Informatics Framework and an interdisciplinary standardized terminology, the Omaha System; and further describes a related translational process to disseminate best practices in diabetes care in China, a country with the most populous cases of diabetes in the world. This project is a prototype of an interdisciplinary strengths-based diabetes care plan to meet the increasing need for reducing the burden of NCDs in a global health setting.

Strengths-Oriented Global Health Informatics Framework and the Omaha System

Health strengths or health assets are defined as any protective and promoting factor or resource that helps individuals, communities, and populations to maintain and sustain health and wellbeing, and reduce health inequalities.10-12 A strengths-based approach aims to highlight evidence of effectiveness to address problems or eliminate deficits with emphasis on positive attributes.12 Such approaches strive to identify protective factors and resources to mobilize solutions that support and promote the health and wellbeing of both individuals and communities.12,13 A limited number of robust evaluations of assets-based actions exists which challenges
professionals to rethink strategies for disease management and health promotion. Building a strengths or assets-based framework to guide care interventions in the management of diabetes for global health communities offers a strong asset to turn interventions and actions into evaluations that generate data and information into measurable knowledge and practice outcomes.

Health care services have traditionally been designed to fix actual or potential health problems of individuals or populations by providing interventions to solve, alleviate, or prevent those problems, needs, and deficiencies, with little focus on enhancing the individuals’ strengths and capabilities or incorporating an individual’s experiences, preferences, perspectives and knowledge. Such an approach places individuals as passive recipients of services rather than active participants in their own care. Leveraging the positive capabilities, strengths, and resources of individuals may allow them to identify problems and prompt solutions for health and wellbeing that promote resilience and improved health outcomes. Health promoting or protecting assets can be harnessed on individual, community, and organizational levels across the domains of health determinants that include individual characteristics, social circumstances, environmental conditions of living and work, behavioral choices related to health and health services, and equitable and sustainable social and economic development.

A prototype of a Strengths-Oriented Global Health Informatics Framework was developed on three levels: individuals, communities/populations, communities/organizations. At the level of individuals, health promoting or protecting assets span across the domains of health determinants including personal, individual characteristics, and health behaviors. At the level of communities and populations, health promoting or protecting assets originate from social circumstances, environmental conditions of living and working, behavioral choices related to health and health services. At the level of communities and organizations, health promoting or protecting assets stem from equitable and sustainable social and economic development.

This Strengths-Oriented Global Health Informatics Framework was then mapped to and represented by the Omaha System Domains (Figure 1). The Omaha System is an interdisciplinary standardized terminology intended to capture health and health care by taxonomically describing all of health as 42 defined Problem concepts within four holistic domains: Environmental, Psychosocial, Physiological, and Health-related Behaviors. Multidisciplinary clinicians use Omaha System point-of-care software in the United States and other countries created by a growing number of computer software vendors who offer Omaha System clinical information systems. This standardized vocabulary is used predominantly in the community and public health settings to document care assessments, interventions, and outcomes.

The Omaha System consists of three classification schemata including the Problem Classification Scheme, the Intervention Scheme, and the Problem Rating Scale for Outcomes. The Problem Classification Scheme has 4 standardized domains that branch into a total of 42 standardized problem concepts which describe assessments for problem-specific strengths and signs/symptoms. The Intervention Scheme is related to the Problem Classification Scheme and has 3 hierarchical levels including 4 standardized categories in action terms and 75 standardized targets followed by customizable care descriptions to document care plans and services for each identified problem concept. The Problem Rating Scale for Outcomes measures the problem concepts using three 5-point Likert-type scales (1 =
lowest to 5 = highest) related to Knowledge, Behavior, and Status (KBS) outcomes. Each of the KBS rating scales presents a continuous framework for evaluating a distinct rating of a problem concept and an intervention outcome over time. It is feasible to use the Omaha System to document both problems and strengths on individual and community levels. The reliability and validity of the Omaha System components have been tested and established in multiple settings in research.

Care pathways encoded with the Omaha System have been integrated into electronic health records and mobile applications. Similarly, the current strengths-oriented diabetes care pathway using the Omaha System can be easily integrated into a web-based or mobile platform to support diabetes care management on the go. Using mobile technology is critical as it has dominated the everyday life of citizens in China. Leveraging the use of technology and data offers the potential in discovery of new paradigms in tracking and managing disease, defining best practice that integrates a patient-centered perspective, addressing quality gaps, and demonstrating improvement in health outcomes.

The Omaha System Strengths-Oriented Diabetes Care Pathway

A Strengths-Oriented Diabetes Care Pathway (Figure 2) was created for the management of diabetes in the global health setting by referencing to evidence-based clinical guidelines developed for standardized diabetes care in the U.S, expert opinions, and literature. Based on the Omaha System domains, the pathway is mapped to the three levels of individuals, communities/populations, and communities/organizations for the Strengths-Oriented Global Health Informatics Framework. This Strengths-Oriented Diabetes Care Pathway identifies both problems, the deficits, and strengths, the health assets and positive attributes using relevant Omaha System problem concepts corresponding to each mapped domain. Based on the identified problems and strengths, the Problem Rating Scale for Outcomes is assigned a Knowledge, Behavior, and Status score, which leads to the Omaha System Intervention scheme. Subsequently, an intervention string combined with the three hierarchical levels of the Intervention scheme is created to capture evidence of effectiveness of what works and trigger solutions which promote positive attributes and health outcomes of individuals, populations, communities, and organizations.

Results and Discussion

Following the strengths-oriented framework and the Omaha System pathway schemata, an open source Strengths-Oriented Diabetes Care Plan was created by mapping to the 2019 standards of diabetes care, literature, and expert opinions. The Omaha System domains and problem concepts captured in the diabetes care plan are illustrated in Figure 3. This diabetes care plan aims to capture optimal diabetes management, which can be achieved by collaborative and systematic engagement of a coordinated team of health care professionals to provide patient-
centered high-quality care based on evidence-based guidelines. Research and evidence also support that optimal diabetes management should also assess and address psychosocial issues and decrease or eliminate financial barriers for diabetes care and management. On the community and organizational levels, optimal diabetes management is supported by identifying, developing, and engaging community resources and public policies that support healthy lifestyles. Social determinants of health are defined as economic, environmental, political, and social conditions in which people live. They have contributed significantly to health inequality worldwide and exert a big impact on health inequities related to diabetes and its complications. This diabetes care plan incorporates all these comprehensive factors and resources on all the various levels.

Figure 3. The Omaha System domains and problem concepts by number.

Note: Env = Environmental; Phy = Physiological; Psy = Psychosocial; HRB = Health-related Behaviors

Incorporating an evaluation scale allows multidisciplinary teams to track disease management and health promotion strategies and measure health-related behaviors and outcomes at both individual and collective levels so that the care intervention process and tools can be modified for better care qualities and results. The care intervention process involves 4 actionable categories in different proportions (Figure 4) of care activities that focus on a total of 31 unique targets (Figure 5).

Figure 4. The Omaha System categories by number.
Figure 5. The Omaha System targets by number.

An intervention string was constructed by combining a problem term from the Problem Classification Scheme, a category, a target, and a customizable care description from the Intervention Scheme. This intervention string delineates an intervention activity or strategy targeted to optimal diabetes care management and health promotion. Examples of the intervention strings from this care plan are displayed in Table 1. These intervention activities subsequently lead back to an iterative process to reevaluate previous identified problems and strengths and associated outcomes that warrant the sustainment or modification of existing interventions or development of new interventions to address problems and strengthen positive attributes and assets.

### Standardized Translation Model

To advance health promotion and disease management in a global setting, a process should be considered to engage standardization of the translation process to disseminate best practices in a global environment. Using a standardized terminology and language such as the Omaha System, health data and information can become easily interoperable, and readily comparable and sharable. Many evidence- and practice-based care plans for management of various chronic populations in community developed by using the Omaha System have been integrated into health information systems that can be disseminated into the global communities. When initiating the translation process of electronic tools for diabetes management within the global context of health management exchange, a standardized translation model (Figure 6) for vocabulary mapping should be taken into consideration to harmonize different languages and achieve a shared purpose of information representation. The translation process of the strengths-oriented diabetes care plan into Chinese utilizes this proposed conceptual translation model.

In this model, a special intermediate tool such as the use of a middleware including standardized terminologies of SNOMED CT, the Omaha System, and others should be used to convert the vocabularies of these systems and align them in one congruent context based on multiple constructs of a vocabulary mapping that harmonizes the two languages with standardization. Such knowledge modeling that provides common data elements and terminology can enable the representation of data, semantics, and knowledge in healthcare information over time and location independent from technology. Specific constructs should be put into the context of lexical, semantic, conceptual, process, and cultural considerations. This way, health management tools can become a standardized data and information exchange resource and discourse for health management and outcome measurement in the community within a global health context.
Figure 6. Internationalization Architecture of Omaha System.

Conclusion

This project demonstrates a novel strengths-oriented interdisciplinary approach to disseminate best practices of diabetes management in global health communities using a standardized multidisciplinary terminology. It offers the potential to bring person-centered collaborative care to multi-levels of engagement that generate actionable and measurable solutions based on both problems and assets of strengths and resources. Such collaboration opens a continued dialogue in the discourse for leveraging the use of global health informatics principles and practice to reduce the burden of diseases around the world.

Abstract

The integration of genetic information in current clinical routine has raised a need for tools to exploit family genetic knowledge. On the clinical side, an application for managing and visualizing pedigree diagrams could provide genetics specialists with an integrated environment with potential positive impact on their current practice. This article presents a web tool (genoDraw) that provides clinical practitioners with the ability to create, maintain and visualize patients' and their families' information in the form of pedigree diagrams. genoDraw implements a graph-based three-step process for generating diagrams according to a de facto standard in the area and clinical terminologies. It also complies with five characteristics identified as indispensable for the next-generation of pedigree drawing software: comprehensiveness, data-drivenness, automation, interactivity and compatibility with biomedical vocabularies. The platform was implemented and tested, confirming its potential interest to clinical routine.

Introduction

Informatics tools able to exploit genetic information in familial inheritance are increasingly necessary in clinical practice. Making sense of the genetic relations among individuals is an important task even in day-to-day medical activities in the genetics area. However, the availability of applications that allow for registering and visualizing family genetic information is not yet up to par with the necessary requirements for the task. In our long-term collaboration with the 12 de Octubre Hospital, Madrid, Spain, genetics specialists showed an interest in having a tool to facilitate the creation, management and visualization of pedigree diagrams, a visual system to represent families, in the day-to-day clinical activities of these specialists. However, the requirements presented to us for such a tool revealed that some characteristics essential for pedigree drawing systems to be of use in clinical practice are not found in the currently available set of platforms for this purpose. The first characteristic should be (a) that the system complies with the Standardized Human Pedigree Nomenclature – a de facto standard - in its updated version and is able to represent even the less-common scenarios that can be of interest for being documented; (b) that the tool is capable of automating the process of drawing the pedigree; (c) that the system is capable of generating the diagram from structured data. Having the characteristics (b) and (c), the diagrams do not need to be stored as visual diagrams (as images, for instance), but as structured data of each individual represented, as well as relations among them. Thus, data retrieved from medical information systems can be represented as pedigree diagrams with minimal intervention of the user. One of the necessities for this tool was that it was easy to use in a clinical scenario. For this purpose, we concluded that another key characteristic should be (d) that the system would present good usability characteristics, enabling the user to interact easily and rapidly with the interface. Thus, specialists could use the tool to create and manage pedigrees during their medical encounters with patients. Additionally, since the tool must be adapted to work in a clinical environment, some integration aspects should be considered. In our analysis, one integration capability that was especially important was that (e) the individuals represented in our tools should have their traits and diseases annotated as terms extracted from widely-adopted biomedical vocabularies (i.e. Human Phenotype Ontology (HPO), SNOMED-CT and the Online Mendelian Inheritance in Man (OMIM)).

In this paper, we refer to the five described characteristics as (a) comprehensiveness, (b) automation, (c) data-drivenness, (d) interactivity, and (e) compatibility. They are particularly important in the context of precision medicine, in which very diverse situations must be represented, and data stored in clinical information systems must be retrieved and shown to the specialist. Then, specialists will be able to take more information into consideration when making,
for example, a diagnosis, or provide a better, more personalized treatment. Additionally, the presented characteristics offer the possibility to better analyze the way in which families are structured and how genetic diseases are inherited, opening possibilities in statistical and medical research.

An analysis of the pedigree diagram drawing tools and platforms currently available revealed that some of the five characteristics can be found in some of these platforms. Examples of such platforms are Madeline 2.0, My Family Health Portrait, CRA Health, Progeny, and GenoPro. However, none of the tools analyzed combine the five characteristics simultaneously. Furthermore, none of the tools implement the updated version of the nomenclature mentioned above, and, to our knowledge, none of the systems support the annotation of diseases as terms from biomedical vocabularies. In order to offer a solution that aims to comply with the five characteristics identified, we developed genoDraw (www.genodraw.com). In this work, we present the foundations on which this system is built.

Methods

We identified the five characteristics that we believe are necessary for a better acceptance of this kind of system in clinical practice. Hence, the foundational idea around genoDraw is to be a platform for the creation, management and visualization of pedigree diagrams. In this section, we present the basis of our approach for the representation engine and the strategies that we applied so that each of the characteristics (a-e) is addressed by genoDraw. In our specific case, a web-based platform was ideal. At the end of this section, we present the architectural aspects of our system and other implementation details.

First, to represent the pedigree diagrams, we follow the Standardized Human Pedigree Nomenclature. This nomenclature is a recommendation of the National Society of Genetic Counselors and it is a current de facto standard in the discipline. The definitions and rules established by the updated version of this nomenclature enable us to define an algorithmic process for the diagram creation in a broad range of reproductive scenarios. Examples include planned adoptions, ovum donations, surrogate gestations, as well as the expected usual situations, such as single and multiple gestations.

Second, to correctly store the necessary entities and links and draw them on a canvas, we represent the diagram internally as a graph (structured data). Entities (nodes) of this internal graph are individuals, gestations and relationships. In each of them, data are stored. For instance, a gestation can be monozygotic or not when more than one child is listed, and an individual might be affected by a certain trait. A second graph, the one to be drawn as a pedigree diagram, is generated using data describing these entities and their relations (biological parenthood, partner of a relationship, etc.). This is accomplished using data describing these entities and their relations (biological parenthood, partner of a relationship, etc.). This is accomplished using the three-step process described below.

The three-step process involved in drawing pedigree diagrams is responsible for transforming the internal graph, which stores what is essential to the representation as structured data, into the representation graph. The representation graph, in turn, follows the nomenclature and does not necessarily contain the same nodes and links as the internal one. In fact, in many scenarios, the representation graph will be composed of more nodes and fewer edges than the internal one. For example, the internal graph stores, for each gestation, each of the parents. However, when a relationship between the parents is identified, only one link between the relationship and the gestation is drawn, and not those between the gestation and each parent. As an illustration of this example, Figure 1 shows, on the left-hand side, the objects of the internal graph relative to three individuals (A, B and C), a relationship (R) and the gestation of C (G), as well as the connections among them. The resulting nodes and links of the matching pedigree diagram, drawn after following the three steps, are shown on the figure’s right-hand side.

The first step of the three-step process generates each of the nodes to be drawn. This step decides which entities are to be drawn or not and draws the squares, circles, diamonds and other artifacts that visually represent each entity. For individuals, characteristics such as gender, being deceased or not, and traits by which they are affected are characteristics that are reflected in the symbol drawn on the canvas. In Figure 1, for instance, the individual C is affected by sickle cell anemia (OMIM: #603903). This disease is annotated as a term from the Online Mendelian Inheritance in Man (OMIM) and, as described later, is included in a collection of traits of the corresponding individual as a reference to such term in the OMIM vocabulary. This characteristic is reflected in the representation graph as a gray mark in the node that corresponds to the individual C. In the case of gestations, only those that correspond to multiple gestations will have drawn at the node other than the gray circle, which we add for usability purposes as discussed later. When
Figure 1: A simple example of generation of a pedigree diagram from an internal graph. The internal graph is represented visually on the left side of the image, and the representation graph on the right side. As we can see, the links between the gestation and each parent are substituted by one link between the gestation and the relationship of the parents. This simplification is only done when possible. In accordance with the adopted nomenclature, an empty circle corresponds to a female individual and an empty square to a male. The horizontal line between $A$ and $B$ is their relationship, and the vertical line symbolizes that both are parents of $C$. The gray circles over the relationship and gestation nodes are added for usability purposes.

A node refers to a relationship, only cases of infertility and divorce are annotated visually. Otherwise, only the gray circle is drawn.

The second step generates the edges between represented nodes. Visually, they are the straight lines that connect related entities in the pedigree diagram. This step is based on rules derived from the nomenclature, and explores the internal graph, searching for specific patterns that correspond to drawing a connection between two nodes of the representation graph. Thus, this is the step that makes sense of the relations between nodes. A person is to be connected with his or her gestation if such gestation is decided to be drawn by the previous step. Similarly, a gestation is connected with each parent, or their relationship, if there is one. A relationship, in turn, is to be connected with both partners. By applying the previously mentioned rules, from a given situation we are able to reach a representation graph that is isomorphic to the pedigree derived directly from following the directives of the nomenclature we adopted, with some extensions that will be discussed later.

The third and last step for displaying a pedigree diagram as a graph is the definition of rules for the positioning of the nodes. In our system, the positions of the nodes are calculated following an optimization process conducted after the three steps. One of the inputs of this optimization process is information about which rules need to be vertically or horizontally aligned. Similarly to a solution proposed elsewhere\cite{11}, we define linear constraints for each of these alignments. The third step is the step which generates such linear constraints. This is done by exploring the internal graph in a similar manner as in the second step (by searching for specific patterns that activate rules for the relative positioning of the nodes). An activation triggers the creation of constraints that are followed by the optimization process. One example of alignment rule is that a node of type gestation is to be vertically aligned to the child if there is only one child. As it is depicted in the right side of Figure 1, the node corresponding to the gestation of the individual $C$ is vertically aligned to the node corresponding to the individual $C$.

After the third step, we obtain a representation of the pedigree diagram. The nodes are drawn on a canvas visible to the user, the connections (edges) between the nodes are also defined and drawn, and the constraints for alignments are defined. From this point on, the representation is handled by an engine specialized at arranging the nodes on the canvas according to an optimization algorithm and displaying this representation to the user. The optimization algorithm outputs positions for each of the nodes complying with the constraints defined. The optimization is, therefore, the minimization of a stress function with constraints. The function measures the difference between an ideal distance and the current distance between two nodes directly connected. This ideal distance is calculated for each edge of the graph and depends on the types of the nodes it connects. The minimization process is done iteratively and is repeated whenever a change to the representation graph is done. For example, when the user moves a node to another position, the minimization is triggered, changing iteratively the positions of the nodes until a new convergence is found. For
the specific purpose of this module, we implement a solution based on an already-existing library\textsuperscript{12} that provides an optimization algorithm that is useful for our necessities and enables the user to interact with the representation graph by moving the nodes.

As an illustration of the whole three-step process, we include Figure 2, in which the individual $B$ is affected by, for example, sickle cell anemia (OMIM code: #603903), has a relationship with $A$ and has had one with $C$. With individual $C$, $B$ had twins. We do not know if the gestation was monozygotic, hence the question mark (?) below the gestation node. Both daughters are affected by the disease. The individual $B$ now has a relationship with $A$, and they adopted $F$. The dashed line is drawn as so because, since the child is adopted, there is a nonbiological relationship between each parent and the adopted child.

![Figure 2](image)

Figure 2: Example of the three-step generation and arrangement processes. On the top-left are nine generated nodes that are the output of the first step of our process, which defines which nodes are to be drawn and draws them according to the nomenclature, with a few stylistic changes. Next, the second step defines the connections between nodes, which are the gray lines drawn. After that, the third step defines the constraints that the optimization engine uses to arrange the nodes on the canvas.

In terms of the characteristics we aimed for our system to possess, by having followed the updated Standardized Human Pedigree Nomenclature\textsuperscript{1}, we can ensure that our system can be, in principle, comprehensive enough to represent all the major scenarios that exist in our society. However, we detected some limitations that violated this ideal. One of the limitations is that, according to the symbology of the nomenclature, it is not explicit how a gestation with multiple children should be represented in the case of gestational surrogacy. Another limitation is that, if two individuals that have a relationship have family members in common, they might be included in different generations, thus, horizontally aligning their relationship edges is not feasible. In our system, we addressed these limitations by extending the nomenclature, making it more flexible when this would not render the pedigree diagram nomenclature ambiguous. Our minor changes provide more consistency and flexibility to the representation. In the case of the representation of multiple gestations, we chose to always show the gestation of a person when the parents of this person are also represented. That way, if it is the case of a multiple gestation, two people will be connected to the gestation. In the case of multiple gestation in the context of gestational surrogacy, for example, with our extension, there is no restriction to the child being only one. For the second limitation, in which the two partners of a relationship are members of different generations of the same family, our solution is the removal of the constraint of the partners being horizontally aligned only when there is a conflict in their generations. By implementing a system with our extended nomenclature, we ensure a wide comprehensiveness, by which the system is capable of representing all the situations that can be modeled following the directives of the nomenclature, which are most of the common situations that one can observe in the population.

Data-drivenness and automation are both addressed by defining our three-step process with the focus on generating
the diagram from structured data of individuals and their relations and by implementing a representation engine based on optimization\(^1\). Up to the end of the third step of our three-step process, the generation is fully automated. Having the nodes, the edges and the constraints (alignment rules) that define the pedigree, the representation engine arranges the nodes following an iterative optimization process. The full automation of the representation engine is not possible mainly for two reasons. The first is that structures reached by the optimization engine can be the result of convergences to local optima. That is, the ideal positioning of the nodes might not be reached. The second reason is that personal inclinations of the user are not considered during the positioning of the entities in the canvas. Both reasons might cause a need for small corrections and adjustments to the arrangement of the pedigree.

By allowing the user to move the nodes of the pedigree while keeping the constraints active, we address part of the fourth characteristic we defined as important for our system, which is **interactivity**. If the disposition of the nodes does not satisfy the user, he or she can change the positions of some nodes and a new iterative process is initiated, and convergence around the new arrangement is reached. One important characteristic of our representation interaction model is that, while a node is being moved, no rules of the disposition of pedigree diagrams are disregarded. That way, while allowing the user to make changes to the drawn diagram, our system ensures that the representation is correct. Another feature that also contributes to interactivity is the possibility to add and remove entities of the internal graph by interacting with nodes and context menus associated with each node of the pedigree. From the changes caused in the internal graph, another representation is generated and displayed. When possible, the positions of the existing nodes are kept, so that the user does not need to make any further changes to the parts of the diagram that were already arranged to their expectations. To edit information regarding a specific entity of the internal graph, we implemented a sidebar menu through which information about individuals, gestations and relationships can be inserted, changed or removed. Additionally, to provide better usability of the representation system, we represent the nodes that would correspond only to changes of directions between lines in a paper-based diagram with a semi-transparent gray circle. This feature enables the user to better understand with which entities of the canvas he or she can interact, either by dragging to define a new position or by clicking to view or edit the data associated with the entity that corresponds to the node clicked.

From a usability perspective, the user interacts with the canvas both directly and indirectly. Direct intervention is preferred for simple actions, such as the creation or elimination of entities. Adding a child to an individual, eliminating one or hiding it from the canvas are also direct interactions triggered using context menus directly on the corresponding nodes in the canvas. Indirect interaction is preferred for more complex actions, such as changing the name of an individual or adding another child to an existing gestation, which are made using a sidebar menu. Depicted in Figure 3 is the interface that allows managing a diagram. As we can see, the context menu in the center can trigger simple actions, while the sidebar menu on the right is used for more complex data changes.

The last characteristic we defined as being fundamental for a pedigree drawing software to include in the current context of data integration is **compatibility** with widely adopted biomedical vocabularies for the annotation of genetic traits and diseases. In this regard, we enable the user to assign traits to individuals in such a way that the traits are considered by the system as terms from biomedical vocabularies. Examples of vocabularies supported by genoDraw are HPO\(^2\), OMIM\(^4\) and SNOMED-CT\(^3\). Depending on license-related aspects, the selection of vocabularies can be changed. In this regard, genoDraw can operate on an unlimited number of vocabularies. This compatibility with biomedical vocabularies provides various advantages, such as common reference for each disease, and the possibility to develop further methods to make statistical analysis of the data inserted in internal graphs.

In terms of the **architecture** of the system, because genoDraw is intended as a platform for the creation, management and visualization of pedigree diagrams, a web-based system was ideal. In Figure 4, we describe the architecture of genoDraw. After creating a pedigree by interacting with our platform and inserting information of individuals and their relations, the user can save locally a file that includes the internal graph. Having this file, the user can load it on the platform to visualize the pedigree and make further changes to it.

As illustrated in Figure 4, genoDraw contains a backend that authenticates the user and provides the necessary files for genoDraw to work in the web browser of the user. The internal graph files are, in our implementation, JSON (JavaScript Object Notation) files managed by the user. An internal graph file contains the necessary information to generate a pedigree diagram (i.e. individuals, relationships, etc.). Such a file can be loaded into the platform but
Figure 3: Interface of genoDraw. The user is editing the example used in Figure 2 to add a partner to the individual F. As we can see in the sidebar menu, the relation between F and A and F and B are of type “nonbiological parenthood”. Other information available for the individual F (i.e. gender, name, fertility, etc.) is shown in the different sections of the sidebar menu, which can be extended and collapsed.

Figure 4: The architecture of genoDraw. The user interacts with a web client application connected with a backend that only handles the distribution of the website itself and the authentication of users. The internal graphs (structured data) are files which are stored locally in the user’s device. One detail of our implementation is that we make use of a database system to handle authentication information. A web server (backend) handles this authentication process and serves the files corresponding to genoDraw to the client. We implemented genoDraw in JavaScript, making use of D3.js and WebCola as libraries for handling the visualization. We selected WebCola as the graph-handling library due to
its capability to keep the alignment constraints active while the user manipulates the graph, as well as its capability to handle the structuring process of the diagram (optimization process) based only on alignment rules (constraints). Furthermore, it allows for an interactive use in a wide range of devices, of which traditional computer devices, such as desktops and laptops, as well as tablets, are the most used by our target users.

Results

We designed genoDraw to be adopted in clinical practice as a platform of intense, day-to-day use. Genetics specialists are expected to use our tool in medical encounters.

To evaluate the usability of our system, we have carried out a usability test. The objective of the test was to analyze the time required for a subject to be acquainted with the platform and to observe usability variables, such as if the user was capable of finding the way to insert or alter specific data in the diagram, and how long it took. Additionally, we obtained feedback from the users with some satisfaction questions. The subjects were 26 graduate students in the area of biomedical engineering who had been previously informed about the nomenclature but had no knowledge of our tool. We first let them explore the platform for a few minutes. Then, we presented the students two scenarios of different complexities in plain text and asked them to represent the scenarios as pedigree diagrams using genoDraw. The scenarios contained multiple gestations, ovum donations, surrogate gestations and adoptions, so as to observe what kinds of usability problems could exist in the insertion of the more complex and uncommon scenarios. Furthermore, we asked the students to insert traits and diseases of each individual as specific terms from standard vocabularies. The results of the usability test revealed that most users were familiarized with genoDraw in less than 30 minutes. We also observed that the time required for the users to represent both scenarios ranged from 20 minutes to 50 minutes. The average completion time was 20 minutes for the first scenario and 10 minutes for the second. In the first scenario, which contained a family with a case of multiple gestation, some of the users had difficulties finding the correct way of inserting such type of gestation. We interpret this as a usability issue, since the only path to add a multiple gestation at that moment was to include an additional child to an existing single gestation. In the second scenario, an ovum donation was to be represented, which meant that the users should insert the donor as biological mother in the gestation of the child. While most of the users found the path to adding such information in the pedigree without much effort, many agreed that it was not an intuitive solution. Having detected these and other usability issues, we addressed them.

To assess the correctness of the pedigree diagrams generated using our system, an evaluation of the tool was required to detect and address any incompatibilities or deviations from the standard nomenclature adopted for our system. In our case, we conducted this assessment by progressing through some case studies step-by-step. These practical scenarios were designed by experts at the Genetics Unit of the 12 de Octubre Hospital to serve as examples for our evaluation in plain text. After methodically introducing each of the examples in genoDraw, we then compared our results with the recommended results also given by the experts. During this evaluation phase, we detected some issues regarding the correctness of the tool and solved them.

An example of one of the validation cases is the following: A couple is formed by a man \(A\) and a woman \(B\). The woman is affected by retinoschisis in its X-linked recessive variant (OMIM code #312700) and has had, with the same man \(A\) with whom she forms a couple, one son \(C\) also affected by the disease, and is pregnant with a child \(D\). She has a brother \(E\) who is also affected and a sister \(F\) who is not. Her father \(G\) is also affected by the same disease and is married to his cousin \(H\), who is the mother of \(B, E\) and \(F\). Our result for this example is shown in Figure 5. Having a representation generated from a case such as the example described, a specialist is able to visualize the family, assessing the risk of the child in pregnancy being affected by the disease, as well as identifying other family members who might be, for example, carriers of the disease.

Discussion

The purpose behind genoDraw is to provide genetics specialists with a tool to address their needs. In this work, we identified these needs as five characteristics the tool must possess, and designed a tool that provides the resources necessary to create, manage and visualize pedigrees via its ability to provide solutions for each of the five characteristics. genoDraw is a tool intended to be used in clinical practice by medical specialists in the area of genetics. For this
reason, we carried out a thorough evaluation of our tool, focusing not only on its correctness, but also on its ease of use. With genoDraw’s current capabilities, a specialist can insert information during a medical encounter and observe specific characteristics of the family of the patient. This is undoubtedly an advantage of any pedigree representation, even when sketched on paper. However, since the pedigree diagrams in genoDraw are generated automatically from the data inserted, the user does not need to plan which entities should be drawn. That way, the composition of a pedigree diagram is as easy as a step-by-step insertion of information. Additionally, since the arrangement of the diagram is done automatically, no planning of where each entity should be drawn is needed. Thus, according to our observations, genoDraw is capable of enabling an improvement in clinical practice.

In terms of the limitations of our tool, some should be noted. The first is that, despite the fact that the representation engine is flexible, it is constrained by the bidimensionality of the canvas on which the diagram is drawn. Thus, issues such as the planarity of the graph being represented or the alignment impossibilities, described elsewhere, are unavoidable. Another limitation is the algorithmic procedure used to arrange the nodes of the graph in the canvas. Although the generated graph is always correct according to the nomenclature with our additional described changes, the structure is defined by a process that does not consider factors such as the personal appreciation of the user, who might want a specific arrangement of the nodes. In this case, we present a solution by enabling the user to make changes to such positions so that the optimization process finds a new convergence around the new structure. Further enhancements improving the tool’s ability to adapt to the user’s preferences should enable the generation of better-arranged pedigree diagrams.

Additionally, the presented platform is currently capable of storing the individuals’ diseases and traits as terms from widely used biomedical vocabularies. Although this is a novel feature, it does not yet enable full integration of the system with other, currently used, systems. We intend now to expand the compatibility of our system towards the integration with the represented individuals’ electronic medical records. This could make of our system a tool that retrieves, updates and uses other relevant information stored in these records to enhance and facilitate the risk assessment and diagnosis of genetic diseases. A future development in this direction will be the expansion of the system with the capability of generating clinical messages that can be stored in clinical environments, thus integrating the tool with other currently used clinical data storage systems.

When compared to other tools that serve the same purpose, we believe genoDraw is uniquely suited. In terms of comprehensiveness, our tool is the only system reported in the literature that complies with all the directives established in the updated version of the Standardized Human Pedigree Nomenclature. In this regard, the flexibility of our model is key to this characteristic. Another solution, for example, considers that every individual is child of a relationship, not being flexible enough to register that one’s biological parents might not have any relationship, such as in the case of sperm donations. As far as interactivity is concerned, our solution for arranging and moving the entities of the pedigree on the canvas enables the user to interact with the diagram without rendering it incorrect. According to our observations, this is superior to other solutions proposed. In GenoPro and in the online version of Progeny, for
example, the structure of the pedigree can be voided by moving nodes. In terms of compatibility with biomedical vocabularies, to our knowledge, genoDraw is the only tool that enables the annotation of diseases as terms from biomedical vocabularies. Lastly, the automation and data-drivenness provided by genoDraw are enough to generate a plausible pedigree diagram for all situations, while other tools that generate pedigree diagrams from data tend to present various limitations in this regard.

Conclusion

In this work, we present genoDraw, a platform for representing, creating and managing pedigree diagrams, which is built around five characteristics that we identified as necessary for the next generation of such tools. The central module of this platform is a representation engine, which is capable of deriving a pedigree diagram from structured data. In order to integrate the system with other medical resources, our implementation is also compatible with annotations of diseases and other traits as terms from widely adopted biomedical vocabularies, in our case SNOMED-CT, OMIM and HPO. Depending on licensing aspects, the selection of available vocabularies can be changed, and many vocabularies are compatible with genoDraw. Our system supports the visualization and creation of pedigree diagrams from and to structured information that can come to be stored in medical information management systems, and the diagrams are generated following the Standardized Human Pedigree Nomenclature in its updated version. Thus, genoDraw is a tool that can improve the current practice of sketching pedigrees on paper by providing genetics specialists with useful computing capabilities that include the ability to conveniently input information during a medical encounter, the fact that this input data is kept as structured data that can be used to update the information of patients, as well as the ability to share internal graph files with other health professionals in order to provide a better, more precise treatment.

In the near future, we intend to integrate genoDraw into the day-to-day workflow of specialists in genetics and other areas for the assessment of the genetic component of various illnesses in patients. In terms of its use in research, we envision genoDraw as being a tool with the potential to support data collection of individuals and their families.

Deep Learning from Incomplete Data:
Detecting Imminent Risk of Hospital-acquired Pneumonia in ICU Patients

Bethesda, MD, USA

Abstract
Hospital acquired pneumonia (HAP) is the second most common nosocomial infection in the ICU and costs an estimated $3.1 billion annually. The ability to predict HAP could improve patient outcomes and reduce costs. Traditional pneumonia risk prediction models rely on a small number of hand-chosen signs and symptoms and have been shown to poorly discriminate between low and high risk individuals. Consequently, we wanted to investigate whether modern data-driven techniques applied to respective pneumonia cohorts could provide more robust and discriminative prognostication of pneumonia risk. In this paper we present a deep learning system for predicting imminent pneumonia risk one or more days into the future using clinical observations documented in ICU notes for an at-risk population (n = 1,467). We show how the system can be trained without direct supervision or feature engineering from sparse, noisy, and limited data to predict future pneumonia risk with 96% Sensitivity, 72% AUC, and 80% F1-measure, outperforming SVM approaches using the same features by 20% Accuracy (relative; 12% absolute).

Introduction
The Centers for Disease Control (CDC) estimates that one in every twenty-five acute care hospitalizations results in a health care-associated infection (HAI). Recent analyses indicates that at least 50% of HAIs are preventable. Not only are HAI used to measure quality of care by the Centers for Medicare and Medicaid Services (CMS), failure to prevent HAIs can result in financial penalties such as those described in the 2010 Patient Protection and Affordable Care Act. Moreover, HAIs are estimated to cost over $9.8 billion USD annually, with hospital acquired pneumonia (HAP) costing an estimated $3.1 billion alone. Hospital acquired pneumonia is the second most common nosocomial infection in the intensive care unit (ICU) and the most common in mechanically ventilated patients. Hospital and community acquired pneumonia require different treatment plans (i.e., antibiotics) than other lower respiratory tract infections. Clearly, the ability to predict pneumonia risk can improve patient outcomes by enabling early interventions, monitoring and improved clinical decision support.

A number of pneumonia risk prediction models have been developed which rely on hand-curated signs and symptoms. In an external evaluation of these models, Schierenberg et. al. (2016) found that existing pneumonia models typically distinguish between risk and no risk, but fail to discriminate between high- and low-risk patients. Moreover, the majority of models target community acquired pneumonia, with the few HAP prediction models being focused on predicting the risk of HAP following a specific procedure. Consequently, we were interested in evaluating whether data-driven techniques enabled by recent advances in deep learning would enable us to automatically predict when at-risk individuals progress to high- (i.e., “imminent”) risk by considering a richer set of clinical observations than those used in prior pneumonia risk prediction models. Specifically, we were interested in harnessing the clinical narratives documented in ICU notes. Clinical narratives provide a rich but underutilized source of information for clinical decision support, potentially documenting and/or summarizing the main observations about the patient, relevant procedures and important positive and/or negative laboratory results. Unfortunately, processing clinical narratives requires overcoming several barriers including the prevalence of missing, inconsistent, or underspecified information. Moreover, while typical risk predictors such as vital signs are continually recorded through a patient’s stay, clinical notes are produced at irregular intervals and often in bursts (that is, there are often multiple days during a patients ICU stay in which no clinical notes are produced). Consequently, inferring pneumonia-risk from clinical notes requires accounting for (1) incomplete or sparse information, (2) gaps in the patient’s time line in which no notes were generated, (3) limited availability of training data, and (4) lack of direct (ground-truth) pneumonia risk labels.

In this paper, we present the Pneumonia Risk predictiOn NeTwOrk (PRONTO) which harnesses modern deep learning techniques to infer and predict when and if an at-risk ICU patient will progress to imminent pneumonia risk within 467
a given time window based on the content of his or her longitudinal ICU notes. Specifically, we identified a cohort of at-risk ICU patients \( n = 1,467 \) who developed pneumonia during their stay and used an emergent deep learning technique known as Recurrent Additive Networks\(^{11}\) (RANs) to jointly predict the progression of pneumonia risk, relevant clinical observations, and temporal interactions based on longitudinal analysis of ICU notes generated for a retrospective pneumonia cohort. We show that not only can PRONTO be successfully trained from a limited, sparse (i.e., incomplete), and noisy data set, but that it substantially outperforms SVM-based alternatives by up to 20\% (relative; 12\% absolute) increased accuracy.

**Background and Significance**

Classic models of disease-risk prediction have relied on a small set of specific risk factors. For example, the Heckerling Clinical Decision Rule for the Diagnosis of Pneumonia evaluates the risk for Pneumonia based on five binary risk factors\(^5\) indicating whether the patient’s (1) temperature is above 37.8°C or (2) heart rate is above 100 bpm as well as whether or not the patient has (3) crackles/rales, (4) decreased breath sounds, or (5) asthma. By comparison, PRONTO considers every risk factor or clinical observation recorded in each clinical note. Consequently, it can be seen as a generalization of these models, though we note that some routine information like temperature may not always be documented in the narrative.

Previous work for disease-risk prediction using natural language processing has largely focused on a small set of features and on classifying risk at the time that each clinical note was written. For example, Bejan et al. \((2013)^{12}\) represented patient’s clinical history as a sequence of days (with no gaps) where each day was associated with a clinical note. They designed a support vector machine (SVM) for classifying whether a patient is positive or negative for pneumonia at each day based on the clinical notes produced up-to and on that day. By contrast, PRONTO allows for gaps in a patient’s record and can predict whether the patient will be positive or negative for pneumonia at given number of days in the patient’s future for which no clinical notes (yet) exist.

Risk prediction at arbitrary times was considered in Goodwin and Harabagiu \((2015)^{13}\) in which the authors constructed a multi-layer Hidden Markov Model to predict the presence or absence of seven risk factors associated with heart failure based on the previous clinical note. Unfortunately, that methodology requires pre-computing co-occurrence information for all observations, which does not scale well to large numbers of observations. PRONTO, by contrast, is able to consider a large number of unique observations (28,782 in our experiments), and can predict the risk that a patient will develop pneumonia in the future.

**Materials**

Our experiments relied on MIMIC-III\(^{14,15}\), a publicly-available critical care database developed by the Massachusetts Institute of Technology (MIT) Lab for Computation Physiology to support research in intelligent patient monitoring. MIMIC-III contains de-identified health data associated with over 40,000 patients. Although MIMIC provides a wealth of structured information including demographics, charts, laboratory tests, medications, and diagnoses, we exclusively relied on the unstructured textual data (i.e., clinical notes). We obtained an initial retrospective cohort of 281,076 patients in MIMIC-III who were coded with a discharge ICD-9 diagnoses indicating community or hospital acquired pneumonia (ICD-9 486). Within this cohort, we considered only ICU stays in which the patient (1) was not admitted with pneumonia (i.e., pneumonia was not community acquired) and (2) was not diagnosed with pneumonia during the first day of their stay (using the approach for detecting pneumonia offset described in subsection C of the Methods section). This resulted in 1,494 unique ICU stay\(^{16}\) for 1,467 patients, with each stay associated with multiple clinical notes generated over multiple days. We created sub-cohorts for training, development, and testing using an 8:1:1 random split (at the patient level).

**Methods**

To account for the sparse or incomplete nature of ICU notes – both in terms of the observations documented within the note and in terms of the gaps in a patient’s stay without any notes – we considered an abstract representation of the patient’s ICU stay. Specifically we discretized the the patient’s ICU stay into discrete, non-overlapping, discontinuous 24-hour windows in which clinical notes were produced. We refer to information documented in each 24-hour window as a **clinical snapshot**, and to the discontinuous sequence of clinical snapshots during a patient’s ICU stay as his or her **clinical chronology** (details are provided in subsection B).

\(^{1}\)Note: we merged re-admissions within a 30 day window into a single ICU stay.
To overcome the noisy and incomplete information associated with clinical narratives we needed to design a predictive model which could: (1) discriminate between relevant and irrelevant clinical observations extracted from clinical notes, (2) learn latent temporal interactions between relevant clinical observations documented on different dates, (3) infer long-distance causal and inhibitive relations between clinical observations, their interactions, and the course of pneumonia. To this end, we present a deep-learning architecture named PRONTO (Pneumonia Risk predictiOn NeTwOrk).

**Figure 1** illustrates our three-step approach for pneumonia risk prediction:

**Step 1:** we automatically extract *clinical chronologies* for each patient in our training cohort;

**Step 2:** we train PRONTO to infer the risk of developing pneumonia based on latent temporal, causal, and inhibitive relations encoded in the clinical chronologies extracted for the retrospective pneumonia cohort described above; and

**Step 3:** we apply PRONTO to predict the risk of pneumonia within an arbitrary temporal window for a given patient based on his or her ICU notes.

Below, we (A) define and describe how we automatically extract clinical chronologies from longitudinal ICU notes, (B) present the architecture of PRONTO, (C) describe how the model can be trained from a retrospective patient cohort without direct supervision, and (D) explain how PRONTO can be used to predict pneumonia risk for new patients.

### A. Extracting Clinical Chronologies

Extracting the clinical chronology of a patient’s ICU stay from clinical notes requires overcoming several barriers. First, both the type of note (e.g., nursing note, radiology, admission report) as well as the frequency of notes varies from day-to-day, admission-to-admission, and patient-to-patient. Second, each note documents a different and incomplete (i.e., sparse) set of observations about the patient’s clinical picture at the time the note was written (with different types of notes emphasizing different parts of the patient’s clinical picture). Third, there are gaps in the patient’s ICU stay in which no notes are generated, and days on which multiple notes are generated.

Consequently we represent a patient’s ICU stay as a sparse, discontiguous sequence of *clinical snapshots* which are defined as the sets of observations about the patient’s clinical picture documented across any ICU notes produced on the same date. Thus, extracting the clinical chronology for a patient’s ICU stay reduces to (1) identifying the clinical observations reported in his or her ICU notes, and (2) organizing the observations into a sequence of clinical snapshots.

**Identifying Clinical Observations.** Clinical observations are often documented as multi-word nouns (e.g., “ventilator associated pneumonia”). Consequently, to identify clinical observations we first pre-processed each clinical note using the OpenNLP sentence splitter, tokenizer, lemmatizer, part-of-speech tagger, and dependency parser. After pre-processing, we identified clinical observations using MetaMap Lite and discarded observations whose semantic types did not correspond to problems, interventions, medications, anatomy, or findings. To detect other attributes, we developed a minor extension to MetaMap Lite based on FastContext, a high-performance re-implementation of ConText. FastContext associated each observation with the following semantic attributes:

- *negation* indicating whether the observation was affirmed or negated in the narrative;
- *certainty* indicating whether the author was certain or uncertain about the observation;
- *temporality* indicating whether the observation occurred in the present, the past, or is hypothetical; and
- *experiencer* indicating whether the observation was associated with the patient or someone else (e.g., family).

We considered only clinical observations which were affirmed, certain, present, and associated with the patient.

[https://opennlp.apache.org/](https://opennlp.apache.org/)
Figure 2: Clinical chronology extracted for a single patient’s ICU stay with 7 clinical snapshots.

**Mathematical Representation.** We represent the clinical chronology for a patient with \( L \) clinical snapshots as a pair \( C = (\delta, O) \) where \( \delta \in \mathbb{Z}^L \) is an elapsed time vector such that \( \delta_i \) indicates the elapsed time between the \( i \)th and \((i - 1)\)th clinical snapshots (where \( \delta_0 := 0 \)), \( O \in [1, V]^{L \times N} \) represents the clinical observation matrix such that each column \( O_i \) indicates the sequence of clinical observations documented in the \( i \)th clinical snapshot, \( V \) is the number of unique clinical observations documented in any clinical note associated with the training cohort, \( N \) is the maximum number of observations considered for any clinical snapshot, and \( L \) is the maximum number of clinical snapshots used for any clinical chronology. In our experiments, \( V = 28,782 \), \( N = 256 \), and \( L = 7 \).

**Figure 3:** Architecture of the Pneumonia Risk predictiOn NeTwOrk (PRONTO), where \( C \) indicates the clinical chronology extracted from a patient’s ICU stay, \( \delta \) indicates the prediction window, and \( \bowtie \) indicates vector concatenation.

**B. Architecture of the PRONTO Model**

Given a clinical chronology \( C \) and a prediction window \( \delta \), PRONTO predicts the risk the patient will develop pneumonia during that window using three phases illustrated in Figure 3:

- **Phase I: Clinical Snapshot Encoding** processes the sequence of clinical observations \( O_i \) in each clinical snapshot \( i \in [1, L] \) to produce an embedded representation \( d_i \) of the snapshot;
- **Phase II: Clinical Picture Inference** processes the encoded clinical snapshots along with their elapsed times to identify latent temporal, causal, and inhibitory interactions and infer the clinical picture of the patient at the end of the given prediction window \( \delta \); and
- **Phase III: Pneumonia Risk Prediction** relies on the inferred clinical picture to predict the probability that the patient will develop pneumonia within \( \delta \) days.

These three phases are detailed in the remainder of this section.

*To keep observations and the elapsed time within comparable domains (i.e., between 0 and 1), we compute the log of the number of elapsed days and project it between 0 and 1 using the hyperbolic tangent function.*

470
Phase I: Clinical Snapshot Encoding. The goal of the first phase of PRONTO is to learn an optimal encoding of individual clinical snapshots. Formally, we represent each clinical observation as a $V$-length one-hot vector. We designed PRONTO to use a Deep Averaging Network (DAN) for this purpose. However, due to the paucity in the literature for encoding sequences of sparse observations, we implemented and evaluated a total of five neural network architectures for encoding clinical snapshots, as shown in Figure 4. We first present well-known architectures for embedding documents and input sequences: Recurrent Neural Networks (RNNs) and Convolutional Neural Networks (CNNs).

RNN Encoder. The RNN architecture illustrated in Figure 4a operates by (1) learning an embedded representation of each clinical observation $O_{i1}; O_{i2}; \ldots; O_{i3}$ and (2) sequentially applying a forward RNN to learn how to compose, combine, or aggregate the embedded clinical observations to produce a single encoding for the entire clinical snapshot by maintaining and updating an internal memory vector. Note: as indicated in Figure 4a, we discard the individual outputs of the RNN and use the final output of the RNN as the clinical snapshot, i.e., $d_i := m_N$. In our experiments, we used Long Short-Term Memory (LSTM) units to build our RNN.

CNN Encoder. Like the RNN encoder, the CNN shown in Figure 4b initially learns an embedded representation of each clinical observation. The CNN then combines the embedded representations of adjacent clinical observations using three parallel convolutional filters, each followed by a maximum pooling layer. The results of the maximum pooling layers are combined (i.e., concatenated) together and projected into a snapshot embedding using a dense (i.e., fully-connected) Rectified Linear Unit (ReLU). As in Kim (2014), we used three filters operating on sequences of 3, 4, and 5 clinical observations with 1,000 kernels.

DAN Encoder. Less well-known than the RNN and CNN, the Deep Averaging Network (DAN) illustrated in Figure 4c also initially learns an embedding for each clinical observation. However, unlike the RNN and CNN, the DAN encoder does not consider the order of clinical observations within a clinical snapshot. The DAN encoder relies on $k$ dense layers to refine the clinical observation embeddings followed by an element-wise average, and $j$ dense layers to refine
the average embedding and produce the encoding of the clinical snapshot. As in Goodwin et al. (2017) we used $k := 2$ and $j := 2$ and ReLU activations on all dense layers.

**Dense Encoder.** Like the DAN, the dense projection encoder illustrated in Figure 4d ignores the order of clinical observations in each clinical snapshot. Unlike the DAN, however, the Dense encoder does not learn embeddings for individual clinical observations. Instead, the one-hot representations of each clinical observation are combined using bit-wise union (binary addition) to produce a single, sparse “bag-of-observations” vector. The bag-of-observations is directly embedded to produce the encoding of the clinical snapshot.

**Sparse Encoder.** Finally, the sparse encoder illustrated in Figure 4e does not learn a continuous embedded representation of a clinical chronology. Instead, it uses the un-embedded “bag-of-observations” vector described above as the encoding of the clinical snapshot.

**Phase II: Clinical Picture Inference.** Because the clinical snapshots provide incomplete information about the clinical picture of the patient (e.g., a snapshot produced from a radiology report describing a chest x-ray is unlikely to include many observations about other anatomical regions), the role of Phase II is to infer or impute the clinical picture of the patient as it relates to imminent pneumonia risk by combining and accumulating information from each clinical snapshot. We implemented Phase II by (1) casting the inferred clinical picture of the patient as the memory vector of a Recurrent Neural Network (RNN) and (2) training the RNN to infer what the clinical picture of the patient looks like after processing each snapshot and accounting for the elapsed time between it and the previous snapshot. Formally, for each encoded snapshot $d_t \in d_1, d_2, \ldots, d_L$ the RNN is trained to predict the clinical picture of the patient after elapsed time $\delta_{t+1}$ such that the final output (i.e., inferred clinical picture) computed from $d_L$ and prediction window $\delta$ captures sufficient information to predict the risk that the patient will develop pneumonia within $\delta$ days.

The RNN used for inferring the clinical picture is the core of PRONTO; consequently, the choice of memory unit used by the RNN is critical to the over-all success or failure of the model. We used a Recurrent Additive Network (RAN). RANs are a simplified alternative to LSTM- or GRU-based recurrent neural networks that use only additive connections between successive layers and have been shown to obtain similar performance with 38% fewer learnable parameters. The lower number of learnable parameters is ideally suited for deep learning with sparse datasets as it avoids the vanishing gradient problem and lowers the ability of the model to “memorize” the training set, improving generalizability. Formally, let $x_t \in m_1, \ldots, m_L$ represent the sequential input to the RNN such that $x_t := [d_t, \delta_{t+1}]$ and $x_L := [d_L, \delta]$, let $h_{t+1} \in [h_{L+1}, \ldots, h_L]$ represent the output of the RNN, and let $m_t \in m_1, \ldots, m_L$ represent the internal memory of the RNN after processing $x_t$. Figure 5 provides the equations used to compute $h_t$ with the RAN.

**Phase III: Pneumonia Prediction.** The final phase of PRONTO is to predict the imminent risk (i.e., probability) that the patient will develop pneumonia within prediction window $\delta$ using the inferred clinical picture $h_L$. We do this using a dense linear projection layer to produce a two-element vector followed by a softmax activation which computes the probability that the patient is at imminent/high- or low- risk for developing pneumonia within $\delta$ days:

$$ P\left( \text{pneumonia} \mid C, \hat{\delta} \right) = \text{softmax} \left( W_p h_L + b_p \right) $$

(1)

**C. Training PRONTO without Direct Supervision**

It is difficult to determine ground-truth labels for risk: risk is inherently difficult for humans to quantify, and using an existing metric of pneumonia risk to train the model would reduce the model to approximating the existing metric rather than learning to distinguish between low- and high-risk. Consequently, in this paper, we used indirect
supervision to train PRONTO. We first detected the onset of pneumonia within the chronology of each patient using the following criteria: (1) if any observation in a content section of the note was a descendent of pneumonia in the UMLS hierarchy; (2) if any observation in a content section of the note had the word pneumonia or any of its acronyms in its UMLS preferred name; and (3) if there was a non-negated mention of the word pneumonia or any of its acronyms in the content section of the note in a line that did not end with a colon. We defined the content sections of an ICU note as any section not corresponding to consults, family history, past medical history, or social history. Because some patients have long ICU stays in which the duration of pneumonia is not always clear, we then truncated our chronologies to end at the last snapshot before the onset of pneumonia. In this way, each chronology in the training set begins with one or more snapshots indicating the absence of pneumonia, \( O_1, \ldots, O_L \), followed by exactly one snapshot indicating the onset of pneumonia, \( O_{L+1} \). These chronologies were used as high-risk examples; i.e., \( P \left( \text{pneumonia} \mid C = \{O_1, \ldots, O_L; \delta_2, \ldots, \delta_L\}; \hat{\delta} = \delta_{L+1} \right) = 1 \). We created low-risk examples by randomly sampling a sub-sequence length \( S \in [1, L-1] \) and truncating each chronology to \( S \); i.e., \( P \left( \text{pneumonia} \mid C = \{O_1, \ldots, O_S; \delta_2, \ldots, \delta_S\}; \hat{\delta} = \delta_{S+1} \right) = 0 \). For example, the chronology illustrated in Figure 2 has the onset of pneumonia in the fifth snapshot and would be associated with two training examples: (1) the chronology including the first four snapshots would be considered as high-risk given the time window \( \hat{\delta} = 1 \) and (2) a randomly sampled chronology ending at the first, second, or third snapshot would be considered as low-risk, given the time windows \( \hat{\delta} \in \{1, 3, 4\} \), respectively. We trained the model by minimizing the cross-entropy loss using Adaptive Moment Estimation (ADAM) with the default initial learning rate \( \eta = 0.001 \).

**Dropout** The sparse and limited nature of our training data allows the model to avoid learning how to predict pneumonia risk and instead just memorize which chronologies are positive or negative for pneumonia based on rarely occurring observations or sequences of observations (i.e., over-fitting). To prevent over-fitting, we evaluated two forms of dropout: (1) layer dropout before each input to the RNN, and between the final output of the RNN and the softmax layer, and (2) vocabulary dropout in which random rows (e.g., observations) of the embedding matrix used in the embedding layer of each snapshot encoder was randomly set to a zero vector. Vocabulary-level dropout prevents the model from simply memorizing a rare subset of (confounding) clinical observations that happen to be associated with pneumonia in our dataset.

**D. Using PRONTO for Inference**

After training PRONTO to predict the disease-risk for a retrospective pneumonia cohort, it can be used to predict the pneumonia-risk for (new) patients in real-time. Specifically, for a (new) patient, we can predict the risk that he or she will develop pneumonia within a given prediction window \( \hat{\delta} \) by (1) extracting the clinical chronology from any ICU notes produced thus far in the patients ICU stay, and (2) using Equation (1) to predict the probability of pneumonia given \( C \) and \( \hat{\delta} \).

**Results**

To evaluate PRONTO, we used a test set of 146 at-risk patients as described in the Materials section. For each patient, we determined \( S \), the snapshot indicating pneumonia onset, and measured the performance of the model when correctly predicting (1) high-risk given the chronology proceeding \( S \) and the elapsed time between \( S \) and the chronology, and (2) low-risk for a random snapshot occurring in the chronology before \( S \). Specific details and examples are provided in subsection C of the Methods section. In this way, we produce a test set with an approximately 57% high-risk and 43% low-risk examples and are able to assess that the model can correctly predict when the risk of developing pneumonia progresses from low-risk to high- (imminent) risk.

We compared the performance of PRONTO against a support vector machine (SVM) and two simple baselines:

- **SVM** Inspired by Bejan et al. (2013),\(^{11}\) we trained a linear SVM to predict pneumonia risk using either (a) only the final snapshot of each training chronology, or (b) using all snapshots in each training chronology (where-in all but the final snapshot are associated with a low risk);
- **Constant** A simple baseline predicting all snapshots as (a) low risk, or (b) high risk; and
- **Random** A simple baseline predicting risk based on (a) the prior probability of high and low risk in the training chronologies, or (b) a uniform distribution over high and low risk.

All models were trained for twenty epochs, and the model parameters which resulted in the highest F\(_1\)-measure on the development set were used for testing.
We measured the Accuracy (A), Area Under the Curve (AUC) of the Receiver Operating Characteristic (ROC) curve, Precision (P), Recall (R), and F1-measure (the harmonic mean between Precision and Recall)\[^{14}\]. To investigate the susceptibility of each system to over-fitting, we report all five metrics on the training, development, and testing sets. Table 1 presents the performance of all baseline systems as well as the performance of PRONTO when using each of the clinical snapshot encoding architectures illustrated in Figure 4. To better understand the behavior of the PRONTO model, we also report the learning curve (measured using AUC) on the training, development, and testing data when using each type of clinical snapshot encoder in Figure 6.

Table 1: Performance when distinguishing between high/imminent and low pneumonia risk when using (1) Support Vector Machines, (2) constant baselines, (3) random baselines, and (4) PRONTO using different clinical snapshot encoding architectures.

\[^{14}\]Note: Due to the class imbalance, we emphasize the F1-measure in our study; the other metrics are reported to illustrate that, unlike the Constant: High Risk baseline, the learned approaches are able to also detect low risk, as evidence by Accuracy and AUC.

Implementation Details PRONTO was implemented in TensorFlow v1.12. Baseline systems were implemented using Sci-kit Learn\[^{25}\] v0.19.2. The width of observation embeddings, snapshot embeddings, and the internal memory used by the snapshot RNN were selected from \{100, 200, 300, 400, 500\} and determined to be 200; the number of kernels considered by the CNN was selected from \{100, 500, 1,000, 2,000\} and determined to be 1,000; the choice of k and j for the CNN and DAN encoders were selected from \{1,2,3\} and determined to be 2; the dropout and vocabulary dropout probabilities were selected between 0 and 1 in increments of 0.10 and determined to be 0.0 (no dropout) and 0.50, respectively. Vocabulary size was not limited, the maximum snapshot size was set to 256 (with an average of 141 observations per snapshot), and the maximum chronology length was set to 7 (with an average of 6 snapshots per visit). All baseline and PRONTO experiments used the same fixed random seed.

Discussion

As shown in Table 1 PRONTO using the Deep Averaging Network (DAN) for encoding clinical snapshots obtained the highest performance, exhibiting a 22% (relative) increase in AUC and a 12% (relative) increase in F1 performance on the testing cohort compared to the best performing SVM (SVM: Final Snapshot). The high performance of PRONTO, especially in terms of Recall, demonstrates that the observations reported in clinical notes alone can be predictive of imminent pneumonia risk. However, the poorer performance of the SVM baselines when using the same observations suggests that deep learning methods can more effectively harness clinical texts even with small datasets. Our results also indicate that model design – particularly in small data settings – has a substantial impact on performance, with sub-optimal models performing similarly to an SVM (in terms of F1). When comparing SVM: All Snapshots to SVM: Final Snapshot, we can see the importance of balancing the distribution of high- and low-risk examples when training the model, indicating that even when the dataset is limited, omitting potential training data can lead to improved generalizability. Interestingly, the dense representation of clinical snapshots provided the highest performance on the training data, but performed poorly compared to other methods on the development and testing set. The DAN, Dense, and Sparse methods viewed observations as unordered set, indicating that the more complex sequential representations may be too expressive to generalize from sparse data.

When examining the learning curves in Figure 6 we can see that all approaches but the DAN quickly over-fit the training
data, suggesting that DANs are better able to generalize when used on sparse and limited datasets. Interestingly, despite being the most complex snapshot encoder we considered, the RNN had the lowest performance, suggesting that considering the sequential order of clinical observations within a clinical snapshot had little impact. We believe this is due to the fact that by reducing clinical notes to observations we are removing much of the context around each observation and likely making their order insignificant.

Finally, we examined the accuracy of the disease onset labels we automatically produced and used for indirect supervision. Specifically, we selected difficult-to-label notes (i.e., notes without pneumonia which indicated infiltrates and/or fever and notes with pneumonia without any mention of infiltrates and/or fever) and randomly selected 50 such notes for manual judgment by two physicians. The two physicians had moderate agreement (82% simple agreement; Cohen’s $\kappa = 0.49$). We first measured the accuracy of disease onset labels by considering a label as correct if it agreed with either physician, with an accuracy of 80%. We also determined an accuracy of 78.6% when measuring the accuracy of labels only for notes with agreement between both physicians. These results suggest that automatic detection of pneumonia onset with natural language processing is fairly reliable, and well suited for indirect supervision.

A. Limitations and Error Analysis

There are a number of limitations to this study beyond the limited dataset. First, we used automatic natural language processing to identify clinical observations from ICU notes. While UMLS allows some level of normalization, we observed cases in which the clinical observations were underspecified. For example, we found observations such as “aim”, “probe”, and “distillation” which are ambiguous without context. Second, we found that the attributes detected by ConText were not always reliable, introducing noise into the clinical observations and, indirectly, into the labels used to train the model. In future work we plan to qualify observations by their contextual attributes (experiencer, negation, etc.) to provide more nuanced information to the model. Third, our model considers each ICU stay as an independent chronology. It is possible that information from a previous admission could impact the risk of a patient developing pneumonia (i.e., by allowing the model to distinguish between new observations and re-occurring observations). Fourth, we used an approximately equal number of negative and positive examples when evaluating the model. While this was an intentional decision to make it easier to compare the relative strengths and weaknesses between different models, it does not give an accurate indication of clinical performance where-in one would expect substantially more low-risk patients. Finally, in this initial study we examined only pneumonia. In future work, we would like to predict other types of health-care associated infections, evaluate in a more clinically-realistic setting, and explore the inclusion of charted information.

Conclusion

In this paper, we described a data-driven deep learning model for distinguishing between low- and high-risk of HAP in an at-risk ICU patient population. We show that not only can our model be successfully trained on incomplete, limited, and noisy data – obtaining 96% Recall, 72% AUC, and 80% $F_1$-measure with less than 1,500 examples – but that it outperforms SVM-based models using the same features by 22% (AUC). Moreover, we empirically evaluated the impact of five different strategies for encoding clinical observations, determining that Deep Average Networks provide the most reliable encoding of multiple clinical observations. We believe our results demonstrate that ICU notes provide sufficient information to predict and distinguish between high and low pneumonia risk within an arbitrary, given time window without feature engineering or structured data. It is our hope that our findings enable deep learning to be more easily applied in other scenarios with incomplete or limited training data.

Exploring Different Approaches in Measuring EHR-based Adherence to Best Practice – A Case Study with Order Sets and Associated Outcomes

Nathan C. Hulse, PhD,1,2, Jaehoon Lee, PhD,1,2 José Benuzillo, MS

1Intermountain Healthcare, Salt Lake City, UT; 2Department of Biomedical Informatics, University of Utah, Salt Lake City, UT;

Abstract

In connection with a recent enterprise-wide rollout of a new electronic health record, Intermountain Healthcare is investing significant effort in building a central library of best-practice order sets. These order sets represent best practice guidelines for specific clinical scenarios and are deployed with the intent of standardizing care, reducing variation, and consistently delivering good clinical outcomes to the populations we serve. The importance of measuring their use and the level to which caregivers adhere to these standards becomes an important factor in understanding and characterizing the impact that they deliver. Notwithstanding the importance of these metrics, well-defined methods for measuring adherence to a given clinical guideline as delivered through an order set are not fully characterized in the medical literature. In this paper, we describe initial efforts at measuring compliance to a defined ‘best practice’ standard by means of content utilization analysis, a calculated adherence model, and relevant clinical key performance indicators. The degree to which specified clinical outcomes vary across these measurement models are compared for a group of order sets tied to treating coronary artery bypass graft patients and heart failure patients. While the patterns derived from this analysis show some uncertainty, more granular methods that look at line-item, or ‘order level’ detail reveal more significant differences in the corresponding set of outcomes than higher-level adherence surrogates.

Introduction

Order set libraries have become an established part of electronic health record (EHR) implementation as EHRs have become increasingly common in the United States. Previous research in the informatics field has shown them to be convenient, thought-provoking, and foundationally supportive of clinical best practice. Studies have shown that well-crafted order set libraries are among the key determinants that predict a successful deployment of a new EHR.

Order sets are a unique component of an EHR installation in that (like clinical decision support rules) they represent clinical knowledge as delivered through interactive user interfaces. They are typically rendered as interactive forms that deliver logical, pre-populated views of commonly grouped orders for specific procedures or clinical conditions. Their overall intent is to help clinicians deliver appropriate care in a simple, streamlined way. (Figure 1 below depicts an order set in the EHR used at Intermountain). The ‘checklist effect’ that they deliver forces users to mentally process and remember steps which could otherwise be easy to overlook in clinical care. Collectively, as caregivers routinely use standardized order sets in delivering care, several key objectives that health organizations hope to realize would include lower overall variation in clinical care processes and by correlation, improved clinical outcomes and lower associated costs.

The benefit afforded by these order set content libraries comes with an associated need for ongoing investment in resources so as to maintain and update the content to ensure validity against current clinical science. Both homegrown and vended order set libraries have arisen in recent years as implementers have noted and characterized the difficulties of building up and maintaining a comprehensive library of order sets. Compiling and maintaining an enterprise knowledge base of order sets has been described as highly resource-intensive. The magnitude of work required to maintain the content contained in these order set knowledge bases has led various groups to implement various automated and machine-learning-based processes intended streamline the review and update workflows that support them. Researchers have noted that with the exponential growth in medical knowledge, that there is a real risk that once implemented, order sets may be inadequately maintained; in essence, driving caregivers to practice outdated medicine on a widespread basis.

Ultimately, the variability of functional pathways afforded by an EHR often allows caregivers multiple ways of performing the same task. Local experience has shown that clinical tools like quick-lists, generic order set templates (e.g. ‘general surgery order set’) personalized derivatives of order set templates (sometimes known as ‘favorites’ or ‘personal order sets’) and even poorly-coordinated central authoring efforts can leave users with a content library that affords them different content vehicles targeted at the very same clinical process. Furthermore, order set usage is not typically mandated by process or workflow, and users are free to electronically order care patterns without them.
entirely. Implementers must be aware of and confront the need to standardize the way that the care teams they manage use centralized order sets through education, active monitoring, and ongoing feedback. Figure 2 illustrates how treatment of a cardiovascular care processes (with acute myocardial infarction depicted as a relevant example) has a broad set of different content utilization patterns as it relates to order set content was used as part of the care delivery process. In this figure, we depict order sets which are designated as an intended standard of care for this condition in the striped bars, whereas the solid bars indicate other content templates that were used. The distribution shows a wide variety of order set content that is used in caring for this single condition. Some of this diversity is to be expected, in the treatment of comorbidities and in addressing personalized needs. Yet, the chart shows the diversity of knowledge content that can address a common condition, and the associated difficulty of standardizing care. In short, publishing thoughtful and relevant content standards as order sets does not ensure they will be uniformly embraced.

It is important to note that variation in order set usage can occur at two different levels. First, caregivers still have the ability to use different content in delivering care (e.g. use a designated clinical standard or something entirely different), but also have the ability to vary in terms of how closely they follow the care outlined within an enterprise standard itself. Order set templates are inherently interactive, and users have the ability to select orders that aren’t part of the template, remove recommended orders, or change default values and order sentences. Inevitably there will be differences not only in what content is or isn’t used, but also in how users interact with the content itself. Measurement models aimed at measuring adherence to a standard of care must be able to account for differences at multiple levels of engagement.

Background

Intermountain Healthcare is a not-for-profit integrated delivery network that serves the populations of the Intermountain West (Utah and southern Idaho). It has 22 hospitals, over 150 clinics, a medical group of over 700 employed physicians and an insurance plan that serves the needs of the people in the region. Collectively, it accounts
for roughly half of the healthcare given in the region and insures a little more than a quarter of the population. In switching EHRs and the toolsets that support them, our main priorities in terms of order set knowledge management were threefold:

1. Build tools and processes to quickly amass and refine a sufficiently comprehensive knowledge base,
2. Provide visibility into usage patterns surrounding their use, including actionable recommendations for improvement
3. Characterize clinical caregivers’ adherence to these standards and their associated impact in clinical outcomes.

Previous efforts have detailed efforts in deriving actionable recommendations for change to order set templates based off collective usage data\(^8,10,15\). In this manuscript, we will focus describe current efforts at characterizing how well a clinical standard is used and the associated clinical outcomes derived from this care.

**Rationale**

We want to be able to clearly understand the implications of owning and publishing an order set library. In order to fully understand the value of our efforts, we want to understand both the extent to which users are engaging with a
clinical content standard (e.g. centrally defined and designate order set), but how they are using it and the combined effects of the above as it relates to clinical outcomes. Our hypothesis in pursuing this investigation is that the more that our measurement algorithms accounts for specific actions, the greater will be our ability to account for any observed differences in the corresponding outcomes. We intend to account for three specific approaches to measurement of adherence in this investigation:

1. Whether or not a designated enterprise content standard was used as part of an encounter for which it was designed
2. A calculated approach that quantifies how closely a user that engaged with the standard
3. A ‘key performance indicator’ approach in which specific key electronic orders are accounted for, regardless of whether the orders originated from a designated enterprise standard order set

Methods

In order to facilitate the study, we engaged with colleagues in the cardiovascular clinical program at Intermountain Healthcare to identify two specific diseases of interest, specifically acute myocardial infarction and heart failure. After discussion with them, we determined to look at ordering patterns related to standards of care intended for treating patients presenting with those conditions. For each, we agreed upon a common cohort definition for the intended targets of specific enterprise content sets. We also assembled a common set of outcomes of interest related to the care processes decided upon. Eight order sets related to treating acute myocardial infarction and six order sets relevant in treating heart failure were identified. These cohort definitions and order sets of interest are detailed in Table 1.

Adherence Measurement Definition 1 – Raw Usage Data - In discussing options surrounding various ways of measuring adherence to a clinical standard, we felt that the act of ordering from a designated order set during an encounter noted as relevant to the content. Simply put, this type of measurement would answer the question of whether or not the designated standard content was regularly used in the contexts for which it was designed. While this type of measurement doesn’t account for the specific actions that occur in a caregiver’s interactions with the order set form itself, it may serve as a sufficiently granular approximation of compliance to the standard since the effort to use it may in and of itself signal an intent to follow the pattern.

Adherence Measurement Definition 2- Calculated adherence scores, based off interactions within order sets – A second approach that we opted to pursue in measuring compliance involves a deeper measurement of how closely the issued orders resemble those that are predefined by the order set itself as a recommendation. In this model, users are credited for issuing orders that are recommended (as defined by preselection in the order set template), credited to a lesser extent for issuing optional orders in the order set template, and penalized for omitting recommended orders and adding ‘ad hoc’ orders to the ordering session (orders that are not included in the template at all). In building these score guidelines, we recognize that caregivers will have the need to deviate from a specific standard and tailor the care that they give. In attempting to assign scores and numbers to these types of interactions, we are attempting only to measure the overall adherence or deviation from the initial order set template, and not offer any critique or commentary as to the clinical appropriateness of the actions taken. In this model, the coefficients for these scoring mechanisms per line item order are detailed in the scenarios below:

- A = Order pre-selected in template & ordered = 1
- B = Order pre-selected in template & not ordered = -.5
- C = Order initially unselected in template, but ordered = 0.1
- D = Order initially unselected in template, and not ordered = 0.0
- E = Ad-hoc order not derived from order set template = -.5

In order to facilitate comparison of calculated adherence scores across order set groupings of variable size, we normalized each of these scores by dividing this score by the total number of orders issued in that encounter. This would allow scores to be meaningful and comparable from scores derived both from small and large templates. We pursued two normalization approaches, one accounting for a maximum score based off the total number of prechecked orders in the template, the second based off the total number of orders placed. The equations below where the variables are measures of the scenarios from the bullet list above were calculated for each ordering scenario for both heart failure and acute myocardial infarction.

\[
\text{Normalized score 1} = \frac{(A) + 0.1(C) - 0.5(B) - 0.5(E)}{\text{Total # of prechecked orders in template}}
\]

\[
\text{Normalized score 2} = \frac{(A) + 0.1(C) - 0.5(B) - 0.5(E)}{(A+C+E)}
\]

Adherence Measurement Definition 3- Key Performance Indicators- In this third adherence definition, we looked to simplify adherence metrics somewhat by focusing strictly on a ‘Key Performance Indicator’ (KPI) in which all predefined orders from an order set template were listed as KPI’s. We opted to pursue this approach rather than a ‘clinical expert defined’ set as we are attempting to explore generalizable methods of measuring adherence that do not necessitate extra steps of human involvement. We interpreted the order set authors’ intent in pre-selecting an order in the template as a stronger indicator that the associated order should probably be issued for the scenario. We then calculated a total count of orders that matched these lists in the encounters that matched the acute myocardial infarction and heart failure scenarios, regardless of whether these orders were derived from the enterprise content standards or not. To normalize these scores, we calculated the total number of KPI’s ordered in the encounter and normalized it by dividing by the total number of possible KPI’s tied to that scenario.

We extracted 12 months of order set usage data for the order sets detailed in Table 1 from Intermountain Healthcare’s enterprise data warehouse, deriving data only from our Cerner EHR system. Data was cleansed and vetted to remove test patients and other non-clinical data sources. The dataset used in the study was de-identified and vetted to ensure that PHI was not available. After extracting relevant ordering data from the encounters identified, we also pulled outcomes data from the cardiovascular clinical program’s outcomes database to align the order instances and scores with specific outcomes data.
In aligning data to specific outcomes results, we opted to group the data in patterns that match the three adherence measurement approaches detailed above. For Adherence Measurement Definition 1, we grouped all providers who used the enterprise standards in one cluster and those who didn’t in another. Summary statistics were prepared for each group. For Adherence Measurement Definition 2, we took the ‘adherent’ group from definition 1, and clustered it into three groups, based off the adherence scores tied to each encounter. Encounters were grouped by score into the above 75th percentile, 25th-75th percentile, and below 25th percentile groups. In similar fashion, Adherence Measurement Definition group 3, we grouped all participants into percentile-based groups. An important difference in this metric compared to the second group is that all participants were measured the same way, since it was not a pre-requisite to use the order set standard at all in order to still measure KPI scores.

**Results**

According to the calculation patterns and data extraction efforts above, we gathered data and summarized basic statistics for each measurement pattern. 1,693 instances of acute myocardial infarction and 1,736 instances of heart failure were identified from the cohort definitions and the 12 month data set from the Cerner EHR system. Table 2 contains the results for Adherence Measurement Definition 1, in which encounters were grouped according to whether or not the ordering provider used the designated order set standard for the specific encounter.

For Adherence Measurement Definition 2, we produced similar statistics, as shown in Tables 3 and 4. Histograms representing the distribution of scores in this exercise are shown in Figure 3 below. These distribution curves are mostly Gaussian in nature, though there are elements that might suggest a bi-modal normal distribution, implying that there may be reason to suspect that the data represents two heterogenous groups of data sources. Although we did not analyze further of what distinguishes the two groups in this study, we feel that it is statistically reasonable to group by <25, 25-75 and >75 percentiles from these bell-shaped distributions. In these clusters, we created three groups for the populations of caregivers that adhered to the enterprise standard order sets. After the scores had been calculated and normalized against the two denominator definitions above, we grouped the scores into three clusters, those above the 75th percentile, those between 25th and 75th, and the bottom quartile (below 25th percentile).

**Table 2-** Summary statistics for outcomes tied to encounters for acute myocardial infarction and heart failure, grouped by whether or not the ordering provider used the designated order set standard for the specific encounter.

**Figure 3 -** Histograms depicting the distribution curves of scores derived for AMI (left) and MI (right) data sets. The data is mostly normal, Gaussian in nature, though there are elements of bimodality in the sample.

Discussion

In exploring the various approaches to measuring adherence to best practice standards through the EHR, we found various patterns in terms of how outcomes differ, based off the generalized approach to measurement. The first approximation to adherence, specifically that of whether or not a designated content standard was used, showed relatively minimal differences in the outcomes distributions that corresponded with each group. Across the two diseases studied, the six outcomes metrics were all comparable, with three of the ‘content standard user group’ content producing slightly more favorable outcomes, and three producing slightly less favorable ones. Overall, whether or not the designated content sets were used did not offer strong differences in the outcomes analyzed in this effort.

Adherence measurement two took a slightly more detailed approach at analyzing the specifics of what users were doing with content inside the order sets of interest. For the acute myocardial infarction data set, almost all of the outcome metrics showed improvements in the highest quartile of adherence measures, with the exception of readmission rate under the second normative denominator. The heart failure data results exhibit similar trending that tends to correlate with stratification of outcomes favoring better outcomes with closer adherence, with the exceptions of length of stay.

The third approach to adherence, specifically that of only analyzing pre-checked orderables and treating them as KPIs, showed a trend for all three outcomes trending to better outcomes as ‘adherence’ to the KPI’s increased for the acute myocardial infarction data. The heart failure showed similar trends in comparing the bottom and middle quartiles, but less so in the highest quartile. In conferring with clinical domain experts on this observation, they noted that the diagnosis and treatment of heart failure is inherently broader by nature and the underlying etiology and associated treatments are more varied.

The approach to normalizing the data scores in the second and third branches of our study seemed to allow for comparative analysis of content sets of varying sizes. By nature, labeling ‘groups’ of order sets as a single standard makes comparison a much more difficult task. A similar type of study in which single order sets were designated as a content standard would make for a much simpler comparison.

One of the underlying premises of our effort is that we would hope and expect that as adherence to clinical standards was measurably improved, that corresponding outcomes would trend in a positive direction. The data we have analyzed doesn’t hold this as universally true, though there are many other co-variates not analyzed by our current approach. Our models are ‘order-centric’ and don’t account for co-morbidities, actual delivery of care, patient compliance, and other factors that have an important bearing on outcomes.

Limitations

We are only basing our preliminary analysis off two content types from a single clinical knowledge domain in cardiovascular medicine. Whether or not similar analyses would be relevant for other clinical domains remains to be seen. Our current model does not account for acuity, and that alone may account for significant impact in terms of how the corresponding outcomes move. Further, this analysis only looks at data from one site and one EHR vendor.

In this analysis, we did not assume any variation existed in how the providers used order sets. We intentionally did not use data derived from order set from use at early stages of implementation so that we could avoid inadvertently incorporating some learning curve effects in the data. However, there are many studies that show that user behaviors in interacting with order sets differ by physician characteristics, clinical specialty, clinical settings, and familiarity or training level to computerized order entry systems16. A more rigorous statistical effort to show that those factors do not cause variations of ordering patterns may be required, as a preliminary assumption to analyze the relations between the ordering patterns and clinical outcomes. To do so, further order set utilization data may be required to analyze it at different levels of granularity.

Next Steps

We intend to pursue similar analyses in other enterprise content standards, including surgical targets of appendectomy, cholecystectomy, and joint replacement surgery. We are hoping to see if similar patterns hold or if more defined ones emerge. Some of these content standards involve a single order set instead of groups of order sets as a designated standard, so we plan to test out similar methods that do not require a normalization step so as to be able to compare scores. Finally, we also intend to test machine-learning models that can derive and identify KPI types of order items
that may be justifiably more predictive and potent than just the set of preselected orders in the original order set template.

**Acknowledgments**

We would like to acknowledge our colleagues at Cerner for their help in identifying data relevant to the order set templates, corresponding metadata, and the order set instance derivatives created from the use of these plans in the clinical data repository. Additionally, we would like to thank clinical data analysts and domain experts from the Cardiovascular Clinical Program at Intermountain Healthcare for their time, feedback, and suggestions on the approaches taken in the manuscript.

**Conclusion**

In this paper, we have characterized the need for methods to calculate adherence to clinical standards, including artifacts distributed through knowledge artifacts like order sets. Three separate approaches for calculating adherence have been described and characterized, including high level content usage, a more detailed mathematical approach for approximating adherence, and a third approach that focuses only on key actions. The various scores and corresponding outcomes for all of these approaches have been presented for two key disease processes of interest, specifically for acute myocardial infarction and heart failure. We hope to extend our models going forward to more fully account for user behaviors in adhering to and varying from clinical standards, as well as the corresponding effects that accompany them in clinical care.

Trust and Privacy: How Patient Trust in Providers is Related to Privacy Behaviors and Attitudes

Bradley E. Iott, MPH1, Celeste Campos-Castillo, PhD2, Denise L. Anthony, PhD1
1University of Michigan, Ann Arbor, Michigan, USA; 2University of Wisconsin-Milwaukee, Milwaukee, Wisconsin, USA

Abstract

Healthcare today requires extensive sharing and access to patient health information. The use of health information technology (health IT) exacerbates patients’ privacy concerns because it expands the availability of patient data to numerous members of the healthcare team. Patient concerns about the privacy of their data may be associated with nondisclosure of their information to providers. Patient trust in physicians, a multi-dimensional perception influenced by patient, physician, and situational factors, can facilitate disclosure and use of health IT. Previous work has done little to explore how specific dimensions of trust in physicians are related to patient information-sharing concerns or behavior. Using data from a nationally-representative survey, we show that patients with higher trust in provider confidentiality have significantly lower likelihood of reporting having ever withheld important health information and lower likelihood of thinking it is important to find out who has looked at their medical records. Patient trust in physician competence is related to higher likelihood of thinking it is important for health care providers to share information electronically. This work sheds light on the importance of considering multiple dimensions of trust for patient behavior and attitudes related to their information sharing with health care providers.

Introduction

The delivery of healthcare today requires extensive sharing and access to patient health information. The use of health information technology (IT) expands the availability of patient data to numerous healthcare providers throughout and between healthcare organizations. Since the widespread expansion of electronic health record (EHR) implementation following the distribution of incentives by the HITECH act, use of Internet-enabled applications for health (e.g., patient portals, mHealth apps) has increased steadily over the past decade. Use of health IT has yielded numerous positive benefits for patients, including increased access to data and improved efficiency1. However, such benefits come with increased concern about the potential for privacy breaches2,3. Indeed patient concerns about the privacy of their health information can impede their access to health care and hinder disclosure to providers4-7, creating incomplete medical records. Complete information sharing by patients with providers is necessary to ensure the quality and accuracy of data available in health information systems.

Patient trust in physicians, a multi-dimensional perception8-10 can potentially remedy the issue. Patient trust in physicians is influenced by patient, physician, and situational factors, and can facilitate disclosure9 and use of health IT11. One dimension, in particular, seems to matter more than others for ameliorating privacy concerns6,12: trust in physician confidentiality. However, few quantitative studies of trust in physicians explore multiple dimensions and those that do have only single measures of each dimension, leaving critical gaps in knowledge about how trust may matter8-10.

Systematic disparities in patient trust in physicians also exist, though again the dimensions of trust matter differently for different groups. Some research finds that racial and ethnic minorities have lower levels of certain dimensions of trust in physicians,13,14 and other research shows that patients with devalued health characteristics have lower trust in physician confidentiality specifically12. Similarly, disparities in use of health IT exist between racial groups and between those with stigmatized health conditions, suggesting the need to further investigate how different dimensions of trust may be related to patient attitudes and behavior related to information sharing.

Here we analyze national survey data to determine how dimensions of patient trust in physicians are related to patient disclosure of health information and to attitudes about information sharing within health care (see Figure 1). Figure 1 situates our analysis in the context of existing work. Our analysis specifically focuses on the association between three dimensions of trust in physicians and patients’ attitudes towards privacy and health information disclosure behavior (represented by the red arrow in Figure 1). Associations between patient demographic characteristics, health status, trust in physician, and health information attitudes and behaviors are indicated by blue directional arrows. Finally, the association between accuracy and quality of data in health IT systems and health
information attitudes and behaviors is represented by a dashed line, as this is an indirect consequence of patients’ disclosure behaviors and a needed focus of future work.

**Figure 1.** Study Framework: Situating our Analysis

*The red arrow represents the focus of our analysis.*

**Methods**

We conducted a cross-sectional, nationally-representative mail survey in 2014 to five thousand households across the United States based on three separate samples of households. For the general population sample, 1800 households were selected. For the Hispanic oversample, 1600 households were selected from the five communities with the highest concentration of Hispanics in the US: East Los Angeles, CA; Laredo, TX; Hialeah, FL; Brownsville, TX; and McAllen, TX. The African-American oversample included 1600 households from the following communities: Detroit, MI; Jackson, MS; Miami Gardens, FL; Birmingham, AL; and Baltimore, MD. In total, 5,000 households were selected. A total of 784 households completed the survey. The response rate of the survey was 15.7%. However, from the original sample of 5,000 households, 481 surveys were returned as undeliverable with no forwarding address available. The survey was conducted by the University of Nebraska Bureau of Sociological Research in partnership with Dartmouth College and was funded by HHS 90TR0003/01.

Data weights account for sample design (including the three sampling frames), nonresponse, and population characteristics to be representative of the national population.

Respondents were asked whether they had ever withheld information from their provider because of privacy and security concerns (1=Yes/0=No). Respondents were also asked two questions about attitudes towards privacy, namely, how strongly they agreed that it is important 1) to find out who has looked at their medical record and 2) that providers share their health information electronically (for each, strongly agree=1/less than strongly agree=0).

The survey also assessed several dimensions of trust in physicians, based on previous literature: trust in physician confidentiality, trust in physician honesty, trust in physician competence, and overall trust in physician. Each dimension was measured with items using a 5-point Likert scale. Trust in physician confidentiality is an aggregate measure created as the average response to three statements, namely “I trust my doctor to keep personally sensitive information private,” “I worry that private information my doctor has about me could be used against me,” and “I worry that my doctor may share embarrassing information about me with people who have no business knowing it.” Trust in physician honesty is an aggregate measure created as the average response to two statements, “I feel my doctor does not do everything s/he should for my medical care” and “I trust my doctor to perform only medically necessary tests and procedures.” Trust in physician competence is an aggregate measure created as the average response to three statements, “I trust my doctor to offer me high quality care,” “my doctor is a real expert
in taking care of medical problems like mine\textsuperscript{15,16}, and “my doctor’s medical skills are not as good as they could be” (reverse coded)\textsuperscript{16,17}. An overall measure of complete trust is included as the response to the statement “all in all, I have complete trust in my doctor\textsuperscript{16,17,19,20}.”

Data analysis was conducted using Stata 15.1. Survey data was analyzed using population sample weights. Logistic regression models were fitted to predict the three binary categorical dependent variables: having ever withheld information from providers due to concern about privacy, strongly agreeing that it is important that healthcare providers share my information electronically, and strongly agreeing that it is important that I can find out who has looked at my medical records. Independent variables are the four measures of trust: trust in confidentiality, honesty, competence, and overall trust. Each model controls for respondent demographic characteristics, self-rated health, health insurance status, and care quality (see Table 1 for descriptive statistics).

**Results**

Table 1 provides unweighted demographic details about the study sample. The majority of respondents in the sample are white (84.6%), educated with at least a BA/BS degree (58%), have excellent or good self-rated health (84.9%), have health insurance (96.0%), and report receiving very good or excellent health care in the previous year (60.5%).

We observe a significant association between trust in confidentiality and whether patients had ever withheld information from their doctor (OR = 0.20, Table 2). However, no significant associations were found between trust in provider honesty and competence and having ever withheld information. In a model predicting patients’
expectation that it is very important that providers share their health information electronically, we find a significant association with trust in physician competence (OR = 2.87), but no significant relationship with trust in physician confidentiality or honesty. Finally, in a model predicting patients’ expectation that it is very important that they find out who has looked at their medical records, we find a significant association with trust in physician confidentiality (OR = 0.59), but no significant association with trust in physician honesty or competence. No model showed a significant association between overall trust and the three dependent variables. All models control for race, gender, education, and age.

Discussion

Trust is an important determinant of patients’ behaviors and experiences of healthcare,9,10,12,13 and here we show how it is associated with information sharing. We provide evidence that specific dimensions of trust in physicians, namely, trust in confidentiality and competency of providers, influence patients’ behaviors and expectations for information sharing in health care. This is in contrast to much previous work which considers trust to be a singular, generalized determinant of patient behavior. We find that specific dimensions of patient trust in physicians have unique associations, namely, trust in confidentiality is associated with lower odds of having ever withheld information and reporting concern about who is accessing their health record information. In addition, patients with higher levels of trust in physician competency have greater odds of agreeing that it is important for providers to share health information with each other. Encouraging patients’ health information sharing, and reducing patients’ withholding, may increase the accuracy and quality of health data available in health IT systems.

This work demonstrates not only that trust in providers is essential for information sharing, but that different dimensions of trust matter differently. This finding further supports previous work showing trust is situational12. Patients’ trust is not a singular, generalized phenomenon, instead it is a nuanced series of relationships based on specific expectations and behaviors. Moreover, we show that the individual dimensions of trust are particularly important to study, as each contributes in different ways to the patient experience and the physician-patient relationship.
Additionally, patient information disclosure and concerns about access are also multifaceted and nuanced. Patients are concerned about who accesses health data and why the data are used\textsuperscript{20}. Perceptions of how data are used may also influence patients’ trust\textsuperscript{20}. Trust in providers is associated with the quality of the doctor-patient relationship. Subsequently, dimensions of trust may play different roles in ensuring good communication between patients and providers, in patients’ use of healthcare services, and for adhering to treatment\textsuperscript{21,22}.

Given systematic disparities in patient trust, in which racial and ethnic minorities have lower trust in physicians\textsuperscript{13,14}, while patients with devalued health characteristics have lower trust in physician confidentiality than others\textsuperscript{12}, further research is needed to examine how these factors may intersect with the dimensions of trust and their relationships to health information disclosure and concerns as shown here. This paper controls for patient age, gender, race, ethnicity, self-rated health, insurance status, and quality of health care but further study is needed to disentangle the relationships and possible interactions between and among them, dimensions of trust and health information sharing. Further, we have little understanding of how features of health IT applications interact with dimensions of patient trust. Health IT application design may unintentionally diminish trust or exacerbate rather than reduce privacy concerns that hinder use of beneficial health IT

These critical gaps in knowledge mean practitioners are missing when some patients, particularly the most vulnerable, may be more likely to have incomplete or inaccurate health data. The consequences of incomplete data include less effective treatment, more potential medical errors, and possible bias in treatment due to lack of data-representation in decision-making algorithms. Similar to a lack of representation in clinical studies, when patients’ data is absent, practitioners risk not learning which patients may most benefit from precision health treatments.

This study has a number of limitations that must be considered. First, data for this analysis come from a cross-sectional sample collected in 2014. Expansions in health IT use since then, as well as the evolution of available technologies, may change patients’ experiences and perceptions of technology. Additionally, qualitative research would allow more in-depth understanding of how different dimensions of trust influence patients’ behaviors and expectations about physicians, health IT, and privacy.

**Conclusion**

New information technologies in health care have the potential to enhance care quality and access, yet the widespread information sharing enabled by them also create new risks and concerns. Patients concerned about privacy may be less likely to disclose health information to providers and may be concerned about how their information is being used and accessed within the health care system. While trust is known to be an important factor in health care delivery and doctor patient relationships, previous work has not shown how specific dimensions of trust in physicians contribute to patient information sharing behavior or concerns. Here we show that one particular dimension of trust, trust in provider confidentiality, is associated with patients’ withholding information from clinicians and concerns about who is accessing their records, while a different dimension, trust in physician competency, is associated with agreeing that providers should share information. This is an important contribution given the increasing reliance on databases of patient information to tailor the delivery of care.

Ensuring that new technologies and their benefits are available to all patients, especially the most vulnerable, is necessary to prevent health disparities from widening as new effective health information technologies come in to widespread use. What is needed is an understanding of how dimensions of patient trust matter for health IT use and endorsement, whether particular dimensions of trust alleviate privacy concerns, and how features of health IT influence patient privacy concerns or usage.

Abstract

We report on the usability of a mobile application, MyPath, that connects patients with personalized information based on their diagnosis and care plan and adapts over time as they progress through the cancer trajectory. We conducted usability tests with cancer survivors and health professionals, measuring three usability factors which could be affected by adaptive content: learnability, errors, and effectiveness. Our results indicate that the adaptive information did not obstruct usability of the system. Participants identified several strengths of the application, including the integration of clinical and non-clinical information, the segmentation of a large information set to reduce mental burden, and the inclusion of multiple media types to accommodate different learning styles. Participants also identified potential barriers to use and offered ideas for future developments. We share how we integrated this feedback into the MyPath system design and reflect on lessons for future personal health information systems.

Introduction

Following a cancer diagnosis, access to informational resources can improve patients’ engagement in their care and overall quality of life1,2. Information about the disease can increase patients’ confidence in their ability to cope with the effects of the disease at home1,3. Most often, patients will rely on health professionals and printed materials for information, though use of online health information has increased over the years4,5. Notably, each of these information sources have limitations that affect their usability and accessibility. For example, patients can be hesitant to raise questions to health professionals6,7. Printed materials can be difficult to organize, particularly as the collection grows over time, therefore making the information difficult to recall or retrieve later in the cancer trajectory, when the information could be best put to use8. Finally, patients have varying degrees of trust in online health information as these resources can be inaccurate and unreliable9.

We are exploring ways to use ubiquitous, mobile technologies to connect breast cancer patients with trusted health information while overcoming these existing barriers to information access. Prior patient-facing cancer management interventions that focus on informational support have been associated with improved symptom management10, increased confidence and engagement in care11,12, and reduced symptom severity and distress10,13. These systems include various features to support patients, including symptom monitoring10,11,14, decision support15, and health management advice12, which can be tailored based on user input14.

While these systems have demonstrated a number of positive effects, they often support a subset of patients’ information needs. Many existing systems focus on a particular moment in the cancer trajectory, such as during chemotherapy or radiation therapy. However, patients’ information needs both persist and adapt over time, as they transition from diagnosis through survivorship16. In addition, current systems tend to focus on helping patients manage the physical effects of cancer. Research consistently finds that patients’ information needs extend beyond physical health, and that patients often feel they do not receive enough information to effectively cope with the disease1,17. Finally, while a small set of systems tailor content to the individual, we have not found examples of automatically adapting content based on an individual’s care plan. Such adaptations can provide patients with timely information to help them prepare for upcoming changes in care. Transitional periods can be vulnerable times in the cancer trajectory which alter patients’ self-management abilities18.

We are working with a team of oncologists, cancer navigators19, cancer survivors, and computer scientists to design a novel patient-facing health management application. This application, MyPath, provides patients with comprehensive health information, spanning beyond physical health information. The information adapts over time based on an individual’s care plan and treatment dates, as well as user input of current information needs.
We are employing a user-centered design process to develop a usable application that provides patients with information that aligns with their particular support needs and preferences. User-centered design involves a systematic process for including the intended users (e.g., patients and healthcare professionals) in the design and testing of interactive health technologies, to ensure that new tools are important and usable to the intended users.20 A core component of user-centered design, and one of the most influential components of the design process, is usability testing.21 In usability testing, a small number of potential users of a system interact with a prototype, with the goal of identifying usability problems before the application is built.22 While usability tests have been used in the design of tailored informational support systems,23 we did not find any prior studies that specifically test the effect of adaptive content on usability. We assess three usability factors: learnability, errors, and effectiveness. Prior studies have shown that adaptive content can influence each of these usability factors.24, 25 In addition to measuring usability factors, we used a think aloud protocol, a method often used within usability assessments, to understand users’ expectations and reactions towards the technology.21 Thus, the objectives of this study were to measure the effectiveness, learnability, and error rates of adaptive information recommendations, identify usability issues through participant feedback, and inform the design of future systems that tailor content over time.

Method

MyPath Description
MyPath is a mobile application that connects a patient with a trusted and comprehensive set of information related to cancer management, which adapts over time as the patient progresses through the cancer trajectory. This design goal was supported by our empirical work with cancer navigators, understanding the different types of support and information needs across the patient population, as well as our work with breast cancer survivors creating journey narratives to assess unmet support needs.26 This work highlighted the broad and changing needs of breast cancer patients as they progress through multiple phases of care, and the need for support systems that reach across multiple phases of care, helping patients to cope with current challenges and prepare for future changes to their care.

MyPath’s database includes over 300 information resources from American Cancer Society, breastcancer.org, and cancer.net. We included these three sources based on oncologists’ recommendations for trusted online health information. MyPath’s information recommendations adapt in two ways. First, there is a user survey that may be completed at any time to immediately receive information related to current questions or challenges. The survey asks the user to select which challenges they are currently dealing with, and includes 58 possible responses. Survey items are based on the NCCN distress thermometer and amended with additional challenges captured in our research with cancer survivors.26 Metadata within the MyPath database associates specific survey responses with relevant informational resources. Thus, when a patient selects a particular response in the survey, such as ‘Nausea’, resources related to that subject will immediately appear in the application when the survey response is submitted. While the research team created the metadata tags, multiple oncologists and oncology nurses validated that resources were appropriately characterized and tagged by the application.

In addition to tailored content based on survey responses, MyPath automatically recommends information as patients prepare for and encounter new treatments. Each MyPath user has a profile that includes all treatments and treatment dates. These dates are used to signal a transitional event that generates recommendations based on the patients’ treatment path. Metadata in the database connects transitional events, (e.g. surgery, radiation therapy, chemotherapy, hormonal therapy) to relevant resources. Resources appear one week before a new treatment, or at the end of a treatment, to help a patient learn what to expect and prepare for this change. For example, if a patient is receiving chemotherapy, then the system will identify the start date minus seven days as a transitional event, and on this date the user will see new resources associated with chemotherapy, which help them learn about the treatment, what to expect, and how to prepare.

MyPath Prototype
Once we established MyPath’s features, we then worked on multiple design options using low-fidelity prototypes to generate a proof of concept and elicit initial feedback from members of the research team. This iterative process led to the creation of a high-fidelity prototype. The prototype was created using the Justinmind prototyping software and displayed on Verizon Ellipsis 8 tablets. The prototype includes four sections: the home page, the information recommendations, the resource view, and the user survey (Figure 1). Within the prototype, participants were able to
interact with all buttons and hyperlinks, allowing them to freely explore the system. When selecting one of the PDF resources, the prototype would link to the original online source, though these resources will be available offline in the final application.

Participants
We enrolled breast cancer survivors who had recently completed treatment. Access to a high number of cancer survivors was difficult as the cancer clinic serves a large, rural geographic region, with many survivors living a far distance from the clinic. Therefore, we also included cancer navigators and oncology nurses, who are highly knowledgeable of common questions and informational needs of patients throughout the cancer trajectory.

Usability task development and procedures
Due to the limited work evaluating adaptive interfaces, particularly in a health context, the usability assessments for MyPath were critical for understanding any complications caused by adapting the content over time. We developed three tasks in the usability test to demonstrate changes to the content over time, summarized in table 1. In the first task, participants were presented with information that would be displayed at the time of diagnosis. Before interacting with the prototype, participants were asked to reflect on either their own information needs during this time, or a common information need of their patients. Participants were then instructed to open the application and find two specific resources relevant to the issue they identified that would be helpful to a newly diagnosed patient. To accomplish this task, participants needed to 1) open the application, 2) select a category, 3) select one of the information pages to read, and 4) repeat steps 2-3 to find an additional resource. In the second task, we presented participants with health information relevant to a patient who was beginning radiation in one week. Again, we asked participants to first reflect on their own information needs during this time, or the needs of their patients. Participants were then asked to find two resources that address those information needs, thus repeating the same actions described in the first task. Notably, between the first and second tasks the facilitator updated the prototype to a second homepage view which had new resources added, thus visually mimicking the adaptive feature of the MyPath system. Participants were not told that the information recommendations would be updated.

In the final task, we asked participants to imagine they were in the middle of treatment and to complete the user survey. While the final MyPath application will suggest resources based on these selections, the prototype did not include this feature. Therefore, we asked participants to describe the types of information they would expect to see appear after completing the survey.
Table 1: Description of tasks included usability tests.

| Task 2   | (A) Think about a question you (or one of your patients) had a week before beginning radiation therapy. Try to find a resource within MyPath that addresses this question.  
(B) Try to find a second resource that addresses this question (from Task 3). |
| Task 3   | Think about a question you (or one of your patients) had during radiation therapy. Complete the MyPath survey and identify one resource that addresses this question. |

Data collection and analysis

All usability sessions took place at the Harbin cancer clinic, in a private meeting room. The study involved a one-hour, one-on-one session with a member of the research team, who has a background in human-computer interaction and over seven years of experience running usability studies. While the facilitator was a member of the team who designed the application, participants were not made aware of this, in order to reduce possible influences on participants’ responses. Each session included the usability test, a post-test questionnaire, and interview. To ensure consistency, the facilitator used a script throughout the study to introduce participants to the study goals and procedures. The usability study was approved by the Georgia Institute of Technology’s Research Ethics Board.

We captured participants’ task performance, usability scores, and post-study feedback in order to assess three usability heuristics: learnability, errors, and effectiveness. Learnability refers to the increase in users’ ability to efficiently accomplish tasks over time, as they become familiar with a new system. Prior research has shown that adaptive interfaces can be unpredictable, thus affecting a system’s learnability. We expected that if the adaptive recommendations in MyPath impaired the system’s learnability, we would not see a reduction in task performance time between the first and second tasks. We measured task performance time as the elapsed time between the participant opening the application and the participant identifying (audibly) two useful resources.

Error rates are another metric used to identify significant usability issues in a design. Errors, noted by the facilitator, included an event in which a participant navigated to a page that did not match their intention (for example, looking for treatment information in the Social Support page), or participants were unable to locate an intended screen (such as the user survey). We used a think aloud protocol to capture participants’ intentions while using the system. In a think aloud protocol, participants are encouraged to think out loud as they interact with the application, so that the researcher may note when participants feel confused or experience difficulties. This method is useful for capturing obstacles that participants face throughout the usability assessment.

Similar to prior research, we included measures of effectiveness in the usability test to ensure that the application features were considered useful by participants. We both objectively and subjectively measured the system’s effectiveness. We used task completion rates as a measure of effectiveness, as a task was only considered complete if participants located resources that they considered useful for coping with the information challenges described prior to the task start. Following the usability test, we also asked users to rate on a 5-point Likert scale if they felt the resources included in MyPath would be useful for addressing their information needs (1=not at all useful, 5=very useful).

Finally, we captured post-study feedback using semi-structured interviews. All interviews were audio recorded. Two researchers transcribed the recordings and conducted a thematic analysis of the qualitative data. This analysis included first open-coding the transcripts independently, and clustering segments to develop theme concepts. The two researchers then compared codes, discussed discrepancies, and revised the coding scheme. One researcher then did a final review of all transcripts, verifying themes across the full dataset. The research team then met to discuss the final themes and identify necessary design changes.
Results

Participant characteristics
We enrolled 11 participants in the usability evaluation, including four breast cancer survivors and seven healthcare professionals. The healthcare professionals had an average of 16 years of experience working with cancer patients, ranging from 1 to 45 years. All participants were female, with an average age of 52 years. Participants’ average technology comfort score was 3.8 on a 5-point Likert scale (1 being very uncomfortable, 5 being very comfortable).

Learnability
We compared the completion times of the first and second usability tasks to assess learnability. We use the completion times of ten participants, as one participant was unable to complete the second task (see Effectiveness discussion below). The average completion time of the second task (mean=33.1, SD=10.5) was significantly lower compared to the first task (mean=58.9, SD=9.8) (t=5.0, df=9, p < .001).

Errors
Participants performed a total of 33 tasks in the usability tests, summarized in table 1. Across these tasks, we identified 13 errors. The majority of errors (70%) occurred in the third task. The most common error was incorrectly navigating to the user survey, with five participants unable to locate the survey button during the assessment. Three participants also had difficulty selecting the checkboxes within the survey, due to the widgets being too small.

Effectiveness
The task completion rate was 97%, with one participant not completing the second task due to not finding information that addressed her described information need. In this case, the participant was looking for transportation support offered within the community. The lack of local resources also came up frequently in the participants’ feedback, as we discuss below. All other participants were able to find multiple resources that they felt would be useful for addressing their described information needs.

During the first two tasks, participants were each asked to identify four informational resources to address patient questions or challenges. Participants were free to view any categories that they believed would include information relevant to their described information need. During these two tasks, participants identified 43 resources which spanned all of the MyPath categories. The most commonly viewed category was Treatments (n=18), followed by Day to Day Matters (n=8), Emotional Support (n=7), Health and Wellbeing (n=6), Overview (n=2), and Social Support (n=2). The range of information needs described by participants, and categories viewed, validates the importance of comprehensive informational support.

The average usefulness score from the post-test questionnaire was 4.2 out of 5. No participant rated the system’s usefulness below a 4, indicating an agreement in the expected utility of the application. However, in the post-test interviews, described below, participants highlight two issues that could impede on the system’s overall effectiveness.

Participant Feedback
We identified six themes during the analysis of the interview data. These themes fell into three categories: system strengths, anticipated barriers, and design recommendations. Table 2 shows a summary of these themes and the number of participants who mentioned each theme at least once during the interview.

All participants believed MyPath would be helpful for future patients. Most often, participants said that they liked that MyPath included a breadth of information, addressing needs spanning beyond physical symptoms and side effects. One participant shared that her priorities did not always align with the information that doctors shared, and she was able to find useful information in the prototype:

I think sometimes physicians, because they do it every day, they don’t realize that there’s a lot of things that are not discussed with patients. Day to day matters, social support. [Pointing to MyPath] I would have looked through here for how do I support my family. I’m a mom. I’m a working mom. What’s there for my family? - Breast cancer survivor

Seven participants commented that MyPath recommended short lists of information. Participants liked that the application would populate with small, digestible sets of information during treatment transitions. Both cancer survivors and health professionals noted that large information sets often become overwhelming and ignored:
Table 2: Participant feedback themes, and the number of participants who mentioned each theme at least once during the post-usability study interview.

</tbody>
</table>

*I like that the lists are short. Sometimes if we give them too many resources they don’t even want to read them.* - Oncology nurse

*I was bombarded by brochures [when I was diagnosed]. This seems like these things are sent directly, specifically to me by the creators.* - Breast cancer survivor

Finally, six participants said that they liked that MyPath included multiple media types. While most of the information was in html or pdf format, the database also included videos and discussion forums. Both the health professionals and cancer survivors thought this would be useful, due to patients’ different learning styles:

*I see there are several videos, and because people learn in different ways, that’s something that I think might be pretty good.* - Breast cancer survivor

[Pointing to a video] *I would rather listen than read.* - Breast cancer survivor

Participants also noted barriers that they believed hurt the usability of the system. Five participants commented on navigation challenges they encountered, or would expect to encounter, which further substantiated the errors we identified in the usability test. Participants were particularly concerned about how to navigate to new resource recommendations:

*Could it highlight the new resources, and a message that said please tap the highlighted field? Could it direct me in some way to go there?* - Breast cancer survivor

While participants were overall positive about the potential usefulness of the MyPath application, four participants also noted that patients respond differently to health information. Participants cautioned that this type of application may not be useful for all cancer patients. As one cancer survivor shared, some people choose not to seek out information:

*There is so much information out there. Some of it is not good. Some people want to know everything. I am not that kind of person.* - Breast cancer survivor

Finally, participants shared ideas for future information systems. The most common recommendation was to incorporate information about patients’ care team and local resources within the patient’s community. Both health professionals and cancer survivors saw this application as an opportunity to help patients connect with in-person support systems:

*You could do a little sentence at the end. If your distress level is 4 or higher, please share this information with your healthcare team.* - Cancer navigator

*I would like more about what is there actually for ME in this community? Is there transportation help? Is there financial help?* - Breast cancer survivor
Discussion

We are developing MyPath, a mobile health application that connects cancer patients to tailored health information based on user input and their care plans, to assess opportunities and barriers of using adaptive systems to increase cancer patients’ access to health information. Thus far, little is known about how dynamic content within an adaptive intervention may affect the system’s overall usability. In this study, we assessed three usability factors that we hypothesized could be influenced by dynamic content: learnability, errors, and effectiveness. Our results indicate that adaptive health information presents a useful approach for making large information sets more manageable for patients, while also raising important usability issues requiring design alterations.

Our first goal within this usability study was to determine if the automatic addition of content over time would interfere participants’ ability to learn how to use the application and find relevant content. Usability studies within other contexts have suggested that adaptive interfaces can interfere with one’s ability to learn a system’s features. To test the system’s learnability, we compared the task completion times of the first and second tasks in the usability tests, which require participants to complete the same set of interactions, but with new information recommendations added to application prior to the second task. We found that task completion times were significantly lower in the second task, suggesting that dynamic content did not interfere with participants’ ability to find relevant information.

We found that the majority of errors were related to navigating to the user survey. Further, participants were concerned about navigating from the user survey to new resources that were added as a result of the survey submission. These errors highlight the importance of adding navigation support to help participants move between system features. Prior work exploring the design space for adaptive systems have discussed the importance of helping users to navigate these complex interfaces, especially if individuals interact with the system infrequently. Our study shows that when recommending health information to patients, adaptive systems need to visualize when, why, and where new information recommendations have been added.

Participants’ high task completion rates and usefulness scores suggest a consensus that participants believe MyPath will be helpful for breast cancer patients. However, during the interviews, participants did suggest that integrating information about one’s care team and other local resources would be important for patients and increase the system’s utility. In-person resources, such as support groups, self-management programs, and peer navigation services, can improve a patient’s quality of life throughout the cancer trajectory. However, a lack of information about available resources can limit patients’ ability or willingness to access local services. Participants in this study frequently commented that adaptive information systems could be help bridge these gaps, connecting patients with in-person support services.

Based on this feedback, we made a number of changes to MyPath. First, we added a local resources category that includes links to the cancer clinic and other support services for cancer patients. Second, we moved the user survey to a more prominent location on the homepage and added a text label. Third, we added a number of navigational support features. We changed the labels within each category to more accurately represent why new resource recommendations were added (labels originally only included the date the resources were recommended). We also included animation to show which categories include newly recommended resources, as well as messages with a description of new resource recommendations that are added after a survey submission or at the start of a treatment transition. Fourth, we added a question to the user survey that asks participants how much distress they are experiencing. When a patient selects a distress level above 4, a message appears suggesting they get in touch with a healthcare professional. These changes are depicted in Figure 2.

The results from this study point to design guidelines for adaptive, patient-facing tools. As noted above, adaptive tools should include clear navigational support for users and may be useful in connecting patients with in-person support when necessary. Participants in this study also raised the issue of cancer patients having different attitudes towards information seeking. We see this issue as an important opportunity for future research. Many cancer patients use information avoidance as a coping strategy. Open questions remain about how health management tools may adapt over time to accommodate this behavior. Future research addressing this question could support the development of informational support that is beneficial for a broader patient population.
Limitations

Our usability assessment included a number of limitations. We worked with a small number of participants, and a larger participant group may identify more usability issues, though research suggests that this participant size typically captures a majority of the usability issues. We chose not to include patients who were recently diagnosed or in the middle of treatment. Often these patients are traveling far distances to come to the cancer clinic for treatment, and we wanted to be respectful of their time and mental well-being. We opted to recruit healthcare professionals and cancer survivors who had progressed through diagnosis and treatment, who would be able to reflect on how patients’ information needs change over time. However, it is possible that the emotional burden of the diagnosis and treatments will influence the effectiveness of the tool. We will use a deployment study to assess real-world barriers to using adaptive health information recommendations throughout the cancer trajectory.

Conclusion

Adaptive content can have unforeseen consequences on the usability of an application. The findings from this study emphasize the importance of incorporating navigation support within adaptive systems. Participant feedback underscored the importance of visible system recommendations, with clear explanations of when and why new recommendations are being presented. Despite navigation challenges, participants consistently stressed the potential benefits of adaptive health information for breast cancer patients, such as helping to make large information sets more manageable and less overwhelming, while also revealing an important opportunity to use such tools to help patients connect with healthcare professionals and local support services. These findings may useful in designing technologies for other illness trajectories in which patients’ information needs change over time, including other types of cancer and illnesses with intermittent serious episodes, in which patients’ and caregivers’ information needs may significantly change over time. We also expect that as adaptive patient-facing tools become more common, this approach to usability testing may be useful for assessing how dynamic content influences usability in other contexts.

Acknowledgments

We would like to thank our participants for volunteering their time to provide their crucial feedback. We would also like to thank the Cancer Navigators of Rome, Lena Crooker, and all of our partners who are a part of the Rome, GA healthcare community. This work is supported by the National Institute of Health (RO1 CA195653).

Machine Learned Mapping of Local EHR Flowsheet Data to Standard Information Models using Topic Model Filtering

Steven G. Johnson, PhD¹, Lisiane Pruinelli, PhD, MS, RN¹,², Bonnie L. Westra, PhD, RN, FAAN, FACMI¹,²

¹Institute for Health Informatics, University of Minnesota, Minneapolis, MN;
²School of Nursing, University of Minnesota, Minneapolis, MN

Abstract

Electronic health record (EHR) data must be mapped to standard information models for interoperability and to support research across organizations. New information models are being developed and validated for data important to nursing, but a significant problem remains for how to correctly map the information models to an organization’s specific flowsheet data implementation. This paper describes an approach for automating the mapping process by using stacked machine learning models. A first model uses a topic model keyword filter to identify the most likely flowsheet rows that map to a concept. A second model is a support vector machine (SVM) that is trained to be a more accurate classifier for each concept. The stacked combination results in a classifier that is good at mapping flowsheets to information models with an overall f2 score of 0.74. This approach is generalizable to mapping other data types that have short text descriptions.

Introduction

Healthcare data is now readily available in electronic form thanks to the continued adoption of electronic health records (EHR). Never before have we had easy access to so much data that has the promise to improve patient outcomes. But the secondary use of this data for analysis and sharing across organizations is stymied because we don’t have robust standard and formal information models to support analyzing and comparing the data¹. An information model is a formal structure for representing the clinical information in the EHR and includes data elements, relationships between the elements, and rules that the data elements should satisfy². While efforts such as the Observational Medical Outcomes Partnership (OMOP), Patient-Centered Outcomes Research Institute (PCORI), Fast Healthcare Interoperability Resources (FHIR) and Clinical Information Modeling Initiative (CIMI) have made good progress toward standardized information models³–⁶, those efforts have not given attention to data captured in the delivery of nursing and other inter-professional areas.

Much of this data is semi-structured and captured as “flowsheet” data⁷. Flowsheet data is used by many healthcare organizations to record custom and non-standardized information into the EHR. It is arranged as a spreadsheet like data entry with rows representing the different data types and columns representing time periods to record observations of the rows. There is usually not an information model that the EHR builders use to model flowsheet data. Flowsheet data is particularly difficult to model because most of it is not coded to standard terminologies like Logical Observation Identifiers Names and Codes (LOINC) or Systematized Nomenclature of Medicine – Clinical Terms (SNOMED-CT). Therefore, flowsheet data can’t be mapped using tools such as Regenstrief LOINC Mapping Assistant (RELMA)⁸ or MetaMap⁹. Flowsheet rows (data types) typically have very little information that describe the data that is being captured.

Recent work has resulted in the development of information models in 10 key areas important to nursing¹⁰. Eight organizations formed an Information Model Validation Work Group (IMVWG) to evaluate and validate these models across their organizations. Two of the models are nearing completion for validation across organizations. One of the models, the Pain Information Model (Pain IM), has been validated and published¹¹. However, a significant problem still remains even after standard information models have been made available for use. The problem is that each organization then has the unenviable task of mapping the standard information models to the data in their local EHR system. This can be a daunting, time-consuming and error prone task, particularly since organizations may have multiple flowsheet rows for the same type of data element. Often these are created for different units, disciplines, or types of settings, and change over time with upgrades to the system.

In the EHR systems of the eight organizations in the IMVWG, flowsheet data types are described using two 90-character fields. The first field is the flowsheet data type’s internal name (called a flo_meas_name), and the second is
the text that is displayed on the data entry screen (called a flo_disp_name). Each flowsheet data type also has a unique identifier, which can be different in each organizations’ EHR (called a flo_meas_id), but those identifiers are not guaranteed to be unique across different systems. For example, different systems can use flo_meas_id=12345. The first may use it to represent “Blood Pressure” and the second can use it to represent “Heart Rate”. Furthermore, the descriptions for the same concept (i.e. “Pain Rating 0-10 Scale”) may use the text “Pain Scale” at one health system and “Pain Rating” at another.

Once a standard information model has been developed (for example, the Pain IM), each of the organizations in the IMVWG assigned staff to map their flowsheet data types to the information model concepts. This was a time-consuming manual process that needed to be done after every model was developed. It required staff to search through flowsheet row descriptions and find the rows that they believed mapped to the concept in the information model. The problem was worse for new organizations that wanted to join the IMVWG. To get the benefit of the work group, they would have to manually map their flowsheet data to all of the information models, which required a large initial commitment of time and resources on their part. In order to make that initial mapping task less daunting, the IMVWG sought a way to automate the mapping process. The work group looked at natural language processing (NLP) and machine learning as possible approaches. Approaches using traditional NLP techniques were deemed unlikely to work because the flowsheet row descriptions are very short, are not sentences and don’t have traditional parts of speech. There has been work on mapping short descriptions as part of the caBIG project, but those tools were focused on rank ordering matches and supporting researchers in manually mapping between common data elements.

The purpose of this study was to develop and implement a technique for mapping local EHR flowsheet data types that have short descriptions to standard information models using a machine learning approach. The technique will be illustrated using the Pain IM.

**Methods**

The overall approach has four steps:

1. Develop a model using the IMVWG manually mapped flowsheet rows as training data for a machine learning algorithm
2. Evaluate the model performance using the f2 score
3. Validate the model predictions by having researchers review the results
4. Update the incorrect mappings from the IMVWG and then re-train and re-evaluate the model

Machine learning is a powerful technique for developing models. The basic approach for mapping the Pain IM to local EHR data was to obtain examples of correctly mapped flowsheet rows to concepts in the Pain IM and use that data as training data to build a machine learned model that can label new flowsheet rows to map it to the right concept in the Pain IM. A portion of the Pain IM is shown in Figure 1.
One task of the IMVWG was for each organization to manually map their organization’s flowsheet rows to the Pain IM. As a result of that work, eight organizations mapped 1,837 flowsheet rows to the 103 concepts in the Pain IM. These previous manually developed mappings served as training data for the machine learning models.

**Model Development**

The method selected for development of a machine learned model was influenced by the flowsheet data structure and volume. In the EHR used by most of the workgroup participants, flowsheet rows are described using 60-120 characters of text. Because the EHR builders had to fit quite a bit of information into a small space, much of the description makes use of abbreviations and short phrases instead of full sentences to describe the flowsheet data types, so the words in the descriptions act like keywords.

The initial attempt to create a machine learned model for predicting labels used a term frequency-inverse document frequency (tf-idf) approach. Each short description (the 60-120 characters of text) that was defined in the EHR that described each flowsheet row is considered a document. Tf-idf creates a bag-of-words count of each of the terms that occur in these descriptions, but gives a higher weighting to rare terms and a lower weight to common terms. This results in word vectors that are the set of features covering all of the flowsheet row descriptions.

For the training, depending on which organization’s data was left out for testing, there were typically 100,000 negative examples (unmapped flowsheet rows) and approximately 500 positive examples (flowsheet rows that were mapped to concepts in the Pain IM), which is an extremely unbalanced dataset for machine learning. And in addition to just looking at each individual word for the bag-of-words parsing, tf-idf was configured to also included all of the unique two- and three-word phrases (bigrams and trigrams). This led to having models with 800,000 to 1,000,000 features.
Training a support vector machine (SVM) using that many features on the unbalanced dataset would be very slow and would not result in good model performance.

There are a number of approaches in machine learning that attempt to address the imbalance including random under- or over-sampling\textsuperscript{14} and SMOTE\textsuperscript{15} that creates synthetic samples. These approaches have disadvantages in that they either add noise or remove potentially useful information. Some studies have found that using model ensembles can intelligently identify sub-samples that will improve model performance when using imbalanced data\textsuperscript{16}. Therefore, a stacked model approach\textsuperscript{17} was pursued where the first model would filter the flowsheet rows to identify rows that should definitely not be categorized as a Pain concept and the second model would be a SVM to more accurately classify a flowsheet row as a Pain concept or not. The first stage of the stacked model significantly reduced the negatives using a topic modeling filter based on the TextRank algorithm\textsuperscript{18}. A topic model was developed for each concept in the Pain IM. The top $N$ topics were selected for that concept (enough to ensure that 100\% of the positive training data was included in the topic filter). This topic filter was then applied to the training data and the second model, a SVM, was trained on the remaining data.

A separate topic model and SVM was built to classify each of the concepts in the Pain Information Model. The Pain IM has 103 concepts, so in the end there were 103 2-stage models run on the unmapped flowsheet data of a new organization to label and map their flowsheet rows. The SVM produces a score which is a probability that a label is correct for a particular flowsheet row. Each model (topic filter and SVM) was applied to the flowsheet rows, and the label from the SVM that produced the highest score (probability) was used to label the flowsheet row. The process is shown in Figure 2. The software was written in Python and used the gensim\textsuperscript{19} library for tf-idf and TextRank and scikit-learn\textsuperscript{20} libraries for the SVM models.
Figure 2. Process for mapping flowsheet rows using a stacked classifier for each Information Model concept

Model Evaluation

The performance of the model was evaluated using the f2 score. The f2 score is a combination of the recall and precision of the model, but it is biased toward recall. The formula for f2 is shown in Figure 3.

\[
F_2 = 5 \cdot \frac{\text{precision} \cdot \text{recall}}{4 \cdot \text{precision} + \text{recall}}
\]

Figure 3. The f2 score defined in terms of precision and recall

In our use case, we don’t mind having more False Positives (when the model labels a flowsheet row, even though it may not correctly map to a concept in the information model) so the f2 score is a good choice for model evaluation. The f2 score weights recall as twice as important as precision. Using a hyperparameter search, an SVM probability score threshold was found that maximized the f2 score across the entire set of SVMs.
In order to simulate the mapping process that occurs when a new organization joins the IMVWG, an approach was taken to train the model on 7 organizations’ mappings and leave one organization out to be used as the testing data to evaluate the model performance. This was done 8 times, leaving a different organization’s data out as the testing data each time.

**Model Validation**

The manually developed mappings from the workgroup were used as the “gold standard” to train the model. These mappings were known to have mistakes, such as a single flowsheet row mapping to the wrong concept or two different concepts in the IM. Or a flowsheet row might not be mapped to the any concept even though the concept existed in the Pain IM. So we also carried out a mapping validation process where the predictions of the model were manually reviewed by at least two researchers to determine if the original “gold standard” mappings were correct or if the prediction from the model was correct.

It would have been difficult to have the researchers manually review all 126,957 flowsheet row mappings from the eight IMVWG organizations. Instead, the researchers reviewed only the model predictions that differed from the IMVWG mappings. The differences fell into four Mismatch Categories:

1. A flowsheet row wasn’t mapped by the IMVWG, but the model predicted a new label that the researchers verified was correct.
2. A flowsheet row was mapped by the IMVWG (and verified correct by the researchers) but the model did not predict any label.
3. A flowsheet row was mapped by the IMVWG, but the model predicted a new label that the researchers verified was correct and better than the IMVWG.
4. A flowsheet row was mapped by the IMVWG, but the model predicted a label that the researchers verified was the wrong label.

Based on this review, the labels of the original IMVWG mappings were updated and the model training and testing process was performed again to determine the final model performance.
Results

The flowsheet row data from eight organizations was aggregated into a database containing information about 126,957 flowsheet rows in total. The model training process was run on 7 organizations’ data and the model was evaluated using the flowsheet data from the organization that was left out. The results of this process when using the original mappings are shown in Table 1.

The f2 score ranged from 0.09 to 0.54 with an overall f2 score of 0.42. There were 1,690 FPs and FNs where the model and the IMVWG mappings did not match. Three researchers (two were clinicians) examined those mappings to determine the correct labels for the flowsheet rows. The Cohen’s Kappa was 0.80, which indicates good agreement between the researchers for what the correct labels should be.

Examples of IMVWG flowsheet labels and predicted labels are shown in Table 2. The table includes examples that were correctly mapped (TP) as well as examples of mappings from each of the four Mismatch Categories.

Using the updated labels, the models were retrained in the same manner by using 7 organizations data for training and then testing on the organization that was left out. This was repeated so that each organization was used as the test data once. The resulting model statistics are shown in Table 3. The f2 scores improved and ranged from 0.59 to 0.86, with an overall f2 score of 0.74.

Discussion

The final model performance was quite good with an overall f2 score of 0.74. This approach will be very useful to new organizations that are added to the IMVWG. They will be able to get a high percentage of their flowsheet data types mapped automatically to the information models. The stacked models did a good job of finding the true positives (flowsheet rows that match the organization’s manual mappings) and true negatives (flowsheet rows that should not be labeled) and the false positives and false negatives were minimized. There are a number of findings from this research discussed below.

*Manual mapping is error-prone.* The first finding is that having human reviewers manually mapping flowsheet rows to concepts in an IM is error prone. There are many examples of mappings that were missed by organizations. When the authors reviewed the results, we found 388 additional flowsheet rows that could be mapped to a concept. This is not surprising since the clinicians in the organization who are performing the mapping can’t possibly be aware of all the places the concept is in their flowsheet data. They were given a tool that can do sophisticated Boolean search expressions using keywords, but that still relies on the skill of the mapper to remember all the ways a concept is represented in their flowsheet data and which keywords to use for a search. A better approach is to have the computer suggest mappings and then the human reviewer only needs to decide if it is a good mapping or not. The automated mapping techniques described in this study makes that approach possible.

*Automated mapping needs good training data.* The models did not perform as well when there were insufficient flowsheet instances present in training data. For example, only two of the organizations had a single flowsheet row named “Pain Level” mapped to the Pain Rating 0-10 Scale concept. When one of the organizations was used as the testing data, there was only one instance of “Pain Level” in the training data, which was not enough for the SVM to be able to consistently classify it to the concept of Pain Rating 0-10 Scale. On the other hand, there were many organizations that used phrases like “Pain Rating” and “Pain Scale”, so the SVM consistently mapped those types of flowsheet rows to the “Pain Rating 0-10 Scale” concept.

*Short description mapping will work in other domains.* This approach is generalizable to other short description mapping problems. Within the EHR, there are many types of data that are described with keyword-like phrases. For example, orders are typically created as a custom list for each healthcare organization. There currently is not a standardized list of orders, but even if one were to exist, the job of mapping each organizations’ orders to the standard would be time-consuming and error prone and would benefit from the approach described in this paper.

*There are some limitations with this research.* This approach was only tested using the Pain Information Model. The approach should work well on the other nine nursing IMs, but the work to carry out that validation still needs to be performed. A second limitation is that performance is dependent on the quality of the IM. Our goal was to map a flowsheet row to the best equivalent concept in the IM, which sometimes meant it was mapped to a higher level.
concept because an exact equivalent concept did not exist in the IM. Also, all of the organizations for this study use the same EHR vendor. It would be helpful to use this approach on flowsheet data types from other EHR vendors to ensure that the approach works with data from all vendors. Finally, the eight organizations involved in this research are diverse geographically, but tend to be medium to large in the size of their institutions and are all from inside United States (US). To fully validate this approach, flowsheet data should be obtained from smaller organizations and organizations from outside the US.

Crowd-sourced mapping. Additional work is needed to develop tools to make it easier to review the mapped data and to specify which labels are correct and which are not. This would make it easy for multiple reviewers from an organization to quickly review how the model labeled their data and also review mappings from other organizations. In this way, the “gold standard” training data would continue to get better and as new organizations join the workgroup, the predicted mappings from the automated process would also improve, thereby reducing the workload across the group.

Conclusion

This research shows that it is possible to use machine learning to automate the mapping of flowsheet rows to standard information models. Furthermore, the same approach should work wherever there is a need to map short description items to an information model. The model performance depends on having good training data from a variety of organizations. There is a need to develop tools and processes to support collaborative mapping of local EHR data to models so that the workload of doing the mapping can be distributed and the benefits of automating the mapping can be used by many organizations.

Abstract

Background: Experiences of sexual trauma are associated with adverse patient and health system outcomes, but are not systematically documented in electronic health records (EHR). Objective: To describe variations in how sexual trauma is documented in the Veterans Health Administration’s EHR. Methods: Sexual trauma concepts were extracted from from 362,559 clinical notes using a natural language processing pipeline. Results: We observed variations in the presence of sexual trauma in notes across five United States regions: Pacific, Continental, Midwest, North Atlantic, Southeast. We also observed variations in the types of notes used to document sexual trauma (e.g., mental health, primary care) and sources of sexual trauma (e.g., adult, childhood, military) mentioned in the EHR. Our findings illustrate potential differences in cultural norms related to patient disclosure of sensitive information, and provider documentation. Standardized protocol for eliciting and documenting sexual trauma histories are needed to ensure Veteran access to high quality, trauma-informed care.

Introduction

Experiences of sexual trauma are associated with adverse patient and health system outcomes and are important to elicit during patient-provider interactions. These experiences are, however, not routinely disclosed by trauma survivors in civilian1–2 and military settings3–5. Moreover, these adverse experiences are not systematically documented in patient medical records due a variety of reasons, including provider norms and patient preferences. Sexual trauma, which includes both experiences of assault and harassment, has been described as part of adverse childhood experiences, as well as in adulthood on college campuses, in the workplace, and in intimate partner relationships. We are increasingly aware of the detrimental clinical outcomes associated with sexual trauma. These include psychiatric comorbidities such as depression, anxiety, post-traumatic stress disorder, and alcohol and drug use disorders6–7. The initial psychiatric sequelae of sexual trauma, in the absence of intervention, may accumulate to affect a broad range of health and psychosocial domains, with symptoms often persisting for several years following the incident. Indeed, long-term consequences of sexual trauma include chronic medical conditions (e.g., chronic pulmonary disease, liver disease, and hypertension)8, legal involvement9, homelessness10, and suicide11.

Disclosure of a history of sexual trauma is an essential first step to receiving counseling or trauma-informed treatment that may address the long-term sequelae of these traumatic experiences12. However, little is known about the circumstances of sexual trauma disclosure in health care settings, or how patient histories of sexual trauma are documented in electronic health record (EHR) notes. Most health care systems lack routine screening for patient histories of sexual trauma. Even when screenings occur, sexual trauma experiences are under-reported due to stigma, shame, and privacy concerns13. For example, a recent study of documentation of sexual trauma in the Veterans Health Administration found that male and racial/ethnic minorities with a history of military sexual trauma were less likely than female and non-Hispanic Whites, respectively, to disclose information regarding sexual trauma on an initial clinical screen14. Some patients only volunteer sexual trauma
information in a therapeutic context, or when rapport has been established with their routine provider. In other cases, sexual trauma is documented when a patient presents to the emergency department for treatment of acute symptoms. An examination of the free text of EHR notes may shed light on the circumstances of patient disclosures of sexual trauma and provider practices of documentation in medical records.

Health care providers document a patient’s medical status, psychosocial circumstances, and historical information through clinical narratives in the EHR, and the presence and availability of this information in clinical documents informs patient care. In the case of sexual trauma, the availability of patient history information facilitates the delivery of trauma-informed care across the health care system\(^5\). However, there is reason to think that sexual trauma history information may not be captured in a standardized way. Use of International Classification of Disease (ICD) codes to record sexual trauma histories is limited, and research in other clinical domains has identified substantial variations in documentation practices\(^6\). To optimize health care efficiency, and to maximize the utility of the EHR, it is important to identify major variations in clinical documentation of sexual trauma histories and to understand the nature of those variations\(^6\).

This paper aims to characterize regional geographic variations in documentation of sexual trauma histories in the Veterans Health Administration (VHA). We chose United States geographic regions as a potential source of variation because these may serve as proxies for sociocultural norms in patient reporting and provider documentation of sexual trauma information\(^8\). To accomplish the study aim, mentions of sexual trauma concepts in the EHR were extracted via a natural language processing (NLP) pipeline. Prior studies have demonstrated the feasibility of using NLP techniques to identify mentions of sexual trauma in the EHR\(^17\), and have examined racial/ethnic and sex differences in patterns of sexual trauma disclosure\(^14\). To our knowledge, this is a first study to explore regional variations in sexual trauma documentation.

The VHA is an optimum setting to explore geographic variations in sexual trauma documentation because of the size of the healthcare system, and because patient histories of sexual trauma have been prioritized for documentation. Indeed, VHA is the largest integrated healthcare system in the United States, serving nearly 6 million unique patients every year through 152 medical centers and nearly 1000 outpatient clinics. Since 2004, VHA has implemented universal screening of all Veterans seeking care in its medical facilities for exposure to sexual trauma during military service (military sexual trauma, MST). Under this model, many patients with a history of sexual trauma have received access to specialized care designed to mitigate adverse outcomes associated with sexual harassment and assault. Eligible Veterans also receive treatment for experiences of sexual trauma occurring outside of military service (during childhood or adulthood). Information learned through an examination of regional variations in VHA medical records may apply to other healthcare systems in the United States, and to international health care settings where sexual trauma is prevalent\(^19\).

**Methods**

**Setting and Study Population**

This study examined documentation of sexual trauma concepts from a national, random sample of Veterans who served in recent conflicts as part of Operations Enduring Freedom/Iraqi Freedom/New Dawn (OEF/OIF/OND) and who received care in VHA medical facilities. We selected a random sample of 10,000 male and 10,000 female OEF/OIF/OND Veterans by linking a Department of Defense (DoD) roster of service members who served in the recent conflicts with administrative data stored in the VHA corporate data warehouse. Data were accessed through the VHA Informatics Computing Infrastructure (VINCI), a secure research portal\(^20\). Veterans were included in this study if they received care in VHA medical facilities, and had a valid MST screen result between October 2009 and October 2014. For each patient, we analyzed 12 months of electronic medical notes that are available in the VHA corporate data warehouse for use in research\(^10\). All study procedures were approved by the University of Utah Institutional Review Board and the Research Review Committee of the VA Salt Lake City Health Care System.

**Procedures**

We downloaded all electronic medical notes associated with outpatient visits for the study cohort in the 12 months following an initial MST screen result. We processed the 12-month set of electronic medical notes using an NLP pipeline, V3NP, that was developed to extract all sexual trauma concepts such as adverse childhood experiences and mentions of sexual trauma in adulthood (including trauma that occurred during military service) from VHA electronic medical records\(^17\). The pipeline was built on the APACHE-Unstructured Information Management applications (UIMA) framework\(^21\). In brief, the pipeline parses the electronic medical note into its component parts such as sections, content headings, lists, sentences, lines, and finally individual concepts (tokens). The individual tokens were then compared to a look-up dictionary of sexual trauma terms. The
dictionary was developed for this pipeline using terms from standard vocabularies and supplemented with expert opinion after review of a set of VHA electronic medical records as there was lack of complete coverage of sexual trauma concepts in the UMLS Metathesaurus and SNOMED-CT. An important feature of the pipeline was to include lexical variants of terms and to exclude concepts that were negated such as “no evidence of sexual trauma”. Thus, the goal of the pipeline was to extract “positively asserted” concepts. All concepts related to sexual trauma extracted by the NLP pipeline as positively asserted (with clinical text surrounding the extracted concept to provide context, “snippets”) were reviewed by a set of trained human reviewers for true positive mentions. As reported elsewhere, the overall positive predictive value for identifying sexual trauma at the individual concept level was 0.90\(^2\). The trained reviewers also determined the type of sexual trauma described in each mention: 1) childhood sexual trauma, 2) adult sexual trauma, 3) military sexual trauma (MST), 4) unspecified sexual trauma, or 5) no sexual trauma (i.e., false positive).

At the document level, we created a binary variable noting any evidence of sexual trauma (yes/no), and a categorical variable with specific type(s) of sexual trauma recorded: adult only, childhood only, MST only, unspecified only, or multiple types of trauma. Documents that only included false positive mentions of sexual trauma, and those documents lacking true positive mentions were coded as having no evidence of sexual trauma.

**Geographic Variables**

All clinical notes were affiliated with a VHA medical center or outpatient clinic where the patient received care. We extracted geocoded attributes of each facility from VHA administrative records. Facilities are coded as urban, rural, highly rural, or insular, based on rural-urban commuting area (RUCA) definitions using the standard VHA classification that has been validated for Veteran research\(^22,23\). We coded clinical notes as urban or non-urban, based on the RUCA classification (RUCA <=1.1 is urban, all other values are non-urban) of the facility where the note was written.

VHA facilities are also categorized into one of five geographic regions of the United States, based on aggregated Veterans Affairs Integrated Service Network (VISN) catchment areas: Pacific, Continental, Midwest, Southeast, and North Atlantic regions (Figure 1). We assigned clinical notes to one of the five geographic regions, based on the facility where the note was written.

![Figure 1: Five United States geographic regions. Region boundaries correspond to Veterans Affairs Integrated Service Network (VISN) catchment areas. Green circles indicate Veterans Affairs medical center locations.](image)

**Statistical Analyses**

We used cross-tabulations to characterize regional variations in notes containing sexual trauma documentation (yes/no), the type of notes mentioning sexual trauma, and types of sexual trauma mentions (e.g., military, adult, childhood, etc). We used logistic regressions to estimate regional differences in sexual trauma documentation (yes/no) and multinomial logistic regressions to estimate regional differences in the types of notes mentioning sexual trauma. All models controlled for patient sex, and used a robust standard error specification to account
for the clustering of notes within VHA patients. Wald joint tests of significance were used to simultaneously test region coefficients.

Results

Of 20,000 male and female VHA outpatients, 14,831 had at least one medical note during the study period. A total of 362,559 notes were processed from the study cohort using the NLP pipeline; and 4,178 of 4,937 (84.6%) notes contained true positive mentions of sexual trauma concepts. The NLP precision was slightly better in the Midwest region (note level positive predictive value [PPV]=88.4%), compared to the other United States regions: Pacific PPV=84.4%, Continental PPV=84.7%, Southeast PPV=82.8%, and North Atlantic PPV=83.0%. Regardless of sexual trauma mentions, the majority of all notes were observed in urban versus rural VHA facilities (n=324,053, 91.8%).

As shown in Table 1, there were regional variations in the documentation of sexual trauma (Wald $X^2 = 59.94$, $p<0.001$). The Southeast region had the largest average number of notes per patient, but a relatively low frequency of notes containing sexual trauma mentions. Only 15.6% of notes containing sexual trauma were in the Southeast region, compared to 20.4% of notes lacking sexual trauma mentions.

Notes Containing Sexual Trauma Concepts

Notes lacking sexual trauma concepts included 1,995 unique note titles, whereas notes containing sexual trauma concepts only included 365 unique titles. As shown in Table 2, notes lacking sexual trauma concepts were often addendums and administrative in nature; nursing, primary care, and mental health disciplines were also represented. In contrast to other notes, most of the notes containing sexual trauma mentions were mental health in nature. Smaller numbers of notes with sexual trauma mentions related to primary care or to VHA compensation and pension (C&P) examinations.

Classification of Note Titles

We reviewed the 365 unique note titles names, and combined note titles with similar names into groups. The note titles broadly fell into six main categories: primary care, mental health, social services, medical or surgical services, emergency or inpatient services, C&P exams, and other. The other category included labs, radiology, person-specific notes (e.g., physician, attending), addendums, and miscellaneous (e.g., no-show note, administrative note).

In notes lacking sexual trauma concepts (Figure 2a), the proportion of primary care and mental health notes were similar across regions of the United States. Of all geographic regions, facilities located in the Pacific states had a higher percentage of mental health notes than the other U.S. regions (15.1% vs. 12.1%-13.8% in other regions), and a smaller percentage of primary care notes (17.4% versus 19.2%-20.8% in other regions).

![Figure 2a: Types of notes lacking sexual trauma mentions, by geographic region](chart)

In contrast to notes lacking sexual trauma mentions, we observed greater regional variation in notes containing sexual trauma concepts (Figure 2b; Wald $\chi^2 = 176.99, p<0.001$). VHA facilities located in Pacific states had a greater percentage of primary care notes (28.3%), compared to facilities in the Southeast (13.1%) and other regions (17.3%-20.0%). Facilities in the North Atlantic had a higher percentage of emergency or inpatient service notes, compared to facilities in other regions (4.5% vs. 1.8%-3.7% in other regions).

![Figure 2b: Types of notes containing sexual trauma concepts, by geographic region](chart)
Region and Sex Variations in Sexual Trauma Mentions

We explored whether the patterns of regional differences in notes with sexual trauma concepts were related to patient sex. Most (94%) of all notes containing sexual trauma concepts belonged to female patients. Thus, the regional distribution of note titles among female Veterans was similar to the total distribution (males and females combined) presented in Figure 2b above. Among female patients, for instance, VHA facilities located in Pacific states were more likely than facilities in other regions to document sexual trauma in primary care (23.8%). VHA facilities in the Southeast were less likely than facilities in other United States regions to document sexual trauma in primary care (10.1%; data not shown). VHA facilities in Pacific states had lower percentages of sexual trauma notes from mental health (39.9%) compared to facilities in other regions (50.3%-60.3%; data not shown).

A different pattern was observed in the notes of male patients (n=248) than in notes of females. As shown in Figure 3, VHA facilities in the Continental U.S. region were more likely to document sexual trauma for male patients in primary care (19.6%), compared to facilities in other U.S. regions (7.7%-9.8%). VHA facilities in the Midwest and Atlantic regions were more likely than facilities in other regions to document sexual trauma concepts for male patients in mental health note types (75.4% and 70.7% versus 38.3%-59.1%). More than in other geographic regions, sexual trauma concepts in Southeast facilities were documented in social service (14.9%), medical/speciality (12.8%), and other (14.9%) notes. Tests of regional variation in the types of notes mentioning sexual trauma were statistically significant in the models for females and males (both Wald test p-values <0.001).

Types of Sexual Trauma Concepts: Geographic Variations by Sex

We also explored the types of sexual trauma concepts picked up by the NLP pipeline: military sexual trauma, sexual trauma occurring in adulthood (outside of the military), childhood sexual trauma, and other sexual trauma incidents where circumstances were not specified. The overall test of regional variations in type of sexual trauma recorded was statistically significant (Wald $X^2 = 99.95$, p<0.001), with distinct regional patterns in the type of sexual trauma documented for female versus male patients.
As shown in Figure 4a, sexual trauma notes for female patients in the Pacific states often referenced adult sexual trauma (43.2%), with relatively smaller percentages of sexual trauma concepts related to military service (34.1) or childhood (11.4%); 9.1% of sexual trauma notes in Pacific states referenced more than one type of trauma. For female patients, sexual trauma notes in the Continental and Midwest regions had the greatest percentage of childhood trauma references (27.5% and 27.7%, respectively); while sexual trauma notes in the Southeast and North Atlantic regions primarily related to military sexual trauma only (71.7% and 63.4%, respectively).

**Figure 4a:** Types of sexual trauma concept documented in notes of female patients, by geographic region

For male patients, the majority of sexual trauma notes referenced military sexual trauma only (56.0%-70.2% across regions; Figure 4b) or multiple types of trauma (9.6%-21.6% across domains). Regardless of region, male patients’ sexual trauma notes rarely referenced non-military sexual trauma.

**Figure 4b:** Types of sexual trauma concept documented in notes of female patients, by geographic region
Discussion

Patient histories of sexual trauma have important implications for patient and health system outcomes, but documentation of this sensitive and personal information lacks standardization. If sexual trauma information is not recorded at all, sexual trauma survivors may have more difficulty accessing high quality, trauma-informed care. In addition, lack of provider awareness of trauma histories could inadvertently lead to poor care delivery and re-traumatization of patients.

We sought to examine regional variations in the extent and nature of documentation of sexual trauma experiences in the VHA’s EHR. While there was relatively small geographic variation in the types of notes used to document non-sexual trauma phenomena, documentation of sexual trauma histories varied across the major United States regions. In the Pacific states, we observed relatively greater proportions of primary care notes and relatively smaller percentages of mental health notes, compared to the other geographic regions. We also found more variation in the types of sexual trauma documented in Pacific states, compared to other United States regions, particularly for female patients. It may be the case that primary care providers in Pacific states have received more training in eliciting sexual trauma histories, or experience less hesitation in recording this information in the EHR.

Our finding of unique patterns of results in male versus female patients highlights some areas where sexual trauma may not be reported due to fear of stigma. Our finding of relatively few mental health notes for male patients in the Southeast region, compared to other United States regions, suggests there may be increased barriers to seeking mental health care or to disclosing sexual trauma in the course of mental health treatment for men in the Southeast. In the Southeast region, we also observed relatively small percentages of sexual trauma notes in primary care and relatively small percentages of non-military types of sexual trauma documented, compared to other United States regions. Importantly, the performance of the NLP pipeline was similar across geographic regions. While the current study was not designed to explain reasons for lack of documentation, our results suggest that cultural factors may be at play. For example, the Southeast is thought to be more culturally conservative than other United States regions, and this could explain relatively low rates of disclosure and documentation of sexual trauma in the clinical setting. Future research is warranted to elucidate how patients and providers navigate discussions of sexual trauma in diverse clinical settings in the Southeast and in other United States regions.

We note study limitations. First, this study did not systematically evaluate false negative captures of military sexual trauma. Additional work is evaluate to determine the performance of the NLP pipeline overall, and across diverse cultural contexts. Second, the study sample included small numbers of notes for male patients in each geographic region, which precluded multivariable analyses that might help to explain regional patterns. Specifically, the study did not examine patient, provider, or health system factors that may contribute to variations in sexual trauma documentation. It is possible that some of the regional variations observed in the current study could be due to patient differences in sexual trauma exposure and help-seeking or to patients requesting that their trauma not be documented. Despite limitations, this descriptive analysis illustrates the utility of NLP methods to detect systematic differences in the documentation of sensitive and personal information in the EHR. Our future work will consider provider characteristics (e.g. age, gender) in combination with patient factors to better understand the variations in sexual trauma documentation observed here.

Conclusions

While there is increasing public health attention on sexual harassment and assault, little is known about how sexual trauma histories are documented and managed in integrated health care systems. To fill this knowledge gap, this study examined the clinical context of sexual trauma documentation, and the nature of traumas reported. We found variations in documentation that are unlikely to be explained by differential exposures alone. Standardized mechanisms of collecting and documenting sexual trauma histories are needed to ensure Veterans’ access to high quality, trauma-informed care. Provider training designed to increase awareness of the cultural barriers and challenges of eliciting and documenting sexual trauma in clinical notes may be an important first step.

Abstract

Transition words add important information and are useful for increasing text comprehension for readers. Our goal is to automatically detect transition words in the medical domain. We introduce a new dataset for identifying transition words categorized into 16 different types with occurrences in adjacent sentence pairs in medical texts from English and Spanish Wikipedia (70K and 27K examples, respectively). We provide classification results using a feedforward neural network with word embedding features. Overall, we detect the need for a transition word with 78% accuracy in English and 84% in Spanish. For individual transition word categories, performance varies widely and is not related to either the number of training examples or the number of transition words in the category. The best accuracy in English was for Examplification words (82%) and in Spanish for Contrast words (96%).

Introduction

Even with the increased use of video and multi-media, text remains an important tool for patient education. However, creating well-written, understandable text is difficult and requires appropriate vocabulary use, correct grammar, and good writing style. One important component for well-written text is the use of transition words to help the reader follow the flow of ideas.

Transition words (also referred to as connectives) are words or phrases that connect linguistic units in a text. For example, single term transition words include “however, then, also, but, thus, so, therefore, and, still, furthermore, rather, or, meanwhile”, and multi-term examples include “even so, in conclusion, other than, as a result, in addition, in the meantime”. In this work, we will use the phrase “transition word” to refer to both single and multi-term transition words. Transition words are categorized according to their role, e.g., “initiating a topic, adversative, comparison, results”. Several different categorizations have been proposed depending on the subfield or goal. In this work, we use 16 categories paralleled across English and Spanish. Table 1 gives a list of the different category types and including examples in English.

Transitions words play an important role in text flow, especially for introducing a new topic for a reader to learn about. The words provide logical connections, help convey the structure of an argument, show information flow, improve coherence and, because of these, affect reader comprehension. Additionally, their use can be an indicator of text type. Several studies have found that their frequency differs depending on the type of text, such as news, conversation, fiction, or academic prose, with the latter containing the most transition words.

In this paper, we focus on the task of predicting transition words in medical text. In general, transition words can occur at the beginning of a sentence or embedded in a sentence to link clauses. We examine the former, i.e. predicting transition words at the beginning of a sentence. For example, given the pair of sentences

After the second year of growth hormone therapy, beneficial bone growth decreases. ____ GH therapy is not a satisfactory long term treatment.

we aim to predict that a transition word should occur at the beginning of the second sentence where the underscore is, specifically, a Results transition category word. In the text that this example was derived from, ‘therefore’ was used, however, other transition words from the same category could have also been used, e.g. ‘thus’ or ‘as a result’. We pose two variants of this prediction task. First, predict if any transition word should be used at the beginning of a sentence. Second, predict if a particular category of transition word should be used.

Previous work has shown how transition words signal relationships between and among the idea hierarchy in text using manual approaches. We view the problem as a supervised learning problem. We introduce a new dataset for transition word prediction in medical texts with data in two languages, English and Spanish. Using this dataset, we establish a baseline using a feedforward neural network trained using backpropogation and provide initial analyses on the difficulty of predicting the individual categories. We conclude with a number of possible future directions.
Historically, readability formulas were popular for guiding simplification and have been used to replace difficult terms. However, these formulas often require large parallel corpora, particularly in the medical domain, and are not helpful as writing guidelines. They also do not leverage modern resources that are currently available, e.g., large corpora with term frequencies to suggest terms with high familiarity as a replacement for difficult terms.

In recent years, computational approaches to improving the readability and understandability of health-related text have started to dominate. Several approaches have been tested as part of rule-based simplification algorithms. For example, when simplifying single words, term frequency (often measured by the Google Web Corpus) is used to replace

Table 1: The number of transition words for each of the 16 categories in English and Spanish along with example transition words in English.

Background

We focus on transition words in the context of text simplification of medical text. The goal of text simplification is to transform texts into simpler variants that are easier to understand by a broader audience without losing content. Our project’s goal is to accomplish this transformation by providing a text editor that guides writers in the simplification process. The tool is developed using data-driven algorithms that are trained on large sets of text and evaluated in user studies to show evidence-based outcomes. Since transition words play an important role in text comprehension, e.g., it has been shown that not understanding them limits text comprehension, making the transition between sentences explicit may assist readers with text comprehension since it helps clarify the logical connections in a text.

Simplifying text to increase reading comprehension for medical and healthcare information is an important task since it may help increase health literacy of patients and their family. Each year, chronic diseases afflict more people and treatments are becoming increasingly more complex, often requiring the need for participatory medicine where patients take an active role in their healthcare. However, the simplification task is difficult because of the complexity of the topics; the lack of large parallel corpora, particularly in the medical domain; and the need for simplifications that do not omit important information or introduce errors.

Historically, readability formulas were popular for guiding simplification and a large, if somewhat older, non-computational group of projects focused on applying readability formulas such as the Flesch-Kincaid grade level formula. The formulas are easily accessible since they are available in common text editing software (e.g., Microsoft Word), online (e.g., http://www.readabilityformulas.com), or through commercial avenues. This research trend is declining since using readability formulas has not been successful. Studies showing a positive effect of their use on reader comprehension are rare. Readability formulas do not identify what aspects of a text are difficult, do not provide writing alternatives, and use features that are rudimentary, e.g., equate word length with difficulty. These formulas do not incorporate current knowledge about the reading process, have limited scientific basis, and are not helpful as writing guidelines. They also do not leverage modern resources that are currently available, e.g., large corpora with term frequencies to suggest terms with high familiarity as a replacement for difficult terms.

In recent years, computational approaches to improving the readability and understandability of health-related text have started to dominate. Several approaches have been tested as part of rule-based simplification algorithms. For example, when simplifying single words, term frequency (often measured by the Google Web Corpus) is used to replace
terms with easier synonyms\(^1\). Several lexical simplification approaches have been suggested that use either hand-crafted rewrite rules\(^2\) or learned rules\(^3\).

In addition to rule-based simplification, there is also a health research stream using machine learning approaches. The algorithms vary from traditional machine learning to evaluate different features\(^4\) to newer deep learning neural networks trained on parallel corpora\(^5\). Evaluations vary, including descriptive comments on outcomes\(^6\), subjective evaluations by experts or laypersons\(^7\), and user studies measuring impact through reading comprehension tasks\(^8\).

While good progress has been made recently on text simplification algorithms, particularly with data-driven approaches, the output is still not good enough quality to be used in real-world applications. Instead, for our project, we focus on human assisted simplification by using automated approaches to help guide content creators in simplifying medical text. For transition words, we plan to identify possible locations in the text where transition words could be used and suggest the category of the transition word, along with a ranked set of candidate transition word options. This paper is the first step towards this goal by evaluating the performance of supervised approaches to the transition word prediction problem.

**Dataset creation**

We created two datasets for the transition word prediction task: one in English and one in Spanish. English and Spanish are the two most commonly spoken languages in the U.S. and examining the task in two languages allowed us to compare how prediction performance differs across languages. Both datasets were based on medical Wikipedia articles using a large list of transition words. Both the English and Spanish datasets are publicly available online along with the transition word lists used to create them.

**Corpora**

Since the frequency of transition words differs depending on the topic of the corpus, it is important to train on a representative corpus. We aim to simplify health educational text and created a corpus from general information on common diseases. We downloaded all articles in English and Spanish Wikipedia tagged with the category “Diseases and disorders”. The English corpus contains 636 articles for a total of 1.3M words. The Spanish corpus contained 493 articles for a total of 637K words. We used these two corpora to derive our transition word examples.

**English Dataset**

To generate our transition word prediction datasets, we first identified a list of transition words in English from different online educational and writing sites listing transition words. We combined information and created 16 categories of transition words containing 387 transition words. Table 1 gives an overview of the categories with the number of transition words in both languages in the category along with example English words for each category. The categories range in size from as large as 63 words (Time) to as small as 4 (Emphasis and Particularization).

To generate the classification examples, we considered every pair of adjacent sentences within the corpus. If the second sentence in a pair contained one of the transition words, then it was marked as a positive example, otherwise, it was marked as a negative example, i.e. when there was no a transition word between the two sentences. This results in a dataset of positive examples, \(<s, s, c>\), and negative examples, \(<s, s>\), where \(s\) is a sentence, \(s\) is the sentence following \(s\), and \(c\) is one of the connectors.

Table 2 shows the total number of examples extracted from the corpus. Overall, just under a quarter of the sentence pairs had connectors in them and were marked as positive. We then further processed the dataset to ensure that each sentence in each example contained at least one noun. This led to the removal of a few inappropriate pairs and a final set of more than 70K examples.

**Spanish Dataset**

Guided by the English transition word list, we had a native, expert Spanish speaker generate a comparable list for Spanish. In most cases, there was a corresponding phrase in Spanish, however, there were a few exceptions. In some cases, this resulted in a reduction of the number of words, for example when there was not a good equivalent in Spanish or if several English transition words corresponded to the same one in Spanish. In other cases, there were multiple equivalent Spanish words for a single English word. The final Spanish transition word list contained the same 16 categories with 423 transition words, slightly more than the English equivalent.

---

\(^1\) https://github.com/dkauchak/ConnectorDataset2019

525
Similar to the English dataset, we generated the dataset in Spanish by considering all consecutive sentences in our corpus and creating positive, i.e., those containing a transition word in the first position of the second sentence, and negative examples. Because there are fewer texts available in Spanish Wikipedia covering the same topics, our Spanish corpus is smaller as is the number of positive and negative examples. The sentence pairs were then further preprocessed in a similar manner as English to ensure each sentence contained at least one noun. The resulting dataset contains approximately 27K sentence pairs (Table 2).

### Predicting Transition Words

Given a pair of adjacent sentences, the goal is to predict whether a transition word should be used between the sentences, specifically, at the beginning of the second sentence. We view this problem as a supervised classification problem and use a feedforward neural network trained on examples of sentence pairs to make both the binary prediction of whether a transition word should be used or not, as well as a more fine-grained prediction for each of the categories of transition words.

#### Features

Transition words are used to indicate how information in the first sentence relates to information in the second sentence. To capture this, we extracted features based on the nouns in the two sentences, which are often the content-bearing words in the sentence. We selected the first five nouns in each of the sentences ($s_1$ and $s_2$) using the Stanford CoreNLP toolkit. For each noun, to generalize beyond its lexical form, we then extracted a 300-dimension word embedding. The embeddings were acquired from large publicly available sets using the FastText pre-trained model. We chose this particular embedding model since it is publicly available, it is based on a large corpus, and it is available in both English and Spanish.

Based on these word embeddings, we extracted 3,601 features:

- The 300-dimension word embedding for each noun (300 for each of the 5 nouns in $s_1$ and the 5 nouns in $s_2$ for a total of 3,000 features). If a sentence contained less than five nouns, those features were given an empty value.
- The average vector of the noun word embeddings per sentence (300 features for $s_1$ and 300 features for $s_2$).
- The cosine similarity between the average word embeddings of the sentence pairs (1 feature).

#### Classifier

Since the task is new, we chose to use a classifier with well-known properties and used a feedforward neural network. We used the R RSNNS package with backpropagation learning, a 0.1 learning rate, and 1 hidden layer. To try and avoid overfitting, we tuned the number of hidden nodes and the number of training iterations on a development set. To pick the number of hidden nodes, we trained the network using 5, 10, and 50 hidden nodes and picked the best performing model based on the accuracy on the development set. We picked the number of training iterations as the

point where the standard squared error started to increase on the development set. Parameter selection was done per task.

**Experiments**

We examined two prediction tasks in both English and Spanish. The first task is to predict whether any connector should be used (Any-vs-None), i.e. the binary prediction between those examples that have a connector and those that don’t. The second task is, for each connector type, to predict whether that connector type should occur or no connector should occur, i.e. 16 separate binary prediction tasks.

**Experimental Setup**

To create a more balanced dataset, for each task, we downsampled the number of negative examples so that the proportion of examples was 1/3rd positive and 2/3rds negative, resulting in a majority baseline of 66.67% by always predicting no connector. For the Any-vs-None task, this resulted in 16,285 positive and 32,570 negative examples for the English task and 7,140 positive and 14,280 negative examples for the Spanish task. For the per category prediction task, we did not classify any category that had fewer than 100 positive examples. Tables 4 and 5 show the number of examples for each of the categories in English and Spanish, respectively. There were five categories in English and five in Spanish with fewer than 100 examples that were ignored.

We used 10-fold cross validation for all experiments and randomly selected one fold of the training portion as the development set for parameter tuning during training. We evaluated the models using accuracy, precision, and recall.

**Any-vs-None Classification**

Table 3 shows the results for the Any-vs-None classification task. In both English and Spanish, the accuracy is well above the baseline of 66.67%. This is particularly encouraging given how many different transition words there are in this task: sentence pairs that benefit from transition words do have marked differences from those that do not use them. Across all metrics, performance was better in Spanish than in English, even though the Spanish dataset had fewer examples and the number of individual transition words was larger. In both languages, the precision and recall numbers were similar indicating that there wasn’t a strong bias of the classifier towards either the positive or negative class. Given how varied the transition words are and the

</tr>
</tbody>
</table>

Table 3: Any-vs-None classification results for the two languages.

**Per Category Classification**

Tables 4 and 5 show the results for individual transition categories for English and Spanish, respectively.

**Accuracy:** Overall, the accuracy for most categories is lower than for the All-vs-None results, with the exception of the Exemplification category in English and the Contrast and Oppositions categories in Spanish. In a few categories, the classifier was unable to perform better than the majority baseline (two in English and four in Spanish). The per category transition prediction problem is generally much more difficult than just predicting whether a transition word should be used or not.

To try and understand the cause of the variation in performance per category, we calculated a one-tailed Pearson correlation between accuracy and the number of examples, the number of transition words in a category, and the number of examples per transition category. There were no significant correlations found for accuracy either in English or Spanish:
The number of examples is not related to accuracy, i.e., having a larger data set (since we keep the ratio between positive and negative examples identical) did not benefit the classifier.

The number of possible transition words was not correlated to accuracy, i.e., having a wider variety of positive examples did not correlate with accuracy.

The average number of examples per transition category (since the number of transition words varies for the different categories) did not correlate with accuracy, i.e., having more examples per individual transition category did not matter.

**Precision**: Generally, precision per category was around 50-60% for many of the categories in both languages, though there are some exceptions, particularly the best performing categories in the two languages. The lowest precision was the same category in both English (35%) and Spanish (41%), *Similarity*.

Similar to accuracy, we calculated the correlation between precision and the same three dataset metrics for both English and Spanish. In this case, we found one significant positive correlation between precision and the number of different transitions words in a category ($r = 0.555, p = 0.038$) for the English data, i.e. precision was better for transition list categories with more words in them. However, taking Bonferroni correction for performing multiple statistical tests, the correlation would not be considered significant. There were no significant correlations for the Spanish data.

**Recall**: Overall, recall was the lowest of the three evaluation metrics. This hints at the complexity of the problem: identifying all of the occurrences of transition word usage is difficult. English, in particular, had several categories with very poor recall scores: *Similarity* (12%), *Cause* (19%), *Contract* (20%), *Time* (20%) and *Opposition* (19%). Similar to precision, the lowest performing category for recall in both languages was *Similarity*.

There were no significant correlations found for English or Spanish between recall and the number of examples, number of transitions words, or number of examples per transition word.

**Table 5**: Spanish transition words classification per category (Ex = Example count, A = Accuracy, P = Precision and R = Recall).
Discussion

In this paper, we have introduced the new problem of predicting transition word usage between adjacent sentence pairs. We created a dataset consisting of medical text examples divided into 16 categories of transition words in both English and Spanish, which is publicly available. Using this dataset, we examined two classification tasks: predicting whether any transition word should be used and predicting the category of the transition word. As a first approach, we used a feedforward neural network with word embedding features trained using backpropagation. We found strong results for the general transition word prediction task (English accuracy of 78% and Spanish of 84%, over a majority baseline of 67%), but more sporadic results for predicting individual connectors with accuracies as high as 97% and as low as 64%.

There are a number of possible directions for future research using this dataset. We viewed the prediction of each category as an independent binary prediction task. This allowed us to understand the difficulty of the transition word prediction task per category and to compare across English and Spanish. For practical applications, this problem should be viewed as a multi-class classification problem where the goal is to predict which of the 16 categories should be used, combined with the general prediction task (either as a separate step or as part of the multi-class prediction problem). Even given the category, there is still the question of which transition word to use. For use in a simplification tool, this then becomes a ranking problem among the possible transition words within a category.

As a first pass to aid analysis, we made some simplifying assumptions in the classification setup that should also be explored. First, we downsampled the negative examples to create a balanced dataset across all examples. For real application, this imbalance will have to be handled appropriately by the classifier. In particular, more evaluation needs to be done to examine how well the classifiers perform when applied to real texts where predictions must be made between every pair of sentences. Second, we ignored predicting on five of the transition categories with less than 100 examples. More data would likely fix this problem, particularly if the dataset were expanded beyond medical-related text.

The per category prediction results were low for many categories. Correlation analysis showed that this was the case regardless of the number of examples available or the number of transition words in the category. Recall, in particular, was generally low across all categories, suggesting that more work needs to be done to identify features that can better differentiate the broad usage of connector words. As an example, Exemplification had consistently strong results. We speculate that the performance was better than other categories because of the nature of the notion of exemplification which is perhaps less abstract than others (i.e., cause) and followed by more predictable and more local structure (an enumeration, rephrasing or repetition) than others. Other categories, however, may require more information for prediction.

Finally, in linguistics and education, the importance of transition words is well established and recognized, however, they have received little attention in the medical informatics and natural language processing communities and we believe they can be useful for a variety of tasks. For example, they can help with summarization by hinting at introductions, ordering, contrast and conclusions. For fact checking and information extraction tasks they can be used to identify and add structure to unstructured information sources. In general, transition words provide guidance about the flow of ideas and can be leveraged by many discourse-level tasks. We hope that the dataset, including the categorized list of transition words, along with the initial classification attempts helps motivate such uses.

A Potential Answer to the Alert Override Riddle: Using Patient Attributes to Predict False Positive Alerts

Timothy I. Kennell Jr., BS and James J. Cimino, MD
Informatics Institute, University of Alabama at Birmingham, Birmingham, AL

Abstract

Electronic health records (EHRs) use alerts to help prevent medical errors, yet clinicians override many of these alerts due to desensitization from constant exposure (alert fatigue). We hypothesize that a clinician might override an alert warning about the dangers of a treatment if the patient’s health is so poor that the treatment is worth the risk or if a patient’s health suggests the treatment is not needed. We used logistic regression with general estimating equations to determine if the Early Warning Score (EWS), a measurement used to predict critical care need, could be used to predict alert overrides. EWS was a significant predictor of overrides for three alerts. Although EWS could not predict overrides for all alert rules, these results suggest that EWS may be helpful for some alerts, but that additional EHR data will be needed for predicting override behavior to a useful degree.

Background and Significance

A hallmark of electronic health record (EHR) systems is the implementation of logic to issue automated alerts and reminders as a form clinical decision support (CDS). Many of these alerts provide clinicians two options: an override option and a non-override option (typically an order cancellation). While this type of CDS can provide useful information when relevant, the messages it provides (referred to in this paper as “alerts”) are often judged as false positives by the receiving clinicians, leading to high override percentages.1 One study showed that primary care physicians can receive up to 56 alerts per day just from an email notification system2 and several studies point to override percentages in the range of 49 – 96%.13,4 Excessive override rates are problematic because they disrupt workflow, reduce the clinician’s quality of life, and can produce “alert fatigue” that may result in “pseudo-false positive” alerts that are inappropriately overridden, to the possible detriment of the patient.5

Methods of reducing the alert volume and the override rate typically focus on improving alert logic to increase its specificity (that is, replace false positives with true negatives).1 Such approaches are complicated by the fact that clinicians do not always accurately report their reasons for overrides.6 Other approaches have included manual review of the literature to prioritize alerts,7 maintenance of a drug-drug interaction database containing alert priorities,8 and dashboard construction, allowing easier manual intervention.9 One study proposed an automated method for predicting overrides per clinician based on previous actions by the specific provider in question and suppressing such alerts going forward.10 Each of these methods is either time-consumptive or not patient-specific.

While alerts typically use basic criteria to determine whether an alert should fire, studies indicate that physicians regularly consider more than what the EHR is using.11 We presume that a significant number of alerts are overridden, not because of fatigue, disagreement with the alert logic, or general stubbornness, but because the clinician has some awareness of the patient’s particular situation that is not covered by the logic. Indeed, although an override of an alert is not the same as a false positive alert, studies have shown many alert overrides are appropriate.12 We suspect that information about the situation may be available in the EHR at the time of the alert and could be used to suppress alerts that are predicted to be overridden. To our knowledge, the use of just-in-time patient-specific data outside that used in the alert logic itself has not been studied. Despite the limited criteria used by alerts, the EHR is overflowing with additional information that might reflect a physician’s decision when overriding an alert. One such example might be a patient’s overall health status. For example, a clinician might ignore a reminder to administer an influenza vaccine if the patient is currently undergoing cardiopulmonary resuscitation. Such an overall health status of a patient is readily available in most EHRs called the Early Warning Score (EWS) (see Table 1 for details on the score calculation.). The EWS is an aggregate score calculated from a patient’s vital signs each time they are recorded and applies increasing values to a patient’s worsening vital signs in order to identify patients at risk of deteriorating.13,14 The score is used for both prognosis of disease and indication for intensive care admission.13

</tbody>
</table>

**Objective**

We reason that extenuating information present in the record, such as the EWS, could be used to suppress irrelevant alerts, even when the alert logic does not consider it. Furthermore, we hypothesize that clinicians override alerts, in part, because of something they know about the patient that is not represented in the alert logic. This paper describes a study of the correlation of patient characteristics *unrelated to specific alert logic that is nevertheless present in the EHR*, with the intent of using such correlations to suppress alerts that are likely to be overridden anyway, thus reducing their adverse effects. We report the application of the above approach with the use of a general measure of patient condition severity.

**Methods**

**Data Source**

All data used in the study came from the University of Alabama at Birmingham’s (UAB) University Hospital. Specifically, the information came from both the Cerner Millenium EHR and PowerInsight, a research copy of the EHR’s database. All data were acquired with IRB approval for data reuse with waiver of consent.

**Alerts**

Initially, we acquired all alerts events ever triggered in the EHR from the time of its implementation in 2010 to 2017. Events that resulted from alerts having no override option were removed from the set as they did not pertain to the objective of the study. The remaining alerts are listed in **Table 2** with a brief description to supplement the name of the alert. Despite the apparent duplication of some alerts, these function in different, nuanced capacities in UAB’s EHR.

**Table 2.** Descriptions of alerts used in the analysis of alert overrides and the early warning score.

Patient Data
In addition to acquiring all alerts for the seven-year period, all patient data recorded during that time period were retrieved. The information included the date of birth for age calculation along with basic demographic information for the analysis such as race and sex. Duplicate patients (based on possession of identical medical record numbers) in the data set were combined while retaining the most specific demographic information. For example, if two duplicate patient records had a race of “Unknown” and “African American”, the final aggregated patient record’s race was set to “African American”.

Early Warning Score
After combining the appropriate patient information with each alert event, the early warning score was added. Since the patient’s vitals, and by extension the EWS, are not guaranteed to be measured at the time an alert event triggers, a reasonable estimate was acquired using the following procedure. For each alert event, a time window consisting of 12 hours before and 2 hours after was created. Then, the EWS within that window and occurring closest to the time the alert triggered was taken to be the patient’s EWS at the time of the event.

Using 12 hours or less prior to the alert increased the likelihood that the EWS would be from the same hospital stay as the alert event and hence more likely to accurately reflect the patient’s current status. Likewise, searching two hours after the alert made it possible to detect EWSs occurring slightly after the alert that would more accurately reflect the patient’s status compared to an EWS taken ten hours prior to the alert. Any alert events without an EWS within the time window were excluded from analysis.

Statistical Analysis
In order to determine if a patient’s overall health status as indicated by the EWS was predictive of an alert’s override likelihood, a logistic regression model with general estimating equations (GEE) was employed. Logistic regression allows modeling of the binary outcome: override or non-override. While capable of modeling this type of outcome, logistic regression expects independence of each alert event. However, an alert can occur on the same patient, breaking the independence assumption of the model. The addition of GEE to the analysis corrected for this non-independence by estimating correlation between alert events.

Following de-identification of the data, the logistic regression model with GEE was performed using SAS 9.4. Each alert was tested in a separate GEE model in order to make interactions between a specific alert and the EWS levels more easily interpretable (i.e. allow negative versus positive correlations between EWS and an alert to be more recognizable). Patient demographics served as covariates in the model in order to account for any variation that might occur due to these categories. Additionally, the amount of time between the EWS measurement and the alert event might affect the accuracy of EWS and, as a result, the override likelihood. Therefore, both the time between the EWS and the alert along with a time / EWS interaction term were included. A conservative Type III analysis was used for each categorical variable. Finally, due to the multiple models being run simultaneously, a Bonferroni correction was applied to all p-values. As 46 models were run, an alpha value of 0.0011 (0.05 / 46) was considered to be significant for Type III analyses.

Results
The UAB EHR contains 52 alerts that offer physicians an override option (see Table 2). Over the seven-year period (starting at the launch of UAB’s EHR), these alert rules represent a total of 4,043,431 unique alert events with approximately 17.37% overridden on average. The events per alert rule range from 1 to 1,998,811 (see Figure 1). Even after excluding rules that occurred less than 1000 times, override percentages ranged from 0.02% or 100% (see Figure 1).

Additionally, the basic demographic information of the UAB patient population was retrieved for inclusion in the models. This information included patient sex, race, and age at the time of the alert. The breakdown of the patient population during the time that alert event data was pulled is shown in Table 3.

The appropriate patient demographic information was combined with each alert event. Then, each alert event was combined with a patient’s EWS closest to the event and occurring within 12 hrs. before the event or 2 hrs. after the
event (see Methods for details). Alert events without an EWS within this time window were excluded leaving a total of 46 alert rules spanning 443,019 events from the original 52 alert rules and 4,043,431 events.

These 46 alerts were then individually analyzed with logistic regression incorporating GEE. Due to limitations of the data for some alerts, 20 were unable to be analyzed for various reasons. The analysis removed eight alerts due to one of the variables having only one value (e.g. all alert events in the data set were overridden), and it removed twelve alerts for insufficient variation in one or more variables. The alerts events in the data with only one type of override status had either a low number of events in the combined data set, extreme override frequencies (high or low), or both.

The results of the remaining alerts are shown in Table 4. After using a Bonferroni correction ($\alpha = 0.05/46 = 0.0011$) to account for using multiple models (one per alert), EWS only predicts override frequency for three alerts: DRUGDRUG, DRUGDUP, and UAB_RULE184_CHESTAPALERT. For two of these alerts (DRUGDRUG and UAB_RULE184_CHESTAPALERT), the time term is also significant in addition to the separate EWS and time terms, suggesting that the time between the EWS measurement and alert event affects the utility of EWS in predicting an alert’s override. Additionally, the interaction term between time and EWS reached significance for a few of the alerts, including the DRUGDRUG and the UAB_RULE184_CHESTAPALERT. This information suggests that both the time between the alert event and the EWS measurement and the EWS itself combine to produce different likelihoods of an alert overrides.

These results can further be visualized in Figure 2. This representation depicts the override percentage of an alert at each EWS level. Although there is not a drastic increase or decrease in override percentage with increasing EWS for the three significant alerts, the amount of data analyzed allows detection of smaller effects. Additionally, as in the UAB_RULE184_CHESTAPALERT alert, the baseline override percentage is already high, and does slightly increase with increasing EWS.

Discussion

EHRs use alerts to warn providers of potential errors or provide suggestions on patient care. The large number of alert events that occur have potentially decreased their utility in certain instances and introduced other issues including alert fatigue. Although most EHRs give the provider a default list of override reasons, these do not always accurately reflect the reasoning behind the override decision. Additionally, appropriate overrides are typically the result of the clinician considering an aspect of the clinical context not considered by the alert logic. This study investigated the potential of using a patient’s health status (EWS) to predict an alert’s override. Presumably, clinicians might override minor workflow suggestions as a patient’s health status deteriorates and adhere to severe alerts (e.g. drug-renal alerts) more frequently as a patient’s EWS increases. Although overrides and false positive alerts are not identical, many alerts are appropriately overridden. Therefore, targeting override prediction is a good first step to removing potentially unnecessary alerts. In order to be as comprehensive as possible, all overridable alerts at UAB were analyzed; however, a patient’s health status might not affect a clinician’s decision for all alerts. For example, while the UAB_ADE8_METFORM_ACIDOSIS alert warning of a contraindicated prescription of metformin might cause a clinician to consider the severity of the patient’s condition, the
UAB_ADE1 HT WT_ALLERGY alert requiring patient allergy, height, and weight information be added to the record might not have the same effect.

Although EWS did not achieve significance for explaining overrides for many of the alerts, it did for three: drug-drug interaction (DRUGDRUG), drug duplicate orders (DRUGDUP), and a chest X-ray advisory (UAB_RULE184_CHESTAPALERT). Regarding the two drug alerts, a clinician might consider the medication more important for the deteriorating patient than the potential of an interaction. Indeed, a previous study showed that the two most common override reasons for drug-drug interaction alerts were ‘clinically irrelevant alert’ and ‘benefit assessed to be greater than the risk’, and this result is reflected in the UAB EHR as the most common override reasons for both the DRUGDRUG and DRUGDUP alert are ‘interaction noted, will take precautions’ and ‘essential therapy, will take precautions’. Similarly, the UAB_RULE184_CHESTAPALERT alert warns clinicians that a chest x-ray has already been performed on the patient within 3 days and suggests not ordering another one. A deteriorating patient would likely increase the likelihood of overriding such an alert as shown in the model results (see Figure 2).

It should be noted that the increase override percentage shown Figure 2 for these alerts is small and might not offer a threshold for EWS at which the alert completely loses utility. However, this result is likely due to the already high override percentage.

Table 4. Logistic Regression with GEE results for the EWS predictor and the EWS * Time interaction term.
Figure 1. The distribution of alert events in the UAB EHR broken down by override status. Alert rules were limited to those that provided clinicians an override option. The length of the bars indicates the log transformed number of the total alert events triggered by the alert rule on the y-axis. The two colors of the bar reflect the ratio of overridden to non-overridden alert events (alerts events that clinicians chose the alternative option to overriding) with the percentage of each alert rule’s overrides displayed to the right of the bar. Many of these alerts have override rates above 70% showing that the UAB institution has similar override rates to the 49 – 96% reported by other institutions.
Figure 2. The effect of EWS on the override frequency of the 26 alerts analyzed by logistic regression with GEE. Override frequency per alert per EWS level was calculated and plotted with an estimated line using simple linear regression. Each data point for a specific EWS and override frequency was duplicated to reflect the number of alert events and weight the information. Thus, the trend lines indicate whether an alert is more or less likely to be overridden with deteriorating patient status. The asterisks indicate alerts in which EWS is a significant predictor of alert overrides. Other alerts have some increase or decrease in override frequency with an increasing EWS suggesting that patient status might play a small part in their override likelihood.
Additionally, the interaction term between time and EWS reached significance for a few of the alerts. This result might be an indication of the accuracy of EWS at the time of the alert. Although the method of selecting the EWS was intended to choose the measurement most reflective of the patient’s status at the time of the alert event, this result might not have been achieved as closely as desired. Thus, the time between the alert event and the EWS measurement might cause EWS to differentially predict alert overrides.

However, EWS did not significantly correlate with the likelihood of an override for many of the alerts. Some of the reasons for this might be due to the fact that a patient’s health status simply does not factor into a physician’s decision to override the alert as discussed above. However, another reason might be that many of the alerts already have an override rate above 75% (see Figure 1) limiting the ability of the models to detect an effect. Additionally, it should be noted that medical alerts widely vary in the decision support they provide. Some simply suggest cost-saving measures as in the chest x-ray alert (UAB_RULE184_CHESTAPALERT). Others provide minor suggestions for patient care such as warning of false positives on a lab test (UAB_RULE232_CDIFF_TOXIN). Some provide critical care advice like the alert warning of a methotrexate prescription on a patient under a specified creatinine clearance (UAB_RULE209_METHOTREX_CRC). Given this variation, a single patient characteristic is unlikely to provide a strong predictor for the overrides of all alerts.

As some of the alerts did approach significance for EWS as a predictor, more covariates or additional predictors are needed to account for the variance in the models. For example, the UAB_ADE9_ANTIHISTELD_V, which warns about prescribing an anticholinergic or antihistamine medication to a patient over 65, might benefit from accounting for previously prescribed and tolerated medications. For other alerts, such as the UAB_RULE184_CHESTAPALERT, previous diagnoses or procedures might be effective at determining whether a clinician would override the alert. Newly recorded procedures might prompt a physician to order a patient X-ray in order to track the individual’s current status.

Alternatively, given there is a need to remove clinically unnecessary alerts, another more effective approach might be to implement a machine learning model to predict overrides. This methodology would incorporate multiple EHR variables along with complex interactions and might come closer to solving the immediate need of removing unnecessary alert events.

Conclusion

High rates of false positive alerts continue to plague clinicians despite decades of work to reduce them. We have explored a methodology for predicting such alerts based on patient data in the EHR available just prior to the time of the alert. The use of the EWS for this purpose may be one small step toward alert reduction. The EHR is replete with many other possible targets for the methodology we describe here, offering the potential for a giant leap forward in addressing this decades-old problem.

ABSTRACT
Sleep change is commonly reported in Alzheimer’s disease (AD) patients and their brain wave studies show decrease in dreaming and non-dreaming stages. Although sleep disturbance is generally considered as a consequence of AD, it might also be a risk factor of AD as new biological evidence shows. Leveraging the National Sleep Research Resource (NSRR), we built a unique cohort of 83 cases and 331 controls with clinical variables and electroencephalography (EEG) signals. Supervised tensor factorization method was applied for this temporal dataset to extract discriminative sleep patterns. Among the 30 patterns extracted, we identified 5 significant patterns (4 patterns for AD likely and 1 pattern for normal ones) and their visual patterns provide interesting linkage to sleep with repeated wakefulness, abnormal REM sleep, and insomnia. This study is preliminary but findings are interesting, which is a first step to provide quantifiable evidences to measure sleep as a risk factor of AD.

INTRODUCTION
Alzheimer’s disease (AD) has become a major public health concern because of its increasing prevalence, chronicity, caregiver burden, and high personal and financial costs of care. About 25% to 40% of AD patients suffer from disturbances of sleep, such as insomnia at night, rapid eye movement (REM) sleep behavior disorder, agitated behavior at sunset and excessive sleeping during the daytime [1]. In addition, sleep apnea syndrome is prevalent in AD patients [2], which is associated with APOE4 that is a well-known risk factor of AD [3]. Those sleep problems occur early on in the course of AD, consistent with the finding that brain regions involved in sleep are affected during the development of AD. This fact implies that these sleep problems can be a preclinical marker for the development of AD [4]. A quantitative tool to measure such a sleep disturbance is electroencephalography (EEG), which is one of the most popular brain signals that records brain’s spontaneous electrical activity on different regions of scalp over a period of time. This signal usually transforms to multiple waves according to frequency domain (e.g., Alpha, Theta, Delta). EEG can quantify sleep patterns. In the normal young adult, sleep consists of five cycle stages:

I. Stage 1 (5%): a period of transition from wakefulness (Alpha wave, 8-10.5 Hz) to light sleep (Theta wave, 4 - 8 Hz);
II. Stage 2 (50%): light sleep with Theta wave (4 - 8 Hz);
III. Stage 3 and Stage 4 (20%): slow-wave activity (SWA) or deep sleep with Delta wave (1 - 4 Hz);
IV. Stage 5 (25%): REM sleep with a fast desynchronized EEG containing Alpha (8 - 10.5 Hz), Beta (15 - 30 Hz), and Theta (4 - 8 Hz) waves [5].

With increasing age, sleep becomes “lighter” in that the percentage of Stage 1 increases and the percentage of Stage 3 and 4 decreases. Patients with AD show an increased number and duration of awakenings [6,7], consequently EEG recordings show that percentage of Stage 1 increases and percentage of Stage 2 and SWA (Stage 3 and 4) decreases more than normal aging does. Another interesting EEG pattern of AD is that the amount of REM sleep decreases and this change is mostly seen in later stages of AD [7]. Also, EEG slowing is observed prominently in REM sleep (other than in the awake EEG) [8,9]. These findings are driven by researchers who have been visually compared EEG between normal elderly and AD patients with their human naked eyes [9]. Unfortunately, this ad-hoc approach is not scalable to large samples and have difficulty in exploring a large combination of patterns associated with temporal changes on frequency bands and brain regions across sleep cycles [6]. Lack of quantifiable measurement can be another issue, which might lead to inconsistency in judgement. Therefore, a computational method that directly learns sleep patterns from observational data becomes more important in discovering meaningful and generalizable latent patterns of sleep EEG.

Dimensionality reduction is a widely-used method to discover such underlying latent space from high dimensional data. Particularly, linear models, such as principal component analysis, linear discriminant analysis, and nonnegative matrix factorization, represent the observed data as a weighted linear sum of latent dimensions and have been widely
applied in EEG analysis [10]. Nonnegative tensor factorization (NTF) is another powerful linear model, which decomposes high dimensional data (such as time-frequency representation of EEG from multiple samples) into linear sum of basis components (which are interpreted as patterns). NTF has been applied to several medical domains, such as phenotyping [11,12] from electronic medical records, temporal patterns from behavioral log [13], and event-related EEG [14–16]. To derive discriminative phenotypes or patterns with respect to certain clinical outcome of interest, an extension of NTF, so called supervised NTF, has been proposed and enforces the basis components to be discriminative to the clinical outcome of interest [12].

In this work, we aim to discover temporal patterns from sleep EEG to differentiate AD from the control (non-AD), using supervised NTF. Previous studies on discovering AD patients’ EEG patterns use only event-related EEG (not focused on sleep EEG, which capture very different characteristic of brain functionality). Also, they are unsupervised approach within AD populations (not supervised approach discriminating AD case and non-demented control) [17,18]. We focus on the sleep EEG and integrate the supervision term explicitly in our objective function to derive discriminative temporal patterns as computational phenotypes.

METHODS

We developed a computational framework to discover sleep EEG patterns that would be discriminative to AD. This framework consists of three steps: i) patient matching; ii) EEG transformation; and iii) tensor factorization (Figure 1).

**Figure 1.** Overview of computational framework to discover discriminative patterns from Sleep EEG. This framework consists of three steps: i) patient matching; ii) EEG transformation; and iii) tensor factorization. For each patient, the raw EEG signal was transformed into frequency-time representation using Fourier transform. The transformed EEG was in a matrix format. We stacked all the individual matrices from each patient into a 3-order tensor.

Datasets

We leveraged two datasets in NSRR [19][20], which contains large collections of de-identified clinical data elements and electrophysiological signals from over 10 NIH-funded sleep cohort studies. Clinical data elements include demographic information (e.g., age, gender, race), anthropometric parameters (e.g., body mass index, height), physiologic measurements (e.g., diastolic/systolic blood pressure, heart rate), medical history (e.g., atrial fibrillation, cancer, depression), medications (e.g., antidepressant, acetylcholinesterase inhibitors for AD) and sleep symptoms (e.g., excessive daytime sleepiness). Electrophysiological signals in the European Data Format (EDF) are the polysomnography recordings (overnight sleep), with various channels such as electroencephalogram (EEG) and electrocardiogram (ECG). The two datasets we used were the Sleep Heart Health Study (SHHS) [21] and MrOS Sleep Study (MrOS) [22][23][24], where SHHS contains a total of 5,804 adults aged 40 or older, and MrOS contains a total of 2,911 men aged 65 years or older.
Since these two datasets were not specifically collected to study the relationship between sleep and AD, we performed retrospective analyses as a secondary use of these two datasets. To determine whether each patient has onset of AD we utilized a clinical variable on a specific medication, acetylcholinesterase inhibitors. Acetylcholinesterase inhibitors is widely used drug for AD. SHHS has a clinical variable asking if the patient has taken acetylcholinesterase inhibitors for AD within two weeks of the study visit. MrOS has three clinical data elements related to AD or AD medication use: (1) Has a doctor or other health care provider ever told you that you had dementia or AD? (2) Are you currently being treated for dementia or AD by a doctor? and (3) AD medication use.

Cohort Selection using Propensity Score Matching
Among 1,959 (MrOS) and 1,893 (SHHS) patients with age > 65, we selected 331 controls normal (CN, non-AD) that match with 83 case (AD) with around 4:1 ratio in terms of potential confounding risk factors to AD. Due to complex nature of AD’s neurodegeneration, many factors contribute to the disease. In order to focus on the relationship of AD and EEG signals, we need to reduce effects of other confounding variables that affect the incidence of AD, such as demographic background (e.g., age, gender, and race) and potential risk factors (e.g., depression, hypertension, diabetes, cardiovascular disease, stroke). We utilized a statistical matching model called propensity score matching (PSM) [25], which matches estimators (i.e., confounders such as depression and hypertension) so that the distribution of EEG signals is independent of the outcome (i.e., AD), conditioned on the confounders [26]. The PSM algorithm finds the matched controls to the cases using two steps: i) computing propensity scores and ii) finding similar controls to each case using propensity scores. First, we obtained propensity scores as probability of AD computed from logistic regression, in which AD incidence is the binary label and confounders are predictors. The propensity scores (PSM) algorithm finds the best combination of n and r that leads to the biggest sample size within a tolerable bias.

EEG Frequency Bands Representation
We derived time-frequency representation from the raw EEG signals. EEG signals have various behaviors in different frequency bands, and the characteristics of different frequency bands have been reported in previous work [27–29]. For example, previous studies demonstrated that spectral power is an important feature for sleep stage research [30], such as: the power of lower frequencies of EEG becomes stronger with the increasing depth of sleep; the EEG signal of Stage 1 has more power between 2-7 Hz; Stage 2 can be characterized by the presence of sleep spindles band (12-15 Hz), and SWA is defined when there are low frequency (less than 2 Hz) waves [31].

We first divided the entire sleep EEG records into non-overlap 30-second epochs during 8 hours (i.e., 8 hours / 30 seconds = 960 epochs). EEG signals after the 8 hours were truncated. After separating EEG time dimension into 960 epochs, we separated the EEG values into several waves depending on its frequency bandwidths using power spectral analysis. The most standard frequency bands include Delta wave, Theta wave, Alpha wave (Table 1). Fast Fourier transform (FFT) is a direct and commonly used spectral estimation method for the EEG frequency analysis [28]. The discrete Fourier transform (DFT) is an efficient numerical algorithm to perform Fourier transform in many practical applications. Let us denote N is the number of EEG values in one epoch and $x_n$ as a single EEG value in one epoch. The DFT of a sequence of N values $\{x_n\} := x_0, x_1, \ldots, x_{N-1}$ is defined as:

$$X_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n \cdot e^{-i(2\pi nk/N)}$$

where $\{X_k\} = X_0, X_1, \ldots, X_{N-1}$ is a transformed sequence with complex numbers of $\{x_n\}$ for $k = 0, \ldots, N - 1$, and $e$ is the Euler’s number. The power spectrum is then obtained with

$$P_k = \|X_k\|^2.$$

The $P_k$ values for $k = 0, \ldots, N - 1$ are then separated according to the 12 frequency bands (Table 1). For example, $P_k$ values lying in every $\frac{1}{3}$ to $\frac{1}{2}$ seconds (4 - 8 Hz) correspond to Theta wave. For each frequency band, we summed all the $P_k$ values and used it as an amplitude value. So, in total 12 frequency amplitude values were generated per every epoch.
Table 1. Extracted EEG frequency bands.

Discovering Biomarkers using Tensor Factorization

Using the EEG time-frequency representation of each patient, we constructed an observed tensor and extracted discriminative temporal patterns by applying supervised NTF to the observed tensor.

Construct Tensor. To derive patterns from time-frequency representation of EEG, we represented each patient’s signal amplitude as a matrix (12 frequency bands × 960 time slots), see Figure 2. We applied log2-transform to the amplitude to make the distribution follow normal distributions and facilitate stable tensor factorization. We stacked those matrices into a third-order tensor $O$ with a shape of (83 AD + 331 CN) patients × 12 frequency bands × 960 time slots (Tensor is a generalization of matrix. Order of a tensor is the number of dimensions. A first-order tensor is a vector, a second-order tensor is a matrix, and tensors of order three or higher are called high-order tensors).

Figure 2. EEG time-frequency representation of all patients forms a tensor. AD= Alzheimer’s disease, CN= Control.

Regularized Nonnegative Tensor Factorization. The most widely used tensor decomposition is the CP method [32]. A third-order tensor $O$ with shape of $I \times J \times K$ is rank-one if it is an outer product of three vectors $a, b, c$, i.e., $O = a \circ b \circ c$ where $\circ$ means the vector outer product. $O_{ijk}$, the element at $(i, j, k)$ in the tensor $O$, is computed as product of elements in the vector, i.e., $O_{ijk} = a_i b_j c_k$. Tensor factorization (TF) is a dimensionality reduction approach that represents the original tensor as latent dimensions. The CP model approximates the original observed tensor $O$ as a linear combination of rank-one tensors [32]; that is, a third-order tensor $O$ is decomposed as minimizing difference between observed tensor and approximated tensor as

$$L = ||O - \sum_{r=1}^{R} a_r \circ b_r \circ c_r||^2$$

where a positive integer $R$ is the rank, $a_r, b_r, c_r$ are $r$-th column vectors in matrix $A, B, C$ with shape of $I \times R, J \times R, K \times R$, respectively. Here, $A, B, C$ are called as factor matrices. When tensor $O$ contains non-negative data (such as amplitude, intensity or counts), we set non-negative constraints $A, B, C \geq 0$ for interpretability of latent dimensions, which is so called nonnegative tensor factorization (NTF). Since our objective is to derive
discriminative patterns, we used supervised version of TF, which adds a supervised regularizer that encourages the 
patterns to be separated according to AD vs CN [12]. The supervised TF adds logistic regression regularizer as

$$L - \mu \cdot \log P(A, y|\theta) = L - \mu \cdot \frac{1}{1 + \exp(-y \cdot \theta A)}$$

where $\mu$ is a weight parameter to balance the tensor error and the loss on regularizer, $\theta$ is parameter for logistic 
regression, and $y$ is label ($y = 1$ if AD; -1 if CN). To further enhance the interpretability via compact patterns, we 
also added $l_1$-norm regularizer to the factor matrix. The $l_1$ regularizer shrinks the less important coefficients to zero, 
as improving interpretability of model:

$$L + \lambda \cdot (||A||_1 + ||B||_1 + ||C||_1)$$

where $\lambda$ is a weight parameter to balance the tensor error and the $l_1$-norm loss. Therefore, our final objective function 
is adding both of regularizers:

$$L - \mu \cdot \log P(A, y|\theta) + \lambda \cdot (||A||_1 + ||B||_1 + ||C||_1).$$

**Discover Patterns using NTF.** We applied this regularized NTF to our EEG dataset. We let factor matrix $A$, $B$, and 
$C$ represent patients (AD + CN), frequency bands, and time slots, respectively. The $R$ latent dimensions in factor 
matrices $A$, $B$, and $C$ represent temporal patterns of EEG. Each EEG pattern consists of a set of frequency bands and 
a set of time slots. Individual frequency band or time slot contributes to the pattern with different extent of 
membership, and the amount of contribution is stored in columns of $B$ and $C$. Likewise, individual patients have 
characteristics of the $R$ patterns with different extent of membership. That is, the column vector of $B$ defines how 
much the frequency bands are involved in each pattern, and the column vector of $C$ defines how much the time slots 
are involved in each pattern. The row vector of $A$ defines how much patients participate (or have membership) in the 
characteristic of each pattern.

**EXPERIMENTS AND RESULTS**

**Propensity Score Matching**

To create our training cohort for regularized NTF, we obtained controls for the cases from our data sources (MrOS, 
SHHS). We used propensity score matching to reduce the effect of age, race, common risk factors (hypertension, 
depression, stroke, diabetes) while trying to keep as much cases as possible. After matching, we lost a few cases in 
order to reduce the bias. We ended up with 83 cases and 331 controls at a roughly 1:4 ratio. Tables 2a and 2b 
summarize the statistics on features before and after the matching.

Discovering Biomarker using Tensor Factorization

We implemented the regularized NTF using Pytorch 11.4 with adaptive momentum estimation (ADAM) for optimization. We set the maximum number of iterations as 1,000. The running time was less than 15 secs with 3 parallel GPUs. We added dropout to logistic regression coefficients for robustness. After extensive parameter tuning, we set dropout rate=0.5, R=30, \( \mu = 0.1 \), and \( \lambda = 0.05 \).

Evaluating NTF methods. We computed discriminative power, sparsity, overlap of patterns that are derived from the NTF methods. We measured the discrimination by the area under the receiver operating characteristic curve (AUC) to classify AD and control. We measured compactness by sparsity and overlap of the temporal patterns. High sparsity means a few frequency bands or time period dominantly characterize each pattern whereas the other bands or time period are negligible, making interpretation of the patterns easy. The sparsity was computed as an averaged Gini index of involvement values in each pattern (i.e., the column vectors of \( B \) and \( C \)) [33]. The overlap measures the degree of overlapping between all pattern pairs [12]. Patterns with less overlap are more distinctly identified. The overlap is computed as an averaged cosine similarity between all pair of column vectors of \( B \) and \( C \). We also computed mean squared error (MSE) to evaluate how closely the derived patterns reflect the observed original data. We compared mean and standard deviation after ten repeated trials. We compared the discriminative power and compactness with different settings of regularizers:

- NTF: Basic NTF model without any regularizers (\( \mu = 0, \lambda = 0 \))
- NTF + logit: NTF with supervised regularizer based on logistic regression likelihood (\( \mu = 0.1, \lambda = 0 \))
- NTF +\( l_1\)norm: NTF with \( l_1\)norm (\( \mu = 0, \lambda = 0.05 \))
- NTF +\( l_1\)norm+logit: NTF with \( l_1\)norm and logistic regression likelihood (\( \mu = 0.1, \lambda = 0.05 \))

Table 3 summarizes interested measurements. We found that NTF with \( l_1\)norm and supervised term outperformed other baselines in terms of discriminative power and compactness. The NTF +\( l_1\)norm+logit showed the highest AUC, sparsity, and lowest overlap (Table 3). The \( l_1\)norm regularizer improved compactness (i.e., increased sparsity and decreased overlap). The supervised regularizer also improved discriminative power (i.e., increased AUC).

Evaluating Individual Patterns. We presented patterns that an NTF +\( l_1\)norm+logit model derives (with AUC=0.6981). After deriving \( R=30 \) patterns, we learned a logistic regression model using the \( R=30 \) patterns as predictors and selected patterns that separate AD and CN with statistical significance (Table 4: Coefficient). Five
Table 3. Discrimination and compactness comparison. We computed average and standard deviation after 10 repeated trials. The number of phenotypes $R = 30$.

Patterns showing $p$-value < 0.05 were: Pattern 2 for CN and Patterns 4, 18, 28, and 30 for AD. That is, Patterns 4, 18, 28, and 30 were positively related to AD whereas Pattern 2 was negatively related to AD. To verify this relationship, we reported the number of patients from AD and CN according to the extent of involving to each pattern, the membership values (Table 4: Membership distribution). We found that in AD patterns (4, 18, 28, and 30) the ratio of AD patients to CN increases as the membership value increases. In contrast, in CN pattern 2 the ratio of AD patients to CN decreases as the membership value increases. These findings are consistent with the logistic regression results in which AD patients are more likely to have larger values on the Patterns 4, 18, 28, and 30; and to have smaller values on the Pattern 2. Note that we initially made cohort with ratio of AD:CN=1:4, thus the number of CN was always larger than the number of AD across all membership values.

We visualized the five representative patterns (Table 4: Visualization). We represented each pattern using heatmap, according to the membership values of frequency bands or time slots. Frequency bands or time slots that dominantly characterize the pattern showed high values (bright yellow), whereas frequency bands or time slots that are less involved in the pattern showed low values (dark purple). Slow oscillation, slow wave activity, and spindle were overlapped with Delta and Sigma waves, so we denoted them separately where each band belongs to.

Patterns can be interpreted in details as follows:

- **Pattern 2 - Healthy normal sleep.** Pattern 2 was more prevalent to non-AD group. Pattern 2 forms a slow oscillation, slow wave activity and spindle, which none of AD EEG patterns have. Pattern 2 is consistent with the existing known fact that AD patient rarely forms spindle in Sigma wave (12 - 15 Hz) [34].

- **Pattern 4 and 18 – Abnormal REM sleep.** Pattern 4 refers to Delta and Theta wave (0.5 Hz - 8 Hz) with slow oscillation and slow wave activity and also Gamma wave (30 Hz -). This activity occurs during at the beginning and the end of sleep. Similarly, Pattern 18 refers to Theta wave (4 - 8 Hz) with Gamma wave (30 Hz -) during the middle of sleep (4 - 7 hour). Because Gamma wave are usually seen during REM sleep, we hypothesized that this combination of slow wave and high frequency wave is from repeated REM sleep stage.

- **Pattern 28 - drowsy sleep.** Pattern 28 was focused on Theta wave 4-8 Hz and Alpha 8-10.5 Hz waves several times throughout the 8 hours of sleep. This pattern is consistent with typical AD patient’s sleep pattern. It is known that AD patients usually wake up several times during nighttime [37]. As a result, the percentage of wakefulness and Stage 1 increases, which refer to the transition of the brain from Alpha waves (8-10.5 Hz) to Theta waves (4-8 Hz).

- **Pattern 30 - Insomnia.** Pattern 30 has very strong signals on Beta and Gamma waves (15 Hz -) during the first one hour and 5 - 8 hour of sleep. This sleep EEG pattern is accordant with that of insomnia patients, in which Beta and Gamma activity usually increase [38]. Insomnia is one of common comorbidities of AD patients [1].
Table 4. Summary of representative five patterns. Logistic regression coefficient and p-value to classify AD from CN. Membership values distribution of AD and CN, and visualization of each pattern. SO= slow oscillation, SWA=slow wave activity. Range of membership values varies according to pattern. SO, SWA, and spindle were presented separately due to overlap.

LIMITATION AND CONCLUSION
Data collected in the National Sleep Research Resource (NSRR) was meant for study the impact of sleep disorders on important health outcomes. Although many clinical variables have been collected, they are mostly focused on sleep but not specific to the AD population. Based on the populational AD occurrence rate (at different ages), we believe there are more eligible patients for the study but it is hard to confirm. So, we end up with a relatively small population but results are still very interesting as we identified several distinctive patterns that are significantly
associated with AD. These results still need further verification and biological explanation. Another limitation is related to the onset time of AD.

In this study, we aimed to derive sleep patterns of AD patients using EEG signals. From the National Sleep Research Resource, we built a unique cohort of 83 cases and 331 controls with clinical variables and EEG signals. We used a regularized nonnegative tensor factorization that can derive discriminative patterns. Among the 30 patterns extracted, we identified five significant patterns with \( p < 0.05 \): health normal sleep with spindle; abnormal REM sleep; drowsy sleep with repeated wakefulness; and insomnia. This study is preliminary but finding are interesting, which is a first step to provide quantifiable evidences to measure sleep as a risk factor of AD.

HarborBot: A Chatbot for Social Needs Screening

Rafal Kocielnik¹, Elena Agapie¹, Alexander Argyle¹, Dennis T. Hsieh², Kabir Yadav², Breena Taira², Gary Hsieh¹
¹University of Washington, WA; ²UCLA Medical Center, CA

Abstract

Accessing patients’ social needs is a critical challenge at emergency departments (EDs). However, most EDs do not have extra staff to administer screeners, and without personnel administration, response rates are low especially for low health literacy patients. To facilitate engagement with such low health literacy patients, we designed a chatbot - HarborBot for social needs screening. Through a study with 30 participants, where participants took a social needs screener both via a traditional survey platform and HarborBot, we found that the two platforms resulted in comparable data (equivalent in 87% of the responses). We also found that while the high health literate participants preferred the traditional survey platform because of efficiency (allowing participants to proceed at their own pace), the low health literate participants preferred HarborBot as it was more engaging, personal, and more understandable. We conclude with a discussion on the design implications for chatbots for social needs screening.

Introduction

Although designed for medical emergencies, emergency departments (EDs) have become a common place where patients seek help for various problems. EDs thus care for patients who present for not only heart attacks and strokes, but also a variety of social ills, such as homelessness, poverty, and hunger. These social concerns disproportionately affect the poor and limit their access to healthcare. Left unaddressed, social determinants drive up cost and utilization, and are a fundamental source of persistent health disparities.

However, despite the growing body of evidence that addressing social determinants improves health outcomes, assessing patients’ social needs remains a critical challenge. Most EDs currently do not screen for social needs and do not have extra staff to administer screeners without interrupting clinical workflow. Without personnel administration (such as research assistant, nurse, etc.), response rates for both paper and electronic surveys are low. This is compounded by the fact that only 12% of Americans have proficient health literacy.

Chatbots offer multiple potential benefits for social needs screening. Chatbots are systems designed to engage with users through natural language, mimicking a human-to-human interaction. Popular examples of chatbots include Apple’s Siri, Google’s Now, and Microsoft’s Cortana. Extended to the context of social needs assessment chatbot can support self-administering of social needs screeners to minimize personnel cost. In contrast to current form-based survey, a conversational approach would be more “chat” like, potentially offering a sense of familiarity similar to mobile text messaging. By creating a sense of interacting with another person, the chatbots may also increase participation engagement. Furthermore, offering text-to-speech output can also facilitate comprehension.

In this work, we present HarborBot, a chatbot for administering social needs screeners. HarborBot’s persona is designed to be professional, trustworthy, and supportive. It uses a chat-like interface to ask the social needs screener, and allows survey takers to ask for clarifications as if they are interacting with a survey administrator. To study its use, we recruited 30 participants, which includes both high and low health literacy individuals, with both ED and non-ED patients. Through a within-subjects study design, participants were asked to take the survey twice, once via HarborBot, and once via an existing survey platform, SurveyGizmo (order randomized).

Our finding suggests that there is a clear divide in preference between the high health literate (HL) and low health literate (LL) participants. Almost all HL participants preferred taking the survey via SurveyGizmo, whereas the LL participants preferred HarborBot. Post-study interviews reveal that HL individuals consider conversational approach to be too slow without allowing them to take the survey at their own pace. On the other hand, LH participants appreciated the audio output of the HarborBot, and thought the conversational design was much more engaging and personal.

Our work offers numerous insights on the role of conversation-based approach for surveys, and advance our understanding of how to more effectively screen for social needs for both high and low health literacy patients.
Related Work

With the growing interests in clinical screening, research has examined the use of technology-based solutions to support the self-administering of surveys, or Computer-Assisted Self-Interviewing (CASI)\(^2\). CASI include the use of online survey platforms, mobile apps, and electronic kiosks. These self-administered solutions may help maximize scalability and speed of data collection while reducing cost. Compared to face-to-face interviewing, self-administered solutions can also reduce social desirability bias, and limit the under-response in sensitive issues\(^2\). Furthermore, technology-based solutions led to fewer item missing responses, with the same response rates, compared to pen and paper self-administered questionnaires (PAPI)\(^4\).

A variation of CASI is Audio Computer Assisted Self-Interviewing (ACASI). The ACASI system allows users to listen to pre-recorded or text-to-speech audios of questions as if they were being asked by experimenters. This is especially valuable for supporting the understandability among low literacy participants\(^5\). The use of ACASI also reduces social desirability bias, making it an effective format to collect sensitive information\(^6\). This is valuable when assessing social needs in the diverse ED population. One drawback is that ACASI systems take longer to interact with\(^7\).

Despite these advantages of existing technology-based solutions, face-to-face is still better when it comes to response rates (in one study, 92.8% face-to-face response rate compared to 52.2% web-survey response rate)\(^8\). These differences, also in ED context\(^9\), have been linked to the motivating impact of interpersonal interactions, but reproducing such effects via technology is still a challenge. Additionally, non face-to-face surveys often bias against nonwhites\(^10\), low income patients, homeless or those that are disenfranchised with mental health and/or substance use\(^9\).

The Potential Role of Chatbots in Survey Screening. The idea of using an interactive system to collect and deliver health-related information has been studied primarily via so called embodied conversational agents (ECA)\(^11\). ECAs allow people to interact with physical or graphical agents that embody a person in appearance, behavior, and dialect. Mimicking a human-like interaction, ECAs are able to improve engagement and trustworthiness\(^12\). They are also perceived by patients with varying literacy levels as acceptable and easy to use\(^13\). However, their potential for screening is less well studied. Only a few research systems have been prototyped to explore patients interviewing\(^14\), and the actual use of these systems is quite limited, as the cost of development these human-like embodiments is high.

One potential lighter-weight alternative to ECA are chatbots which are composed of six key features\(^15\). First is the concept of thread as app, where the app-centric homescreen is replaced by a threaded conversation with streams of messages and notifications. Much like the interaction one has with another through chat messages. Second is history awareness, where the bot keeps a log of past interactions with users in the thread. Third is an enhanced user interface (UI), where the interaction need not be limited to plain text, but can also include images, audio output, structured messages. Fourth is limited natural language processing (NLP), which is to prevent breakdowns due to technology limitations. Still, chatbots try to mimic conversation with a human partner, e.g., by using “is typing” indicators, dynamic utterances and persona-driven emotional responses. Fifth is message self-consistency, where the intent of each message is clear and stands on its own. Finally, use of guided conversations to prevent users from getting lost.

Like ECAs, chatbots have multiple features that can be ideal for a low literacy population. For example, the audio output can facilitate understandability; the conversation-like interactions can foster a sense of interacting with another person, making the interaction more personal and engaging. But chatbots also differ from ECA in a couple of critical ways. One is that chatbots do not require a graphical or physical embodiment of the agent. This minimizes the cost of development and offers a more scalable solution. People can interact with chatbots even through their mobile devices. Another key difference is that chatbot mimic text messaging. Demographic surveys have shown that people with lower SES (more likely to have lower health literacy and higher social needs) are increasingly reliant on mobile text messages to communicate\(^16\). The chat-like interface may be more welcoming and intuitive for those users.

Chatbot based surveys were shown to increase user engagement and produce higher quality responses\(^17\). Such effects, however, have only been demonstrated with low-stakes demographics and marketing online surveys, and with general population. It is unclear if and how such benefits could be translated to clinical setting and low literacy population. Furthermore, low literacy in ER poses unique challenges in term of understandability and comfort with sharing information. Finally, prior work has provided very little in terms of linking the particular chatbot design aspects to their effect on the users, which limits its value for informing future design decisions. Our work aims to fill these gaps.
We designed and implemented a custom chatbot called HarborBot to test a conversational approach to surveys. HarborBot interacted with users through chat and voice. It communicates via chat messages, that it can also read out, as if it is speaking. Users interacted with the system primarily through buttons (for structured responses) and text (for text-based questions). HarborBot is implemented as a webapp and we had our participants interact with it on tablets.

**Design Process.** To create HarborBot we followed an iterative design process in which a team of 2 senior HCI researchers and 6 design students followed three general design phases: 1) Requirements gathering - the team consulted 3 ED practitioners, who are also co-authors on the paper, and existing literature related to patient experience in ER, 2) Design exploration - the team explored various low-fidelity prototypes and gathered feedback on them from ED practitioners and via small scale usability tests, 3) Refinement - the most promising prototype was developed further and refined with positive elements from other prototypes. This process resulted in the final HarborBot system.

**User Interface.** We used BotUI - a Javascript framework to build conversational UIs. Messages to and from HarborBot appear in standard elliptic chat bubbles with users messages distinguished from the bot’s by different colors. Prior to the appearance of messages from HarborBot, animated ellipses are shown in the chat bubble with a delay to denote that the bot is typing (Fig 1 f), akin to that of iMessage or similar interfaces.

BotUI allows for the creation of different question types, which we used to cover the types of questions asked by the screener. Each message from BotUI would be one of these types: skip, yes/no, input, options, or many options. Skip (see Fig 1 c) was a unique type that would move onto the next message of HarbotBot’s script without user responding. Yes/no (Fig 1 A), and options (Fig 1 B) use the standard buttons offered by BotUI. For questions involving multiple possible answers (i.e., checkboxes), we used a vertically stacked list of options that allowed users to choose multiple options before submitting (Fig 1 D). Free response (Fig 1 C) required a text field and device’s keyboard to respond.

**Persona.** There were several personality considerations we made in the design of HarborBot. Most importantly we emphasized striking a balance between a serious and friendly tone. If HarborBot was too friendly, users may feel the conversation is not being taken seriously. If too serious, users will lose the feeling of comfort we want them to have in answering personal questions. We also intentionally avoided any use of humor seeing as it would be inappropriate in the context. In addition, given the stressful nature of patients’ experiences in EDs, we sought to make HarborBot empathetic. However, we tried to do so without pitying the user or being condescending in any way. To accomplish this, HarborBot used occasional confirmatory phrases, such as: “Okay, I’m getting a better idea of where you are at.”, “Got it”, and assurances, such as: “The next questions are about your personal safety and may be tough to answer.”

The voice of HarborBot was an important part of the interaction with the user. By default, HarborBot used a female

---

1BotUI - https://botui.org/
voice taken from the Microsoft’s Bing Voices\(^2\). Users could adjust the volume of the voice or mute it entirely for privacy reasons or personal preference.

**Dialogue-Based Interactions.** We employed thread as app principle to support survey-taking. Survey questions and user replies were presented as streams of messages in threaded conversation akin to chat messaging. We allowed users to skip and ask for clarification of the questions. Each question posed by HarborBot offered a couple of utility options using round buttons next to the answer area. The Skip button (Fig 1 c) allowed the users to skip questions that felt uncomfortable or they couldn’t answer. After skipping, HarborBot would proceed on with the script. We supported rephrasing the question to offer its simplified version for low literacy individuals (Fig 1 b). We used Readable to make sure our rephrased versions were at most at a fifth grade reading level. Selecting this option is akin to saying “I didn’t quite understand that.”, which would make HarborBot re-ask the question using the simplified phrasing.

Additionally, we implemented an edit button (Fig 1 a) next to each past answer in case user needed to change it. Selecting this option would make HarborBot ask the corresponding question again and allow the user to provide a new answer. This is akin to users saying to the bot “Can I change my response to that question?”

Occasionally, HarborBot would respond with conversational remarks. These utterances were essential to developing Harbor’s personality, and engaging users in a conversation. Some of these interactions are dynamic based on a rule-based approach. For instance, if a user indicated they did not have a steady place to live, HarborBot would not ask the remaining housing questions. If the user response indicated a negative social situation, HarborBot would acknowledge it with a sympathetic affirmation, such as “That must be stressful, I’m sorry to hear that.”

**Method: Study**

We conducted a within-subjects study with 30 participants to compare the experience of answering a social needs survey using two different platforms: HarborBot (Chatbot) and a more traditional interface for taking surveys - Surveygizmo (Survey). We recruited participants with high and low health literacy at two study sites. We expected the Chatbot interface will be 1) more engaging, 2) more understandable, and 3) more comfortable to share information with, while 4) preserving response quality. We also expected these effects to be pronounced with low literacy users.

**Study Procedure.** Users interacted with both survey interfaces using a tablet’s web browser. After interacting with one interface, participants reported their perceptions and experience. They then repeated the same procedure for the second interface. We randomized the order of interaction. After completing both, we conducted an interview.

**Social Needs Survey.** In both platforms users answered the social needs survey developed by the Los Angeles County Health Agency (LACHA)\(^18\). This survey comes from over two years of work from the committee on the Social and Behavioral Determinants of Health, with members from the Departments of Health Services, Mental Health, and Public Health. The survey asks 36 questions related to demographics, financial situation, employment, education, housing, food, and utilities as well as questions related to physical safety, access to care, and legal needs. A number of questions can be considered sensitive, such as: “Have you ever been pressured or forced to have sex?”, “Are you scared of being hurt by your house?”, “Did you skip medications in the last year to save money?”

**Measures.** Participants evaluated both survey platforms in terms of workload (NASA TLX survey\(^19\)), engagement in the task (questions adapted from O’Brian’s engagement survey\(^20\), e.g., “I was really drawn into answering questions.”, “This experience of answering questions was fun.”, “I was absorbed in answering questions.”), understandability of content (“I understood the questions that were asked of me.”), and willingness to share information (“I was comfortable answering the questions.”). These measures have been commonly used in prior studies of chatbots\(^13\).

Participants health literacy was measured using Rapid Estimate of Adult Health Literacy (REALM)\(^21\) which assesses participant’s ability to read health materials and instructions, at a comprehension level of high school or lower\(^21\). We used the Newest Vital Sign (NVS) health literacy scale\(^22\) to assess likelihood of limited health literacy based on numeracy, prose and document literacy measures. NVS was used for fast recruitment (under 3 minutes).

During interview we asked about preferences for the two survey platform, the specific features of the platforms, participants’ comfort in sharing information in each platform, and perceptions of the personality of the chatbot.

\(^2\)https://docs.microsoft.com/en-us/azure/cognitive-services/speech/api-reference-rest/bingvoiceoutput
Recruitment. We recruited participants from two study sites. In the Seattle metropolitan area participants were recruited through Craigslist, flyers at local community centers, and the Institute of Translational Health Sciences’s research subjects’ pool. In the Los Angeles County participants were recruited from a large county safety net hospital (Harbor-UCLA), by two of the authors who are physicians there. ED visitors were handed out a flier at discharge, or while waiting. Participants were 18 or older and had a conversational level of English proficiency. The study was approved by the IRB at both sites.

Participants. 30 participants were recruited (17 males, 10 females, 3 declined to answer) ranging from 23 to 65 years of age (M=39.63, SD=12.91). They reported completing 13.15 (SD=3.73) years of education on average. 22 reported English and 4 Spanish as their primary language. One person reported bilingual fluency and 3 people declined to answer. Finally we had a diverse ethnic backgrounds: Hispanic or Latino: 9, Black or African American: 8, White: 6, Multi race: 2, and 4 reported other ethnicity or declined to answer.

11 participants were assessed as low, and 19 as high health literacy. Participants were considered low literacy if they scored at a seventh to eighth grade level or below, on the REALM scale, or got a score that suggests high likelihood (50% or more) of limited literacy on the NVS scale.

Analysis. Quantitative data comprised user responses for Chatbot and Online Survey interface, Chatbot interaction logs, and post-interaction survey responses for each platform. These were matched by participants’ unique id and the analysis focused on descriptive statistics of user interactions, especially with Chatbot, and on comparison of answer equivalence for the two platforms. Differences in survey responses were assessed using paired t-tests and interactions between interface type and participant’s health literacy levels were explored using linear mixed effects models.

The interviews took between 7 and 25 minutes (M=17.56, SD=9.21), conducted by three and analyzed by four of the authors. Each researcher wrote a detailed summary of interviews they had not conducted, including quotes. We then developed a codebook following a top-down and bottom-up approaches. Initial codes for the top-down pass were informed by the interview questions (why participants liked or disliked each survey platform, attitudes towards sharing information, perceptions of Chatbot). The interview structure itself was informed by the literature. We then refined the codes based on themes that emerged from the data in a bottom-up fashion. Each interview summary was coded by a researcher on the team (who had not conducted the interview, or written the summary). The coded interview summaries were used to identify themes. Three of the authors discussed the overall themes until consensus was reached. Researchers consulted with the audio and transcriptions of the interviews to ensure validity of the coding.

Quantitative Results

Preferences. Low health literacy (LL) participants preferred using Chatbot over the Survey with 8 out of 11 expressing such preference. At the same time, 17 out of 19 high literacy (HL) participants preferred Survey. This difference was statistically significant ($\chi^2 (2, N = 30) = 12.5$, p < .001).

Time to Completion. Participants had to respond to 36 questions in the social needs survey, but they could also skip answers. They spent significantly ($t(27)=2.23$, p<0.05) more time answering questions via Chatbot (M=9:26 min; SD=3:14 min) than via Survey (M=6:48 min; SD=6:28 min). We found no significant difference between answering time (avg. of both interfaces) for LL (M=9.43 min, SD=3.23) and HL participants (M=7.36 min, SD=4.20). We also found no significant interaction between the interface and literacy level on time.

Equivalence of Responses. An important question is whether the two interfaces result in the same data quality. We explore two measures: per-item response rates and data equivalence. On average participants provided almost identical number of answers via the two interfaces: 32.93 (SD=3.48) questions answered with Chatbot and 33.00 (SD=2.95) with Survey. This suggests comparable response rates. In terms of data equivalence 87.0% (SD=11.6%) of the responses per user were the same across the two interface versions.

Reasons for Response Discrepancies. We found that skipping an answer in one interface, but not the other was the primary cause of answer discrepancy (48% of mismatches). There was, however, no significant difference between the two platforms in skipping behaviors. 25% of mismatches was a result of skipping a question in Chatbot only and another 23% due to the opposite. Furthermore, the order in which users encountered the interfaces had no significant impact on skip rates: 8.0% (SD=9.3%) when answering the survey the first time, and 7.8% (SD=8.2%) when answering
the survey the second time. Hence the platforms are not different in this respect. One interesting finding from our explorations is that there seems to be an anchoring effect with users skipping more often when starting the study with Chatbot, for their responses to both platforms: Chatbot (M=9.8%, SD=29.7%) and Survey (M=9.8%, SD=27.2%) than when starting with Survey: Chatbot (M=5.2%, SD=22.3%) and Survey (M=4.9%, SD=21.6%). This is most likely due to the skip option being more explicit in the Chatbot and users wanting to be consistent in their answers.

Manual examination of the remaining mismatches revealed varied and non-systematic reasons for discrepancies such as: low equivalence only in the very first introductory question (53.3%), direct contradiction (e.g., user answered “Yes” in one interface and “No” in the other); similar, but not the exact same answers (e.g., answer: “Yes, help finding work” vs. “Yes, help keeping work”), ticking an additional option in a multi-choice answer (e.g., “Unemployed - looking for work” vs. “Unemployed - looking for work, Disabled”) and a possible misinterpretation of the question (e.g., when asked for income per month, user typed “2000” in one interface and “24,000” in the other).

Workload (NASA TLX). Analysis of the NASA TLX survey responses revealed a difference in task load index (avg. of all items denoting workload, α: 0.83) between Chatbot and Survey. Participants reported a higher workload when using Chatbot (M=2.460, SD=1.241), compared to Survey (M=2.167, SD=1.284; t(27)=-2.020, p=0.05). Given the scale from 1–lowest to 7–highest, this still represents a low perceived workload. We also found a main effect of literacy level: there was a higher perception of workload across both platforms by the LL participants (M=2.955, SD=1.335) than the HL ones (M=1.921, SD=0.948; t(27)=2.439, p<0.05). The interaction effect was not significant.

Engagement, Understandability, and Comfort with Sharing Information. Analysis of the engagement index (average of O’Brian’s engagement questions, α: 0.82), revealed a higher reported engagement for LL participants (M=3.920, SD=0.502) than HL ones (M=3.469, SD=0.402), (t(27)=2.672, p<0.05). We also found a weakly significant interaction between interface and literacy with LL participants being more engaged with the Chatbot than HL ones, but less engaged with the Survey (Chatbot*Low, β=0.485, SE=0.262, p=0.064). This represents a half a point increase on a 5-point likert scale for engagement. Trends in the same direction, but no significant differences were found for understandably and comfort with sharing information.

Qualitative Results
In this section, following mixed-methods approach, we complement and expand on the quantitative findings. Participants varied not only in their preferences for Chatbot or Survey, but also in the particular aspects they liked about each, as well as in which design aspects were instrumental in creating particular perceptions and experiences. Participants valued the engaging conversational aspects of the Chatbot. Especially LL participants found the conversational interface more caring in the context of a sensitive topic. In contrast, HL valued the efficiency of the SurveyGizmo interface and felt slowed down by the Chatbot. Some participants found the Chatbot more robotic, disingenuous or pushy at times, but these seem to result from the particular way in which HarborBot implemented conversation.

Strengths of Our Conversational Approach
Engaging. Most participants found the conversational features of the chat more engaging than the Survey, regardless of the health literacy level. Participants felt like they were having a conversation with a person when using the Chatbot. More than half the participants attributed such perception to the use of voice: “she was reading the questions and I can answer it ... seemed like a conversation ... like someone was talking to me and it gave me the opportunity to answer back and then they answered back” (H59). Other participants felt the ellipses made it feel like having a chat with someone (H76, L77), and even referred to the the Chatbot as “she” (8 participants). Some participants valued that the Chatbot felt like a person: “I liked... how it talked to you, reads you the questions ... it spoke directly at me” (L60), “I thought it was someone asking me those questions” (L72).

Aside from the voice and ellipses, the conversational utterances also contributed to the perception of interacting with a person (L75, L58, L72, H32, L60, L36, H41, H59). One participant found them motivating: “Saying 'you got it,' It’s giving you motivation ... nice to hear that once in a while” (H73). Another felt like the conversation was adapting to the answers to be more relevant: “seem like they tried to give you a little positiveness based on your answer” (H59).

Caring. Participants perceived the Chatbot as caring, particularly in the LL group. These participants had a generally positive attitude towards the social needs survey questions (L51, L55, L58, H73) and this topic resonated with their
personal experiences “It felt like it was telling me about my life. That was really amazing, like woow” (L71). Therefore, some of the perceptions of the Chatbot might have been accentuated by the positive perception towards the survey topic. Many participants described the personality of the Chatbot using terms such as: caring, kind, patient, helpful, calm, familiar, or concerned (H35, H41, L52, L55, L57, L61, L77). Participant also reported the voice of the Chatbot was aligned with this caring personality: it was soothing (H57), had cadence (H32), helped a nervous participant feel more comfortable (L55) and was “nice and sweet made me feel relaxed” (L77).

The Chatbot was designed to provide supportive utterances in response to some of the participants answers. Many participants liked these utterances (L60, L36, H32, H41, H58, H59). One participant though the utterances made him feel “comfortable to answer the questions” (L61), and that they provided a positive reinforcement to keep on answering (H59). Participants perceived Chatbot utterances such as “I am sorry to hear this” as the Chatbot “trying to be understanding” (H59). Some found these utterances to be very applicable to the conversation context. For example L61 considered the Chatbot response: “That must be stressful” to be a reaction to the information she shared: “she probably said that because of my financial situation” (L61), which she felt would be calming for people “to not be stressed, I would think it would be helpful” (L61). Other participants felt the supportive utterances gave them confidence: “nice lady giving me confidence ... with good tone of voice” (L75).

Understandable. Several LL participants (5 of 11) reported having trouble with reading and understanding the written questions in the Survey. They liked using the Chatbot because it facilitated their understanding, which they attributed to the audio feature: “When I hear it I have a better understanding of the question” (L61) or that “just hearing it I could ... relate better to the question” (L53). Some participants reported using the feature that replayed audio, to better understand a particular item (L51, L58, L61, L73). This was especially useful when they missed some words or did not fully comprehend some of the contents at first: “I didn’t get it at first, so I wanted to go back and listen to it again before answering” (L58). Several also mentioned that they would have liked it if the answers were spoken via audio as well, to make them more understandable (L61, L54).

Accessible. Some participants had particular needs that the Chatbot was able to satisfy much better than the Survey. One participant who reported vision problems, preferred having questions read to them: “If it is too small I can’t see it so I prefer to have the questions read to me anyways” (H73). Another participant reported feeling very comfortable with the Chatbot because she was regularly experiencing panic attacks and considered ED stressful: “I was thinking I was texting somebody ... that made me forget where I was at ... it was like texting my sister my mom and waiting for them to respond back. And that made me feel patient” (L77). In contrast, she found it particularly difficult to take the Survey: “by myself ... it felt awkward and alone” (L77).

Weaknesses of Our Conversational Approach

Inefficient. HL participants cared about efficiency, primarily reflected in the speed of completing the survey. The majority of HL participants (17 out of 19) preferred to use the Survey because of that. Several mentioned that the traditional interface enabled them to be faster than the Chatbot (H21, H22, H24, H59), or to go at their own pace (H36). Participants attributed being slowed down to various conversational features of the Chatbot. Some felt the Chatbot was slower because they needed to wait for the ellipses before a new question would appear (H35). They were also able to read faster than the questions were read by the bot: “when she was talking at me. I felt like I was going at a slower pace” (H23). Also not having to engage with additional conversational utterances was seen as more efficient (H35, H56). The audio feature was perceived as interfering with reading and thinking (H23, H40, H70, H21, L71). One LL participant preferred the Survey because they could concentrate more: “to read is better ... Because that way I could like concentrate more and think about more and you know ... I could read my letters more and makes it better for me.” (L58).

Pushy. Somewhat surprisingly, a few participants perceived Chatbot as being pushy, based on the tone and the speed at which questions were asked. Some participants felt the questions asked were very direct (H57, L72, H52). L72 felt like he was answering questions to a teacher, and had to provide correct answers. H57 and L72 thought there could be more utterances to help prepare the survey taker for some very sensitive questions in the survey. H57 also felt that some of the questions were trying to repeatedly get information that he had already declined to provide: “if I say none of the above ... don’t be pushy” (H57). Others also felt rushed in providing the answers to the Chatbot. For example,
the use of ellipses, and the short delay between its messages made it feel like the Chatbot was moving faster than the participants were comfortable with (H23, H63). Participant H63 felt like the questions kept coming and he had no control over when they would be read.

**Robotic and Disingenuous Voice.** Some participants, primarily in the HL group, perceived the Chatbot as being robotic. Some participants found the voice not sounding natural (H21, H22, H23, L58, H59, H63, H70, H76), for example sounding “truncated...monotone...seemed pretty artificial to me.” (H70). Some perceived the Chatbot as disingenuous when the utterances did not meet their intended purpose (H63, H40, H23, H52): “I feel like they were trying [to make] the software to feel sympathetic, or empathetic, that was weird” (H63). Another participant perceived utterances as defaults: “it felt like defaults rather than someone 'feeling for you’” (H40). The perception of artifical responses led another participant to perceive the Chatbot as fake, and was reminded of customer support: “kind of just programmed, recorded in, to appear to be more personal...hell there’s nobody there somewhat disingenuous... It reminded of... dealing with the phone company” (H70).

**Inconclusive Impact on Willingness to Disclose Information.** Most participants, regardless of health literacy level, reported being comfortable sharing information asked by the survey questions. However, the human-like interactions of Chatbot did affect some participants’ willingness to disclose information, although participants reported effects in both directions. For some, if they thought they were interacting with a person, they felt more reluctant to share sensitive information, or tell the truth: “I might be more honest if I’m reading [the question] ... if someone else ask me about them, I might lie” (L72). Another participant showed concern about the identity of the potential conversational partner: “it was a robot, I didn’t mind, but I think if it was a human being I would mind... and you really don’t know who’s on the other end” (H40). In contrast, some participants were more willing to disclose because of the human-like interactions. “If it says ‘I would like to more about you’. It gives me the confidence to open up, because each question that follow sounds so interesting and it gives me the opportunity to interact with the person on the other side ... it wetens my appetite to give out more information” (L75).

**Discussion**

**Main Findings.** In this paper, we proposed the use of a chatbot (HarborBot) for social needs screening at emergency departments and compared it to a traditional survey tool (SurveyGizmo). Based on interviews, interaction logs, and survey responses we demonstrate that the conversational approach is perceived as more engaging by all the participants, and further as more caring, understandable, and accessible among the low health literacy (LL) ones. Importantly, we also demonstrate that the conversational approach results in similar response rates and 87% equivalence in the collected data. At the same time, we found the conversational approach to be more time consuming (in line with reports from prior work on ACASI) and prone to be perceived as somewhat pushy, robotic, and disingenuous which was, however, mostly the perception of participants with high health literacy (HL).

**Positive Design Aspects.** Numerous strengths of the conversational approach for LL population can be linked to conversational features. First, various features of the chatbot facilitate understanding. The audio output is especially valuable for participants who are less proficient readers. Second, the ability to ask the bot to rephrase the question offered a way to ask for clarification that is currently not a feature in online survey platforms. Third, chatbots can create a sense of interacting with a human. The utterances can make the survey takers feel cared for and engaged. Such positive interactions made some participants feel relaxed and even motivated to answer more questions.

**Challenging Design Aspects.** We were surprised that the conversational features felt pushy for some, especially HL participants. Such perception was linked to the tone of the questions and to the speed of the interaction. In terms of tone it is possible that our literal use of the wording of the survey questions was not the most appropriate for creating a conversational feel. In terms of speed of interaction, the use of voice might be a contributing factor. As reported in prior work agent asking questions via voice can create a perception of response urgency. This could be improved by adding assurances like “please take your time.”, manipulating intonation, or making it more explicit that the ellipses represent someone is typing (rather than the system is waiting for a response). The second reason for pushy feel could be related to the fixed speed of conversation. Human-human conversation involves not only exchanging information, but also coordinating various aspects of the exchange, e.g., its speed. If a participant needs more time to think, a real person, would pick it up from verbal and non-verbal cues and adjust the speed. Our HarborBot is currently incapable
of making such adjustments. Such fixed speed may feel too fast or too slow for some users.

HarbotBot felt “caring” for LL and “robotic” for HL participants. This might be related to the different expectations and tolerance levels for voice quality and may be improved with use of a better quality text-to-speech service (technical challenge), human pre-recorded audio clips (which comes with limitations in flexibility), or modifications of intonation and prosody using approaches such as Speech Synthesis Markup\(^3\). Another way may be to generate more personalized and diverse utterances\(^24\).

**Future Design Directions.** Given the division of preferences for chatbot/survey between the HL and LL groups, one possibility for a real-world use could be to have two versions of the tool and either intelligently assign or have patients pick the version they would prefer to engage with. While, long waits in healthcare setting make it less of a problem, a number of design opportunities can still be explored to make the chatbot interactions more efficient, such as simplifying the script, or providing user control over time between messages. While we focused on examining the effects of the conversational approach for a LL population, our findings suggest a potential for accessibility-focused uses of the chatbot. Participants who were hard of seeing mentioned they appreciated the audio output. Further, one participant with anxiety attacks appreciated the human-like interactions, which made them feel like chatting with a loved one, at home.

Finally, it is not clear based on our results, how the conversational approach affects people’s comfort in responding to questions, and any potential desirability biases. Prior work suggests that the self-administered screeners would reduce social desirability bias, and limit the under-response in sensitive issues\(^6\). This is because people will not feel like someone is monitoring or judging them. We thought the Chatbot may strike a happy medium between being perceived as human-like to enhance engagement, while not being perceived as a person for people to feel uncomfortable with disclosures. It is not clear if we were able to achieve that balance. Some participants who thought the Chatbot was human-like did not mind sharing and commented that it was more motivating, while others that thought the Chatbot was human-like were concerned with sharing. It is possible that the very initial greeting from the bot sets the tone for the rest of the interaction\(^25\). This requires additional research.

**Limitations**

Recruiting low health literacy participants with basic English proficiency is difficult. Thus our sample size for this group is limited. Still, our results appear fairly robust; our claims are supported through both quantitative and qualitative data. With our quantitative data, even with the small sample size, our primary outcome variables achieved statistical significance. Also with our qualitative results, we reached data saturation early.

We were able to study actual ED patients interacting with HarborBot, which boosts the ecological validity of our findings. Nonetheless, a number of important generalizability questions require future work. For example, would our general findings hold with a different population (e.g., non-English speakers, different cultural backgrounds), or a different set of questions? Furthermore, while we focus on examining the acceptability of chatbot for social needs screening in the ED, a critical next step is to study its feasibility and how it may be integrated into existing workflows.

**Conclusion**

In this paper we have proposed the use of a chatbot as a tool for social needs screening in emergency departments. We designed and built HarborBot to enable a more human-like interactions during the self-administering of surveys. Through a mixed-methods study with 30 low and high health literacy participants recruited at two different sites, we showed that compared to traditional online survey, the conversational interface offers benefits such as increased engagement, facilitating understandability and making the interaction feel more personal and caring. These benefits were especially appreciated by low health literacy participants. However, the high health literacy ones mostly preferred traditional survey as it was more efficient. Our work advances the understanding of conversational agents, and offers valuable insights on the design and potential role of chat interfaces for social needs screening.

Abstract

**SMART on FHIR applications** are standards-based tools integrated with electronic health record (EHR) systems and intended for dissemination across EHR platforms. A key challenge for disseminating many apps is that EHR vendors provide different levels of support for FHIR. Thus, app developers must balance functionality versus portability. In this case study, a feature-rich app for neonatal bilirubin management was developed prioritizing physician-requested functionality, with custom FHIR interfaces implemented within the EHR as needed. Following wide intra-institutional use, several approaches are being pursued for adapting the app for cross-institutional dissemination: user surveys and interviews to identify least-valued app features which could potentially be omitted; enabling the application to provide differential features depending on available EHR FHIR capabilities; replacing custom FHIR interfaces with native EHR FHIR interfaces as they became available; and using a canonical logical data model known as *QUICK* that can be mapped to different FHIR versions and profiles.

**Introduction**

**SMART on FHIR applications**

The Health Level Seven International (HL7) Fast Healthcare Interoperability Resources (FHIR)\textsuperscript{1} data interface standard is used by the Substitutable Medical Applications and Reusable Technologies (SMART) platform launched in 2010 for clinical app integration into electronic health record (EHR) systems.\textsuperscript{2} SMART on FHIR applications retrieve relevant data through application programming interfaces (APIs) and are integrated with EHR authorization mechanisms so that they can be embedded within EHR systems with single sign-on capabilities.\textsuperscript{3} Apps can be authored by third parties or by internal app development groups. One of the main promises of SMART on FHIR is its potential for “plug-and-play” interoperability, which could allow an organization to import an app developed elsewhere and utilize it with ease.\textsuperscript{4} Consequently, it has been proposed that SMART on FHIR applications could enable advanced functionality to be cost-effectively disseminated, even to health systems with limited information technology resources.\textsuperscript{5} Every year, more and more SMART on FHIR applications are being developed: the SMART on FHIR app gallery contains 69 SMART on FHIR applications as of March 2019.\textsuperscript{6} Duke Health shared their SMART on FHIR platform information and demonstrated feasibility of deploying 5 apps.\textsuperscript{7} However, the healthcare community is still early in its adoption, implementation, and evaluation of SMART on FHIR applications. Clinical outcomes have not been evaluated yet for most apps and many published reports have focused only on implementation feasibility.\textsuperscript{8,9} Only a few apps have been reported to be used by multiple healthcare systems successfully.\textsuperscript{10}

**Key challenge to dissemination: limitations in EHR-supported FHIR capabilities**

Dissemination is the process of spreading an application from the organization where it was developed to multiple EHRs. We define portability in this context as how easily an application can be disseminated. EHRs are generally compliant with the US Core FHIR profiles,\textsuperscript{11} which define a minimum set of data interfaces using the FHIR standard. However, these FHIR profiles have limitations. For example, the official version of these profiles as of March 2019 (version 1.0.1) does not include support for the FHIR Encounter and ServiceRequest resources, retrieval of clinical notes, or filtering a search for past medications based on a date. Even in the most current draft version of these profiles (version 2.1.0)\textsuperscript{12}, there is no support provided for writing data into the EHR, placing orders, or retrieving relevant clinical data such as family health history, baby’s birth time, or detailed information on a patient’s smoking history (e.g., packs per day). Moreover, even when included in the US Core FHIR profiles, terminologies may not be standardized in the profiles (e.g., medication routes are not required to use a standard terminology), and EHRs may differ in their interpretation and implementations of the profiles. Differences may also exist at the level of healthcare systems using the same EHR platform, providing further challenges to dissemination. Thus, to maximize the potential for dissemination, SMART on FHIR applications must constrain their data...
requirements to those supported by US Core FHIR profiles, and in particular to those profiles that are most uniformly implemented by EHR vendors. While such an approach may not be an issue in some cases (e.g., when developing an application for demonstration or proof-of-concept purposes, or if a use case can be fully satisfied using available data interfaces), in many cases the desired user functionality may not be supportable using existing EHR FHIR interfaces. This situation is expected to improve in future years as the US Core FHIR profiles continue to evolve, and as EHR vendors continue to increase their FHIR capabilities. However, for the foreseeable future, the need to balance portability with functionality will be a real concern for SMART on FHIR app developers.

At the University of Utah, a number of SMART on FHIR applications have been developed and implemented for operational clinical use since 2017. The first of these applications to be deployed for production clinical use was a neonatal bilirubin application. This application is in near-universal clinical use in the newborn nursery, and it is being prepared for external dissemination. Here, we use this neonatal bilirubin application as a case study for examining potential approaches to balancing functionality versus portability of SMART on FHIR applications which can often pose competing demands. The objective of this paper is to assist others developing SMART on FHIR applications to make more informed decisions on how to best achieve the right balance between functionality and portability.

Methods

Implementation Setting

Development of SMART on FHIR applications was performed by the Knowledge Management and Mobilization (KMM) group at University of Utah Health, an academic health system, as part of the ReImagine EHR initiative. University of Utah Health uses the Epic EHR. The KMM team consists of 9 clinical informaticists with expertise in areas including software development, software architecture, standards-based interoperability, and biostatistics. Two of the team members are physicians, 4 are PhDs, 2 are co-chairs of HL7 Work Groups, and 7 are certified to make custom Epic Web Services in the Epic EHR. Team members meet regularly with EHR vendor colleagues to help ensure that any custom interfaces developed are aligned with the vendor’s approach to FHIR. Team members gained expertise in making FHIR extensions to the EHR through the development and implementation of a number of SMART on FHIR apps for clinical use at University of Utah Health, engagement in the standards development process, and technical validations of cross-institutional app deployments in different EHR platforms through inter-institutional collaborations as well as HL7 FHIR Connect-a-thons. The Department of Biomedical Informatics at the University of Utah also has a sociotechnical team which provides evaluation services.

Preparing for Cross-institutional Dissemination

We considered the following approaches for adapting the app for cross-institutional dissemination: (1) initial implementation based on clinician needs, with custom FHIR services implemented as needed, (2) gathering feedback from app users to identify least-valued app features which could potentially be omitted if difficult to disseminate, (3) enabling differential features based on EHR FHIR capabilities, (4) progressive replacement of custom FHIR services with native EHR FHIR APIs, and (5) use of a canonical logical data model known as QUICK that can be mapped to different FHIR versions and profiles.

Initial Implementation Based on Clinician Needs

In 2016, a SMART on FHIR app for neonatal bilirubin management, which we call the Bili App, was requested by pediatric physicians. The KMM team evaluated whether it would be possible to simply use the SMART on FHIR bilirubin app available in the SMART on FHIR gallery as a demonstration application. However, the physicians determined that the original app would not meet their clinical needs and would not be useful to them, due to inadequate support for key recommendations in the underlying clinical guideline from the American Academy of Pediatrics. While the demonstration application required only limited data, such as laboratory data conformant with US Core FHIR profiles, it did not provide sufficient perceived utility for the end users. Thus, the KMM team decided to enhance the app to support the requested functionality. These enhancements impacted portability of the application by requiring data APIs that are not currently supported by US Core FHIR profiles.

Following significant enhancements by University of Utah Health, the Bili App was released for clinical use on April 12, 2017. The app uses FHIR version STU3 (3.0.1), US Core FHIR profiles version 1.0.1 and QI-Core FHIR profiles version 2.1.0. The app was recognized with several awards in the Department of Health and Human
Services’ Provider User Experience Challenge. The app is in near-universal use for babies born in the University of Utah newborn nursery.

Gathering Feedback from App Users

As some of the features were known to be potentially difficult to disseminate on other EHR platforms due to the lack of needed FHIR interfaces in these platforms, we gathered user feedback to determine the most valuable features. Gathering feedback from the users included interviews and surveys conducted by the KMM team’s Director of Evaluation (PK) and a member of the Department of Biomedical Informatics’ Sociotechnical Service Line (HK). We asked medical directors of the newborn nursery and outpatient clinics to invite attending and resident physicians to participate in in-person sessions that included a survey and a semi-structured interview. Three residents and 4 attending physicians agreed to participate, representing both inpatient and outpatient settings. Usability assessment was approved by the Institutional Review Board (IRB).

During the in-person sessions, we showed participants a de-identified screenshot of the Bili App (Figure 1) with 16 screen components: 1) patient bilirubin test results, 2) phototherapy thresholds (green lines), 3) exchange transfusion thresholds (red lines), 4) phototherapy administration (yellow bar), 5) discharge from the hospital (light blue bar), 6) outpatient phototherapy order (orange bar), 7) gestational age, 8) direct Coombs results, 9) mother’s lab results, 10) other neurotoxicity risk factors, 11) albumin < 3.0 g/dL, 12) recommendations (blue box), 13) rebound hyperbilirubinemia risk (green box), 14) table of bilirubin measurements, 15) table of albumin measurements, and 16) hyperbilirubinemia risk tab. First, we asked users to assess the value of all 16 features. Second, we asked whether the providers would still use the app if it no longer included any one of 8 features deemed to be most difficult to disseminate. Responses were arranged according to the median value and visualized using box-plots. Interview times averaged 20 minutes and included screen recordings of clinicians using the app for the assessment of bilirubin levels for providers’ recent actual patients. The semi-structured interviews included the following questions: What decisions are supported by the app? What works well in the Bili App? What are issues and/or limitations? Can you think of any enhancements that would help you?

Enabling Differential Features Based on EHR FHIR capabilities

In the course of other projects that involved integration of FHIR applications across institutions and EHR vendor platforms, the project team came to realize that other EHR vendors may simply not enable third parties to add extensions to their FHIR interfaces. Moreover, through the review of EHR vendors’ FHIR documentation, as well as actual interaction with them through HL7 FHIR Connect-a-thons, it became quickly apparent that EHR vendors differ in their support for FHIR versions and profiles. Thus, we explored potential options for supporting different levels of data availability.

Progressive Replacement of Custom FHIR Services with Native EHR FHIR APIs

During the course of the project, the EHR vendor incrementally added additional FHIR interfaces. Several of these interfaces were capable of replacing the data pulled by custom FHIR services. Also, in discussions with the EHR vendor, it was learned that some of the data points which had been pulled through custom FHIR services could be pulled instead through vendor-provided FHIR APIs following data mapping that could be configured in the EHR.

Use of a Canonical Logical Data Model

In an effort to extend the expressivity of the US Core FHIR profiles to support clinical quality improvement efforts, the HL7 Clinical Decision Support (CDS) and Clinical Quality Information (CQI) working groups developed QI-Core FHIR profiles. We used a view over the FHIR QI-Core profiles that hides FHIR-specific implementation details, notably FHIR extensions (e.g., birthtime). However, QI-Core profiles cannot shield implementers from other implementation challenges (e.g., FHIR cross-resource inconsistencies) because the QI-Core logical view is a one-to-one view directly based off of a specific version of FHIR. Moreover, because of the evolving nature of FHIR, as well as differences in how FHIR is implemented in EHRs, coupling a SMART on FHIR application with a specific FHIR version or implementation could be costly and potentially not scalable. Just during the course of this project, multiple versions of FHIR were released, with sometimes substantial changes occurring between releases. Use of a more consistent and FHIR-version-independent logical model could mitigate some of these challenges.
Results

Overview of Approaches Taken to Manage Functionality Versus Portability

We applied the following approaches for adapting the app for cross-institutional dissemination with the goal of balancing the functionality of the Bili App with its portability. We aimed to adequately meet the needs of clinician users while also maximizing the Bili App potential reach and impact. As described in detail below, the approaches involve (1) initial implementation based on meeting clinician needs, with custom FHIR APIs implemented as needed, (2) gathering feedback from current users through surveys and interviews about their valuation of specific app features, (3) enabling the application to provide differential features depending on available EHR FHIR capabilities, (4) progressive replacement of custom interfaces with native EHR FHIR interfaces as they became available, and (5) using a canonical logical data model that can be mapped to different FHIR versions and profiles.

Initial Implementation Based on Clinician Needs

We started by developing a fully-featured app based on user needs. To support this application, several custom FHIR APIs were developed to obtain required information not supported by the native EHR FHIR interfaces at the time, including for the patient’s gestational age, the mother’s laboratory data, the patient’s discharge time, and the timing of outpatient phototherapy orders. We developed these required FHIR APIs, leveraging and “wrapping” non-FHIR APIs natively supported by the EHR where possible. These custom FHIR APIs were made available to the Bili App alongside the native EHR FHIR APIs through an intermediate proxy.

Following initial deployment, additional improvements were made based on user feedback. Figure 1 shows the current version of the Bili App for a test patient. Numbers have been added to the screenshot corresponding to the key user interface components enumerated in the Methods.

![Figure 1. Screenshot of Neonatal Bilirubin Application for a Synthetic Patient](image)

The Bili App currently requires 15 data elements which are retrieved from the EHR as FHIR resources through native and custom APIs. Data elements and associated dissemination concerns are summarized in Table 1. In other health systems, different coding terminologies might be used to record the same data elements, or some elements might be unavailable.

**Gathering Feedback from App Users**

User assessment of the value of app features is summarized in Figure 2. The numbers in the figure correspond to the feature labels included in the screenshot in Figure 1. Surveying for valuable features clearly showed that some features are perceived as more important than others. Two features were perceived as highly important by all participants: bilirubin results and phototherapy thresholds. Most of the users stated that they would still use the app if any one of the 8 difficult-to-disseminate features was omitted. We found that the hyperbilirubinemia risk tab and table of albumin measurements had medium to low value for most users. Auto-population of gestational age was valued highly by most users.
Figure 2. Participant Survey Responses

Interviews allowed us to get a deeper understanding of why users found some features less valuable than others. For example, users noted:

"I don’t use this tab at all <pointed to Hyperbilirubinemia Risk tab>. I know other people do on the inpatient side, but I’m not very familiar with it and haven’t used it to change my decision one way or another. Kind of redundant with this <main tab>..."

"We hardly ever draw albumin on babies. I feel like maybe for premies we might be looking at that, but we hardly ever have it on record."

In the interviews, providers tended to report what should be added, not what could be omitted. This is consistent with the psychological literature that users do not like to give away what they already have. Many users asked to add the rate of rise. For example, one user noted the following:

"It would be wonderful if it could automatically calculate rate of rise (the calculation is not hard or time consuming, but an automated value would be helpful for busy clinic days)."

Enabling Differential Features Based on EHR FHIR Capabilities

We are refining the system to be able to adapt to differing levels of data availability (Figure 3). For example, when a mother’s laboratory data cannot be automatically pulled through the FHIR interface, instead of leaving those data elements blank in the app, the app could be configured to not include a placeholder for those data elements in the first place. To an extent, the application is already configured to account for differences in FHIR data availability. For example, for patients who are not born at our healthcare system but are instead transferred in or simply followed up in the outpatient setting, the app prompts the user to enter the missing patient birthtime rather than pulling it from the EHR. We are planning to extend this type of differential functionality based on known and anticipated differences in FHIR capabilities across EHR systems. As an extreme case, we are also considering developing a stand-alone version of the app that can function without the provision of any EHR-provided data.
Progressive Replacement of Custom FHIR APIs with Native EHR FHIR APIs

During the course of the project, several FHIR APIs were introduced by the EHR vendor, which allowed for replacement of custom FHIR APIs. Data that could now be supported natively through use of the EHR vendor’s FHIR API include the patient’s gestational age and the date and time of the patient’s discharge from the hospital. In addition, we learned that inpatient phototherapy administration times could be pulled through a native EHR FHIR Observation API following configuration in the EHR to map nursing flowsheet data to LOINC. Thus, whereas a custom FHIR Procedure API was originally used to identify when phototherapy was administered in the inpatient setting, this information can now be retrieved using the native EHR FHIR interface for Observations.

Use of a Canonical Logical Data Model

To mitigate dissemination challenges associated with FHIR versioning, we propose using a canonical logical data model which allows the core SMART on FHIR application to be written against one data model rather than many data models, thus decoupling application logic from the FHIR versions used in messages. Currently, one of the authors (CN), who is a co-chair of the HL7 Clinical Information Modeling Initiative (CIMI) Work Group, is developing such a logical data model known as the HL7 Quality Improvement and Clinical Knowledge (QUICK) logical model. The QUICK logical model is based on multiple standards and models including HL7 FHIR,\(^1\) HL7 Virtual Medical Record (vMR),\(^19\) the National Quality Forum Quality Data Model (QDM)\(^20\), HL7 US Core FHIR profiles,\(^12\) and HL7 QI-Core FHIR profiles.\(^16\) The scope of the QUICK logical model consists of classes and attributes currently identified as needed for CDS and quality measurement. The QUICK logical model is under development at HL7 and is expected to be balloted as part of the HL7 January 2020 submission cycle.

Discussion

Summary of Findings

While SMART on FHIR provides a promising potential approach for widely disseminating innovative extensions to the EHR, the still evolving nature of EHR vendors’ support for FHIR poses challenges to such widespread dissemination. Specifically, in cases where needed FHIR APIs are not broadly supported across EHR vendors, a SMART on FHIR app developer must consider tradeoffs between functionality and ease of dissemination. In this manuscript, a neonatal bilirubin management SMART on FHIR application was used as a case study of how this...
tradeoff can be appropriately managed. The approach taken involved the following methods. First, we started by ensuring that user requirements are met in an initial implementation for production clinical use, with custom FHIR service being developed in coordination with the EHR vendor where needed. Second, surveys and interviews were conducted with users of this fully-featured application, with a goal of identifying those features that provide the least perceived value to end users, as those features could potentially be omitted when externally disseminating the tool if they require FHIR interfaces that may not be generally available. Third, we are enhancing the application so that its feature set can adapt to differing levels of data availability. Fourth, custom FHIR APIs were replaced with EHR vendor-provided interfaces as those interfaces became available, so that the need for developing or sharing custom FHIR APIs is reduced. Finally, we are moving towards the use of a canonical logical data model, so that the core logic can remain unchanged while enabling interaction with different FHIR versions as well as profiles supported by EHR vendors. While we have not yet empirically validated that these approaches will enable functionality to be optimized while still supporting widespread dissemination, we believe that these complementary approaches will enable us to achieve these goals moving forward.

Strengths and Limitations

One important strength of this study is that we used several complementary approaches spanning qualitative methods (interviews and surveys) as well as deeply technical approaches (e.g., developing custom FHIR APIs directly into EHRs and using a canonical logical data model). Thus, we were able to expand the potential approaches available to us. For example, if we had not possessed the capability of building custom FHIR APIs directly into the EHR for production clinical use, it is uncertain whether we could have developed a SMART on FHIR application for neonatal bilirubin management that would have adequately met the needs of our clinicians. Indeed, we had started by proposing clinical use of the SMART on FHIR demonstration application for this use case that had been available for some time on the SMART on FHIR app gallery. Despite the fact that this application had been successfully demonstrated across multiple EHR platforms, our clinicians felt that introducing this application into our clinical environment would provide little value without the enhancements we ultimately implemented. As a second strength, this study was conducted by a project team that included national experts on FHIR and its evolution in the standards community (KK and CN). One of the authors (KK) also serves on the Board of Directors of HL7 (the standards development organization that specifies FHIR) and the U.S. Health IT Advisory Committee. As such, the project team is well-positioned to understand the current state and future direction of the FHIR standard and its adoption by the health IT community and is actively contributing to its evolution through our implementation experience. As a final strength, our approach can be applied to a wide range of clinical use cases, as it allows new FHIR interfaces to be developed and used where needed. This approach does not rely solely on FHIR capabilities that are universally supported across EHR vendors, as our experience has indicated that many actual clinical needs cannot currently be adequately met using just these FHIR interfaces.

An important limitation of the study is that we are still in the process of disseminating the SMART on FHIR Bili App. Thus, we do not yet have empirical evidence that the approach used will be successful in balancing functionality with portability. A second limitation is that this approach involves making enhancements to the FHIR interfaces natively provided by the EHR vendor. Such enhancements could become a barrier to dissemination due to the cost of development and integration. For organizations that do not possess this capability, or whose EHR vendors do not permit such extensions, the only option remaining would be to advocate for the needed capabilities to be implemented by the EHR vendor. Finally, a third limitation of this study is that it is technically more complex to implement than an approach focused on using only those FHIR capabilities natively provided across EHR vendors. While this may be functionally adequate in some use cases, in other cases this would significantly hamper the functionality that can be achieved and the degree to which duplicate manual data entry can be avoided.

Lessons Learned and Recommendations

Through this study, several insights were gained on the process of balancing functionality and portability. First, while improving, existing FHIR capabilities provided by EHR providers are often inadequate for meeting the needs of clinical users. Second, the degree to which EHR vendors support and empower their clients to enhance FHIR interfaces is variable. Third, while most EHR vendors provide support for US Core FHIR profiles, these profiles still provide optionality for EHR vendor implementation, leading to vendor differences in implementation. Fourth, mapping of local codes to standard codes is still oftentimes required. Finally, while promising, enabling widespread dissemination of functionally rich SMART on FHIR applications can still present significant challenges.
Based on our study findings and lessons learned, we recommend that stakeholders in the healthcare community cooperate in identifying their most important needs with regard to FHIR and advocate for their universal support in the US Core FHIR profiles and EHR vendor implementations of those profiles. There is substantial ongoing work in this area, for example by the U.S. Core Data for Interoperability and Interoperability Standards Priorities Task Forces of the U.S. Health IT Advisory Committee. Moreover, given the limitations of US Core FHIR Profiles in addressing end user requirements, we (CN and KK) are currently proposing FHIR Implementation Guides that extend beyond US Core FHIR Profiles for adoption by the Healthcare Services Platform Consortium (HSPC), Clinical Information Interoperability Council (CIIC) and HL7 as part of the Reimagine EHR initiative.

Interested stakeholders are encouraged to engage in these forums, as well as directly through HL7 and other venues to advocate for their priorities. Second, we recommend that SMART on FHIR app developers explicitly consider the trade-offs between functionality and portability, as well as to use one or more of the approaches described in this study for managing those trade-offs. Finally, we recommend that end-users be engaged throughout the process to ensure that the approach taken adequately meets their clinical and workflow needs.

Future Directions

In the future, approaches to measuring the cost and utility of providing desired features that extend beyond US Core FHIR profiles should be explored. Such measurement could allow formal evaluation of the extent to which the benefits of adding such features outweigh the costs. Expanding such cost-benefit analysis on the national level could help identify priorities for the development and implementation of standards including the US Core FHIR profiles.

Moving forward, we are continuing to develop new FHIR capabilities in the EHR, including SMART on FHIR applications and CDS Hooks decision support services. Other applications that we have developed or are currently developing for clinical use include a population health management system for individuals at risk of early onset familial cancers, a surgical referral dashboard, a procedure capacity management application, a lung cancer screening shared decision making app, a diabetes treatment outcome prediction app developed in collaboration with Hitachi, opioid-related decision support tools developed with CDC and ONC support, and EHR-integrated medical calculators developed in collaboration with MDCalc. We believe in the potential for SMART on FHIR applications to improve patient care and reduce physician burnout. As one physician noted when interviewed regarding the Bili App:

“We need to be thinking way beyond the bilirubin app. The sky is the limit.”

Conclusion

As leaders in SMART on FHIR application development, we share here our journey in preparing one of our first SMART on FHIR applications intended for wide dissemination. We demonstrated the feasibility of satisfying user requirements through developing custom FHIR APIs not supported natively by our EHR. Unfortunately, this approach would require a significant investment of resources on the part of adopting organizations and thus poses a barrier to dissemination and adoption of the application. To address this challenge, we recommend that such FHIR services be considered as a starting point for the development of future FHIR implementation guides that extend or build upon the US Core FHIR profiles. The implementation of such standards-based APIs by EHRs would reduce the barriers to dissemination. Until such a time, a holistic approach that combines both technical and user-centered qualitative methods is recommended for optimizing functionality versus portability for SMART on FHIR applications.

Abstract

Electronic health records are an increasingly important resource for understanding the interactions between patient health, environment, and clinical decisions. In this paper we report an empirical study of predictive modeling of seven patient outcomes using three state-of-the-art machine learning methods. Our primary goal is to validate the models by interpreting the importance of predictors in the final models. Central to interpretation is the use of feature importance scores, which vary depending on the underlying methodology. In order to assess feature importance, we compared univariate statistical tests, information-theoretic measures, permutation testing, and normalized coefficients from multivariate logistic regression models. In general we found poor correlation between methods in their assessment of feature importance, even when their performance is comparable and relatively good. However, permutation tests applied to random forest and gradient boosting models showed the most agreement, and the importance scores matched the clinical interpretation most frequently.

Introduction

Electronic health record (EHR) adoption grew from 9.4% to 83.8% in hospitals across the United States over the last decade, mostly due to incentives provided by the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009¹. Thus for the foreseeable future, EHR data will be one of the most comprehensive and promising resources for understanding the interactions between medical care and patient health and outcomes. EHR data integrate disparate information about patients and their health history, including patient demographic data, diagnoses, medication prescriptions, clinical lab measures, physician’s notes, and radiological imaging data². An increasing number of health care systems are integrating genetic data as well³, which allows data analysis to span biology and medical informatics.

EHR data can support a number of knowledge discovery tasks such as predictive modeling, identifying disease co-morbidity, and identifying patient sub-types. Besides its use in diagnosis, this knowledge can be leveraged to generate new hypotheses or improve clinical trial design². This paper focuses on the first task: predictive modeling of patient outcomes, which can impact care in several ways. First, models that predict patient outcomes can be used at the point of care for assisting in clinical decision making. Second, the models can be used to identify trends in undesirable patient outcomes and support new clinical procedures that amend those trends. Third, predictive models can point to underlying factors that affect a patient subgroup’s response to a treatment, thereby improving scientific understanding of human health.

Despite the potential for EHR data, current statistical and machine learning (ML) methods are limited in their capacity to learn from these data for a variety of reasons. Many commonly used methods do not natively handle mixed data types or longitudinal data collected at non-uniform intervals. More fundamentally, it is not known a priori what underlying structure a given collection of EHR data might contain, and thus the best choice of ML method is non-trivial. This uncertainty has pushed the research field towards black-box, high-capacity methods embodied by deep learning. The common deep learning approach to EHR analysis is to develop unsupervised auto-encoders¹,4,5 that perform dimensionality reduction. Although potentially useful, the resulting data representations may not improve predictive models of patient outcomes. Another deep learning approach is to train ensembles of large recurrent neural networks, an approach shown to yield slight improvements over baseline logistic regression models⁶. In either case, the crucial task is to identify explanatory features of models² and interpret them. This task has been noted as a weakness of state-of-the-art approaches using deep learning⁷.

In order to address interpretability, we focused our analysis in this paper on the interpretation of various ML models

for the task of disease prediction. We trained 3 state-of-the-art ML methods to predict 7 patient diagnoses with varying prediction horizons. For each ML model that was developed, we compared model-specific and model-agnostic feature importance scores, including coefficient importance, Gini importance, univariate effect size, and permutation importance. We then conducted a correlation and interpretability analysis for 7 diseases to determine 1) how well the important features comport with reality, 2) how well different measures of importance agree, and 3) how well ML models agree, taking into account their predictive performance. The main finding of our analysis is that permutation importance, a model-agnostic method, produces the most clinically relevant interpretations, as long as the underlying model produces good predictions. Among models with high predictive performance on test sets, permutation importance scores were highly correlated, and interpretable in the sense that they matched clinical understandings of these diseases.

Methods

In this section we describe the data resource and the preliminary data processing used to formulate the prediction task. We then describe the ML approaches and feature importance measures used in this paper, along with their strengths and weaknesses. Code to reproduce the analysis in this paper is available online.

Geisinger Health Records

We conducted our analysis on a set of data from 899,128 patients from the Geisinger Health System, collected between 1996-2015. For each patient we collected their available lab measures, demographic information and diagnostic codes, summarized in Table 1. We split the laboratory measures into two groups: common measures, for which the missing rate was less than 46.5% across patients, and rare measures. This threshold was chosen via a sample size analysis by Beaulieu-Jones et. al.8. For the common measures, the median lab values were used as predictors. Missing values for these measures were imputed using softImpute9. The choice of imputation algorithm was made based on a previous study of imputation methods, conducted on the same patient population8.

We determined disease status using ICD-9 diagnosis codes. These diagnosis codes represent 80% of the total diagnosis codes in the EHR, and all codes between 1996 and 2015. ICD-10 codes were available for patients with recent encounters; however, since these codes are non-trivial to integrate, we left this task to a future study. In order to

---

1http://github.com/EpistasisLab/interpret_ehr
improve our confidence in ICD-9 codes as a proxy for diagnosis, we required that cases had 3 instances of these codes in their medical record. Controls were conversely selected from those patients that had no instances of the corresponding code in their record.

We constructed the learning task as follows: given a patient’s record some length of time before their diagnosis, predict their outcome status. We constructed predictive models with a prediction horizon of one day, six months, and one year prior to diagnosis to assess the sensitivity of our predictions to recent information about the patient. Since some patients did not have up to one year or six months’ worth of medical records, the cohort for each studied disease shrank slightly as the horizon increased. However, this effect was minimal as shown in Fig. 1.

**Figure 1:** Number of cases for each disease and prediction horizon.

**Machine Learning Methods**

In order to classify a patient’s disease status, we build a classification model $\hat{y}(x)$ trained on a labelled set of training examples, $\{y_i, x_i\}_{i=1}^N$. Each of the $N$ examples represents a patient, where $x \in \mathbb{R}^d$ is a $d$-dimensional vector of predictors (from Table 1) and $y \in \{0, 1\}$ is the patient’s outcome, encoded as 1 if the patient is diagnosed and 0 otherwise. We use $X$ to refer to a matrix of predictors/features, with $N$ rows and $d$ columns.

We analyzed three ML methods for predicting patient outcomes: penalized logistic regression (LR), random forest (RF), and extreme gradient boosting (XGBoost). We chose to use LR and RF due to their pervasiveness and accessibility to researchers. XGBoost was chosen as well due to its strong performance in many recent competitions, and subsequent adoption as the out-of-the-box classifier of choice$^{10}$. For each of these methods, we briefly summarize their methodology below and discuss how one may interpret the models that result.

**Penalized Logistic Regression**

Logistic regression trains a linear model on the log-odds ratio of the outcome being positive, i.e.

$$\log \left( \frac{Pr(y_i = 1|x_i)}{Pr(y_i = 0|x_i)} \right) = \beta^T x_i$$

where $\beta = [\beta_1, \ldots, \beta_d]$ are coefficients associated with each predictor. In our analysis, we assumed the predictors are standardized to unit variance and mean-centered so that the intercept is zero.

In standard logistic regression, the coefficients are chosen to maximize the log-likelihood of the observations. Penalized regression applies an additional penalty term that is proportional to the magnitudes of the coefficients, as:

$$\max_\beta \left\{ \sum_{i=1}^N [y_i(\beta^T x_i) - \log(1 + \exp(\beta^T x_i))] - \lambda \sum_{j=1}^d ||\beta_j|| \right\}$$

(2)

The $\lambda$ term determines the strength of regularization; a larger $\lambda$ forces the coefficients to be closer to zero. The norm $|| \cdot ||$ may be the L1 norm (lasso$^{11}$) or L2 norm (ridge regression$^{12}$). The coefficients in Eqn.1 can be interpreted
as the change in the log-odds of the outcome per unit change in the corresponding predictor, correcting for all other predictors. As a result, LR is one of the most popular methods for interpretable modeling.

In addition to the log-odds interpretation, it is common to use the coefficient magnitudes ($|\beta|$) as an estimate of the importance of each predictor. With standardized predictors this seems reasonable, since the factors with the largest effect sizes have the most influence on the log-odds ratio of the prediction. However, as others have pointed out, this interpretation has serious caveats\cite{13, 14}. Most notably, when model assumptions are violated, the coefficient values will be incorrect. In the presence of multicollinearity, for example, the coefficients may compensate for correlations in $x_i$ when maximizing the objective function (Eqn. 2). In this scenario, it is no longer valid to interpret their effect on the log-odds ratio of the outcome independently, since the predictors are dependent on each other.

Many techniques to address multicollinearity of regression models have been proposed\cite{13, 15}. For example, one can drop features with high variance inflation factors, add interaction terms, or conduct feature selection to remove correlated variables. Penalized regression tends to improve estimates of the coefficients in cases of multicollinearity since the penalization term improves the condition of $X$ from which the estimates are derived\cite{12}. Nevertheless, the success of these techniques must be validated empirically. In our analysis, we considered lasso and ridge regression with varying degrees of penalization ($\lambda$), using both the traditional coefficient magnitude interpretations as well as a model-agnostic permutation test that is described below.

**Random Forest**  Random forest is an ensemble ML model that trains several decision trees using a combination of bootstrap aggregating (a.k.a. bagging) and random feature selection\cite{16}. The final model output is determined by a majority vote of the outputs of the individual trees. One of the attractive features of RF is the ability to estimate the importance of each features in the trained model. This feature importance is known as the Gini Importance.

Decision trees (the basic ML models comprising the ensemble) use a heuristic to determine which feature to split on while recursively constructing the model; in our case this heuristic is the Gini criterion. By storing these heuristic measures at each node, the importance of each feature can be estimated quickly from the model. The Gini importance of each feature is estimated by measuring the mean decrease in the heuristic that is brought about by splitting on that feature in any place within the forest. This score is normalized across the forest and across features so that all Gini importance scores sum to 1.

Several authors have pointed out issues with this method of determining feature importance\cite{17–20}. For one, features with a higher number of split points (e.g. continuous features) are more likely to have a high importance purely due to the number of splits. This is due to sampling bias: an optimal split chosen among more candidate points is more likely to reduce the Gini criterion purely by chance\cite{17, 20}. In addition, because feature importance is defined relative to the training data, the bootstrap sampling approach utilized by RF can introduce a bias: for a given training instance, only certain variables and/or levels of variables will be competing when the optimal split point is chosen during tree construction. This has led to the observation in genetics studies that Gini importance prefers SNPs with larger minor allele frequencies\cite{21}.

**XGBoost**  XGBoost is an ensemble ML method based on gradient boosting of individual decision trees. Rather than simultaneously training a forest of trees like RF, gradient boosting creates an ensemble by iteratively training decision trees on weighted training samples, where the weights are updated each iteration to reflect the residual error of the current ensemble. XGBoost uses a form of regularized gradient boosting proposed by Friedman et. al.\cite{22} and includes additional optimizations that have led to its prominence among the leading entries to several ML competitions\cite{10}. By default, XGBoost also uses Gini importance as an internal feature importance score.

**Other feature importance measures**

In addition to the internal feature importance measures from constructed models, we considered two other approaches: a univariate regression score and permutation importance.
**Univariate Score**  For this score we simply calculate the magnitude of the marginal effect of each standardized predictor in \( x \) by fitting univariate LR models and filtering out insignificant coefficients according to a \( p \)-value threshold of 0.05. This is the simplest feature importance measure tested here, and unsurprisingly has strong assumptions, namely that a predictor’s importance is independent of all other factors. It is also important to note that significant predictors may not make useful predictions, as discussed in other work\(^2\).

**Permutation Importance**  We use a model-agnostic permutation importance score first proposed by Breiman et al.\(^6\) to estimate the importance of the features in the trained models. Permutation importance is defined as the mean decrease in accuracy of the trained model when each feature is permuted. We calculate the permutation importance of predictor \( x_j \in x \) by the following steps:

1. Create a permuted test set \( \{y_i, x'_i\}_{i=1}^{N_t} \) in which \( x_j \in x \) is randomly shuffled. \( N_t \) is the number of test samples.
2. Generate predictions on the normal test set, \( \hat{y}(x) \), and permuted predictions, \( \hat{y}(x') \)
3. The permutation importance (PI) is the mean decrease in accuracy due to the perturbed feature, i.e.:

\[
PI(x_j) = \frac{1}{N_t} \sum_{i=1}^{N_t} \mathbb{I}[y_i = \hat{y}(x_i)] - \frac{1}{N_t} \sum_{i=1}^{N_t} \mathbb{I}[y_i = \hat{y}(x'_i)]
\]

Permutation importance has a few desirable properties. By using a randomly shuffled predictor as the permutation, permutation importance score compares the importance of each feature to an identically distributed predictor, thereby reducing potential bias. Furthermore, this score is produced on test data which renders a more accurate portrait of how the model behaves with new data. Permutation importance also allows us to make apples-to-apples comparisons of the importance of different ML models trained on the same data.

Downsides of permutation testing include its complexity and its inability to handle variable interactions. Permutation importance scores require generating predictions on the test set twice for each predictor, which may be computationally intractable for larger feature spaces. The permutation scores also do not take into account that predictors may naturally vary together. This can cause misleading interpretations for certain models. As an example, consider a model with two correlated features. Although the model may assign a weight of zero to one of the features if they always change together, a permutation test would indicate that one of the correlated features is unimportant. For the model this is true but the context is important. Therefore, the interpretation of permutation importance scores must take into account whether predictors are expected to change independently.

Permutation importance has been extended to address correlated variables\(^1\) and also can be extended to incorporate statistical tests\(^5\). Many other model-agnostic measures of feature importance exist, such as Relief and its variants\(^2\). However, Relief scales with the number of samples squared, making it intractable for tens to hundreds of thousands of patients.

**Experimental Setup**

For each outcome, we created an evaluation cohort of cases and controls. We used all cases, and sub-sampled the controls to match the sex and age quartile of each case. This results in datasets twice the size of the samples in Fig. 1 with 147 total predictors. To evaluate each ML method, we conducted 10 repeat trials on random shuffles of the data. For each trial, the data was split 50/50 into training and test sets. We conducted hyper-parameter tuning via 10-fold cross validation on the training set for each method. We then evaluated the tuned model on the test set and reported the area under the receiver operator characteristic curve (AUROC).

The internal feature importance measure of the tuned method applied to the entire training set was stored, in addition to permutation importance scores for the model on the test set. For each patient outcome, we examined the important features and assessed their interpretability. We also looked at the correlation between feature importance scores in a pairwise fashion to determine agreement between the models.
**Results**

The results for each disease, grouped by ML method and prediction horizon, is shown in Fig. 2. We find across diseases that XGBoost (XGB) performs the best, followed closely by RF. LR under-performs these tree-based ensemble methods, especially for predicting Alzheimer’s disease and esophageal reflux. The differences in performance between the methods on all diseases at each prediction horizon are significant ($p < 9.5 \times 10^{-12}$) according to pairwise Wilcoxon rank-sum tests with Bonferroni correction.

We find reasonably high AUROC performance across diseases. With a one year prediction horizon, the best model (XGBoost) achieved median AUROC values of 0.85 for Alzheimer’s disease, 0.91 for Diabetes, 0.96 for Diabetes with renal manifestations, 0.85 for esophageal reflux, 0.91 for kidney disease, 0.88 for liver disease, and 0.87 for sleep apnea. We find that predictive ability diminishes as the prediction horizon increases, as expected. The exception is the predictions for esophageal reflux that trend higher for the ensemble methods with longer prediction horizons.

We find that, across diseases, the Gini importance scores for XGBoost do not align very well with the expected importance scores. An example of this is shown in the scatter plots in Fig. 3, which shows XGBoost and RF importance measures using both Gini importance (top) and permutation importance (bottom) for the diabetes models. From left to right, the prediction horizon increases. We expected the presence of a hemoglobin A1c lab to be very predictive of outcome one visit prior to diagnosis, and for other risk indicators such as high average glucose levels, high BMI, and high triglycerides to be more predictive at six months to one year. We see this behavior with the RF importance scores to an extent, but observe less intelligible Gini importance scores from the XGBoost model. The XGBoost Gini importance scores suggest the anion gap measure (a potential sign of diabetic ketoacidosis) and age (a universal risk factor) are the most important. However, the permutation importance measure applied to both models (bottom) generated good agreement with expected predictors, and also shows that the two models actually agree to a large extent about which factors are important.

XGBoost tends to over-estimate the importance of age on nearly every outcome, likely due to the bias of the Gini importance measure discussed earlier. Age is a continuous variable in our analysis (it is calculated using the visit date), so despite being corrected for via quartile-matching among the controls, there appears to be enough variability.
Figure 3: Pairwise comparisons of feature importances for predicting diabetes. The prediction horizon increases to the right. Top: Gini importance scores for Random Forests and XGBoost. Bottom: Permutation importance for the same models. The permutation importance scores show better agreement between the models and produce more intuitive clinical interpretations.

Across outcomes, RF permutation and XGBoost permutation scores are very correlated (Pearson’s $R^2=0.95$) as shown by the pairwise comparisons in Fig. 4. The Gini importance measures for these models show somewhat lower correlation with each other ($R^2=0.85$), and the correlation with LR coefficient magnitudes (LR-importance in Fig. 4) is lower still ($R^2=0.37$ with RF and $R^2=0.34$ with XGBoost). In addition, the permutation importance of the LR models is uncorrelated with all other importance measures ($R^2 \leq 0.55$) aside from the LR coefficient magnitudes ($R^2=0.81$). This may be due to in part to the lower performance of these models for prediction (see Fig. 2) and due to the conflicting behavior of LR and permutation importance in the presence of collinearity, discussed in the methods section. Finally, the univariate importance score produce the importance scores that agree least with the other approaches, suggesting that a univariate analysis is insufficient for determining the important factors of these diseases.

We summarize the important features for each disease prediction using RF permutation importance in Fig. 5, with one visit predictions on the left and one year prediction models on the right. Diseases and their most important predictors are clustered. The predictions from one visit prior to diagnosis are the most interpretable; diabetes and diabetes with renal manifestations cluster based on the HbA1c test, with microalbumin indicating kidney complications for the latter diagnosis. Liver disease and sleep apnea cluster based on the importance of BMI. Alanine aminotransferase is the next most important predictor of liver disease, as expected. Kidney disease predictions depend on creatinine, urea nitrogen, age and glucose measurements, which are all expected. Alzheimer’s disease predictions depend on age in addition to cobalamin (vitamin B-12) measures. Cobalamin tests are typically ordered to rule out symptoms of a cobalamin deficiency (e.g. memory loss) prior to Alzheimer’s diagnosis. The most difficult interpretation is for esophageal
**Discussion**

EHR data can be used to support the development of predictive models that may assist clinicians at the point of care, as well as provide insight into factors driving outcomes. In this paper, we evaluated the ability of three state-of-the-art ML approaches to produce interpretable predictive models for 7 patient outcomes, considering prediction horizons of up to one year from diagnosis. We focus on methods for assessing feature importance of the constructed models, including model-specific and model-agnostic approaches. We find that gradient boosting (XGBoost) generates the most accurate predictions across outcomes, but that its internal measure of feature importance (Gini importance) is insufficient for a reliable clinical interpretation of the model. Applying the model-agnostic permutation importance score to the resultant models fixes this shortcoming and results in models with sensible interpretations. Permutation
importances match clinical intuition and agree between the XGBoost and RF models.

We plan to address the following shortcomings of this analysis in future work. First we would like to include additional predictive factors in our analysis, including smoking status, socio-economic measures, and disease comorbidities. We plan to incorporate ICD-10 disease codes from 2015-present available in Geisinger’s health records for assessing diagnoses. We also plan to expand the number of diseases studied and the prediction horizon to characterize the point at which models are no longer predictive of outcome. Additionally, we plan to validate the constructed models on a separate patient population to determine how generalizable these predictive models are given the idiosyncrasies of individual health care systems.

Abstract

Calculating Differentially Expressed Genes (DEGs) from RNA-sequencing requires replicates to estimate gene-wise variability, a requirement that is at times financially or physiologically infeasible in clinics. By imposing restrictive transcriptome-wide assumptions limiting inferential opportunities of conventional methods (edgeR, NOIseq-sim, DESeq, DEGseq), comparing two conditions without replicates (TCWR) has been proposed, but not evaluated. Under TCWR conditions (e.g., unaffected tissue vs. tumor), differences of transformed expression of the proposed individualized DEG (iDEG) method follow a distribution calculated across a local partition of related transcripts at baseline expression; thereafter the probability of each DEG is estimated by empirical Bayes with local false discovery rate control using a two-group mixture model. In extensive simulation studies of TCWR methods, iDEG and NOIseq are more accurate at 5%<DEGs<20% (precision>90%, recall>75%, false_positive_rate<1%) and 30%<DEGs<40% (precision>recall>90%), respectively. The proposed iDEG method borrows localized distribution information from the same individual, a strategy that improves accuracy to compare transcriptomes in absence of replicates at low DEGs conditions.

Introduction

Precision medicine aims to deliver “the right treatments, at the right time, to the right person” [Kaiser 1]. However, clinical research, medicine, and pharmacology need new tools to achieve that goal. The prevailing system of one-size-fits-all drug development has led to the ten top-grossing USA drugs being ineffective for more than 75% of users, and these patients typically cannot be identified until after therapeutic failure has occurred. The success of precision medicine hinges on identifying the precise aberrant mechanisms at play during an individual’s disease course to optimize treatment based on that individual’s biology.

Single-subject RNA sequencing (RNA-Seq) analysis considers one patient at a time, with the goal of revealing an individual’s altered transcriptomic mechanisms. Relative to traditional cohort-based analyses, a major challenge of single-subject RNA-Seq analysis is the estimation of gene expression variance which is required to identify differentially expressed genes (DEGs). In cohort-based methods, gene variance is calculated across a heterogenous set of samples, and the statistical methods employed leverage and rely on those replicates. However, they also emphasize consistent and average responses which may not accurately represent a single patient when the disease is heterogenous or stratified. Alternatively, the variance can be assessed between two conditions in one subject and three replicates. Yet, obtaining sufficient isogenic replicates for one subject to answer more precision questions poses a major difficulty due to (i) limited tissue availability, (ii) the risks associated with invasive tissue-sampling procedures, and (iii) general costs and inefficiencies with the current technology. Even though there is a great body of work for identifying DEGs in RNA-Seq data—even frameworks for N-of-1 studies either for a single analyte or by pooling gene products in pathways, to the best of our knowledge, no methods have been designed or validated at the gene level to determine the effect size and statistical significance of a single-subject, single RNA-Seq studies in two conditions without replicates (TCWR). Strategies to implement standard RNA-seq analysis methods for comparing TCWR have been proposed in the respective methods’ publications without comprehensive evaluation. Typically, these standard methods, usually requiring large cohorts, have been adapted to identify DEGs in TCWR by imposing restrictive transcriptome-wide distribution assumptions, thus limiting localized inferential opportunities.
Three critical obstacles hinder the analysis of single-subject TCWR studies. These include i) patient-level inferential capability in absence of biological replicates, ii) sensitivity to fold-change inflation in low-expression genes, and iii) rigid parametric data assumptions for variance estimation. To overcome the current technical limitations in analyzing RNA-Seq data, we propose a new method that borrows localized information across different genes from the same individual using a partitioned window to strategically bypass the requirement of replicates per condition: iDEG (individualized Differentially Expressed Genes). iDEG applies a localized variance-stabilizing transformation to estimate a gene’s distribution that borrows information from genes with similar baseline expression. While variance-stabilizing transformation has been previously used to identify DEGs across a large number of subjects or replicates, our approach differs from these since it has been developed to be applied directly on two paired transcriptomes from a single subject by computing the localized dispersion parameters in different windows of genes with similar expression at the baseline.

In this work, we evaluated the performances of iDEG and other four standard approaches applied to single-subject TCWR studies (edgeR, NOISeq-sim, DESeq, DEGseq). We also designed simulation studies under several conditions to stratify the range of applicability of our proposed strategy, which could eventually complement other RNA-seq analyses in TCWR studies. This study demonstrates the utility of variance-stabilizing transformations within subject in absence of replicates in two conditions, which is distinct from previous implementations of variance-stabilizing methods conducted across replicates or subjects.

Methods

The iDEG algorithm: iDEG

The iDEG algorithm (Figure 1) is an easy-to-implement, single-command function written in R with a computation speed of one second for identifying a subject’s DEGs on 8GB Ram computer. The subsequent sections expand on the main iDEG steps shown in Figure 1.

1. Normalize Library Sizes
2. Partition genes into windows
3. Obtain window-specific estimates
4. Apply VST function, h()
5. Compute Z-statistic
6. Estimate locfdr

Modeling read counts via a re-parameterized Negative Binomial (NB) distribution

We model read counts \( Y_{gd} \) as following a re-parameterized negative binomial distribution with mean \( \mu_{gd} \) and dispersion \( \delta_g \). Thus, \( Y_{gd} \sim \text{NB}(\mu_{gd}, \delta_g) \) with the following probability mass function, mean, and variance, respectively. Since for
any subject, both transcriptomes are sequenced separately, they are treated as conditionally independent, conditional on the subject*.  

\[
P(Y_{gd}|\mu_{gd}\delta_g) = \left(1 + \delta_g\mu_{gd}\right)^{\frac{1}{2}} f\left(Y_{gd}\right) \left(\frac{\delta_g\mu_{gd}}{1+\delta_g\mu_{gd}}\right)^{Y_{gd}} ; E(Y_{gd}) = \mu_{gd}, \ Var(Y_{gd}) = \mu_{gd} + \delta_g\mu_{gd}^2 \quad \text{(Eq. 1)}
\]

To identify DEGs from a pair of transcriptomes, we must test multiple hypotheses \(H_g; \mu_{g1} = \mu_{g2}; \ g = 1, \ldots, G\), where \(\mu_{g1}\) and \(\mu_{g2}\) are the theoretical mean expression levels for each gene “g” in sample 1 and sample 2, respectively. We define the DEG set by \(G = \{g: \mu_{g1} \neq \mu_{g2}; \ g = 1, \ldots, G\}\) and its set-theoretic complement of non-differentially expressed genes, or “null gene set” by \(G' = \{1, \ldots, G\}\setminus G\). In presence of replicates, each hypothesis can be tested with a two-sample comparison, using Welch’s t-test statistic: \(t_g = (\bar{Y}_{g1} - \bar{Y}_{g2}) / [(S^2_{g1}/N_{g1} + S^2_{g2}/N_{g2})^{1/2}]\) were \(\bar{Y}_{g1}\) and \(\bar{Y}_{g2}\), \(S^2_{g1}\) and \(S^2_{g2}\), and \(N_{g1}\) and \(N_{g2}\) are each groups’ respective sample mean, standard deviation, and size. However, when there is only one observation for \(Y_{g1}\) and one for \(Y_{g2}\), neither \(S^2_{g1}\) nor \(S^2_{g2}\) are computable. We thus propose iDEG: an algorithm that transforms \(Y_{g1}\) and \(Y_{g2}\), such that a simple function of the transformation allows for modeling all genes with the same distribution. This is done by pooling the genes together and estimating their common variance, hence bypassing the single-subject, single-replicate limitation.

**Normalize read counts with unequal library sizes (Figure 1, Panel 1)**

In practice, unequal DNA library sizes may exist; thus, the first step is to normalize library sizes if necessary. We use the quantile-adjusted conditional maximum likelihood (qCML) procedure by Robinson and Smyth *, for normalization, and subsequently, iDEG is applied.

**Partition genes into windows to estimate local mean and variance (Figure 1, Panel 2)**

Marioni et al. demonstrated the aptness of using expression means to estimate a gene’s variance*. Therefore, by extension, in iDEG we assume that genes of comparable expression levels are assumed to behave similarly (genes with similar means share similar variances). Thus, after normalization, the next step is to group genes into \(W\) non-overlapping windows of similar expression levels to approximate each window’s local mean and variance parameters. In the re-parameterized NB distribution, the variance of a given gene, \(g\), is a function of its mean, \(\mu_g\), and dispersion, \(\delta_g\). Thus, the genes are partitioned to obtain their local, window-specific parameters. We define the \(w^{th}\) window by the \((w-1)^{th}\) and \(w^{th}\) percentiles, for \(w = 1, \ldots, W\), \(G_w = \{g: (w-1)^{th} \text{ percentile of } Y_{g1} < Y_{gw} < w^{th} \text{ percentile of } Y_{g1}\}\). To provide robust parameter estimates, we recommend a large positive integer, \(W\), so that each window contains between 150 and 200 genes. However, the final predictions are not overtly sensitive to the choice of \(W\) (< 10% difference, data not shown – available upon request).

**Compute each window’s parameters (Figure 1, Panel 3)**

As seen in (Eq. 1), \(\text{Var}(Y_{gd}) = \mu_{gd} + \delta_g\mu_{gd}^2\). Therefore, when estimating variance locally, we are actually estimating the dispersion parameter \(\delta_g\) for each gene count. This local estimation provides a more numerically fair evaluation of genes as it allows for comparisons relative to their mean expression counts. Particularly, it enables a better estimation of dispersion and variance parameters for genes with extremely high or low expression counts, since these genes are grouped together into windows, and share window-level parameter estimates in order to over-inflate or deflate their variability by averaging it out across the entire transcriptome. This is done in effort to mitigate challenges with making DEG calls in lowly and highly expressed genes. This value is required for the variance-stabilizing transformation (VST) calculation (Eq. 3; Figure 1 Panel 4). However, variance cannot be estimated when only a single observation is available. For RNA-Seq data analysis, one common assumption is that the dispersion \(\delta\), is equal across samples 1 and 2, and that dispersion is a function \(q\) of the mean, \(\mu_g\). Thus, in the absence of replicates, we partition genes into small windows to estimate the functional mean-dispersion relationship, \(\delta = q(\mu)\), and hence the variance. We propose a two-step nonparametric procedure to obtain: (i) an initial estimate of \(\delta\) by pooling genes locally; and (ii) a refined estimate of \(\delta\), by estimating \(q(\mu)\) with a smooth curve-fitting technique. In this approach, all non-differentially

---

* A note on notation, since iDEG models each patient’s paired transcriptome individually, the subscripts for each subject are omitted since only a subject is handled at a time in any given calculation.
expressed (null) genes belonging to the same window \( G_w \) roughly have the same mean \( \mu_w^* \) and the dispersion value \( \delta_w^* \). Thus, \( Y_{gd} \sim NB(\mu_w^*, \delta_w^*) \) \( \forall g \in G_w, d = 1, 2 \) where \( \mu_w^* \) and \( \delta_w^* \) are the window-specific mean and dispersion values for null genes in \( G_w \), while \( d \) specifies if the count comes from sample 1 or 2.

The initial window estimates \( \mu_w^* \) and \( \sigma^2_w \) as \( \hat{\mu}_w = \text{Median}(Y_{gd}) \) \( \forall g \in G_w \) and \( \hat{\sigma}^2_w = \text{Median}(|Y_{gd} - \text{Median}(Y_{gd})|) \) \( \forall g \in G_w \), respectively. Since \( \text{Var}(Y_{gd}) = \sigma^2_{gd} = \mu_{gd} + \delta_{gd} \mu_{gd}^2 \), we estimate \( \delta_w^* \) with \( \hat{\delta}_w^* = (\sigma^2_w - \hat{\mu}_w^*)/\hat{\mu}_w^* \), for all windows \( w = 1, \ldots, W \). To further improve the estimate of the dispersion parameter, \( \delta_g \), a smoothing spline technique is used to fit a functional mean-dispersion relationship, \( \delta_g = q(\mu_g) \), by solving the following optimization problem:

\[
\hat{q}_\lambda = \min_{q \in Q} \sum_{w=1}^{W}\left(\delta_w^* - q(\hat{\mu}_w^*)\right)^2 + \lambda \int [q''(t)]^2 \, dt \quad \text{(Eq. 2)}
\]

where \( Q \) is the second-order Sobolev space on \([0, 1]\) containing \( q \), and \( \lambda \) is a smoothing parameter (selected via generalized cross validation). After the fitted curve \( \hat{q}_\lambda \) is obtained as in Eq. 2, the refined estimate of \( \delta_g \) is computed as \( \hat{\delta}_g = \hat{q}_\lambda(\hat{\mu}_g^*) \), \( \forall g \in G_w, w = 1, \ldots, W \). Figure 2 illustrates the functional mean-dispersion relationship and calculation.

![Figure 2](image-url)  
**Figure 2.** Localized, window-specific dispersion estimates as a function of log (mean expression). iDEG partitions the transcriptome into \( W \) equal-sized genomic windows of similar expression size and then calculates the over dispersion parameter relative to the gene’s mean expression. The number of windows \( W \) is a parameter in the iDEG function-call and should be empirically calculated relative to the transcriptome size. After conducting a few numerical studies, we recommend setting \( W=100 \) in order to allow for over dispersion estimates of highly and lowly expressed genes to be representative of their groups.

Summarizing, we get:

a) Initial Estimate of dispersion  
\[
\text{Var}(Y_{gd}) = \sigma^2_{gd} = \mu_{gd} + \delta_{gd} \mu_{gd}^2 \Rightarrow \hat{\delta}_w^* = (\sigma^2_w - \hat{\mu}_w^*)/\hat{\mu}_w^*
\]

b) Refined estimate of dispersion  
\[
\hat{q}_\lambda = \min_{q \in Q} \sum_{w=1}^{W}\left(\delta_w^* - q(\hat{\mu}_w^*)\right)^2 + \lambda \int [q''(t)]^2 \, dt \Rightarrow \delta_g = \hat{q}_\lambda(\hat{\mu}_g^*)
\]
These equations come from the fact that in the negative binomial, variance (equation a) is a function of both mean and dispersion. So, the above equation (a) is rewritten version of the typical variance equation, with the stars and hat superscripts denote that it is now an estimate of the theoretical values for each partitioned window, $w$. As shown in (b), once window-level parameters are estimated (e.g., $\hat{\mu}_w$), then a window-level dispersion parameter is estimated for all genes in that window (e.g., $\hat{\delta}_g = \hat{q}_g(\hat{\mu}_w) \forall g \in G_w$), by fitting refined, functional estimate of dispersion.

**Apply the Variance Stabilizing Transformation ($h(Y_{gd})$) to each gene (Figure 1, Panel 4)**

After fitting $\hat{\delta}_g$, we apply the variance stabilizing transformation $h$ to the counts, $Y_{gd} \forall g \in G_w$:

$$h(Y_{gd}) = \frac{1}{\hat{\delta}_g} \sinh^{-1} \sqrt{Y_{gd} \hat{\delta}_g} + \left(\frac{1}{\sqrt{\hat{\delta}_g}} - 1\right) \sinh^{-1} \sqrt{\frac{Y_{gd} + \hat{\delta}_g}{\hat{\delta}_g}} \forall g \in G_w \text{(Eq. 3)}$$

This transformation\(^{22}\) of the expression $Y_{gd}$ in each window $w$, results in an approximately constant variance across all windows of the transcriptome (Figure 3), regardless of the expression mean, $\mu_{gd}$. That is $h(Y_{gd}) \sim N(h(\mu_{gd}), 1)$, where $d$ specifies if the count comes from sample 1 or 2. Therefore, the difference of the two independent normal random variables (e.g., $h(Y_{g1}) - h(Y_{g2})$ ) approximately follows a common normal distribution with mean 0 and a constant variance: $Z_g = (1/\sqrt{2})\{h(Y_{g1}) - h(Y_{g2})\} \sim N(0,1)$. We suggest replacing $\sqrt{2}$ by a robust estimate of standard deviation (e.g., median absolute deviation)\(^{23}\). In most single-subject analyses, the estimated dispersion parameter, $\hat{\delta}_g$, is small, but when $\hat{\delta}_g \geq 2/3$, the VST $h(Y_{gd})$ is not numerically stable. To avoid this issue, we suggest replacing $h$ with $h^{*} = \left(1/\sqrt{\hat{\delta}_g}\right) \sinh^{-1} \sqrt{Y_{gd} \hat{\delta}_g}$, $g = 1, \cdots, G$; $d = 1,2$. If a negative value of $\hat{\delta}_0$ is obtained, we conservatively set it to zero to assume a larger variance.

**Figure 3. Variance Stabilizing Transformation (VST).** Panel A depicts the raw difference $D_g = Y_{g1} - Y_{g2}$ for 20,000 simulated genes (Methods Simulations), suggesting that the variance of $D_g$ increases as the mean $\mu_{g1}$ increases; hence, there is no uniform cutoff to differentiate DEGs and null genes. Panel B illustrates that, for null genes, VST makes the variance of $D^{*}_g = h(Y_{g1}) - h(Y_{g2})$ constant regardless of mean $\mu_{g1}$.

**Compute the summary statistic for each gene (Figure 1, Panel 5)**

In the context of noisy data and large-scale inference, performing individual tests neglects the parallel structure of RNA-Seq data. Moreover, actual data mean and variance may not be close to their theoretical values of 0 and 1 due to various reasons (e.g., correlation across genes, correlation between samples, or failed mathematical assumptions). Therefore, we estimate an empirical null distribution $N(\mu_0, \sigma_0)$ to test these individual hypotheses.

Since differentially and non-differentially expressed genes generally follow different distributions, the probability density function of $Z_g$, $f(z)$, is naturally modeled by a two-group mixture: $f(z) = \pi_0f_0(z) + \pi_1f_1(z)$. Here, $f_0$ and $f_1$ are the probability density functions of genes in $G'$ and in $G$, while $\pi_0$ and $\pi_1 = 1 - \pi_0$ are their respective membership proportions. We assume a normal distribution following previous work from Dean and Raftery- that applied a two-group mixture model to identify differentially expressed genes, assuming a normal distribution for the null genes and a uniform distribution for the DEGs. However, we relax their assumptions for the marginal distribution and assume an exponential family. We approximate $f(z)$ using a smooth K-parameter exponential

586
family distribution, $f(z) = \exp \left( \sum_{k=0}^{K} \beta_k z^k \right)$, and estimate the parameters ($\beta_0, \beta_1, \cdots \beta_k$) using Efron’s approach.

**Estimate the local false discovery (locfdr) for each and identify DEGs (Figure 1, Panel 6)**

Finally, to control the false discovery rate (fdr), we adopt Efron’s idea to estimate the local fdr (locfdr) using the R package locfdr and estimate $\pi_g$, $f_0(z)$ by maximum likelihood. Efron et al. have shown locfdr’s close connection to the BH false discovery rate procedure; therefore, after estimating locfdr($z_g$), it identifies differentially expressed genes by comparing locfdr($z_g$) to a pre-specified $\alpha$-cutoff value. The final set of differentially expressed genes identified by applying the iDEG procedure is denoted by $\hat{G}$.

**Simulations (Figure 4)**

To compare the performance of iDEG to existing methods – including edgeR, DEGSeq, DESeq, and NOISeq – extensive numerical studies were conducted assuming that RNA-Seq data follow the NB distribution with a varying dispersion parameter $\delta_g$. Of note, these methods assume the NB distribution for data, which is used in the simulation; except for NOISeq that is nonparametric and DEGseq which assumes a binomial distribution. Baseline (normal tissue) and case (tumor sample) transcriptomes are both simulated and assumed to contain $G = 20,000$ genes; the library size of one transcriptome is 1.5 times larger than the other one. The single-subject RNA-Seq datasets are simulated with different percentages of DEGs, including DEG percentage = 5%, 10%, 15%, 20%, 25%, 30%, 35%, and 40%, and also with different window sizes $W = 10, 100, 1000$ (data not shown). For windows size of 10, 100, and 1000 the accuracies of the simulations remained consistent across each of these simulation conditions. $Y_{g1} \sim NB(\mu_{g1}, \delta_g)$ and $Y_{g2} \sim NB(\mu_{g2}, \delta_g)$, where $\mu_{g1}$ follow a discrete uniform over the range $B = \{5, 6, \ldots, 10,000\}$, and the dispersion parameter $\delta_g$ has been set to $\delta_g = 0.005 + 9/(\mu_{g1} + 100)$, per Anders and Huber-. Probabilities for gene expression means, $\mu_{g1}$, are sampled from:

$$P(\mu_{g1}) = (1/500)e^{-(1/500)\times \mu_{g1}}, \quad g = 1, \ldots, 20000.$$  

For the case transcriptome, we set $\mu_{g2} = \mu_{g1}$ for $g \in G'$ and $\mu_{g2}$ follows a Poisson distribution. $d$ is a random variable, and $d = (\mu_{g1} + k \sqrt{\mu_{g1}}) / \mu_{g1}$, $k \sim$ Normal (4,1). Here, $s$ indicates increasing expression ($s = 1$) or decreasing expression ($s = -1$) of a gene in the case transcriptome relative to baseline. Finally, for each gene $g$, we simulate one observation for $Y_{g1}$ and $Y_{g2}$, respectively and test the hypothesis $\mu_{g1} = \mu_{g2}$. At each iteration, a baseline and a case transcriptome are generated to simulate a distinct RNA-Seq dataset. Methods are assessed by their Precision, Recall, and FPR, and $F_1$ score, $F_1 = (2 \cdot \text{precision} \ast \text{recall}) / (\text{precision} + \text{recall})$. The average number of identified DEGs is also reported. Of note, we excluded from the comparison GFOLD, a standard approach that can be applied to TCWR studies, as it only ranks genes without providing a measure of significance, thus prohibiting the accurate comparison with the remaining techniques using precision-recall curves or ROC curves.

**Results**

Figure 4 depicts the accuracies obtained in the simulations while Table 1 contextualizes each method’s performance relative to the number of DEG calls and the number (and %) of genes seeded as DEGs. Of note, we have also conducted complementary analyses with a Poisson distribution and showed similar ordering of accuracies between the evaluated methods (data not shown). For windows size of 10, 100, and 1000 the accuracies of the simulations remained consistent (data not shown) and opted for setting $W = 100$ to balance computation time and parameter estimation robustness. As seen in Table 1, NOISeq-sim, edgeR, DEGseq attain a high precision (defined as > 90% precision) across all simulation conditions (5% through 40% DEGs seeded) at the expense of lower recall and a large number of false positives. For example, as seen in Table 1, 5% DEGs, NOISeq-sim, edgeR, and DEGseq all result in a larger of false positives than there are actual seeded genes. Conversely, iDEG attains a high precision (defined as >90%) at the expense of making a smaller number of DEG calls, thus attaining lower recall. The $F_1$ score shown in Fig 4-C is the harmonic mean of the Precision and Recall metrics, aggregating the precision-recall trade-offs made by individual techniques into a single technique. Although iDEG never attains as high a recall as DEGseq, edgeR, and NOISeq-sim, it better balances its precision-recall trade-off into a higher overall $F_1$ score at FDRs<20%, while NOISeq does better at FDR>30%, and the two methods show similar $F_1$ scores at 20%<FDR<30%. Of note, DESeq failed to make any DEG calls across the majority of the simulation conditions (since it either produced “0” or “1” fdr-adjusted probability predictions), preventing us from evaluating their performance at any reasonable false discovery cutoff.
Figure 4. Performance results. NOISeq-sim’s and iDEG’s F-scores are more accurate than that of other methods at 5%<DEGs<20% (iDEG) and 30%<DEGs<40% (NOISeq-sim). At DEG=5% and FDR<10%, iDEG provides an interesting compromise between precision and recall, while NOISeq provides a better compromise when the percentage of DEGs is higher than 30%. Panels A & B: Precision recall curve at 10% FDR for 1,000 and 8,000 seeded DEGs among 20,000 transcripts, respectively. Panel C: F₁ scores. Average F₁ scores resulting from 1,000 repeated experiments with vertical bars representing one standard deviation.

Discussion

No single method has emerged as the optimal approach for all conditions. Low expression levels are extremely susceptible to unstable fold-change estimation, as a 5-fold increase from 2 to 10 counts on a dynamic range of 0 to 100,000 should not be treated equivalently to that between 10,000 and 50,000. Standard practice filters out genes with counts below a certain threshold (typically 5 or 10). However, this solution does not address fold change (FC) inflation above the threshold (e.g., FC>2 at 15 counts), nor how to compare distinct FCs at different expression levels. Alternatively, favoring absolute count difference to identify DEGs leads to a systemic bias towards genes with high expression. Conversely, favoring FC results in a systemic bias towards lowly expressed genes. Either of these solutions yields higher false positive rates. For DEGs<30%, the variance stabilization within partitioned windows proposed in iDEG is shown to address this dilemma of dealing with fold change inflation by comparing FC values relative to their expression levels, perhaps because conventional approaches impose stringent data assumptions that may compromise downstream inferential processes.
Table 1. Performance results of TCWR simulations. At different percentage of DEGs in TCWR simulations, distinct methods obtain the best precision and recall, with iDEG, NOISeq and edgeR producing the best combinations of precision and recall. Of note, edgeR, DEGseq, and DESeq were not designed nor validated for studies without replicates; however, their authors proposed to utilize them in these conditions by defining specific parameters. NOISeq-sim offers high recall and precision with DEGs=40% i.e. when 8,000 genes are dysregulated among 20,000. On the other hand, iDEG obtains high precision with moderate to high recall in all conditions. EdgeR provides moderate precision with very high recall for DEGs>20%.

As we proceeded to validating iDEG in biologic or clinical datasets, a review of literature identified few candidate datasets that comprised targeted mutations over an isogenic background and yield high DEG rates (e.g., DEGs>50%) that did not reflect rates expected in clinical care. In addition, the state of the art in generating reference standard consisted in comparing one method against itself as the overlap of DEGs across conventional methods was low in spite of 30 replicates in isogenic conditions. Because of these two considerations, we decided to publish the results of a comprehensive improvement in reference standard generation as a companion paper33. We have thus generated multiple distinct reference standards (one per conventional method) and developed a “fair” evaluation of methods to identify DEGs in paired conditions without replicates using biological datasets (each method is compared to all other methods but not itself)33. This companion biological paper33 is limited to datasets with high DEGs as no reference datasets were available for low DEGs conditions, while the current simulation explores both low and moderate DEGs levels. We will extend window-level approximations for all techniques considered in our companion paper33 in future studies.

We note several limitations to the current study. First, conventional techniques were not explicitly designed for absence of replicates and are tested in those conditions. In addition, each method assumes some distribution (DEGseq assumes a binomial distribution; iDEG, edgeR, and DESeq assume a Negative Binomial distribution; and NOISeq is non-parametric). Since the distributional form in real-data is never truly known (only approximated), simulating a transcriptome necessarily entails distributional assumptions in every simulation study, which limits its generalizability to real studies and inherently may favor some methods over the others. In cases where biological replicates exist, the existing conventional methods are better powered and more appropriate for inference as their assumed distributions and parameters can be estimated. In cases where biological replicates are unfeasible, the assumptions of these conventional methods are violated, and their performance is not guaranteed. In some cases, some DEG detection techniques actually cannot produce a DEG call in TCWR. This limits the number of techniques available for comparison in our simulation study. Moreover, as seen with DESeq, DEG techniques designed for replicated studies are not necessarily fully operational or effective in TCWR, therefore it is not necessarily recommended to pick an arbitrary DEG technique and use it in non-replicated TCWR studies. We conducted the simulations against these methods to illustrate the need for new approaches to study single-subject transcripts in TCWR conditions. In addition, a true gold standard to evaluate iDEG and other methods is not as simple as obtaining replicates and running conventional methods as pointed out by recent papers34,35.
Conclusion

Over the past decade, state-of-the-art techniques in RNA-Seq data analysis have delivered powerful new tools for extending large-scale inference to small-sample settings. The primary goal of iDEG is not to replace these, but rather to expand the scope of RNA-Seq studies into the single-subject, single-replicate realm and provide novel research opportunities and test methods for controlling fold change inflation at low expression ranges. In iDEG, we have shown the novelty of window partitioning to borrow localized distribution information across genes, and its improved accuracy over alternate methods in low DEG conditions (DEG<20%). Furthermore, this approach could potentially be applied to improve the accuracy of existing parametric and non-parametric differential expression tools. In future studies, we envision to i) extend the window partitioning component of iDEG into other techniques, ii) to locally identify differentially expressed pathways (by incorporating ontologies and knowledge graphs), and iv) to apply it to other ‘omics measures, (e.g., metabolomics, proteomics, etc.).

List of Abbreviations

- DEGs = differentially expressed genes
- FC = fold change
- FCI = fold change inflation
- FDR = false discovery rate
- iDEG = individualized Differentially Expressed Genes
- locfdr: local false discovery rate
- NB = Negative Binomial distribution
- RNA-Seq = RNA Sequencing
- TCWR = two conditions without replicates
- VST = Variance Stabilizing Transformation

High Performance Computing on Flat FHIR Files
Created with the New SMART/HL7 Bulk Data Access Standard

Dianbo Liu, PhD,1,2 Ricky Sahu,3 Vlad Ignatov,1 Dan Gottlieb, MPA,4 Kenneth D. Mandl, MD, MPH1,4

This project was supported as a Leading Edge Acceleration Project (LEAP) under contract 90AX0022/01-00 from the Office of the National Coordinator of Health Information Technology

Abstract
The FHIR Bulk Data API is designed to create a uniform capability for population-level exports from clinical systems, into a file format often referred to as “Flat-FHIR.” Leveraging the SMART backend services authentication and authorization profile, the approach enables healthcare providers and organizations to define and access cohorts from electronic health records and payor claims data with “push button” simplicity—a substantial advance over the current state, where each site of care needs highly skilled extraction transform and load (ETL) efforts.

Introduction
Healthcare providers and organizations using electronic health records do not currently have access to turnkey, standardized methods to export bulk data on large cohorts of individuals. Instead, local teams expert in extraction, transformation and loading of data and in medical terminologies are needed. Yet, there are myriad use cases for population datasets; a healthcare organization may want to frequently upload patients’ data from an electronic medical record system to a research data warehouse. To date, the most widely used FHIR API, SMART on FHIR, is targeted at retrieving data on a single patient at a time. Using this API for population data exports, requires thousands or even millions of queries. In order to facilitate population-level analysis, the SMART project is collaborating with Health Level Seven International (HL7), to extend the FHIR API with a Bulk Data Access method that can be used for large scale sharing from any healthcare system with FHIR implemented as interoperability layer.

The FHIR Bulk Data Access API used a NDJSON-based data format as the default export format for the FHIR data. The resulting file is referred to “Flat FHIR.” JavaScript Object Notation (JSON) is a text data format widely used and with long history. Newline delimited JSON (NDJSON) format makes use of new line to separate different values where each line is a JSON object removing the necessity of loading the entire data set into memory when reading or writing values. When used for FHIR data, each line represents a separate record such as an immunization record of a child or demographic information of a patient.

As the standard becomes more widely adopted and the file size of exports grow, analysts will need to select a data format for efficient computation. To plan for robust analytics on Flat FHIR exports, we seek to compare computation directly on the native NDJSON format with two others—AVRO and Parquet. AVRO is a binary data format, which stores both the data definition and data in the same field and was originally developed for Hadoop. A key feature of AVRO is the support of evolutionary data schemas. Parquet is a binary column oriented data storage format, which means the data were stored by columns instead of rows by the management system. Implemented using record-shredding and assembly algorithms, Parquet files can be efficiently compressed efficiently.

Methods
Dataset
Synthetic data for 1,400,000 immunizations among 152,072 patients were generated using MITRE’s Synthea. The data includes patient ID, diagnosis, medical encounters, social determinants of health, medications and immunization records.
Computational environment
Analyses were conducted using Spark 2.4.0 in Scala 2.11.12 with the spark-avro_2.11 module. The processor was a 2.8 GHz Intel Core i7 cpu with 16 GB 1600 MHz DDR3 RAM, and a solid state hard drive. Java version 1.8.0_202 was used when needed for Scala, Python or Spark functions.

Format conversion and file reading and writing
Flat FHIR file Data in an NDJSON format were loaded into Spark and then converted to AVRO (using Spark-avro_2.11 module) or Parquet (read in to Spark as Spark as dataframes and then written into files) NDJSON, AVRO and Parquet were all read into SQL queries. A series of different SQL queries were tested on all three data formats in the Spark environment. The execution time calculated for each query (Table 1) includes both the query and visualization of head of the query results.

Machine learning platform compatibility
All data loaded into Python can be converted to numpy array or dataframe for use in the machine learning platforms Tensorflow, PyTorch and PySpark. We defined compatibility as the ability to directly load and stream untransformed data into the into machine learning algorithms for training or inference purposes. Petastorm is a Python library developed for machine learning models training directly from Parquet file format data. Petastorm supports Tensorflow, PyTorch and PySpark. When looking at compatibility with existing cloud based machine learning engine, we considered the data format if it can be directly taken as input file with conversion based on the user guide or the description on the cloud service website, and without conversion to comma separated value (CSV) or other formats.

Results
Data File
The Flat FHIR file size was 771 MB in NDJSON format. An example of an individual patient record is shown in Figure 1.

Figure 1. An example of the immunization record of a synthetic patient.

Storage size and write/read speed
Reading and writing speeds and storage requirements were compared for native NDJSON, and AVRO and Parquet formats. On average, one patient immunization record occupies 10.3 bytes in an NDJSON file, 0.7 bytes in AVRO and 1.2 bytes in Parquet (Figure 2A). The average reading speed per immunization record is 1.2 µs for NDJSON, 0.2 µs for AVRO, and 0.3µ seconds for Parquet. On average it took 4.6 µs, 5.2 µs, and 5.1 µs to write a immunization record into NDJSON, AVRO and Parquet file respectively.
Figure 2. Storage size, reading and writing speed of in NDJSON, Flat-FHIR AVRO and Parquet formats. (A) Storage sizes (bytes/immunization record). (B) Reading/writing speed (µs/immunization record) SQL query speed

The first query extracted all the information from the data file. The second query extracted all plain descriptions of immunization such as “Influenza, seasonal, injectable, preservative free” from a data file. The third query retrieved patient IDs for patients who did not receive the vaccine during the visit. The fourth query joined the immunization and patient demographic information. On average, SQL queries on data in AVRO and Parquet format execute faster than in NDJSON format.

Machine learning platform compatibility
Compatibility of NDJSON, AVRO and Parquet with the Tensorflow, Pytorch and PySpark were examined. NDJSON is compatible with PySpark and Pytorch but not Tensorflow. AVRO works with only PySpark. Parquet is compatible with all three machine learning platform using Petastorm library (Table 2).

In addition to machine learning platforms that run locally, we tested the, compatibility of data formats with four widely used cloud based machine learning engines, Amazon cloud service machine learning engine, Google Cloud Machine Learning, Microsoft Azure, and IBM cloud machine learning. While Google Cloud machine learning engine works with all three data formats, all the other three engines do not work with NDJSON, AVRO or Parquet (Table 2).

Discussion and Conclusion

The FHIR and SMART-on-FHIR standards improve interoperability between different data silos and make cross-silos app development possible. The FHIR Bulk Data API may similarly improve population health analysis. To meet different requirements of clinical practices and medical research, different data formats should be considered based on a project’s requirements.

NDJSON, as the default data format used by the FHIR Bulk Data API, has a simple structure, higher writing efficiency and is human readable. However, storage size and query speed are sacrificed under some analytic conditions. AVRO and Parquet have higher storage efficiency and faster query speed, but are slower to writing and are not human readable. Parquet is most compatible with the machine learning platforms we evaluated. Given these findings, our tentative recommendation is to use the NDJSON NDJSON format for data exchange, and performing analytic tasks on small data sets, but transform the data into Parquet format for large scale analytic projects. Given the costs of using cloud hosted environments, these efficiencies could lead to millions of dollars of savings.

Abstract

Clinical outcome prediction based on Electronic Health Record (EHR) helps enable early interventions for high-risk patients, and is thus a central task for smart healthcare. Conventional deep sequential models fail to capture the rich temporal patterns encoded in the long and irregular clinical event sequences in EHR. We make the observation that clinical events at a long time scale exhibit strong temporal patterns, while events within a short time period tend to be disordered co-occurrence. We thus propose differentiated mechanisms to model clinical events at different time scales. Our model learns hierarchical representations of event sequences, to adaptively distinguish between short-range and long-range events, and accurately capture their core temporal dependencies. Experimental results on real clinical data show that our model greatly improves over previous state-of-the-art models, achieving AUC scores of 0.94 and 0.90 for predicting death and ICU admission, respectively. Our model also successfully identifies important events for different clinical outcome prediction tasks.

1 Introduction

The ever-growing massive Electronic Health Records (EHR) data expose an opportunity for large-scale data-driven health analysis and intelligent medical care. Predicting clinical outcomes, such as death and intensive care unit (ICU) admission, plays an important role in improving the performance of healthcare systems. For instance, accurate clinical prediction based on patients existing medical records can enable advanced and timely medical intervention.

Clinical outcome prediction is challenging because it is hard to utilize rich temporal information encoded in the sequence of clinical events in EHR data.¹ In particular, EHR data usually consist of clinical events with irregular intervals² from heterogeneous sources, including patient health features (vital sign measurements, laboratory test results, etc), medical interventions (procedures, drug inputs, etc), and expert judgments (diagnoses, notes, etc).³ The temporal order of these events is critical for predicting clinical outcome. For example, patient health features can be affected by previous medical interventions, and in turn determine subsequent medical interventions through expert judgments.

Conventional approaches that directly apply classic deep sequential models, such as recurrent neural networks⁴,⁵ (RNN) and convolutional neural networks⁶ (CNN), usually fail to capture temporal dependencies in such long irregular event sequences,⁷,⁸ as long-term dependencies can easily exceed the modeling capacity. To handle irregularly timed events, some extensions of the classic models have been developed, such as time-aware RNN⁹ or CNN.¹⁰ However, their performance is still largely unsatisfying due to the limited ability to capture long-term dependencies.

This work aims to address the above challenges. We first make a key observation that, though the clinical events in EHR data can exhibit strong temporal patterns at a long time scale, the events occurring within a short time period usually do not have a definite order. Specifically, unlike word sequences in natural languages where word tokens are ordered by grammar rules, clinical events recorded in a short period of time are instead a series of events, such as clinical laboratory test results, that only reflect the patients status in different views. Therefore, direct temporal modeling of such short-range events as in previous work can introduce noise and harm the temporal predictive performance. Instead, local dependencies of these events should be modeled as event co-occurrence, and we can further select critical events from each of these short-range event groups as the basis for modeling the real temporal dependencies at

*Corresponding author.
a long time scale. A key difficulty to this end is that the criterion for distinguishing long-term temporal dependencies from the local co-occurrence of critical events in a short range can vary across different diseases and phases, especially in the irregular EHR data.11,12

To address the difficulties mentioned above, we propose a hierarchical neural network for clinical outcome prediction. Specifically, we adaptively segment irregular event sequences into sequential groups to distinguish short-range co-occurrence and long-term temporal dependencies as well as to learn hierarchical representations of the event sequence. At the low level, the model automatically identifies critical clinical events in each group and aggregates the events to form event group representations. At the high level, meaningful long-term dependencies of clinical event groups are captured in a sequence representation vector by a recurrent neural network. Compared to traditional methods, the proposed method has several advantages:

- Our model can deal with the temporal irregularity of clinical event sequences by adaptively segmenting an event sequence into sequential groups.
- Our model learns a hierarchical representation of long and irregular event sequences to capture long-term dependencies of clinical events.
- The model is capable of discovering critical event groups as well as critical events in each group, through a temporal attention and event attention mechanism. This provides useful clinical insights for accurate prediction.

2 Related Works

2.1 Modeling EHR Data

Most existing works based on EHR data have either focused on stationary clinical text and images, or ignored irregular time intervals of temporal clinical events. For example, previous work trained the semantic embeddings for the categories of clinical events for adverse drug event detection, or proposed a multi-view learning method that generalizes Canonical Correlation Analysis for an arbitrary collection of matrices involving missing data. These works make predictions based on the clinical events with regular time intervals, and cannot distinguish short-range order from long-term temporal order of different diseases and patients. Our work addresses the issue by adaptive segmentation of clinical event sequences.

As long-term temporal dependencies are hard to capture, many works use a small subset of the whole EHR information, to avoid dealing with the long clinical event sequences. Some works select a subset of the numerical clinical features (the numerical attributes of clinical events) in the EHR data according to the expertise of clinicians. For instance, Yoon only uses a set of 21 (temporal) physiological streams comprising a set of 11 vital signs and 10 lab test scores to predict ICU admission. Some works used graphical models to model patients health status. Some techniques transform selected 99 time series features of all the EHR data into a new latent space using the hyper-parameters of multi-task GP (MTGP) models to model patient similarity. Recently, RETAIN used two reversed recursive neural networks (RNN) generating attention variables of sequential international disease classification (ICD) code groups for the prediction. However, the codes are grouped by the fixed-length time slots for distinct patients and diseases, and local dependencies and long-term dependencies may be mixed up. But these works can lose significant information, due to the expert bias when selecting a limit fraction of all clinical features in EHR as the input of the models, and fail to provide new data-driven insights for better healthcare.

2.2 Clinical Outcome Prediction

The clinical outcome prediction problem is studied by many works. However many of them cannot take advantage of the temporal information in EHR data for prediction. Some of these studies used latent variable models to decompose bag-of-words free-text extracted from clinical event descriptions into meaningful features to predict patient mortality. “Deep patient” arranged all clinical descriptors (features) in a period of time in a sparse vector without temporal information and trained the deep representation of patients with a 3 layer denoising autoencoder for diagnosis. Some work studied how to diagnose and predict Alzheimers disease (AD) with a hybrid manifold learning for non-temporal clinical feature embedding and the bootstrap aggregating (Bagging) algorithm. There is also a work model EHR
data by factorizing the medical feature matrix into a latent medical concept mapping matrix and a concept value evolution matrix, and then they averaged all vectors in the evolution matrix to predict heart failure.\textsuperscript{27} Our model learns the hierarchical representations of clinical event sequences to utilize the temporal information for clinical outcome prediction.

3 Data and Task Descriptions

We give the notations and data descriptions of the predictive tasks in the following.

Clinical Events in EHR

A clinical event is a record in the database of EHR, which describes a clinical activity of a particular patient at a certain time. The events can be measurements of vital signals, injection of drugs, results of laboratory tests, and so on, which are summarized in Table 1. Each clinical event has some attributes, including categorical attributes and numerical attributes. For example, the lab test event $e_t$ has 2 categorical features and 1 numerical feature: $e_t = \{\text{LabItem} : \text{Cholesterol}, \text{AbnormalLabel} : \text{Abnormal}, \text{ResultIndex} : 51\mu/L\}$. The meaning of this event is the result of the Cholesterol test is $51\mu/L$, which reflects an abnormal health status. An episode of a patient EHR data is a clinical event sequence, which may consist of hundreds of clinical events.

Clinical Outcome Prediction

Clinical outcome prediction is to dynamically predict whether a clinical outcome will happen in 24 hours based on an episode of a patient. We aim to dynamically predict two outcomes in this work. In the first “death prediction task”, the outcome is death in hospital or discharge to home. In the second “ICU admission prediction task”, the outcome is clinical deterioration (need to be immediately transformed to ICU), or stable clinical status.

Patient Cohort Setup

We set up two datasets from one real clinical data source, MIMIC-III\textsuperscript{3} (Medical Information Mart for Intensive Care III), which is a large, freely-available database comprising de-identified health-related data associated with over forty thousand patients who stayed in intensive care units of the Beth Israel Deaconess Medical Center between 2001 and 2012.

We extract 18192 kinds of clinical events with their attributes from the database to get event sequences of patients (the events with top frequency are listed in Table 1). The events whose frequency is less than 2500 are dropped out. And we also drop out the admissions, of which the time span from the beginning to the target clinical outcome is less than 36 hours. Each input of a sample is an episode of a patient clinical event sequence 24 hours before the target outcome. The statistics of final clinical event sequences in the two tasks are summarized in Table 2.

4 Methodology

In this section, we introduce the technical details of our proposed model. Our model first segments the whole clinical event sequence into several event groups via the adaptive event sequence segmentation module. Then the model learns hierarchical representations of event sequences with both event attention and temporal attention mechanisms. The architecture of our model is illustrated in Figure 1.

4.1 Adaptive Segmentation

To distinguish long-term temporal dependencies from co-occurrence of important events in short range, we adaptively segment an event sequence for a patient into sequential groups, according to the irregular record time of events. As events in the same group are exchangeable, sequential groups can avoid the influence of the short-range order noisy in clinical events. Moreover, sequential groups reduce the length of the sequences fed to RNN, which makes capturing long-term temporal dependencies easier.

We find segmentation points of an event sequence by minimizing the maximum time span of the resulting segments. Formally, given a event sequence \( \{e_t\} \), \( k-1 \) segmentation points can split the sequence into \( k \) groups \( \{G_i\}_{i=1}^k \), where the event group \( G_i = \{e_t | t'_i \leq e_t.time \leq t'_i+1\} \) is an episode of clinical events from time \( t'_i \) to time \( t'_i+1 \), where \( e_t.time \) is the record time of the event \( e_t \). And the time span of a group is defined as the time difference of the last event and the first in the group, namely \( \text{span}(G_i) = \max_{e_k,e_j \in G_i} \{e_k.time - e_j.time\} \). So the optimal choice of the segmentation points can be found by minimizing the following:

\[
t'_1, ..., t'_{k+1} = \arg\min_{t'_1, ..., t'_{k+1}, k \leq M} \max_{1 \leq i \leq k} \{\text{span}(G_i)\}
\]

where \( M \) is the max number of groups and \( k \leq M \) is the constraint to avoid the segmentation too fine-grained.

The adaptive segmentation is designed in a way of the combination of greedy method and binary search. We binary search the minimal upper bound of the maximum time span of all groups. And we then verify the searched upper bound of time spans by trying to greedily construct a solution satisfying the constraints of \( M \) and the time span upper bound. The time complexity of the algorithm is \( O(L \times \log T) \), where \( L \) is the length of the event sequence and \( T \) is the difference of end time and start time of the sequence. We can regard this algorithm as an algorithm of linear complexity with a big consistent coefficient.
Figure 1: The overall architecture of our model. The original irregular event sequence is segmented into sequential event groups by the adaptive segmentation module. Then our model learns the hierarchical representation of the sequential event groups. In the low-level representations, each event group is represented as a vector $g_i$ by the event attention. In the high-level representations, the embedded sequential groups are modeled by general recurrent units (GRU) with inter-group temporal attention.

Clinical events have many attributes, which are not considered in previous popular methods, such as word2vec, GloVe and so on. To represent clinical events with their attributes, we embed each clinical event $e_t$ into the low dimension space as a vector $v_t$ in the way described in the previous work. The representing vector $v_t \in \mathbb{R}^N$ (where $N$ is the event embedding dimension) is the sum of event type vector (as basic event information) and event attribute encoding vector (as the description of event feature).

4.2 Hierarchical Representations with Attention Mechanisms

Based on the sequential event groups, the model can learn hierarchical representations to capture long-term temporal dependencies. In the low-level model, the model automatically identifies critical clinical events in each group via event attention mechanism and aggregates the events to form event group representations. In the high-level model, the meaningful long-term temporal dependencies of clinical event groups are captured by a recurrent neural network with temporal attention mechanism in the sequence representation. The hierarchical representations help to learn long-term temporal dependencies in the original event sequences.

4.2.1 Event Group Representation

To select the significant events in each group and compact events in the same group into one vector as the event group representation, the event attention mechanism are added in the low-level model.

Given sequential groups produced by the adaptive segmentation module $\{G_i\}_{i=1}^T$, where $G_i = \{v_{i1}, ..., v_{ini}\}$, attention score of each event in the group is calculated by the event attention mechanism. The scalars $\alpha_{i}^{t}$ are the event attention weights that govern the influence of event embeddings $v_{i1}, ..., v_{ini}$ in the group $G_i$.

We use a multi-layer perceptron (MLP) with one hidden layer to generate $\alpha_{i}^{t}$ based on the event embedding vector $v_{i}^{t}$ and the hidden state of the previous time as follows:
\[ q_i^t = w_q \times \tanh(W_e \times v_i^t + W_h \times h_{i-1} + b_h) \]

where \( 1 \leq i \leq T, 1 \leq t \leq n_i \).

\[ \alpha_1^i, ..., \alpha_{n_i}^i = \text{softmax}(q_1^i, ..., q_{n_i}^i) \text{ for } 1 \leq i \leq T \]

where \( h_{i-1} \in \mathbb{R}^S \) is the hidden state of the previous gated recurrent units (GRU),\(^29\) (which will be described in the following section) \( q_i^t \) is the latent layer of the event \( e_i \) at group \( i \) and \( W_e \in \mathbb{R}^{H \times N}, W_h \in \mathbb{R}^{H \times S}, b_h \) and \( w_q \in \mathbb{R}^H \), are parameters to learn. Notice that \( H \) is the hidden layer dimension and \( S \) is the GRU hidden state dimension.

The resulting attention scores \( \alpha \) reflect the importance of each event in a group according to the temporal context of the group. Events in the \( i \)-th group are weighted averaged with \( \alpha \) to get the group representation \( g_i \in \mathbb{R}^N \) as the input to the \( i \)-th GRU unit.

\[ g_i = \sum_{t=1}^{n_i} \alpha_i^t \times v_i^t \]

4.2.2 Sequence Representation

To spot the critical phases over the sequence for the final decision and capture long-term temporal dependency of event groups, gated recurrent units (GRU)\(^29\) equipped with temporal attention mechanism is employed as the high-level model.

\[ h_i = \text{GRU}(h_{i-1}, g_i, \theta) \]

where the function \( \text{GRU}(\cdot) \) represents the recurrent unit, which use the previous hidden state \( h_{i-1} \) and current input vector \( g_i \) to update the hidden state. And \( \theta \) represents all the parameters of GRU.

The vector \( \beta = (\beta_1, ..., \beta_T) \) contains the temporal attention weights of each group in the sequence. And we use a fully connected feedforward network to generate \( \beta \) from the output of GRU at each time as follow:

\[ \beta = \text{softmax}(w_{\text{temporal}} \times O_T) \]

where \( O_T = (h_1, h_2, ..., h_T) \in \mathbb{R}^{S \times T} \) is the output matrix and \( w_{\text{temporal}} \in \mathbb{R}^S \) is a vector of parameters to learn.

The sequence representation \( s \) is the weighted average of the output matrix \( O_T \). We use \( s \) to predict the true label \( \hat{y}_T \) of the sequences.

\[ s = O_T \times \beta \]

\[ y_T = \text{sigmoid}(w_p \times s + b_p) \]

where \( w_p \in \mathbb{R}^S \) and \( b_p \) are parameters to learn.

The cross-entropy loss function is used to calculate the classification loss of each sample as follows:

\[ \text{Loss}([e_t], \hat{y}_T) = \hat{y}_T \times \ln y_T + (1 - \hat{y}_T) \times \ln(1 - y_T) \]

where \( \{e_t\} \) is the input event sequence and \( \hat{y}_T \) is the label indicating whether the clinical outcome happens. And we can sum up the losses of all the samples in one mini-batch to get the total loss for back propagation.

5 Results and Discussions

5.1 Comparison Methods and Settings

We compare our model with popular models in the literature, which include bag-of-words vector classifiers (i.e. support vector machine\(^30\) (SVM), logistic regression\(^31\) (LR), random forest\(^32\) (RF)) and deep sequential models, such as RETAIN\(^23\) and RNN\(^12\) (implemented with GRU).

Due to the fact that SVM, LR, RF cannot handle a sequence input, the event sequence is compressed into a 0-1 vector in which the \( i \)-th element indicates whether the \( i \)-th event happens, and then fed into SVM, LR, or RF to make the outcome prediction. We implement these bag-of-words vector classifiers using scikit-learn (https://scikit-learn.org).

</tbody>
</table>

Deep sequential models (i.e. RETAIN\textsuperscript{23} and RNN\textsuperscript{12}) take the original event sequence as their inputs as described in section 4.1. We implemented our model and neural network based baselines with Keras (https://keras.io).

The event embedding size is set to 32 while the hidden layer size is set to 64. The max number of groups $M$ is set to 32. When training the models, we used Adam\textsuperscript{33} with the mini-batch of 32 samples and the “early stopping” strategy when the performance of validation set drops down.

5.2 Evaluation Metrics

Metrics for binary labels such as accuracy are not suitable for measuring the performance on imbalanced datasets. Therefore, similar to the works\textsuperscript{18,23} we adopt ROC curves (Receiver Operating Characteristic curves) and PRC (Precision-Recall curves) for evaluation metrics. Both of these two curves reflect the overall quality of predicted scores, according to their true labels. To get quantitative measurements, the area under ROC(AUC) and the area under PRC(AUPRC) are utilized.

5.3 Quantitative Results

Table 3 shows the AUC and AUPRC of different models on the death prediction and the ICU admission prediction tasks. From the results shown in Table 3, we can draw the following conclusions:

First, on the whole, deep sequential models(including RETAIN, RNN and the proposed model) outperform non-sequence models(including SVM, LR, and Random Forest) on both tasks, which suggests that temporal information is effective in the outcome prediction tasks.

Second, our model outperforms all the sequential models. For example, on the “ICU admission task”, the proposed model improves AUC by at least 3.4% and AUPRC by at least 3.0% compared other models on all tasks. The improvement verifies our claim that it’s more proper to capture temporal dependencies of clinical event sequences in a hierarchical way.

5.4 Ablation Studies

In this section, we perform ablation studies to examine the effects of our proposed techniques, namely the event attention mechanism, the temporal attention mechanism, and the adaptive segmentation module.

The first study over two attention mechanisms is performed on both tasks. Specifically, we re-train our model by ablating certain components:

- **W/O E-Attn**, where no event attention is performed and a group representation is set as the average of the event embeddings in this group.

- **W/O T-Attn**, where no temporal attention is performed and the sequence representation is set as the final output of the GRU.

Results of attention mechanism ablation studies are represented in Table 4. We can see that both attention mechanisms

</table>

Figure 2: Ablation study over attention mechanisms. The fix-length segmentation splits the event sequence into groups of equal size (except the last one).

contribute to the strong empirical results of our model represented previously. It is noteworthy that the event attention, one of the important parts of hierarchical representations, plays a more critical role in our model compared to the temporal attention, especially on the death prediction task.

Besides the attention mechanisms, study over the adaptive segmentation is performed on the death prediction task. We re-train our models by replacing the adaptive segmentation module with the fix-length segmentation which splits the original sequence into groups of equal size events (except the last group). Group size of the fix-length segmentation a hyperparameter. Notice that the fix-length segmentation degenerates to no segmentation if group size is set to 1.

Figure 2 shows the AUC and AUPRC of the proposed model where the adaptive segmentation is replaced by the fixed-length segmentation with different group sizes in the death prediction task (the trend in the ICU admission task is similar). We can see that the performance goes down when the group size becomes too small or too large. We infer that if the number is too small, local dependencies of events are modeled as long-term dependencies. And if the number is too large, long-term dependency is lost when the corresponding events are assigned to the same group. Besides, it’s obvious there is a performance gap between the adaptive segmentation and all other segmentation methods, which verifies our claim that the adaptive segmentation can help model long-term dependencies and is suitable for long irregular event sequences.

5.5 Important Events

We analyze the events to which our proposed model pays most attention in prediction. In particular, we use the median of all event attention scores of an event type on a specific task as the importance of the event type on the task.

Top important events on two tasks are listed in Table 5. We can see that even though our model mainly focuses on laboratory tests (such as “Heart Rhythm” and “Blood PH”) on both tasks, the specific events attracting the model on two tasks are different due to their different prediction targets. It is also perhaps surprising that owing to our data-driven approach, our model can select “Family Communication” as an important event type on the death prediction task, which may be ignored by doctors.

6 Conclusion

In this paper, we proposed a model to learn hierarchical representations of long and irregular clinical event sequences of EHR data for clinical outcome prediction. We validate the performance of our model on real clinical datasets for death and ICU admission prediction tasks. The significant improvements indicated that our model is suitable for irregular timed EHR data and can capture long-term temporal dependencies of clinical event sequences for precise clinical outcome predictions.

Abstract

To accelerate medical knowledge discovery, an increasing number of research programs are gathering and sharing data on a large number of participants. Due to the privacy concerns and legal restrictions on data sharing, these programs apply various strategies to mitigate privacy risk. However, the activities of participants and research program sponsors, particularly on social media, might reveal an individual’s membership in a study, making it easier to recognize participants’ records and uncover the information they have yet to disclose. This behavior can jeopardize the privacy of the participants themselves, the reputation of the projects, sponsors, and the research enterprise. To investigate the dangers of self-disclosure behavior, we gathered and analyzed 4,020 tweets, and uncovered over 100 tweets disclosing the individuals’ memberships in over 15 programs. Our investigation showed that self-disclosure on social media can reveal participants’ membership in research cohorts, and such activity might lead to the leakage of a person’s identity, genomic, and other sensitive health information.

Introduction

To accelerate research and improve health care outcomes, various programs are gathering health-related information from individuals to build large cohorts1–3. The primary objective of these programs at the early stage is to collect a wide range of data from their participants, including genomic, phenomic (via surveys and electronic medical records), and demographic information4, 5. The data are then made accessible to researchers to explore hypotheses, study associations, and develop new approaches to manage one’s health6, 7. One common nature of these programs is that they are large and getting larger with respect to the number of participants and the size of collected data. One example of such a program is the Personal Genome Project (PGP), which was launched by Harvard researchers to improve the personalization of medicine4. This program has collected more than 10,000 genomes of participants from a variety of countries8. The 100,000 Genomes Project serves as another example, which has collected the genomes of one hundred thousand British participants to improve research on rare diseases9. And, to investigate how genetic predisposition and environmental exposure contribute to disease development, UK Biobank is now generating whole genome sequencing data on over 500,000 individuals10.

These programs aim to make data widely available, an endeavor that is realized by sharing data with trusted researchers and, at times, with the public2. However, the sharing of individual-level health data raises privacy concerns. This is because participants might consent to making their genome and health data available to researchers (or to the public), but not revealing their identity, which can result in unexpected economic or reputational loss11. As such, the majority of large cohort programs adopt strategies to protect their participants’ identity12, for example, through the application of de-identification routines.

Yet, there are concerns about the degree to which protection can be sufficiently realized in the age of big data. This is because there are various ways in which privacy may be compromised in such systems. For instance, there have been a number of re-identification attacks designed to leverage a wide range of data types13, 14. In 2013, Sweeney and colleagues15 re-identified the names of more than 40% of the PGP participants by linking demographic data (ZIP code, gender, and date of birth) of de-identified records to the voter registration lists. Though these attacks often require a non-trivial amount of time, effort, and money to realize in a manner that would be considered detrimental to a program16, there are several developments that are enhancing the opportunities for penetrating the privacy of individuals in such environments. The first is that participants are increasingly becoming partners in the research environment. The second, and partially an artifact of the first, is that participants are using social platforms to discuss
their experiences in the research domain on a widely accessible scale\textsuperscript{17, 18}. The third is that the research programs themselves may encourage volunteers to tell their stories publicly, with the goal of encouraging people to join the study. Revealing such information makes it evident that the social media sharer is a member of the cohort. This makes it easier for would-be attackers to identify the sharer in the resource. This can be specifically accomplished by using the sharer’s personal information that might be revealed on social media, as well as demographics that might be accessible through information brokers, to link the sharer to their record in the program’s de-identified dataset\textsuperscript{19}. While some individuals may feel comfortable revealing certain information about themselves (e.g., a family history of heart disease), they may not be comfortable revealing their whole genome. As such, this behavior potentially jeopardizes the privacy of the participants themselves, as well as the reputation of the project.

To study the plausibility of an attack, we investigate the frequency of membership disclosure on social media. To do so, we selected a number of research studies from the Database of Genotypes and Phenotypes (dbGap) at NIH and Wikipedia Cohort Study Category\textsuperscript{20}. We then set out to ascertain if any membership disclosure transpired in a popular social media platform, Twitter. To do so, we gathered over 100,000 tweets related to these cohorts and selected approximately 4,000 that contained keywords (e.g., participant, join, volunteer) indicative of potential disclosure. As will be illustrated below, we discovered membership disclosure tweets that revealed the participation of over 100 individuals. We inspected Twitter profiles for these individuals, which indicated demographics, health conditions, and occupations that might be leveraged to link to an individual’s de-identified record. All of the mentioned information provides an opportunity to find the users’ record in the study cohort and uncover additional information that has yet to be revealed in an identified manner, such as the participant’s genome or potentially stigmatizing health information.

This investigation also reveals several patterns. First, we show that membership-related tweets often contain certain types of words (e.g., join, participant, and volunteer). Second, over 80% membership disclosed participants have a non-negative attitude towards the program they are involved in. Sentiment analysis shows that most of these participants are happy to be a part of the cohort, which might be the incentive for some participants to reveal information about themselves. Third, longer lasting and larger cohort studies usually have more membership leakage on Twitter. We note that this is a hypothetical study only and we did not actually re-identify these individuals in the cohorts they claim to be a member of. Nonetheless, our results show that posts on social media can reveal participants’ membership in research cohorts and such activity might lead to the leakage of a person’s identity, genomic and other sensitive health information.

Related Work

The personal health information that has been disclosed on social media has been leveraged to study health-related behaviors\textsuperscript{17, 21, 22}. In spite of the great potential research value, there still exist many concerns regarding the sharing of personal health status or negative health risk behaviors in online environments\textsuperscript{23}. For example, Morgan et al.\textsuperscript{24} showed that one-third of investigated college students reported having posted a picture depicting substance use on social media platforms. Sharing such information will not only trigger privacy concerns about the disclosers themselves (e.g., damage to reputation), but may have the potential to influence other people’s behavior. For instance, it was observed that discussions about prescription abuse over Twitter may aggravate substance abuse\textsuperscript{25, 26}.

Additionally, it should be noted that people share their own information as well as that of other people in online environments. It has been shown that individuals disclose information about a wide range of acquaintances, ranging from family members to friends to high profile persons in the media\textsuperscript{22, 27}. For example, Christofides et al.\textsuperscript{28} illustrated how undergraduate Facebook users posted personal information (e.g., dates of birth and email addresses) in their profiles, but also shared photos of their friends performing potentially sensitive acts (e.g., drinking alcohol at parties).

Our work differs from the aforementioned studies in that we focus on the privacy issues regarding the membership of participants in biomedical research programs on social media. Specifically, we study self-disclosures made by the program participants themselves, as well as investigate the disclosures made by the organizations who own and have responsibility to protect the participants’ data. In doing so, our research contributes to the health information privacy field by highlighting a new type of privacy risk: the cohort membership leakage through social media.
**Cohort Selection**

We selected study cohorts from the database of *Genotypes and Phenotypes (dbGap)* and *Wikipedia cohort studies category*. *dbGaP* was developed to archive and distribute the data and results from studies that have investigated the interaction of genotype and phenotype in humans. It contains 483 biomedical research studies. By contrast, *Wikipedia* provided a convenient list of long lasting cohort studies, such as the *1970 British Cohort Study*. To make our investigation more general, we chose as many different types of studies as possible. The selected cohorts are diverse in three aspects: objective, time, and population.

**Objective.** We selected cohorts to focus both on a specific disease, such as *Type 1 Diabetes Genetics Consortium*, as well as a particular demographic, such as the *Nurses’ Health Study* or gender with in the *Million Women Study*.

**Time.** Cohort studies are not a new phenomenon. Some of the cohorts considered have a long history. For instance, the *Framingham Heart Study* began in 1948. Still, some of the studies are relatively new, for example, the *Qatar BioBank* was launched in 2012. Additionally, we selected studies to have a wide range in duration. Certain longitudinal studies have lasted for decades, while some achieved their objectives in a short period and thus were quite limited in length.

**Population.** The selected cohorts have a varying number of participants. There are multiple cohorts with relatively small sizes, such as the *International HapMap Project*, which collected human genomes from 1,000 participants. By contrast, several cohorts contain hundreds of thousands of participants, such as the *100,000 Genomes Project*.

**Methods**

We partition our search procedure into two steps. Here we provide a high-level overview of the process. The first step is data collection. In this step, we find all of the possible tweets related to the selected cohorts. The second step is data filtering. In this step, we choose a portion of the tweets from step one and manually review these tweets to find the participants of studies. We then perform sentiment and frequency analysis on the tweets that disclose membership in a biomedical research study. The workflow is summarized in Figure 1.

**Figure 1:** The framework for research cohort membership discovery. The processing begins by collecting all tweets that contain the name of cohorts of interest. The tweets are then subject to a membership keyword filter. The remaining tweets are manually reviewed.

**Data Collection.** To collect tweets related to the selected cohorts, we use the names (and abbreviations) of the 77 studies as search keywords and collect all related tweets with a python crawler. By doing so, we obtained 139,529 tweets. Manually reviewing all of the tweets to find those revealing an individual’s participation information would be quite time consuming and error-prone. Since this is a pilot study, and our goal is to demonstrate the possibility of membership disclosure instead of finding all such tweets, we narrowed the scope of our search based on our knowledge to a portion of the tweets that are most likely to contain information about membership disclosures. When we manually reviewed some of the collected tweets, we found that most of the self-disclosed tweets exhibited the following pattern:
“I joined xxx research project today!”,”I am a participant of the xxx program.” or “Now I became a volunteer of the xxx study.”

**Data Filtering.** We filtered the tweets with the following keywords: participant, participate, join, and volunteer, and discarded the remainder of the tweets. It should be recognized that this search method does not guarantee completeness. We lose tweets about disclosure that lack such search terms. For example, “I sent my test sample to xxx project today.” is not caught by the filter. This step yielded 12,698 tweets. For most of the projects, there are fewer than 500 tweets with the keywords of interest. Thus, we manually reviewed all of these tweets to find those that reveal membership disclosure. For cohorts with more than 500 tweets, we randomly select 500 for manual review. Details about the number of tweets collected for each cohort are provided in Table 1. For brevity, we depict the top 50 cohorts that returned the most tweets. Information on all 77 cohorts is available on Github1.

**Sentiment and Frequency Analysis.** The previous step yielded 4,020 tweets. We manually reviewed these tweets, and labeled the tweets containing membership disclosure information. We performed sentiment and frequency analysis on the target tweets posted by project participants. We first removed all the links, hashtags and @ characters from the tweets. We then fed the preprocessed tweets into TextBlob (version 0.15.3) for sentiment analysis. TextBlob is a python package for natural language processing (NLP). For each tweet, TextBlob generates a sentiment score in the range from \([-1, +1]\), where -1 means extremely negative and +1 stands for extremely positive. Next, we partitioned the tweets into words through a process of normalization and tokenization (which partitions a tweet into a set of words), lemmatized (which transforms a word from its original form to its base form; e.g., walks becomes walk) all the words using python NLP package nltk (version 3.3). For the lemmatized words, we removed stop words (e.g., i, ia, in ,the). Since we used cohort names to collect all the tweets, we also dropped all of the words in cohort names, such as “study”, “project”, “health” and “genome”. We then counted the frequency for the remaining words.

**Results**

Table 1 reports the number of tweets collected, filtered and reviewed for 77 selected cohorts. Each of the first six cohorts in Table 1 has more than 10,000 related tweets, which in total accounts for 70% of the total collected tweets. All of the cohorts in the top 25% have over 1,000 tweets. The number of tweets collected from these 19 cohorts accounts for 91.8% of all the tweets. There are 26 cohorts with fewer than 100 related tweets. The distribution of tweets filtered by the selected keywords is roughly the same as the distribution of the total collected tweets. The set of cohorts in the top 6 occupied 87.5% of the filtered tweets and the top 19 cohorts generated 97.6% of filtered tweets. In general, the research programs with larger volume and longer time span have to had more tweets. In particular, programs involving government support often fall into this category.

Among the 4,020 selected tweets, we found 109 that communicated membership disclosure. The results of this investigation are shown in Table 2. These tweets come from 15 of the cohorts (19.5%). They reveal the membership of more than 115 participants. We present some examples of disclosure tweets in Table 3. Notably, 86 of these tweets (78.9%) were posted by cohort participants. In these cases, participants’ leaked either their own or their friends’ membership information when they talked about their experience with some cohort study. This discovery confirms the findings of Yin et al.36 and Mao et al.27, where it was observed that individual’s self-disclosure on social media may reveal other people’s sensitive information. The remaining 23 tweets (21.1%) come from the program’s official account or researcher/organizer of the study. In these cases, the participants’ information was revealed because the program shared a volunteer’s story.

We discuss self-disclosed and program-disclosed tweets separately in the following sections.

**Self-disclosed tweets.** Self-disclosure tweets refer to the tweets posted by cohort participants. These tweets usually have a similar style, such as “I joined/participated in the xxx study” or “I am a participant/volunteer of the xxx program.” Some users wrote an additional sentence to explain why they joined the program or how they feel about it. An analysis of the sentiment of self-disclosed tweets revealed that 71 of the 86 users (82.5%) have a neutral or positive attitude about their participation while 39 of the tweets (45.3%) have a sentiment score greater than 0. Such a positive

attitude shows that most self-disclosed volunteers are happy with the program they participate in and their disclosures on social media express their support or compliment for the program rather than criticism. Words like proud and love often appears in these tweets. Table 4 provides the frequency of the 26 most common words.

At the same time, a small portion of the tweets suggests a negative emotion. For example: “I’ve been a participant for two years, but have not had any feedback.” The distribution of the sentiment score is shown in Figure 2. Self-disclosure tweets usually only reveal the user’s membership; however, at times they may involve their family or close friends. In such cases, one or more of the users’ family members may have a rare disease (e.g., a child who experiences a congenital heart attack) and they joined the research project together to find out why and how to treat it.

Figure 2: Sentiment analysis of 86 self-disclosed tweets. The score ranges from $[-1, 1]$, where -1 means very negative and +1 stands for very positive.

Program-disclosed tweets. At times, the programs post about volunteers’ participation experiences on social media as a way to promote the program and attract the public to join. Most of these tweets reveal a volunteer’s membership often with health information, along with a link to, or a video about, the volunteer’s story. Volunteers talk about why
Table 3: Examples of membership disclosure tweets. We replace the person and cohort names with xxx and rewrite the sentences to mitigate the risk of revealing the program and participants.

they joined the program, as well as what they gained from entering the program. This approach may be useful in attracting people to join the program, but this activity also increases the risk of the volunteer to re-identification.

**Disclosure tweets are more likely to be associated with larger cohorts.** As shown in Table 5, the cohorts with membership disclosure tweets cover more than 10,000 participants. The studies that began more recently tend to have more members active on the Internet, such that they appear to discuss their involvement more often. Some of the tweets posted by participants in long term studies showed that these participants have a stable relationship with the program. These users specifically shared their long term participant experience and feelings about the program. The word “years” appears six times in 32 tweets.

**Tweets can contain search keywords but lack user membership information.** 3,901 of the 4,020 (97.3%) selected tweets do not contain user participant information. Program-related accounts posted most of these tweets and tended to follow one of two patterns. The first is to call for volunteers: “Come and join the xxx research program.” The second is a thank you message to their participants: “xxx participants finished sequencing! Thank you, everyone, for taking part in our research!” On the other hand, tweets posted by users revealed their interest or concern about the program. For example: “I am interested in join the xxx study, but I am worried about my privacy.” In general, it was observed that people are willing to join cohort studies and make their contribution, but a concern of privacy protection is an impediment. For example, 16 tweets talked about the participants’ email address disclosure problem of Personal Genome Project UK.

**Potential Risk of Membership Disclosure.** Based on this analysis, we partitioned the risk of membership disclosure into three types: membership disclosure, identity disclosure and attribute disclosure. Here, we will discuss these privacy threats and illustrate how they relate to the specific population we studied.

Summary 109

The problems induced by membership disclosure are best illustrated with several examples. First, imagine that a volunteer has disclosed his/her membership in some research program. An attacker collects the volunteer’s demographic information (e.g., residential geographical area, gender, and date of birth) from the social network (e.g., the user’s Twitter profile) and links this information to the de-identified participants’ records published by the research program. If a unique linkage to a record transpires, then the attacker has achieved an identity disclosure\(^{19}\). If multiple records are linked to the user, but they share the same (or similar) sensitive attribute value(s), then a successful attribute disclosure attack\(^{37}\) has been perpetrated. Even if their values for the sensitive attribute are different, the attacker can guess the right one with some confidence. By contrast, previous high-profile attacks are limited in that they need to make assumptions about whether a targeted individual is indeed in a dataset. Thus, their claimed attacking powers need to be discounted by the prior probability that a targeted individual has been selected from a broader population\(^{38}\). In our scenario, the attacker is confident that the targeted individual is in the dataset. As a consequence, the discovery of membership significantly increases the likelihood of a successful attack. This attack adds significant power to all the previous attacks, which include the following:

1. Membership Disclosure. As noted earlier, the action of disclosing one’s membership leaks some of the users’ sensitive information. For instance, a project may be disease-specific, such that all of the participants have the same diagnosis. Similarly, some of the users join a study because they, or their relatives, have a rare disease. When they post such information online, their health information is leaked as well.

2. Identity Disclosure. By sharing membership and other personal information over social media, users can be identified. This can be accomplished by collecting self-disclosed users’ personal information from their profile, such as their real name, race, gender, residence, education level, and occupation. To illustrate this issue, we randomly selected ten users and inspected their Twitter profile. It was found that nine out of ten users revealed their real face as their avatar, eight shared their location to a specific city, seven talked about their occupation or education level in their biography, six used their real name as their account name and two users made their date of birth public. With such information on hand, an attacker could find the person through a people search website, such as Intelius.com or InstantCheckMate.com. Moreover, program-disclosed individuals are more readily identifiable because the story shared by programs often contains detailed information about the storyteller. In this case, we learn the volunteer’s personal information from the story, as well as their health information.

3. Attribute Disclosure. Research programs may publish their data to the public or share it with researchers in a de-identified fashion. However, if a malicious attacker has access to the cohort data, along with additional information about the self-disclosing participant (collected from the user’s social media profile), then the attacker can use such information as quasi-identifiers to link to the participant’s record in the cohort database. As mentioned earlier, Sweeney et al. showed that they could identify more than 40% PGP participants using their ZIP code, gender, and date of birth,
and obtain participants’ sensitive information, such as medical conditions and DNA sequence\textsuperscript{15}.

\section*{Discussion and Conclusion}
