This investigation illustrates that an individual’s membership in a biomedical research study can be disclosed in social media in several ways. We uncovered tweets that revealed the membership over 100 participants in 15 research programs. Approximately 80\% of the tweets correspond to user self-disclosure, while the remaining correspond to disclosures made by the program organizer. We found that 39 out of 86 (45.3\%) self-disclosed users have a positive attitude towards joined research project. The terms “proud”, “interest”, and “love” were communicated by multiple self-disclosers. The personal information reported in the profiles of the social media users increased the risk of identification, which increases the likelihood that an attacker could link to their record in a de-identified dataset about the cohort, leading to further privacy intrusions, such as the re-identification of genomic information. A program may disclose participants membership when they introduce volunteer and share their story to the public as a way to increase program influence and recruit more participants. These stories may contain personal information and sensitive health information about the volunteer.

Still, there are certain limitations to this work, which pose as next steps for research. First, our search procedure is somewhat ad hoc, such that we failed to detect some tweets about membership disclosure that lack certain words (e.g., participant or volunteer). Second, we studied disclosure behavior only on Twitter, but the same problem may exist in other social platforms, such as Facebook and Instagram. A comprehensive study on additional popular social platforms is needed. Third, the current process requires a final manual review, but it is likely that, with enough instances of disclosure, an automated approach for discovery of such tweets could be developed. At the same time, we believe that if automated approaches can be designed to detect such disclosures, they may also be oriented to assist individuals and program managers to recognize when disclosure is happening inadvertently. It may be that such detection and reflection of the potential risks of such actions may change decisions to reveal such information, and at least lead to more informed decision making.

Mitigating the risk of membership disclosure is not an easy problem to solve. In closing, we wish to offer several possible strategies that may warrant consideration. First, given this threat, research programs could inform participants about the risk of membership disclosure and make it clear that if self-disclosures are made that their privacy may not be guaranteed. At the same time, research programs should inform participants of such threats when asking whether they can share information about participants (e.g., through stories). Alternatively, the program could consider sharing stories without mentioning the volunteers real name or quasi-identifiable information.

Foundations for Studying Clinical Workflow: Development of a Composite Inter-Observer Reliability Assessment for Workflow Time Studies
Marcelo Lopetegui, MD, MS¹, Po-Yin Yin, RN, PhD², Peter Embi, MD, MS³, Philip Payne, PhD²

Abstract
The ability to understand and measure the complexity of clinical workflow provides hospital managers and researchers with the necessary knowledge to assess some of the most critical issues in healthcare. Given the protagonist role of workflow time studies on influencing decision makers, major efforts are being conducted to address existing methodological inconsistencies of the technique. Among major concerns, the lack of a standardized methodology to ensure the reliability of human observers stands as a priority. In this paper, we highlight the limitations of the current Inter-Observer Reliability Assessments, and propose a novel composite score to systematically conduct them. The composite score is composed of a) the overall agreement based on Kappa that evaluates the naming agreement on virtually created one-seconds tasks, providing a global assessment of the agreement over time, b) a naming agreement based on Kappa, requiring an observation pairing approach based on time-overlap, c) a duration agreement based on the concordance correlation coefficient, that provides means to evaluate the correlation concerning tasks duration, d) a timing agreement, based on descriptive statistics of the gaps between timestamps of same-task classes, and e) a sequence agreement based on the Needleman-Wunsch sequence alignment algorithm. We hereby provide a first step towards standardized reliability reporting in workflow time studies. This new composite IORA protocol is intended to empower workflow researchers with a standardized and comprehensive method for validating observers’ reliability and, in turn, the validity of their data and results.

Background and Rationale.

Time-motion studies (TMS) have been widely adopted in biomedicine to study workflow¹. Among the various approaches available, “workflow time studies” provide the most exhaustive approach for understanding clinical workflow¹. In this technique, observers continuously follow a subject for a predefined period of time and record tasks as they occur, producing a sequence of time-stamped tasks².³. This approach allows observers to track unexpected instances of tasks, accounting for task fragmentation, interruptions, and the real-world variability of clinical workflow. Although the introduction of electronic time capture tools has facilitated the recording process by allowing observers to direct their attention on the subjects being studied⁴, there are still concerns of overburdened observers due to the complexity of the data capture process and its effect on data quality.

Like any other method requiring a human data collector, workflow studies are subject to variability and error in the data-capture process. Therefore, well-designed studies often conduct inter-observer reliability assessments (IORA) in order to acknowledge the amount of error introduced to the study due to the inconsistency among data collectors. Although IORA are essential for the overall validity and reliability of a study’s results, IORA are not a common practice in most clinical workflow TMS⁵. IORA are systematically underreported and, when conducted, no specifications on the implementation are provided, raising concerns on the data quality produced by these TMS.

When attempting to conduct IORA in workflow time studies, researchers are faced with three major problems, including a) variability of the observable entity, b) multi-dimensionality of workflow analysis, and c) pairing observations.

a) Variability of the observable entity.

The most-cited method, the Kappa coefficient ($\kappa$), is a landmark in the development of agreement theory and one of the most-used methods to assess reliability in the biomedical sciences⁶. However, unlike most inter-rater reliability assessments (i.e. two radiologists diagnosing x-rays), in TMS the assessment is conducted on an entity that is variable and non-constant over time: clinical workflow can be different for every combination of patient, clinician
and location. Thus, IORA in workflow time studies must be conducted by having two independent observers conduct a synchronous observation, following the same subject at the same time, and without interchanging data or thoughts until the observation is concluded. In view of the nature of clinical workflow, it is impractical to attempt IORA with more than two simultaneous observers due to the disruption of the workflow and an augmented Hawthorne effect caused by space constraints.

b) Multidimensionality of workflow analysis.

Besides the difficulties involved with conducting synchronous IORA sessions, the data schema resulting from these IORA sessions (Figure 1) raises concerns about the suitability of the described statistical methods, and several questions arise. Are workflow researchers analyzing the reliability of identifying the occurrence of relevant tasks? Or are they assessing the agreement in naming those tasks? Or the duration of the tasks? Most studies assess agreement in naming tasks, which results in only a partial assessment of reliability, by focusing only on one dimension of the workflow data and thereby losing the ability to identify other types of errors, like a late start of an observed event.

c) Pairing observations

In a typical implementation of Cohen’s kappa for biomedical research, two observers need to “name” (categorize) a predefined number of “items” (petri dishes, tissue samples, etc.). In contrast, in workflow time studies observers must first recognize the existence of the “items” (detecting that a task is happening), name them, and accurately time-stamp them. This usually results in a different number of observations being recorded by independent observers (one observer identifies multiple tasks while the other observer only identifies one, like the case presented in Figure 1). Which tasks are considered for the paired analysis? And how are they paired?

Problem Statement.

As workflow researchers, we are interested in every aspect of clinical workflow: the sequence (order in which tasks occur), time of occurrence (time when tasks occur), count (number of task occurrences), and duration of tasks required to accomplish an activity or goal. The multi-dimensionality of the data produced by workflow time studies provides the required information for such comprehensive analyses. Thus, each aspect should be taken into account when conducting inter-observer reliability to ensure that we are maintaining the integrity of the data captured.

In a previous review, only 6% of TMS were aware of this issue and, in an initial effort towards conducting a more comprehensive IORA, they attempted to use a combination of two methods\(^7\)\(^8\) (intra-class correlation for time and Kappa for categorization).

Given the current state of the art and the limitations encountered, we hypothesize that a composite score for assessing each dimension would provide a more meaningful and comprehensive methodology to train observers and report reliability in workflow time studies. We aim to develop a comprehensive IORA methodology for workflow time studies, contributing to advancing the standardization of workflow research.

\(^a\) Usually, one of these observers is highly knowledgeable in the environment being studied and participates in the tasks definitions (specifying start and end milestones for each observable task), and is considered to be the gold standard to train less-experienced observers. There are no guidelines or consensus on how to define the gold standard.
Methods.

Research questions involving clinical workflow focus on different aspects of the workflow itself. Questions include: How much time do subjects devote to a task? What do subjects do at any given time? What is the duration of specific instances of tasks? What is the sequence of tasks required to complete an activity? When does a given task occur? Each of these questions requires data precision in different dimensions of the observations. Thus, an IORA should assure the reliability of identifying tasks, including naming and timing those tasks (the agreement on the start time and the duration of the task), and the sequence of tasks being captured.

Given the common use of Kappa in TMS, it could be considered as a sufficient, but limited, approach for assessing IORA in workflow time studies. Kappa provides a meaningful and interpretable score for the dimension being assessed, but can only assess one dimension, which opens a chance for bias and misleading IORA scores, jeopardizing the validity of study results.

To the best of our knowledge, the pairing process of the observations in workflow time studies has never been fully described in the literature. This is not trivial, because a) given that each observer can create a different number of observations during the activity, different pairing permutations are possible; and b) depending on the pairing approach, Kappa is measuring different aspects of the data.

Figure 2 describes two proposed computationally achievable pairing methods to prepare the data for Kappa. The first approach artificially breaks the observation into atomic events of one second of duration. This allows us to calculate an agreement based on the number of seconds that both observers are recording the same task name. We named this approach “proportion-kappa” (PK). In the second approach, researchers must arbitrarily match tasks from both observers. It might seem intuitive to perform the matching based on the order of the tasks; however, it fails with insertions/omission scenarios (when the trainee records more than one task for any given task from the gold standard,
or vice versa). Even if both observers end up with the same number of tasks recorded, it might be due to one of them creating a balanced number of insertions and omissions. To overcome these complex scenarios, the desired task matching is achieved by pairing any given task to the task it overlaps the most (time-wise). This approach seems more natural, since it compares each task as a unit, while being flexible with expected minor time-gaps in tasks’ start times. Once pairs are created, researchers can evaluate the agreement on naming those tasks and/or evaluate the duration of the matched pairs. We called this approach “naming-kappa” (NK).

Although PK measures the agreement on naming artificially-created one-second tasks, it is technically evaluating the agreement on the number of seconds sharing the same task name: the overall length of time observers agree it took to complete a task. On the other hand, although in NK we are matching based on time (overlap), we are technically measuring the agreement on naming.

In both approaches, the Kappa coefficient accurately describes proportion agreement or naming agreement. But using only one dimension IORA, is insufficient to assure data quality. For example, PK could serve as a valid IORA technique if the research question focuses on overall time devoted to specific tasks. However, PK fails if the research question concerns the tasks’ frequency or the average duration of tasks required to complete the activity. Furthermore, PK does not consider the task frequency, and is sensitive to tasks’ duration, which allows bias if there are long idle times during the observation (captured as “others”). Thus, even if observers fail at identifying or timing tasks of interest, as long as they agree in “other” tasks, they might reach a good reliability (although Kappa contributes to reduce this bias compared to percentage agreement alone). On the other hand, NK completely disregards tasks’ duration and is non-sensitive to idle time, but is insufficient if the research question focuses on “how much time subjects devote to a given task”, since the pairing does not consider precise start times or precise durations.

Therefore, we designed a composite score comprising five metrics as described below, the first two of which use the Kappa statistic.

**Metric 1: Proportion-Kappa (PK).**

PK provides an appropriate reliability assessment to evaluate the agreement over time devoted to specific tasks. The result of this agreement provides a corrected estimate of the proportion of time two observers agree on the task name, which ensures data validity for studies focusing on time devoted to specific tasks. The abovementioned limitations of PK are tasks’ frequency and overweighting idle time, which should be compensated by other types of agreement assessments.

**Metric 2: Naming-Kappa (NK).**

NK provides a means to analyze the agreement on naming tasks recorded by the observers, weighing each record equally, and not being influenced by the duration of the task. This balances the concern of overweighting long duration tasks on the agreement introduced by the PK method.

**Metric 3: Duration Concordance Correlation Coefficient (D-CCC).**

The only methods used to assess reliability of tasks’ durations in published TMS are the Bland-Altman and the intra-class correlation coefficient. Although the intra-class correlation coefficient stands as a more suitable approach to assess consistency of the tasks’ durations compared to Pearson’s correlation, like Bland-Altman, it assumes that the true value is unknown, thus only measuring the similarity among the measurements. We propose the use of a more suitable measure of agreement concerning continuous variables for non-exchangeable observers (i.e. having a gold-standard): the concordance correlation coefficient (CCC). In basic terms, the CCC evaluates the degree to which pairs of observations fall on the 45° line through the origin. It is composed by the Pearson correlation coefficient (measuring how far each observation deviates from the best-fit line), and a bias correction factor (measuring how far the best-fit line deviates from the 45° line through the origin). It has been described as a robust test on as few as 10 pairs of data, improving the suitability for short observation periods. The incorporation of this method into our IORA protocol would provide the assessment of data validity for research questions concerning individual tasks’ durations.

In order to implement the D-CCC, paired tasks are also required. Tasks need to maintain duration data, thus the PK second-by-second approach is inappropriate. The “most-overlapping task” pairing approach used in NK preserves tasks’ duration. However, in this case, we are only interested in tasks where observers agree on the name, having in mind that the disagreement in naming is already being penalized in NK. Also, in the insertion or omission scenarios, the NK pairing approach creates multiple pairs of the longest task with the overlapping insertions. However, this metric attempts to provide an assessment of data for research questions concerning individual tasks’ duration: hence each task should be paired only once. Once pairs are created with the NK “most-overlapping” approach, all pairs of tasks with non-matching names are dropped (penalized in NK). Where insertions/omissions occur, the gold
standard task is only paired to the task from the insertion block with the same name. If more than one task with the same name exists in the insertion block, the first instance of the task is matched (see Figure 3). Although we feel inclined to add the duration of all tasks with the same name from the insertion block and compare them against the long overlapping task, we consider that the PK pairing is already doing so. In this case, we are interested in the duration of each instance of a task. Thus, only one task from the insertion block should be paired and evaluated. Although this makes the metric very sensitive for insertion/omission scenarios, it provides an assessment of the impact of the insertion (how early it happened relative to the expected duration of the stopped task).

**Metric 4: Sequence-Needleman-Wunsch (S-NW).**

In order to assess reliability considering the sequence of tasks recorded, regardless of their start time and duration, we exploited the transdisciplinary nature of informatics. Sequence comparison is the most important primitive operation in computational biology, serving as a basis for many other, more complex, manipulations. In the bioinformatics arena, assessing sequence alignment of similar strings is a common need, with existing working solutions that provide optimal alignments for similar DNA strings, usually complemented with a similarity score. This is used to study phylogenetic trees, gene mutations, or to reconstruct full DNA sequences based on a master string (among many other uses). Thus, the arrays of data produced by IORA sessions could be represented as two DNA strings. By removing the time and duration dimensions of the observation (taken care of in other scores), each task would represent a “nucleotide,” thus an observation output could be thought of as a sequence of nucleotides, with insertions left unpaired and penalized, as a nucleotide insertion would be in a DNA alignment.

We propose the use of the Needleman-Wunsch algorithm: one of the most-used global comparison algorithms that relies on dynamic programming to compute the similarity between two sequences. First, a similarity matrix is created, based on arbitrary scores for each match, mismatch, or gap. Then, the optimal alignment is reconstructed based on the similarity matrix, and a score is derived from a pre-computed matrix.

The first row and column of the matrix are initialized with multiples of the gap penalty: they represent the score received if only gaps were created (the alignment if the other string is empty). Then, the other cells are computed based on the three adjacent cells already populated \([gs(i-1),tr(j)], [gs(i-1),tr(j-1)]\) and \([gs(i),tr(j-1)]\). This can be thought of as the three options to match the current “nucleotides-tasks”:

a) Align \(gs(i)\) with \(tr(j-1)\) and pair a space with \(tr(j)\) [\(tr(j)\) being an insertion].

b) Align \(gs(i-1)\) and \(tr(j-1)\) and pair \(gs(i)\) with \(tr(j)\) [\(gs(i),tr(j)\) being either a match or mismatch].

c) Align \(gs(i-1)\) with \(tr(j)\) and pair \(gs(i)\) with a space [\(gs(i)\) being an insertion].

Thus, the score to populate on the cell \([tr(i),gs(j)]\) is given by the equation:

\[
[tr(i),gs(j)] = \max \left\{ \begin{array}{l}
[tr(i),gs(j-1)] - G \\
[tr(i-1),gs(j-1)] + P[tr(i),gs(j)] \\
[tr(i-1),gs(j)] - G
\end{array} \right. 
\]

Where \(G\) corresponds to the gap penalty, and \(P\) corresponds to either the “match” score or the “mismatch” score. Once the similarity matrix is computed, a recursive algorithm computes the optimal alignment. We empirically set the scores of -1 for the gap penalty, 0 for a mismatch, and +3 for a match.

In order to produce a meaningful score to be interpreted by the workflow researcher, we propose to transform linearly the theoretical maximum and minimum alignment scores to 0-1 boundaries. The theoretical maximum corresponds to “P-match” times the number of tasks of the longest string, while the theoretical minimum corresponds to negative difference of tasks between the two strings (only mismatches for the pairs, plus gap penalties for the remainder).

**Metric 5: Timing Agreement (TA).**

The timing agreement represents the degree of synchronization by both observers in recording the start time of a task. Given the lack of formal methods to assess this, we propose to report the median time-gap of paired tasks from the D-CCC assessment, grouped by task: the median time (in seconds) of the difference between start times of paired tasks (positive if the trainee is behind the gold standard, negative if the trainee is ahead). We believe this metric might not play a useful role in reporting agreement as a global score since the interpretation may vary depending on the variance of individual tasks (a median time-gap of 2 might be representing being 10 seconds ahead on task “A”, and late 2 seconds on task “B” and 12 seconds on task “C”). However, this metric might be of great contribution to train observers and evaluate tasks based on the magnitude and the sign of the time-gap. We suggest to report the...
median time-gap by task, accompanied by all the time-gaps for that task. This will provide a quick assessment of any potential difficulties on identifying start times for specific tasks.

In this paper, we synthesized a small data set of an IORA session, and used the proposed composite IORA scores to demonstrate their meaning and interpretation. Implementation of the new methods proposed were based on data set shown in Figure 3.

**Figure 3:** Synthesized scenario depicting a brief IORA session with a trained observer (goldStandard) and a trainee.

**Results.**

**Application of the composite IORA protocol.**

**Proportion-Kappa (PK).**

For the synthesized scenario (Figure 3), this score results in a Kappa coefficient of 0.744 and 82% agreement. This demonstrates an overall substantial agreement between the observers, which is particularly relevant if the research question focuses on how much time subjects devote to any given task.

**Naming-Kappa (NK).**

This score results in a Kappa coefficient of 0.718 and 80% agreement, demonstrating a substantial agreement on naming tasks between the observers, which is of interest if the research question relates to “what do subjects do at any given time?”.

**Duration Concordance Correlation Coefficient (D-CCC).**

In the synthesized scenario, the trainee performed well, confusing task D with C, and creating an insertion of B while A was described by the gold standard. The “most overlapping” pairing approach produced 10 pairs of tasks. Following the proposed modifications, 3 pairs are dropped: D(5)-C(5) since observers failed at naming them, and A(10)-B(3) and A(10)-A(2) since they correspond to the left-over after pairing the insertion (see Figure 4).

Thus, using Lin’s$^9$ concordance correlation coefficient in STATA (concor command) results in 0.906. Unlike Kappa, there is no specification in the literature on a descriptive scale for the degree of agreement achieved with Lin’s CCC, only existing a lower bound for an acceptable CCC of 0.75 (not universally accepted)$^{13}$. 

**Figure 4:** The “most overlapping” pairing approach produced 10 pairs of tasks, displayed at the right with the duration of the tasks between parentheses. Then, three pairs are dropped in order to implement the D-CCC: one non-matching pair and two pairs of the insertion block.
Sequen

Figure 5 shows the similarity matrix corresponding to the synthesized scenario, based on the strings gs= O-A-D-B-A-C-A-B and tr= O-A-C-B-A-C-A-B, for the gold standard and the trainee observer, respectively. In the synthesized scenario, the computed maximum score is 19 (Figure 5). The theoretical maximum corresponds to 3x10, while the theoretical minimum corresponds to -2. Thus, the linear transformed final score for the current example would be 0.656 ([19+2]/ [30+2]). This is a quantified interpretation for a visual inspection: 7 out of the 10 tasks were correctly matched, one mismatch, and two insertions.

In the synthesized scenario, accuracy for timestamping each task was: 0 seconds for A (0;0;1), 0.5 seconds for B (0;1), and 1 second for C (1), based on the pairing achieved using the D-CCC pairing shown in Figure 4.

Expanding the impact of a meaningful IORA: contributing to an optimized training feedback.

The composite IORA metric intends to empower researchers with a means of ensuring reliability and validity of the data in a quantitative, comparable, and systematic manner. However, there is room for a further contribution: besides informing the researchers “how good” or “how bad” observers are doing based on the metrics calculated, we thought to include visualizations that would help better understand how the scores are calculated and provide an answer to “what” and “when” they disagree. For example, both Kappa metrics, the contingency table highlights discrepancies (any cell not in the diagonal). Also, a side-to-side visualization of both observations permits a global qualitative IORA, which, although not useful for reporting purposes, might be very helpful in training the observers, highlighting times and tasks that produce discrepancies. Similar to the clinical workflow analysis tool (CWAt) and the sample report of Mache’s tool, we developed a graphic representation for an IORA session (Figure 6).

Finally, a simple scatter plot of the durations assessed by the D-CCC helps identify where the timing discrepancies are occurring. The scatter plot depicts the concordance between the duration of each task captured by the gold standard and the trainee. Everything below the plot’s purple diagonal represents a task captured by the trainee having a logged duration that is shorter than the gold standard; anything above represents a task captured by the trainee having a logged duration that is longer than the gold standard (Figure 6).
Discussion.

As previously described, studying workflow goes beyond simply calculating duration of events. In order to fully understand workflow, analyses focus on what happens, when, and for how long, and usually analyze the order in which those tasks occur (the sequence required to complete an activity). Having evidenced the limitations of using a single statistical test to ensure reliability of the observation, and given the lack of a single exhaustive test to accomplish comprehensive IORA, we postulate that using multiple instances of existing tests, one for each dimension, might provide IORA in a more meaningful manner.

Given our experience designing and conducting time-motion studies, achieving scores consistently high, like the one in our synthesized scenario, is not common, and reliability efforts shouldn’t pursue optimal scores in every dimension. Although we recommend assessing every dimension, agreement goals should be directed to the specific research question under study.

Besides the contribution as a reporting tool, our proposed IORA stands as a major contribution to the standardization of the observers’ training, which is usually only reported as total hours of training. With our IORA

---

**Figure 6:** Composite score example. Interpretation for this report: Overall, both observers have an almost perfect PK agreement (relevant if data intends to represent the overall time devoted to any given task). Strong agreement for NK. D-CCC: satisfactory (not directly interpretable, most paired tasks on 45-degree line). Sequence agreement: satisfactory (2 insertions out of 20 recordings). Training recommendation based on report: Review specifications on when “treatment” (blue) ends [avoid trainee early stop, that created the insertion]. Review when “education” (green) begins [improve timing agreement]
approach, researchers have powerful means to direct efforts on observers’ training, by both visually examining details of the observation and by evaluating agreements trends over time in the training period. Thus, instead of reporting hours of observers’ training alone, they will be able to report training until X agreement is achieved in Y dimension (the one of more relevance for the research question).

These metrics were implemented and calculated to produce meaningful and interpretable results, however the D-CCC and S-NW haven’t been used before, and thus interpretations and extrapolation of the scores aren’t straightforward. Although range and directionality of the scores are logical, further intensive testing and validation studies are required to define meaningful cut points. This will allow us to study IORA scores over long periods of observations (assessing observers’ fatigue), study IORA at different points of the study, not just the training portion (assessing observers’ drift), and many other interesting related issues such as the effect of the initial number of tasks on IORA.

Limitations.

The PK, NK, and D-CCC are statistical estimates, and confidence intervals for the estimates are dependent on the sample size. For the PK, a large number of pairs is usually created (number of seconds in the observation), and narrow confidence intervals can be achieved. However, for the NK, the number of pairs corresponds to the number of tasks recorded and, for the D-CCC, to the number of tasks recorded minus the discrepant tasks. Thus, when the number of tasks recorded is small, the NK and D-CCC are bounded by large confidence intervals, jeopardizing the significance and meaningfulness of the scores obtained.

The S-NW and the TA interpretation are not affected by sample size. The S-NW provides a normalized arithmetic score, interpretable independent of the sample size (number of tasks recorded in the observation): insertions are more heavily penalized in shorter observations and vice-versa. Likewise, the TA is a composite descriptive statistic (the median and quartiles), interpretable regardless of the sample size.

We recommend that, if only a small number of tasks are recorded during an observation, individual scores should be carefully considered. We believe the PK might be the most representative score to report in those cases.

Potential improvements to our proposed IORA include the use of weighted Kappa to calculate the agreements. Based on an ontology of commonly used tasks in healthcare, mismatches could be penalized differently depending on how similar or different the two concepts are.

Despite the limitations of a percentage agreement, we believe that, since observers are trained before the IORA session and little guessing is likely to exist, providing the Kappa statistics accompanied by the percentage agreements might be of aid in interpreting the agreement16.

Conclusion.

Confirming that the establishment of IORA protocols and guidelines are a priority in validating continuous observation TMS, we evidenced the limitations of using a single metric IORA, and limitations related to the data manipulation required to implement it. We confirmed that assessing inter-observer reliability with Kappa, although partially useful, misrepresents and overestimates the real agreement, since it only focuses on one dimension of a multi-dimensional data set.

We proposed a composite IORA protocol, including a set of methods to assess each relevant dimension in workflow time studies: a proportion agreement, naming agreement, duration agreement, sequence agreement, and timing agreement. We demonstrated our proposed IORA methodology in a synthesized scenario.

We hereby provided a first step towards a standardized reliability reporting in workflow time studies. This new composite IORA protocol is intended to empower workflow researchers with a standardized and comprehensive method for validating observers’ reliability and, in turn, the validity and representativeness of the data collected.

Bootstrapping Adversarial Learning of Biomedical Ontology Alignments

Ramon M. Maldonado, MS¹, Sanda M. Harabagiu, PhD¹
¹University of Texas at Dallas, Richardson, TX, U.S.A.

Abstract

Learning how to automatically align biomedical ontologies has been a long-standing goal, given their ever-growing content and the many applications that rely on them. Because the knowledge graphs underlying biomedical ontologies enable neural learning techniques to acquire knowledge embeddings as representations of these ontologies, neural learning can also consider ontology alignments. In this paper, we present the Knowledge-graph Alignment & Embedding Generative Adversarial Network (KAEGAN) which learns (a) to represent the relational knowledge from two distinct biomedical ontologies in the form of knowledge embeddings and (b) to use them for ontology alignment, by also relying on the ontology semantics. KAEGAN is a Generative Adversarial Network trained using bootstrapping to iteratively improve the learned alignments. Experimental results show promise, demonstrating that jointly learning ontology alignment and knowledge representation improves upon learning either in isolation.

Introduction

Over the past two decades, the biomedical research community has increased its efforts to produce ontologies encoding biomedical knowledge, justified by the steady increase in biological and biomedical research and the growth of data that is being collected in all areas of biology and medicine. Not only is the number of ontologies increasing and their size growing, but their relevance in biomedical research is also rising as (a) they contribute to the interpretation of the biomedical data and (b) enable complex inference from their encoding. The BioPortal* of the National Center for Biomedical Ontology (NCBO) is the most comprehensive repository of biomedical ontologies in the world (as of this writing it includes 760 ontologies, with over 9 million classes and almost 40 million indexed records). Many of the ontologies available from the BioPortal became widely used resources, as evidenced by thousands of publications citing them. However, many of the ontologies exhibit overlapping information, which imposes the task of ontology alignment, i.e., finding mappings or correspondences between concepts and relations in different ontologies¹.

Biomedical ontology alignment has been performed using various methods, including rule-based and statistical methods²-⁴. More recently, neural methods for incorporating contextual and background information have been applied to ontology alignment as well. Wang et al.⁵ propose a neural model that learns to align concepts from different ontologies using external definitions and context information. Kolyvakis et al.⁶ approach the problem from the perspective of representation learning, aligning concepts using the word embeddings of their descriptions and automatically generated description paraphrases. However, while both approaches determine concept matches using learned embeddings of the concepts in each ontology, neither approach informs their concept embeddings with the relational knowledge contained in the ontologies. Biomedical ontologies encode knowledge by capturing ontological and biomedical expertise in the form of the knowledge graph of structured relations between medical concepts specified in an ontology. The task of distilling the structured knowledge from a knowledge graph into concept and relation embeddings is called knowledge graph embedding.

Recent work⁷-⁹ in learning knowledge graph embeddings has shown that ontological knowledge can be successfully expressed as real valued vectors associated with (i) each concept and (ii) each relation type available in the knowledge graph. The resulting learned knowledge embeddings can be used in a wide range of applications¹⁰ including determining the plausibility of any possible relation between arbitrary concepts in the ontology. In our previous work¹¹, we have shown how knowledge embeddings learned from the Universal Medical Language System (UMLS)¹² improve the performance of a neural prediction model when these knowledge embeddings are used to enrich the model’s representation of medical concepts. Furthermore, knowledge graph embedding methods have also been recently applied to general-domain and cross-lingual knowledge graph alignment with promising results¹³,¹⁴. Intrigued by these recent findings, we sought to extend knowledge-embedding-based alignment techniques to the biomedical domain in this work. For this purpose, we devised the Knowledge-graph Alignment & Embedding Generative Adversarial Network.

*http://bioportal.bioontology.org
KAEGAN method for jointly learning knowledge graph alignment and embedding. KAEGAN embeds the knowledge graphs associated with two distinct biomedical ontologies into the same semantic embedding space such that the learned knowledge embeddings can also be used for ontology alignment. KAEGAN uses a novel adversarial learning framework to learn alignment-oriented knowledge embeddings. More specifically, KAEGAN uses multiple generators to model interactions inside and across two knowledge graphs in order to embed them into the same semantic space, ensuring that aligned concepts will have similar embeddings. The ontology alignment is bootstrapped by iteratively predicting new alignments informed by the most similar alignment-oriented knowledge embeddings. We show that by jointly learning knowledge graph alignments and knowledge embeddings for any pair of biomedical ontologies, we improve the results of learning either knowledge embeddings or knowledge alignments in isolation. Therefore, the main novelty of KAEGAN arises from its adversarial framework which enables joint learning of knowledge alignments while learning how to discriminate valid relations in each knowledge graph, both with competitive results.

Data

In this work we focused on the knowledge embedding representation and alignment of three ontologies available from BioPortal: SNOMED Clinical Terms, the National Cancer Institute (NCI) Thesaurus, and the Foundational Model of Anatomy (FMA). SNOMED CT, the largest of the three ontologies, encodes medical terms used in clinical documentation and reporting, consisting of 349,548 medical concepts as of January 31, 2019. The NCI Thesaurus is an ontology providing a reference terminology for 66,724 cancer and cancer-related medical concepts. The Foundational Model of Anatomy (FMA) is an ontology with the stated goal of representing the phenotypic structure of the human body, encoding 78,989 concepts. Each of these ontologies is distinct and was designed independently. Consequently, a subset of the concepts in each ontology also have representations in the other two ontologies. As each of these ontologies has been integrated into the Unified Medical Language System (UMLS), we used UMLS as a reference alignment for evaluating the quality of the learned knowledge alignments. We were inspired by the Ontology Alignment Evaluation Initiative’s (OAEI) Large BioMed Track, which in fact uses these three ontologies and the reference alignment provided by the UMLS to evaluate ontology alignment systems in a yearly competition. The OAEI Large BioMed track is an evaluation for unsupervised systems and does not concern itself with distilling ontological knowledge into embeddings. As such, we have adapted the alignments provided by the OAEI to the supervised knowledge graph alignment problem.

SNOMED Clinical Terms, the NCI Thesaurus and FMA proved to be ideal ontologies for our work since they not only have a widely accepted alignment evaluation, but each ontology contains rich relational knowledge that can be used to inform the learning of knowledge embeddings, enabling KAEGAN to jointly learn knowledge graph alignment and embedding.

Methods

To learn knowledge embeddings informing ontology alignments we have designed the Knowledge-graph Alignment & Embedding Generative Adversarial Network (KAEGAN), which learns (1) how to embed two distinct biomedical ontologies into the same semantic space such that pairs of concepts from different ontologies can be aligned based on their similarity, while also (2) encoding the semantics of both ontologies in the same, shared embedding space. In KAEGAN, knowledge alignments are learned using the structure of the ontologies, i.e. relying on (a) the relations spanning concepts and (b) the attributes of concepts. KAEGAN also leverages a Generative Adversarial framework to learn high-quality alignment-oriented knowledge embeddings, which in turn are used to iteratively bootstrap the learning of ontology alignments. To describe the functionality of KAEGAN, we first present the way in which alignments between ontologies are learned and then we detail the way in which KAEGAN learns alignment-oriented embeddings.

Learning Ontology Alignments. Formally, let $C_X$ and $C_Y$ denote the set of concepts encoded in ontologies $X$ and $Y$, respectively. An alignment $A = \{(c_x, c_y) \in C_X \times C_Y | c_x \equiv c_y\}$ is a set of pairs of concepts from $X$ and $Y$ that

---

1http://www.cs.ox.ac.uk/isg/projects/SEALS/oaei/
represent equivalent concepts across the ontologies. For example, the concept “Arterial structure” from SNOMED CT represents the same concept as “Artery” in the NCI Thesaurus (concept C0003842 in the UMLS), so there would be a pair (Arterial_structure, Artery) in A. It should be noted that $c_1 \equiv c_2$ cannot hold if $c_1$ and $c_2$ are from the same ontology, so a concept $c_x$ from X can be aligned with at most one concept $c_y$ from Y, and vice-versa. We consider a subset of $A, A'$ as training data. This allows us to model alignment as a classification problem where the probability, $q(c_y|c_x)$, of a concept $c_y$ being aligned with a concept $c_x$ is a function of the similarity of their concept embeddings:

$$q(c_y|c_x) = \text{softmax}(\text{sim}(c_x, c_y)) = \frac{e^{\text{sim}(c_x, c_y)}}{\sum_{j \in Y} e^{\text{sim}(c_x, c_j)}}$$ (1)

$$\text{sim}(c_x, c_y) = \frac{\bar{v}(c_x) \cdot \bar{v}(c_y)}{\|\bar{v}(c_x)\|_2 \|\bar{v}(c_y)\|_2}$$ (2)

where $\bar{v}(c_x)$ represents the concept embedding for $c_x$, whereas $\text{sim}(\cdot, \cdot)$ is computed by the cosine similarity.

Inspired by Trivedi et al.\textsuperscript{14}, we adopt a contextualized concept embedding method that is particularly well suited to knowledge graph alignment. LinkNBed\textsuperscript{14} contextualizes concept embeddings using (1) concept attributes and (2) the neighborhood of nearby concepts in the knowledge graph. In a biomedical ontology, concept attributes encode auxiliary information via attribute triples of the form $(c, t, v)$ where $c$ represents a concept, $t$ represents an attribute type, and $v$ represents the attribute value, usually a string. For example in the National Cancer Institute Thesaurus\textsuperscript{19}, the concept ε=“Eicosapentaenoic Acid” has the attribute $t=$“definition” value $v=$“A class of polyunsaturated fatty acids with 20 carbons and 5 double bonds”. To further contextualize each concept embedding, nearby concept embeddings are aggregated using random walks in the knowledge graph. Formally, the embedding $\bar{v}(c)$ for the concept $c$ in KAEGAN is calculated as:

$$\bar{v}(c) = \sigma(v_0(c) + W_n N_e(c) + W_a A_e(c))$$ (3)

where $\sigma$ is the sigmoid function, $v_0(c) \in \mathbb{R}^d$ is an initial $d$-dimension embedding of $c$; $N_e(c)$ is the aggregate neighborhood context embedding of $c$; and $A_e(c)$ is the aggregate attribute embedding of $c$, while $W_n, W_a \in \mathbb{R}^{d \times d}$ are weight matrices. More specifically:

- The aggregate neighborhood context embedding $N_e(c)$ is computed by averaging the initial embedding vectors $v_0(c_i)$ for each concept $c_i$ in the neighborhood of $c$. The neighborhood of a concept $c$ is approximated as the set of concepts other than $c$ encountered on $k$ random walks of length $l$ executed when starting at $c$.

- The aggregate attribute embedding $A_e(c)$ is computed by max-pooling over the attribute embeddings of each attribute of $c$.

An attribute embedding $a$ is calculated by passing an attribute type embedding $a_t$ and an attribute value embedding $a_v$ through a fully connected sigmoid layer: $a = \sigma(W_t a_t + W_v a_v)$, where $W_t, W_v \in \mathbb{R}^{d \times d}$ are weight matrices. Attribute type embeddings are learned from scratch for each attribute and attribute value embeddings are learned using PARAGRAPH2VEC\textsuperscript{20} as in Trivedi et al.\textsuperscript{14}.

Using the concept embeddings to calculate $q(c_y|c_x) \forall(c_y, c_x) \in C_Y \times C_X$, we can measure the quality of a predicted alignment according to $q$ using cross entropy:

$$- \sum_{x \in X} \sum_{y \in Y} 1_{(c_x \equiv c_y)} \log q(c_y|c_x)$$ (4)

However, Equation 4 will only measure how well the model captures similarity between concepts aligned in the training data, which represents a small subset of $C_X \times C_Y$. Inspired by Sun et al.\textsuperscript{13}, we extended Equation 4 to incorporate uncertainty for unlabeled alignments, using the function $\phi(c_x, c_y)$ in place of the indicator function of Equation 4:

$$\phi(c_x, c_y) = \begin{cases} 1 & \text{if } c_x \text{ is aligned in the training data} \\ \frac{1}{N_{\text{unl}}} & \text{if } c_x \text{ is unlabeled} \end{cases}$$ (5)

where $N_{\text{unl}}$ is the number of currently unaligned concepts from $Y$. $\frac{1}{N_{\text{unl}}}$ represents a uniform distribution over the possible alignment candidates for $c_x$ and serves to bias the system against erroneous alignments. Using $\phi$ in the
cross-entropy calculation of Equation 4 in place of the indicator function, we obtain the Alignment Classification loss, $L_C$:

$$
L_C = - \sum_{x \in X} \sum_{y \in Y} \phi(c_x, c_y) \log q(c_y|c_x)
$$

By minimizing $L_C$, KAEGAN learns the probability alignment function, $q$, which enables the maximum likelihood alignment between $X$ and $Y$ to be found. As in Sun et al.\textsuperscript{13}, we produce an alignment between $X$ and $Y$ given an alignment probability function, $q$, by solving the max-weighted matching problem on the bipartite graph whose nodes are concepts from $X$ and $Y$ with edges $\langle c_x, c_y \rangle$ denoting alignment weighted by $q(c_y|c_x)$. We only consider alignment between each concept pair $\langle c_x, c_y \rangle$ for which $q(c_x, c_y)$ is above a certain threshold. It should be noted that this represents a max-weighted, one-to-one matching between subsets of $X$ and $Y$ with maximum total likelihood according to $q$.

Moreover, Sun et al.\textsuperscript{13} have shown that such alignments can be iteratively refined through bootstrapping by adding newly predicted alignments to the training data at each iteration and altering the predictions if a more likely alignment emerges. Specifically, at iteration $i$, given a training alignment $A'_i$ (where $A'_0 = A'$), KAEGAN learns alignment-oriented knowledge embeddings for each concept in $C_X \cup C_Y$ using the adversarial method described in the next section, after which the alignments are learned and new concept matches are added to $A'_{i+1}$. If a more likely matching emerges for a particular concept according to $q$, the less likely matching is simply replaced. KAEGAN terminates when no new concept matchings are added to the alignment.

**Adversarial Learning of Alignment-Oriented Knowledge Embeddings.** In order to learn alignment-oriented knowledge embeddings KAEGAN uses a Generative Adversarial Network\textsuperscript{16} (GAN) composed of a Discriminator and four Generators illustrated in Figure 1. In the traditional GAN framework, two competing networks - a Discriminator and a Generator - are pitted against one another in a zero-sum game. The Generator learns to map from a latent space to a data distribution of interest, while the Discriminator learns to distinguish candidates produced by the generator from the true data distribution. Recently, GANs have been applied to the problem of Knowledge Graph Embedding\textsuperscript{8,11}, showing promising results. In this work, we extend the GAN framework for learning knowledge graph embedding\textsuperscript{8} to learn alignment-oriented knowledge embeddings. In KAEGAN, the Discriminator learns alignment-oriented embeddings that are used to discriminate between valid and invalid relation triples from both biomedical

---

**Figure 1:** Adversarial Learning of Knowledge Graph Embeddings for Biomedical Ontology Alignment.
ontologies\footnote{A relation triple $\langle c_1, r, c_2 \rangle$ is defined by a relation encoded between two concepts $c_1$ and $c_2$ from the same biomedical ontology.} while ensuring that any aligned concepts from the pair of ontologies have similar embeddings, given a probability of alignment between the concepts, defined as $q$. The relation triple $\tau = \langle c_1, r, c_2 \rangle$ is considered to be valid if the concept $c_1$ is related to the concept $c_2$ by the relation $r$ in either of the knowledge graphs $X$ or $Y$ and is said to be invalid otherwise. For example, in the NCI Thesaurus, the concept “Artery” is encoded as a type of “Blood Vessel” represented by the relation triple $\langle \text{Artery, IS\_A, Blood\_Vessel} \rangle$. The Discriminator should be able to discriminate between such a valid relation and an invalid relation such as $\langle \text{Artery, IS\_A, Opiate} \rangle$. Observing that the majority of randomly constructed invalid relation triples can be trivially recognized as invalid, the four Generators of KAEGAN learn to produce more plausible – yet still invalid – relation triples in an attempt to fool the Discriminator, e.g. $\langle \text{Artery, IS\_A, Blood\_capillary} \rangle$. In order to facilitate alignment, the Discriminator is trained to evaluate the plausibility of both intra-graph relation triples produced by Generators $G_X$ and $G_Y$ and inter-graph relation triples produced by Generators $G_{XY}$ and $G_{YX}$.

Consider two relation triples $\tau_x = \langle c_1^x, r^x, c_2^x \rangle$ and $\tau_y = \langle c_1^y, r^y, c_2^y \rangle$ from the knowledge graphs represented by ontologies $X$ and $Y$, respectively shown in Figure 1. Attempting to fool the Discriminator, Generator $G_X$ uses $\tau_x$ to generate an invalid triple $\tau'_x = \langle c_1^x, r'^x, c_2^x \rangle$ by swapping out either $c_1^x$ or $c_2^x$ with another concept from $X$ such that $\tau'_x$, while invalid, is more plausible than a randomly sampled triple (e.g. $\tau_x = \langle \text{Artery, IS\_A, Blood\_Vessel} \rangle$ and $\tau'_y = \langle \text{Artery, IS\_A, Blood\_capillary} \rangle$). Generator $G_Y$ does the same for triple $\tau_y$, generating the invalid triple $\tau'_y$ using $Y$. The Discriminator’s job is then to determine which of $\tau_x$ and $\tau'_x$ and which of $\tau_y$ and $\tau'_y$ is more plausible using the loss function, $L_H$. Generators $G_{XY}$ and $G_{YX}$ operate similarly, however they generate invalid triples by sampling concepts across the knowledge graphs corresponding to the pair of biomedical ontologies. Specifically, $G_{XY}$ generates the invalid triple $\tau'_{xy}$ by first relying on the valid triple $\tau_{xy}$ and replacing either $c_1^y$ or $c_2^y$ with its aligned concept from $Y$, $c_1^x$ or $c_2^x$, based on an alignment $A'$, available from the training data used for learning ontology alignments. Then $G_{XY}$ samples a concept from $Y$ to replace $c_1^y$ or $c_2^y$ to produce $\tau'_{xy}$. For example, consider the triple $\tau_x = \langle \text{Artery, IS\_A, Blood\_Vessel} \rangle$ from FMA. Blood_Vessel could be replaced with the concept Human_Blood_Vessel from NCI to create $\tau_{xy} = \langle \text{Artery, IS\_A, Human\_Blood\_Vessel} \rangle$ and the generator might sample the semantically related concept Angiogram to produce $\tau'_{xy} = \langle \text{Artery, IS\_A, Angiogram} \rangle$. $G_{YX}$ operates in the same way to create $\tau_{yx}$ and $\tau'_{yx}$ from $\tau_y$.

In order to discriminate valid relation triples from invalid relation triples, the Discriminator is trained to measure the plausibility of a triple $\tau = \langle c_1, r, c_2 \rangle$ where $c_1, c_2 \in C_X \cup C_Y$ are concepts and $r$ is a relation from either $X$ or $Y$. KAEGAN models relation triple plausibility scores using translational knowledge graph embedding. Pioneered by TransE\cite{bordes2013translating}, translational knowledge graph embedding methods model relation triple plausibility as a translation on the embedding space. TransE models a relation triple $\tau = \langle c_1, r, c_2 \rangle$ by first projecting $c_1, c_2$, and $r$ onto a shared embedding space to produce embeddings $\vec{v}(c_1), \vec{v}(c_2)$, and $\vec{v}(r) \in \mathbb{R}^d$, where $d$ is the dimensionality of the embedding space. The vector $\vec{v}(r)$ is used as a translation vector from $\vec{v}(c_1)$ such that $\vec{v}(c_2) \approx \vec{v}(c_1) + \vec{v}(r)$ if the triple $\tau = \langle c_1, r, c_2 \rangle$ is a valid relation triple. In this way, TransE models the plausibility of a relation triple using the distance between the destination concept embedding and the source concept embedding translated by the relation embedding: $f_D(\tau) = \| \vec{v}(c_1) + \vec{v}(r) - \vec{v}(c_2) \|_{L2}$. The concept embeddings $\vec{v}(c_1), \vec{v}(c_2)$ are computed using Equation 3 and the relation embedding $\vec{v}(r)$ is calculated via simple embedding lookup.

In order to learn the plausibility of the relations encoded in an ontology, KAEGAN minimizes the following marginal loss function:

$$L_R = \sum_{\tau \in X \cup Y} \max(0, f_D(\tau) - \gamma_1) + \max(0, \gamma_2 - f_D(\tau'))$$

where $\gamma_1, \gamma_2$ are margin hyperparameters and $f_D(\tau')$ is the score of an invalid triple generated by either $G_X$ or $G_Y$ using $\tau$. While the triple $\tau$ represents semantic knowledge that we wish to encode in our knowledge embeddings,
\( \tau' \) represents erroneous knowledge that KAEGAN should be implausible. The two margin parameters \( \gamma_1, \gamma_2 > 0 \) where \( \gamma_2 > \gamma_1 \) enforce the property that plausible triples have lower score than negative triples since \( f(c_1', r, c_2') - f(c_1, r, c_2) \geq \gamma_2 - \gamma_1 > 0 \). By modeling the margin with two parameters and setting \( \gamma_1 \) to a small positive value, we also enforce the property that plausible triples have low absolute scores, which has shown to be effective for alignment-oriented embedding\(^{13,21}\).

The corrupted triple \( \tau' \) is sampled by either Generator \( G_X \) or Generator \( G_Y \) depending on whether the original triple \( \tau \) was encoded in ontology \( X \) or in ontology \( Y \). Given a triple \( \tau_x \in X \), Generator \( G_X \) generates the corrupted triple \( \tau'_x \) by producing a probability distribution \( P_X(\tau'_x | \tau_x) \) and sampling from that distribution. The distribution \( P_X \) is calculated using Generator \( G_X \)'s own scoring function \( f_{G_X} \):

\[
P_X(\tau'_x | \tau_x) = \frac{e^{f_{G_X}(\tau')}}{\sum_{\tau^* \in Neg^X} e^{f_{G_X}(\tau^*)}}
\]

where \( Neg^X \) is a set of invalid relation triples derived from \( \tau_x = (c_1^x, r^x, c_2^x) \) with either \( c_1^x \) or \( c_2^x \) replaced with another concept from ontology \( X \) such that the resulting relation triple does not occur in the knowledge graph \( X \). KAEGAN uses the DistMult\(^8\) scoring function, defined as \( f_{G_X} = (\vec{v}(c_1) \odot \vec{v}(r)) \cdot \vec{v}(c_2) \), where \( \odot \) is element-wise multiplication and \( \cdot \) is the dot product. DistMult has been shown to excel in probabilistic systems that learn knowledge embedding models\(^11\). Intuitively, \( P_X \) is used to sample the most plausible, yet still incorrect triples in an attempt to fool the Discriminator. Generator \( G_Y \) samples from the distribution \( P_Y \) calculated using the scoring function \( f_{G_Y} \) defined similarly.

For alignment-oriented embeddings, the scoring functions \( f_D, \) (of the Discriminator) and \( f_G \) (of the generators) should have the replacement property that if \( c_1^x \in X \) has an aligned concept \( c_1^y \in Y \), \( f(c_1^x, r^x, c_2^x) \approx f(c_1^y, r^x, c_2^y) \) when \( f \) is either \( f_D \) or \( f_G \). That is to say, if a concept from a plausible triple of ontology \( X \) is replaced with an aligned concept from ontology \( Y \), the new triple should remain plausible under both scoring functions. The same property should hold if \( c_2^x \) is replaced with its aligned concept or if a concept from a triple from ontology \( Y \) is replaced with an aligned concept from ontology \( X \). The replacement property of \( f_D \) and \( f_G \) ensures that relation semantics are preserved across knowledge graphs. In order to capture this property, we minimized the cross-graph marginal loss, defined as:

\[
L_A = \sum_{\tau_x \in X^A} \max(0, f_D(\tau_{xy}) - \gamma_1) + \max(0, \gamma_2 - f_D(\tau'_{xy})) \\
+ \sum_{\tau_x \in Y^A} \max(0, f_D(\tau_{yx}) - \gamma_1) + \max(0, \gamma_2 - f_D(\tau'_{yx}))
\]

where \( X^A, Y^A \) represent the subsets of triples in the knowledge graphs of the ontologies \( X \) and \( Y \) that involve concepts aligned across ontologies; \( \tau_{xy} \) represents a triple \( \tau_x = (c_1^x, r^x, c_2^x) \in X \) with either \( c_1^x \) or \( c_2^x \) replaced with its aligned concept from \( Y \), and \( \tau'_{xy} \) represents a triple \( (c_1'^x, r^x, c_2'^x) \in X \) with either \( c_1'^x \) or \( c_2'^x \) replaced with an incorrect concept from \( Y \) that does not represent a true alignment, sampled by \( G_{XY} \). \( \tau_{yx} \) and \( \tau'_{yx} \) are defined similarly.

As in previous work\(^9,11\), because the Generators involve a sampling step, they were trained via Policy Gradient\(^22\) where each Generator was trained to maximize the reward it receives from the Discriminator, in the form of the Discriminator’s score of the generated relation triple, \( f_D(\tau'_x), f_D(\tau'_y), f_D(\tau'_{xy}), \) and \( f_D(\tau'_{yx}) \).

### Results

The alignment-oriented knowledge embeddings learned by KAEGAN were evaluated in terms of their ability to (1) produce an alignment between two biomedical knowledge graphs, and (2) model the semantics of the two encoded knowledge graphs. For the evaluations, we used the three ontologies from the OAEI large-bio track described in the data section: the National Cancer Institute Thesaurus\(^6\), the Foundational Model of Anatomy\(^7\), and a subset of SNOMED CT\(^5\). For the alignment task, we randomly sampled

**AML²**

Table 2: Evaluation of biomedical ontology alignment using alignment-oriented knowledge embeddings.

20% of the aligned concepts of each pair of ontologies to create our initial training Alignment, $A_0$, reserving 10% for validation, leaving the remaining 70% as test data, summarized in Table 1. For both tasks, we evaluate KAEGAN against the following alternate configurations of KAEGAN to explore the efficacy of the methods used therein:

1. **KA-Classifier** is a neural classifier that learns a similarity function $q(\cdot)$ which minimizes the objective in Equation 6, but does not use the relational information of the two knowledge graphs being aligned. KA-Classifier is meant to evaluate the effect of relational information on embedding-based alignment. KA-Classifier does not use either loss from Equations 8 or 10 and therefore can not be trained in an adversarial fashion.

2. **KAEGAN-No Class** is a configuration of the KAEGAN system that does not use the classification loss, $L_C$. KAEGAN-No Class learns to embed and align concepts using only the relational information from the two knowledge graphs as represented by $L_R$ and $L_A$. This configuration serves to evaluate the effect of $L_C$ on both alignment and embedding.

3. **KA-Discriminator** is a model comprised only of the Discriminator of KAEGAN, meant to evaluate the effect of the GAN training regime. KA-Discriminator is trained using standard negative sampling instead of the Generators.

4. **KAEGAN-No Context** is a configuration of KAEGAN that uses simple embedding lookup for $\tilde{v}(\cdot)$ in Equation 3, eschewing context information from attributes and concept neighborhoods.

5. **KAEGAN-No Attr** is a configuration of KAEGAN that does not use attribute information, leaving $W_a A_c(c)$ out of Equation 3.

6. **KAEGAN-No Neigh** is a configuration of KAEGAN that does not use neighborhood information, leaving $W_n N_c(c)$ out of Equation 3.

Following the Ontology Alignment Evaluation Initiative³, ontology alignment is evaluated using Precision (P), Recall (R), and $F_1$ as well as Hits@10 and Mean Reciprocal Rank as in Sun et al.¹³. Hits@10 reports the percentage of concepts $c_x$ for which the true aligned concept $\hat{c}_y$ is one of the top-10 most likely matches according to $q(c_y|c_x)$. Mean reciprocal rank reports the average reciprocal rank of the correct aligned concept among all possible concepts, ranked by $q$. 

633
The ontology alignment results are presented in Table 2. We compare the different configurations of KAEGAN to the top performing system from the OAEI Large BioMed track, AgreementMakerLight (AML), a hand-engineered expert system which leverages background information found outside the ontologies being aligned. While not at the level of AML, clearly, the full KAEGAN model out-performs the alternate configurations for each matching. Interestingly, the worst performing configurations were the KAEGAN-No_Context and KAEGAN-No_Attr models, illustrating the importance of attribute information for ontology alignment. Moreover, the strong performance of the KA-Classifier model and the relatively poor performance of the KAEGAN-No_Class model demonstrate the efficacy of modeling alignment matching explicitly through the alignment classification loss, $L_C$.

To determine the ability of the learned knowledge embeddings to model the semantics of the embedded knowledge graphs, we evaluate the embeddings based on their plausibility and completeness following the evaluation procedure outlined in previous work. Plausibility evaluation is cast as a link prediction problem called Relation Triple Classification (RTC). RTC is performed using a plausibility function defined as $\rho = -f_D$, the negation of the scoring function of the KAEGAN’s Discriminator. Given a relation triple $\tau = (c_1, r, c_2)$, we use $\rho(\tau)$ to classify $\tau$ as either a valid or invalid relation triple depending on if $\rho(\tau) > \omega$ for some threshold $\omega$. To perform RTC, we split the relation triples from each knowledge graph into 85%/5%/10% train/validation/test splits. For each triple in each validation and test set, we create an invalid triple by replacing either the source or destination concept and add the invalid triple to the respective set. We then use the trained model to score each triple from the validation set and select the optimal value of $\omega$ for each model. We evaluate RTC on the test sets using Precision (RTC-P) and Recall (RTC-R) as in previous work. RTC-P can be thought of as measuring plausibility while RTC-R measures completeness. To further quantify plausibility, we use three standard knowledge graph embedding metrics: (1) Pairwise Plausibility Accuracy (PPA); (2) Hits@10 (H@10); and (3) Mean reciprocal rank. PPA measures how often a model can select the valid triple from a pair of triples $(\tau, \tau')$ where $\tau'$ is a corrupted version of $\tau$. H@10 and MRR measure how well the model can use plausibility, $\rho$, to rank unseen valid triples above invalid triples. To compute H@10 and MRR, we first create a set of rankings, one for each triple in the test set. Each ranking is created by replacing either the source or destination concept and add the invalid triple to the respective set. We then use the trained model to score each triple from the validation set and select the optimal value of $\omega$ for each model. We evaluate RTC on the test sets using Precision (RTC-P) and Recall (RTC-R) as in previous work.

The results presented in Table 3 indicate that KAEGAN is able to model the semantics of distinct knowledge graphs by embedding them in the same semantic space facilitated by modeling their alignment. The KA-Classifier model does not perform knowledge graph embedding, so it is not evaluated along with the other configurations. Likewise, we do not evaluate KAEGAN against general-purpose, non-alignment-oriented embedding models (e.g. Trans-X, SePLi²², or TATEC²⁴) in order to focus on the impact of modeling alignment on knowledge graph embedding. Although it should be noted that the general KAEGAN learning framework can accommodate any general purpose embedding paradigm,
such as the ones listed above, by replacing Equation 3. The improvement of KAEGAN over KAEGAN-No_Class shows that using alignment classification improves relational learning. Likewise, the improvement of KAEGAN over KAEGAN-Discriminator demonstrates the efficacy of the GAN learning framework. It should be noted that, while the removal of concept context in the form of attributes and neighborhoods has a marked effect on performance, the decrease is minimal compared to its effect the alignment task.

**Discussion**

In general, the results show that KAEGAN is able to embed distinct knowledge graphs into the same semantic space such that the learned embeddings can be used for both ontology alignment and representation learning. The ontology alignment experiments presented in Table 2 elucidate several interesting phenomena including the importance of attributes in ontology alignment. Since attributes are useful in qualifying the concepts - making them distinct from the other concepts in the ontology - it is not unexpected that ignoring them results in the large performance drops seen by KAEGAN-No_Context and KAEGAN-No_Attr. The name and description attributes are particularly helpful, since many concepts have similar names or descriptions across ontologies. However, the performance of KAEGAN-No_C demonstrates the efficacy of leveraging the structured knowledge in the form of relation triples for alignment. One possible reason for this is that concepts with differing names and descriptions from different ontologies may share similar relations with more well-defined concepts, causing the model to discover their alignment. Another interesting trend we can glean from the alignment experiments is the small improvement of Hits@10 over Precision, a fundamentally more difficult evaluation. Precision is akin to ‘Hits@1’, but when we relax the evaluation to the top 10 we only see a 2% increase on average. This finding indicates that when the model finds an alignment it is generally correct, but when the model is not able to determine alignment correctly, the probability it learns for the correct alignment is especially low.

While the alignment results show promise, they do not surpass the current state-of-the-art on the OAEI Large BioMed track, represented by AgreementMakerLight (AML)\(^4\). AML is hand-engineered for aligning large biomedical ontologies, leveraging outside ontologies\(^{25-27}\) as intermediaries to facilitate matching. We believe KAEGAN can be improved in the same way – by jointly modeling the alignment more than two ontologies. We plan to address extend KAEGAN to an arbitrary number of ontologies future work. Likewise, noting that AML makes use of string matching, we believe KAEGAN can be improved by incorporating character-level information about a concept’s name and other attributes.

Unlike AML, KAEGAN jointly performs knowledge embedding as well as alignment. The results presented in Table 3 indicate that biomedical knowledge embeddings learned from distinct graphs are improved by jointly modeling the alignment between the graphs. We believe the primary reason for this is that by modeling both graphs in the same semantic space, each graph can inform the other - filling possible knowledge gaps and providing additional context for both overlapping concepts and the rest of the graphs. Guo et al.\(^{28}\) have shown that semantically smooth knowledge embeddings can be achieved by imposing constraints on the learned embeddings. The alignment classification loss \(L_C\) plays a similar role in KAEGAN constraining aligned embeddings to be similar to one another, imposing its own type of smoothing which is shown to improve results.

**Conclusion**

In this paper, we presented the **Knowledge-graph Alignment & Embedding Generative Adversarial Network (KAEGAN)**. KAEGAN learns to jointly embed distinct biomedical ontologies into the same semantic embedding space such that the resulting embeddings can be used for knowledge graph alignment. KAEGAN leverages relational knowledge encoded in the knowledge graph of an ontology as well as attributes of the medical concepts to learn alignment-oriented embeddings. In addition to ontology alignment, the learned embeddings can be used to model the semantics of the encoded knowledge graphs. Results indicate that learning to align and embed the knowledge graphs jointly improves upon learning the alignment and the embedding separately.

Abstract

With the advent of interoperability standards such as FHIR, SMART, CDS Hooks, and CQL, interoperable clinical decision support (CDS) holds great promise for improving healthcare. In 2018, the Agency for Healthcare Research and Quality (AHRQ)-sponsored Patient-Centered CDS Learning Network (PCCDS LN) chartered a Technical Framework Working Group (TechFWG) to identify barriers, facilitators, and potential solutions for interoperable CDS, with a specific focus on addressing the opioid epidemic. Through an open, multi-stakeholder process that engaged 54 representatives from healthcare, industry, and academia, the TechFWG identified barriers in 6 categories: regulatory environment, data integration, scalability, business case, effective and useful CDS, and care planning and coordination. Facilitators and key recommendations were also identified for overcoming these barriers. The key insights were also extrapolated to CDS-facilitated care improvement outside of the specific opioid use case. If applied broadly, the recommendations should help advance the availability and impact of interoperable CDS delivered at scale.

Introduction

In 2018, while overall opioid prescribing appears to be on a downward trend, misuse of prescription opioids continues to remain fairly stable and opioid related deaths continue to rise.1 Opioids are the second most commonly abused substance in the United States.2 Of the significant efforts to curb this epidemic, one is the development and dissemination of opioid prescribing recommendations for chronic pain from the Centers for Disease Control and Prevention (CDC).3 Part of the challenge in implementing change, however, is applying recommended practices in
routine clinical care. Clinical decision support (CDS) integrated with the electronic health record (EHR) and combined with staff- and patient- oriented strategies, can change clinician behavior and increase adherence to clinical guidelines, including prescribing, but CDS implementation, adoption, and use remains challenging.

While the United States healthcare system has widely adopted EHR technology, and while that adoption generally includes CDS, the overall development and utilization of effective CDS remains somewhat limited. Emerging standards such as the Health Level 7 International (HL7) Fast Healthcare Interoperability Resources (FHIR), CDS Hooks, and Clinical Quality Language (CQL) specifications are becoming increasingly well adopted by EHR vendors, providing a critical link to fully integrated CDS. Requiring support for application programming interfaces (APIs) for enhancing data portability and third-party application integration is also an important facilitator of CDS integration. Interoperable CDS may potentially finally unlock the benefits of converting to electronic records, particularly when patients are engaged through patient-centered CDS.

Despite the promise of widespread care improvement facilitated by interoperable CDS, the reality is that this promise remains a vision for healthcare in general. There are emerging efforts to address this challenge in multiple domains including the opioid epidemic. However, much more needs to be learned on how best to leverage interoperable CDS to improve care widely.

In 2015, the Patient-Centered CDS Learning Network (PCCDS LN) was established to improve collective learning of patient-centered CDS by the Agency for Healthcare Research and Quality (AHRQ). In 2018, the PCCDS LN focused on the opioid epidemic as an important care domain for identifying how best to leverage patient-centered CDS to improve patient care. To do so, two Working Groups were chartered: an Opioid Action Plan Working Group (OAPWG) and a Technical Framework Working Group (TechFWG). The primary goal of the OAPWG was to develop a plan for patient-centered CDS applied broadly and effectively to improve pain management and opioid use. One work product of the OAPWG was the development of highly desirable, consensus patient-centered CDS-enabled future state vision scenarios for patient-centered CDS-enabled pain management/opioid use.

Led by K. Kawamoto and L. Marcial, the primary goal of the TechFWG was to review this future state vision through the lens of CDS implementation and identify the current state, barriers, what resources are available, and recommendations for moving forward. This Task Force was also charged with identifying implications that can be moved forward beyond opioids. Efforts of the TechFWG focused on applying patient-centered CDS in health care delivery and the needs of the healthcare team including the prescribing clinician, with some thinking around the patient perspective. Key considerations of the opioid use case context included:

1. The need for complete and accurate understanding of past, current, and potentially most beneficial treatments in making pain treatment decisions.
2. The ability to quickly and accurately assess opioid-related risks (e.g., OUD, overdose, misuse/abuse).
3. The call to better integrate, synthesize, and interpret information in PDMP reports and other urine drug screen results.
4. To more efficiently and effectively identify trends in relevant patient outcomes over time (e.g., pain, physical function, co-morbid mental health).
Here, we describe the findings from the PCCDS LN TechFWG which encompass barriers, facilitators, implications and recommended actions for advancing patient-centered CDS to address the opioid epidemic.

**Methods**

*Subject matter expert (SME) recruitment.* Participation in the TechFWG by SMEs was voluntary. Calls for participation were sent via email to the PCCDS LN mailing list and to the list serves of the HL7 CDS Work Group, HL7 Clinical Quality Improvement (CQI) Work Group, American Medical Informatics Association (AMIA) CDS Work Group, and AMIA Implementation Work Group. Interested parties were asked to complete an online form with basic demographic information, availability, and interest in serving on the TechFWG.

*TechFWG goals and charter.* The TechFWG was chartered to address four goals: 1) Facilitate shared decision-making tools delivered via CDS, 2) Discuss opportunities and barriers presented by technologies and standards such as SMART on FHIR and CDS Hooks, 3) Identify gaps in needed standards and their adoption, and 4) Produce a whitepaper and/or manuscript on barriers and facilitators.

*TechFWG deliberations.* A total of 8 web conference calls were held biweekly between June 11, 2018 and October 1, 2018. All participants were asked to contribute both during and between meetings and to volunteer to present work of their own to the broader group on CDS-related initiatives. Final report-out and vetting of the recommendations occurred during the PCCDS LN Annual Conference on October 15, 2018 in both a general session as a briefing and a breakout session to solicit additional input.

*TechFWG composition.* The TechFWG included stakeholders from various disciplines. The TechFWG members who contributed in at least 4 of the 8 calls or otherwise made substantial contributions to the final deliverables were invited to participate as co-authors of this manuscript.

*Deliverables.* The deliverables of the TechFWG, and the focus of its activities, consisted of 1) the identification of barriers, facilitators, and required actions to enable effective patient-centered CDS for pain management as envisioned by the OAPWG. Identified barriers were grouped into categories through group consensus, 2) Insights on these barriers, facilitators, and required actions for effective patient-centered CDS in general, extrapolated from these issues identified in the pain management use case, and 3) A summary of the findings and recommendations and its dissemination. This manuscript presents results of the TechFWG deliberations in terms of these deliverables.

**Results**

*Membership and participation:* A total of 54 subject matter experts (SMEs) volunteered to serve on the TechFWG. Participation averaged about 20 members per biweekly call, and 20 members contributed to at least 4 of the 8 calls or otherwise made substantial contributions to the TechFWG deliverables including this manuscript. Of these 20 members, 7 were affiliated with academic institutions, 4 with consulting firms, 3 with government, 3 with research organizations, 2 with EHR vendors, and 1 with a health system (many participants had overlapping roles).

*Barriers, Facilitators, and Needed Actions for Advancing PCCDS for Pain Management:* The TechFWG members identified key barriers in six categories: (1) regulatory environment, (2) data integration, (3) scalability, (4) business case, (5) effective and useful CDS, and (6) care planning and coordination. These are detailed in Table 1 and summarized below (additional details available...
from the PCCDS Learning Network). Based on the findings from the specific use case of pain management, key generalizable insights were extrapolated. These generalizable insights and recommendations are summarized in Table 2.

**Regulatory environment:** Key identified barriers in the regulatory environment include differences in state-level regulations on the allowed use of prescription drug monitoring program (PDMP) data and allowed prescribing of controlled substances. Important identified facilitators in this area included initiatives that connect PDMPs across states as well as state regulations requiring e-prescribing of controlled substances. *Needed Actions:* In terms of recommended actions, the TechFWG recommended unifying regulations according to the evidence base on a national level, encouraging voluntary coordination at the state level, and, at the local level, defining and sharing cohesive evidence-based guidelines that incorporate federal and state regulations.

**Data integration:** As a key challenge, methods for capturing source data, ensuring its quality and availability, specifying the data format, facilitating patient matching, reading relevant data from and writing data into records, and visualizing relevant data can be restrictive or limited. While these data issues are large, pervasive, and perhaps daunting barriers, the TechFWG felt that a facilitator included the fact that opioids are an important national concern with a defined scope, thereby enabling a directed conversation on how specific needed data can be aggregated and analyzed effectively. *Needed Actions:* In terms of recommendations, the TechFWG recommended improving data integration by defining data needs and interoperability requirements tied directly to their clinical application. At the federal level, this might include funding the development of a set of data needs for specific decision makers, a set of consolidated requirements specifications for interoperability, and research on visualization best practices to support clinicians and patient decision making. For providers and patients, we can facilitate improved data quality by giving patients access to update their own data. Vendors need opportunities to more fully test and verify architecture and standards for semantic interoperability in an iterative fashion.

**Scalability:** Assuming the needed data are available, tools to scale patient-centered CDS are still somewhat nascent and often require the additional step of localization. There is substantial promise in emerging repositories to support the availability of CDS artifacts. In addition, relevant standards and support of those standards continues to mature. *Needed Actions:* To facilitate improvements in scalability, the TechFWG identified the need for a national authoritative body that agrees on and promotes human readable and computer-interpretable guidelines and funds research on best implementation strategies for desired CDS. Professional societies continue to develop and provide clinical endorsement of guidelines, while also encouraging widespread adoption of an appropriate technical framework to support interoperable CDS based on these guidelines. Vendors can also provide support in the form of approaches to better centrally manage trusted CDS.

**Establishing a clear business case and providing incentives:** The return on investment for CDS has still not been clearly established and the incentives of today are not yet well aligned with the needs of patients and providers. The advent of value-based care initiatives may help provide some of the needed incentives to advance CDS. *Needed Actions:* Broadly, we must establish and promote the business case for CDS using incentives across stakeholder groups to improve patient care. CMS and other payers could help by incentivizing the achievement of quality goals and best practices through the use of CDS while also funding research to identify and mitigate unintended consequences. Federal and state entities can support and further incentivize the implementation of CDS solutions. The CDS ecosystem can leverage all of its stakeholders to find ways to improve the performance and reduce the cost of CDS.
### Table 1. Key barriers, facilitators, and needed actions for enabling effective PCCDS for pain management

<table>
<thead>
<tr>
<th>Category</th>
<th>Barriers</th>
<th>Facilitators</th>
<th>Needed Actions</th>
</tr>
</thead>
</table>
| **Regulatory environment**    | • There are state-specific regulations on controlled substances, but many states prohibit incorporating the actual PDMP source data into the EHR and CDS.  

  • State-by-state regulations for prescribing limits and/or regulations restrict the ability to prescribe opioid antagonists and there may be limits or incentives for those that can be written electronically which subsequently limits associated CDS.  

  • Federal regulations and recommendations may not align with mechanisms to facilitate CDS implementation.  

  | • Initiatives that link resources up help, e.g., PMP InterConnect, a product from the National Association of Board of Pharmacy that connects PDMPs from 44 states.  

  • In some states there is mandated e-prescribing of controlled substances, e.g., New York.  

  • The Promoting Interoperability program includes 2 opioid e-prescribing measures: query of PDMP (optional in CY 2019 and required in CY 2020) and verification of an opioid treatment agreement (optional for CY 2019 and CY 2020).  

  | • Federal and state lawmakers can:  

  o support the development of unified national-level regulations and encourage voluntary coordination among state medical boards. NOTE: In general, there is a relative lack of evidence underlying regulations and policy.  

  o enable the sharing of source data, and mandate or encourage e-prescribing for controlled substances to further enable point-of-care CDS  

  o create policies and regulations based on evidence and support collection of evidence where lacking |
| **Data integration**          | • It is difficult to access all relevant data across multiple health systems, and health IT systems over time (e.g., medications, supplements, lab tests, imaging, referrals, care plan/controlled substance agreements, functional status, diagnoses and side effects).  

  • Source data may have poor data quality, are temporally limited, and are difficult to both patient-level match and to de-duplicate and may not be in a structured, standard form that facilitates matching, reconciliation, and de-duplication  

  • Existing data structures were created without semantic interoperability as the goal, bi-directional information exchange may not be well supported, e.g., no clear way for controlled substance agreements to be pushed out by a prescriber to other prescribers in a state.  

  • A lack of consensus on a ‘data interoperability architecture’ for universal use inhibits achieving greater overall interoperability.  

  • Visualizations to support interpretation are often limited and scales are subjective, e.g., pain scale.  

  • SMART and other interoperable apps/services may be important in this ecosystem for opioid use  

  | • Opioid use and pain management, a national focus, may serve as a catalyst for CDS.  

  • There is a need to collect well-defined data for aggregation and summarization. The OpenNotes movement could be leveraged for data cleaning and reconciliation. Some patients and health systems are already engaged in Open Notes and it could be used for patients to review and clean data. Natural Language Processing can also be used to mine free text, e.g., for after-the-fact conversion to structured data or for facilitating real-time data entry.  

  • A dashboard for relevant data, e.g., pulling up first-line treatments that have already been tried.  

  • There are some semantic interoperability standards available and adopted for relevant data that could facilitate data integration and summarization:  

  • There are some semantic interoperability approaches/efforts that could be applied to help (e.g., Argonaut project, efforts at HIT Advisory Committee (HITAC) efforts to define priority healthcare uses and needed standards).  

  • Population health management tools  

  | • Concrete interoperability requirements need to be defined for this space. Need to identify achievable goals with associated clinical needs. This applies equally to CDS/knowledge interoperability (see also Scalability).  

  • Federal government could fund the development of a consolidated requirements specification for interoperability.  

  • Data quality and de-duplication issues are still persistent. Need to enable patients to help in this de-duplication and data reconciliation process. Patient involvement will help ensure this is a patient-centered and patient-engaged process.  

  • Probably the missing link here is the available data in structured, semantically interoperable form. Once available, SMART should be useable for data summarization. There appears to be sufficient momentum through federal funding sources such as NIH, AHRQ, CDC in this area, as well as other non-grant resources.  

  • Architecture and standards for semantically interoperable data are still not available, adopted, or verifiable to the extent needed.  

  • Terminology standards and resources are needed for relevant concepts. |
### Establishing a clear business case and providing incentives

<table>
<thead>
<tr>
<th>Management, but they have limited abilities to contribute data back in/write due to API limitations.</th>
</tr>
</thead>
<tbody>
<tr>
<td>The current system as it exists is generally a reflection of the current business incentives. In other words, the system we have now is optimized for the incentives we have now.</td>
</tr>
<tr>
<td>Cost of implementing desired solutions can be an important barrier. There needs to be a financial ROI case for the needed CDS and other HIT solutions, but such ROI information may not be clear or even available.</td>
</tr>
<tr>
<td>Change is happening in terms of overall incentives to incorporate CDS and improve quality:</td>
</tr>
<tr>
<td>- Value-based care should result in an incentive shift toward care that is better for opioid use and desired actions for opioid management.</td>
</tr>
<tr>
<td>- Pharma incentives to be seen as helping with this issue.</td>
</tr>
<tr>
<td>- Providers are motivated to avoid regulation-related, penalties, lawsuits, maintain licensure, etc.</td>
</tr>
<tr>
<td>- Many state medical boards are starting to put in opioid related requirements</td>
</tr>
<tr>
<td>Incentives are still limited/do not support improving pain management and opioid management. CMS is important, but private payors are also getting actively engaged in this area. We need quality measures around what is desired.</td>
</tr>
<tr>
<td>One potentially promising approach would be coming up with best practice recommendations that can be adopted by state medical boards and supported by technology.</td>
</tr>
<tr>
<td>Need payments for desired outcomes and potentially use of appropriate CDS tools (processes), including extra time required by clinicians for optimized patient care.</td>
</tr>
</tbody>
</table>

### Effective and Useful CDS

| What makes CDS effective is still not adequately defined and CDS interventions still often fail to achieve the desired outcomes. |
| The effectiveness of the vast majority of CDS interventions is never actually measured and it is unclear whether CDS interventions that are effective in one setting or clinical area would be useful in another setting or clinical area. Effectiveness of CDS may not be seen unless or until it exists at scale. |
| CDS platforms, whether standards-based or EHR vendor-based, may have many limitations to effectiveness. |
| There are a number of CDS best practice approaches published already. |
| There are also guides on IT usability that address issues such as access, uptake, adherence, and effectiveness, e.g., the ONC EHR usability change package. |
| Behavioral nudges have been shown to be important and may be fairly easy to scale for impact, e.g., the default number of opioid prescriptions dispensed. |
| There are a number of guidelines available to serve as the basis for CDS. |
| There is a need to continue to advance research to identify factors that contribute to CDS effectiveness and improve reporting of CDS intervention results. |
| Users of CDS platforms could help define desired/needed enhancements and join together in asking for those enhancements to be made. Incentives to develop more effective CDS are needed. |
| Sharing of CDS and good examples of effective CDS could allow for higher-quality CDS. |
| There is a lack of agreement on documentation templates/expectations in this space, an authoritative body should step forward to develop consensus on this. |

### Scaling CDS

| Scalable clinical decision support and knowledge sharing, whether via shared knowledge artifacts, or applications, or as services, is currently in its infancy. Common interoperability architecture also needs to be defined and adopted, e.g., SMART on FHIR, CDS Hooks. |
| There are local factors that need to be accounted for such as: business needs, practice settings, clinician types, patient populations, workflow approaches, documentation templates, and local resources. |
| There are a few computer-interpretable guideline repositories. |
| There is a white paper on how to establish trust in this ecosystem. |
| Some hybrid approaches exist where the “hard part” of guideline development is shared inter-institutionally, and each organization can adapt it to the local environment. |
| Standard value sets, such as those from the National Library of Medicine’s Value Set Authority Center. |
| Trust requirements are needed, especially for centrally managed CDS. |
| It may be useful to prioritize across domains to help ensure content quality e.g. the overall medication list, to consolidate guidelines whenever possible, and to better engage patients. |
Care Planning and Coordination

- There is a need for strong communication and shared mental models of care plans across organizations and providers, as well as between patients and their caregivers. Communication and information sharing among these providers can be suboptimal.
- Care plans are rarely synchronized while they evolve over time and are touched or updated by various stakeholders across organizational boundaries.
- Opioid use, a big enough, well recognized problem, may incentivize competing organizations to agree on common approaches to treatment and better coordination and cooperation.
- There is some ongoing HIE, TEFCA, etc. work on care planning and coordination, e.g., IHE models on dynamic care plans, with somewhat limited implementation.
- There is a need for demonstration projects funded by government, payors, to investigate how pay-for-value-incented providers can improve intra- and inter-institutional care planning.
- There is a need for more research around creating understandable and technically portable care plans for patients, and for more dynamic care planning.

Table 2. Derived insights for advancing PCCDS in general

<tbody>
<tr>
<td>Regulatory environment</td>
<td>It is challenging to harmonize across different regulatory domains and keep CDS information up to date.</td>
<td>Need accessible systems that link up regulatory resources and to maintain and update these centrally.</td>
<td>Governmental support of central management and use of source systems and data, including EBM and regulatory information, can buoy the data that underlies CDS.</td>
</tr>
<tr>
<td>Data integration</td>
<td>We rarely collect disparate source data with a fully integrated end in mind resulting in incomplete, missing, or incorrect data, limiting the effectiveness of CDS.</td>
<td>Various semantic interoperability standards and approaches can be used to improve the quality of source data and patients can assist with this.</td>
<td>Need a unifying interoperability specification to facilitate high-quality data collection informed by patient feedback.</td>
</tr>
<tr>
<td>Establishing a clear business case for CDS</td>
<td>The bulk of the challenge in establishing the ROI for CDS results from the current incentive system and the cost of implementing CDS.</td>
<td>Merit-based incentives and greater interoperability will help catalyze CDS integration.</td>
<td>Linking merit-based payments to quality measures, desired outcomes, the use of evidence-based practices, and/or the integration of CDS systems will establish a clear ROI for using CDS.</td>
</tr>
<tr>
<td>Effective and Useful CDS</td>
<td>CDS effectiveness remains poorly understood and implementations still suffer from usability (alert fatigue), adoption and information quality (trustworthiness) issues.</td>
<td>CDS best practices, usability best practices, quality guidelines, and behavioral nudges, are effective tools to support CDS implementations.</td>
<td>Engaging users in the specification, design, and implementation of CDS systems, creating publicly shareable success stories, and conducting research on factors that contribute to CDS efficacy and dissemination of CDS success stories can improve CDS implementations.</td>
</tr>
<tr>
<td>Scaling CDS</td>
<td>There is no common interoperability architecture to support the scalability of CDS.</td>
<td>Shareable repositories of CDS artifacts, guidelines, and standard value sets will improve CDS implementation at scale.</td>
<td>Emerging efforts to address trust for shared CDS will help support the expanded use of shareable CDS.</td>
</tr>
<tr>
<td>Care Planning and Coordination</td>
<td>The current environment does not support dynamic, multi-stakeholder, multi-environment care planning and coordination.</td>
<td>Need dynamic care plans and better engagement of the patient in the care planning process.</td>
<td>Need demonstration and research projects to focus on dynamic care planning (inter and intra-institutional) in the merit-based incentive context.</td>
</tr>
</tbody>
</table>
Effective and useful CDS: Making effective CDS both generally and specifically for opioids requires more insights. However, there is significant knowledge regarding CDS and usability best practice approaches. In addition, there is some evidence that simple behavioral nudges may also be effective. Needed Actions: The key is to identify and promulgate CDS successes and the factors that ensure success. To improve our insights into effective CDS, government should continue to fund research and researchers should continue looking for the most effective approaches to improving care using CDS. Increasingly, these efforts should engage users to provide the necessary input to ensure that CDS platforms meet user-centered design goals and vendors should help identify effective CDS and best practices and share these broadly.

Care planning and coordination: The complexity of patient care requires a shared understanding of the care planning process, including any integrated data available, among all members of the care team. The scale and impact of the opioid epidemic alone could help catalyze agreement on common approaches to coordination and treatment. Needed Actions: To mitigate this complexity, we need to develop an approach to cross-institutional care planning to better facilitate coordination. National-level funding for cross-institution demonstration projects and opportunities to incentivize value-based care will help. Researchers need to be encouraged to develop a body of evidence to guide the dynamic care planning process. We need relevant standards to help develop, pilot, and refine approaches to care planning and coordination.

Discussion

Summary of Findings. In 2018, the AHRQ PCCDS LN convened the TechFWG with the goal of identifying technical barriers to patient-centered CDS, with a particular focus on pain management. The TechFWG recruited 54 members, of which 21 members contributed substantially. Through 8 virtual meetings and 1 face-to-face meeting, the TechFWG members started with a vision for patient-centered CDS for pain management as defined by the PCCDS LN Opioid Action Plan TechFWG, then identified the barriers to realizing this vision at this time due to technical and related barriers. The core barriers were in the areas of 1) regulatory environment, 2) data integration, 3) scalability, 4) business case, 5) effective and useful CDS, and 6) care planning and coordination. Facilitators available for these barriers were identified, and recommendations were formulated for needed actions to address these barriers. When distilled into generalizable recommendations independent of the specific use case of pain management, the main recommendations from this work were as follows:

- Advocate to address conflict and overlap between federal, state, and local regulations.
- Define data needs and interoperability requirements with achievable goals tied more directly to clinical needs.
- Reach agreement on a vision of CDS at scale and develop specifications and implementations to reach this goal.
- Establish and promote the business case for CDS by incentivizing and educating stakeholder groups.
- Identify and broadly disseminate CDS success stories and related factors.
- Develop a standards-based approach to cross-institutional care planning to facilitate care coordination.

Strengths and Limitations. An important strength of this work was that by looking at the opioid use case in particular, the domain was specific enough to think through the implications at a good level of detail while the impact is broad enough (national-level) to facilitate generalization beyond...
this domain. A second strength is that we successfully convened a broad group of subject matter experts with insights and expertise in key domains, including standards-based interoperability, opioid and pain management CDS, and industry perspectives. Finally, a third strength is that the specific domain chosen is a critical one facing the nation, such that the insights and recommendations provided could have near-term impact on an important societal problem. With regard to limitations, one limitation is that the deliberations were based on a specific domain. Thus, it is possible that the barriers and associated recommendations are incomplete. However, many of the TechFWG members had broad experience in CDS in general, and the TechFWG explicitly sought to identify generalizable findings from their deliberations. Finally, as another related limitation, the focus on the pain management domain may have resulted in the inclusion of barriers that may not be as relevant in other patient-centered CDS use cases, such as regulatory barriers to data integration.

**Future Directions.** As the next step in this work, the PCCDS LN will be convening a Patient-facing CDS Demonstration Working Group (PFWG) which will seek to advance important components of the recommended actions developed in this work. The PFWG will tackle the patient-facing perspective of CDS and consider both design and technical factors that ease or inhibit the development of patient-centered CDS applications. The goals of the PFWG will be to actually convert an existing provider-facing SMART on FHIR CDS application based on the CDC guideline for morphine milligram equivalent dosing to a patient-facing application which can be directly accessed by patients, whether through the Web or a smartphone. In tandem with this technical development, the PFWG will also develop a set of human-centered usability design guidelines for patient-facing patient-centered CDS applications. This work will culminate in a set of recommendations for actionable steps that interested stakeholders could take to advance patient-centered CDS applications from prototype to use by patients, caregivers, and direct care clinicians.

CDS holds significant potential for improving the delivery of high-quality, patient-centered care, including for critical societal barriers such as the opioid epidemic. The findings from the PCCDS LN TechFWG could prioritize the needed actions for advancing patient-centered CDS to tackle these important barriers.

Abstract

Sharing of individual participant data is encouraged by the International Committee of Medical Journal Editors. We analyzed clinical trial registry data from ClinicalTrials.gov (CTG) and determined the proportion of trials sharing de-identified Individual Participant Data (IPD). We looked at 3,138 medical conditions (as Medical Subject Heading terms). Overall, 10.8% of trials with first registration date after December 1, 2015 answered ‘Yes’ to plan to share de-identified IPD data. This sharing rate ranges between 0% (biliary tract neoplasms) to 72.2% (meningitis, meningococcal) when analyzed by disease that is focus of a study. Via a predictive model, we found that studies that deposited basic summary results data to CTG results registry, large studies and phase 3 interventional studies are most likely to declare intent to share IPD data. As part of an HIV common data element analysis project, we further compared a body of HIV trials (24% sharing rate) to other diseases.

Introduction

Sharing of de-identified individual participant data1 is encouraged by the International Committee of Medical Journal Editors (ICMJE).2 Since 2019, authors that publish trial results in an ICMJE member journal (more precisely for trials that begin enrolling participants after Jan 1, 2019) are required to include a clear data sharing statement in the trial’s registration data2. This does not mandate actual individual participant data (IPD) sharing; it only mandates describing whether IPD data will or will not be shared. However, many funders of clinical studies have a separate policy that promotes actual data sharing.3 Data sharing is closely related to a trial registration mandate required for applicable trials in the US. ClinicalTrials.gov (CTG) is the world’s largest registry of interventional trials and observational studies4. CTG study record administrators are encouraged to keep the study record in the CTG registry current in order to facilitate public review of ongoing or completed studies. Since 2015, CTG allows study record administrators to specify an IPD data sharing plan.

We investigate the question of data sharing from the perspective of a study sponsor that is highly motivated to share data and consequently keeps the CTG study record current. Since 2017, CTG also added the ability to provide links to study protocol, Case Report Forms (CRFs), other study documents, or IPD. In case of documents, these can be uploaded directly to CTG or provided via a link. For IPD, only links are accepted. CTG’s ability to refer to other trial results platforms made CTG a central place and a good starting point to not only discover relevant clinical studies but to obtain important study documentation and IPD. We assumed that motivated study record sponsors would take advantage of CTG serving as the starting point to provide study metadata to the public. We fully acknowledge that the ability to provide a data sharing plan and provide an external link to de-identified IPD was only added in December of 2015 and trials that did first registration prior to this date were unable to do so at the time. However to assess the impact of the timing issue, we looked at how often such trials update the IPD data sharing plan retrospectively (during a registry record update). As of December 20, 2018, we found that a total of 18,457 studies (6.3% of 292,680 registered studies at that time) that initially registered when specifying a data sharing plan was not possible (prior December 1, 2015), that retrospectively answered ‘Yes’, ‘No’ or ‘Undecided’ to the question about an IPD data sharing plan. A total of 4,134 studies answered ‘Yes’, 10,379 answered ‘No’ and 3,944 answered ‘Undecided’. This finding shows that thousands of trials indeed update their CTG registration record, and it partially confirms its importance as a central public record.

In this study, we analyze study data sharing by disease domain. As part of a larger project focusing on analysis of clinical trials and their common data elements for the HIV and AIDS domain, we further focus on describing the body of all HIV trials (we use the term HIV trials to refer to both HIV and AIDS trials) and compare patterns of data sharing in HIV with other medical domains.
Methods

Determining data sharing on disease level

We used relational database representation of CTG study registration data called Aggregate Analysis of ClinicalTrials.gov (AACT) created at Duke University. The AACT database is created by parsing XML representation of each study from CTG. We adopt the CTG terminology and use the term study to refer to both an interventional trial and an observational study. We used SQL language to query and extract data from AACT and R language to analyze the data. The study repository at https://github.com/lhncbc/r-snippets-bmi/tree/master/CTG/sharing contains selected analytical code and supplementary result files.

To assign a given trial to a disease, we used CTG’s condition field. Each CTG study must specify a study condition that is defined as: ‘The name(s) of the disease(s) or condition(s) studied in the clinical study, or the focus of the clinical study.’ For example, the TOPKAT trial (NCT01352247) has ‘Knee Osteoarthritis’ as a single specified study condition. CTG aggregates similar condition entries into higher level groupings based on Medical Subject Headings (MeSH) terminology (CTG field: condition_mesh). The majority of trials (40.5%) have a single condition specified per study when all CTG studies are analyzed. A total of 29.9% of trials have two conditions and 29.6% have three or more conditions specified. Our intent was to analyze sharing by MeSH keyword, so studies that specified multiple keywords were included in any analysis for each specified keyword. To avoid bias in our analysis of overall sharing, we removed conditions that were considered outliers which had less than 15 registered studies.

To analyze data sharing intent, we used CTG’s field called plan_to_share_IPD. During study registration, the study record administrator must indicate whether there is a plan to make individual participant data (IPD) collected in the study, including data dictionaries, available to other researchers (typically after the study is completed and a possible data embargo period has expired). The data sharing plan has ‘Yes’, ‘No’ and ‘Undecided’ as possible answers. To avoid bias, we only looked at studies which first registered after December 1, 2015 when this feature was available during first registration, studies that provided an answer in the plan_to_share_IPD field, and studies that had an enrollment greater than zero (we refer to this set of studies as Set_A). For analysis purposes we viewed ‘Undecided’ as not stating that the study plans to share and so included it as a ‘No’ answer. A related second field in CTG is plan_to_share_IPD_description, which is a free text field where details of the plan are described. If the answer was ‘No’ or ‘Undecided’, the description field can be used to explain why IPD will not be shared or why it has not been decided yet.

Predicting Sharing

To explore what factors influence a decision to share study IPD, we developed a predictive model. The model used logistic regression analysis due to the categorical nature of the outcome variable. The predicted outcome variable was the answer of ‘Yes’ to the plan_to_share_IPD field in CTG. In order to select predictors, we first conducted a descriptive analysis of available CTG study level metadata for studies that answered ‘Yes’. Based on this analysis, we subsequently selected a set of predictors either used in past analyses of CTG data or identified in a review by two clinical informatics experts. The prediction model was done in an exploratory mode. A comprehensive model was out of scope.

HIV use case

Because of a larger project that focuses on common data elements in HIV, we analyzed as a case study the HIV body of trials. We did several HIV-specific analyses.

Sharing ratio: First, we created a set of MeSH terms that belong to the HIV/AIDS domain (reviewing only MeSH terms present in CTG) and compared HIV sharing ratios to other diseases.

Manual review of data sharing plan description: Second, we analyzed more closely the other data sharing CTG fields for HIV trials. CTG specifies the plan description should describe what specific individual participant data sets will be shared and how they will be shared. We only did this type of review for HIV studies (due to feasible sample size) and not for all CTG studies in Set_A. An example of a plan description is ‘de-identified participant level data will be available through the clinicalstudydatarequest.com platform upon request’. We manually reviewed plan descriptions (CTG field name: plan_to_share_IPD_description) for the 69 HIV studies that said ‘Yes’ to plan_to_share_IPD with a goal to assess how well the meaning of the IPD sharing fields were being understood by CTG study record administrators and how often a well specified plan is being articulated. Elements of a good plan were clearly specified by ICMJE. We also looked at instances and common answers where the fields were possibly misunderstood and
Predicting sharing (for HIV): We used the same predictive model approach to assess trial factors that predict IPD data sharing for HIV trials. We contrasted how HIV-specific model predictors are different from the general model (for all trials).

Results

We queried the AACT database on December 20, 2018 and analyzed 287,626 studies that were registered on CTG at that time. Of those registered studies, 74,582 provided an answer to the plan_to_share_IPD question. Overall, 9,435 studies (out of 287,626, 3.3%) are sharing IPD (without regard to first submission date or MeSH disease term for study focus), 46,017 studies (16.0%) are not sharing IPD and 19,130 studies (6.7%) were undecided on sharing IPD.

Determining data sharing on disease level

When we filtered the above set of studies with our selection criteria of (1) only include those registered after December 1, 2015 (the date when the CTG registry introduced additional data sharing questions), (2) that provided some answer (Yes/No/Undecided) to plan_to_share_IPD, and (3) had listed the enrollment of greater than zero, the number of analyzed studies reduced to 62,166 studies (21.6% out of 287,626; referred to as set_A). Supplemental file S1_diseases.xlsx (Tab1-all_keywords) at our study repository shows sharing ratio for all 3,138 MeSH keywords in this set of studies. The overall sharing ratio (without regard to MeSH term) for studies meeting these criteria is 10.8%. To better review sharing rate across diseases, we have removed outlier MeSH disease terms that have fewer than 15 total studies (e.g., adenocarcinoma in situ and coronary aneurysm; see Tab2-without-rare-MeSH-terms in the S1 file). The two MeSH terms with the highest sharing ratios were ‘meningitis, meningococcal’ (sharing rate of 72.2%) and dengue (61.1%). The lowest sharing ratio was zero, where no studies for those MeSH terms planned to share IPD. Zero sharing rate was observed for 70 MeSH terms. Example MeSH terms with a zero sharing rate and the highest total count of studies were biliary tract neoplasms (0 sharing out of 51 total studies), bone diseases (0 sharing out of 43 total studies), and obstetric labor, premature (0 sharing out of 39 total studies). A review of sharing rate and total count of studies for MeSH keywords with the largest count of total studies (after December 1, 2015), reveals the following MeSH keywords: diabetes mellitus (16.5% sharing out of 1,656 total studies), breast neoplasms (9.9% sharing out of 1,068 total studies) and depression (13.6% sharing out of 825 total studies).

Predicting sharing

Descriptive analyses that were executed in support of selecting appropriate predictors are available in supplemental file S2-sharing-descriptive-results. The predictive model was executed for all studies in set_A with the predicted
outcome being an answer of ‘Yes’ to plan_to_share_IPD. The answer of ‘Undecided’ was essentially treated in the same group as an answer of ‘No’. Table 2 lists the relative effect of the predictors (their coefficients) and the predictor type (e.g., binary, categorical, continuous). Study sample size (CTG uses term enrollment to refer to study size in terms of number of enrolled participants) was converted into a categorical variable based on bin thresholds determined in the preparatory descriptive study (see section Study size in supplemental file S2). Large studies were considered having enrollment over 200, medium studies having enrollment of between 51 and 200 and small studies having enrollment of 50 or less.

To assess the predictors, the absolute value indicates its importance in the overall model. The positive sign of a predictor indicates higher probability of IPD sharing whereas negative sign indicates lower probability. Table 2 shows that the highest positive predictor is study size (studies with 201+ participants; coefficient 1.2) The second highest positive coefficient overall (has_results: Yes) was if the study has basic summary results deposited in CTG results registry. The highest negative predictors are sponsor types (categorized under Agency_class) of Other and U.S. Federal Agency. Outside of these sponsor types the two predictors with the largest negative coefficients, indicating a lower probability of sharing IPD were an observational study type and if the phase is listed as N/A, which includes studies on devices and behavioral interventions. While study type did not have as large an effect as other analyzed predictors on whether a study would share, observational studies and patient registries do have a negative effect on the probability of a study sharing.

In terms of terms of study sponsor, NIH sponsored studies are the most likely to share and has the highest positive effect of any sponsor type on the probability of a study sharing (0.296). The only other sponsor type with a positive effect on sharing is Industry (0.031). The other two sponsor types, U.S Federal agencies (non-NIH) and Other, had the greatest negative coefficients overall, indicating a significantly lower probability of IPD sharing by studies with these sponsors. Other, which includes foreign institutions, universities, hospitals and non-profit organizations, had the highest negative effect (-0.617) while U.S. Federal agencies, such as the VA and FDA had the second highest negative effect (-0.556). One surprise in the result or the coefficients of the predictor was that a study being phase 1 was not a negative predictor but rather had the highest positive effect of any phase on the probability of a study sharing.

We executed the prediction model for each MeSH term and the results are available in supplemental table S3-prediction-by-MeSH-term.

**HIV use case**

Sharing ratio: Table 3 shows all HIV/AIDS MeSH terms found in CTG and their sharing ratios. It shows that for the largest HIV MeSH term (HIV infections) the sharing rate was 24.5% which is more than double the average rate of
10.8% observed across diseases. The sharing rate for HIV places it in the top 5 percentile when looking at sharing ratio of all MeSH terms (when outliers are removed).

Manual review of data sharing plan description: Since the inclusion of the plan to share IPD field in CTG there have been 69 studies with HIV related MeSH terms that have answered ‘Yes’ to plan_to_share_IPD for which we manually classified their data sharing plan descriptions. Of the 69 studies reviewed, 51 had well specified plans to share IPD, in which a specific platform for data sharing was stated or a process for which researchers can follow to obtain study data was articulated. There were 18 studies that had plans listed that were not well specified and were possibly misunderstood. Examples of common answers fitting this possibly misunderstood category were: (1) the field was left blank, (2) a plan will be developed in the future, (3) data will be shared via publications and/or presentations, and (4) data will be shared with the participants and investigators in the study. All of which are examples of plans that do not properly articulate a method to share IPD with interested parties and external researchers. In our 2017 prior work (across all diseases, not just HIV), we also noted that the plan was describing summary data sharing and not participant level data, which is another possible misunderstanding. The full list of the 18 misunderstood descriptions is available in the supplemental file S4-plans. CTG also allows trial administrators who answer ‘No’ or ‘Undecided’ to include an explanation of why they answered one of these two options, in the plan description field. Of the 215 HIV studies that answered ‘No’ or ‘Undecided’, 22 included an explanation in the plan_to_share_IPD_description field. Further showing possible misunderstanding of the IPD sharing fields, 7 of the 22 had descriptions of sharing plans that were well specified and included processes for outside researchers to obtain IPD. Such plan descriptions seem to imply ‘Yes’ to sharing; however, official CTG data had ‘No’ or ‘Undecided’ recorded.

Predicting sharing (for HIV): We executed the model using just the HIV set of studies as input and reviewed the results, focusing on the predicted effects of each variable for HIV studies compared to those of the overall model presented earlier.

Table 4. Prediction model results for HIV studies showing predictor coefficients (ordered by absolute value)
For HIV related studies, shown in Table 4, we found the most important predictors of sharing to be similar to those of the general model. The two highest positive coefficients were study size (studies with 201+ participants; coefficient of 2.01) and whether a study had basic summary results deposited in CTG. Compared with the general model, having summary results deposited (and several other predictors) had a much higher absolute value (‘has_results: Yes’ had 9.0 absolute value for HIV vs. 0.97 for the general model).

There were also some differences in the general versus HIV prediction model results. Certain factors that had a positive effect in the general model had a negative effect in the HIV model. This included the factors of both Phase 1 and Phase 3 as well as NIH sponsored studies. The largest negative factor on whether an HIV study would share IPD data was whether the study type was an observational patient registry. This is not a surprise as one major factor in sharing IPD is the completion of the study. Since patient registries do not have a limited temporal scope (are long term research projects) and are always actively adding data, the IPD dataset is technically never complete and has a different policy and sharing pattern than a typical interventional trial or time-limited observational study.

Another noticeable difference for the HIV model is the positive effect start date has on the sharing of HIV data compared to the minimal weight start date had on the general model, indicating a trend in increased sharing of HIV studies over time.

Discussion

Our study is the first to analyze intent to share IPD data by disease using CTG registration data. We show that there are significant differences in IPD sharing ratios across diseases (using MeSH terms). We also show different factors or predictors that impact IPD data sharing. The fact that studies that deposited basic summary results to CTG result registry are more likely to share IPD data is helpful in our larger project where we seek IPD data (or data dictionaries) for a large set of trials in a given disease (e.g., HIV, asthma or lymphoma). For trials where no answer to the question about IPD data sharing on CTG was provided (but basic summary results were deposited), a data outreach effort that first targets large trials with basic summary results may be the most pragmatic approach. Our study also shows that HIV studies share IPD at a higher rate (24.3%) than a general set of studies from the same time period (10.8%). HIV studies have a higher sharing rate despite the fact that the HIV-infected population may be considered a sensitive population.

Relevant previous studies

Prior to our analysis, we considered previous relevant literature on CTG data analysis and data sharing. Chen et al. analyzed digital health studies in CTG. Other analysis by Tse et al. and Durham look at challenges associated with CTG data and made recommendations on the use of CTG data. Stergiopoulos et al. reviewed the overall completeness of CTG records and the information present on CTG. Finally, Federer et al. analyzed data availability statements on a journal article level in a single journal PLOS ONE. To our knowledge, our study is the first to analyze (and compare across diseases) sharing of IPD data on study level using CTG registry data.

Limitations

The results presented have several limitations. First, in our analysis of sharing by disease, we used MeSH keywords and treated each MeSH term as a unique condition. We did not aggregate similar MeSH terms into possible higher level disease categories. This would require additional grouping knowledge base which we did not want to custom develop. This multiple keywords per disease can be observed, for example, on HIV keywords (see table 3) showing similar entries such as ‘hiv infections’ and ‘hiv seropositivity’. For HIV use case analysis, we also kept results on MeSH term level (without aggregation) and considered the term with the most studies to be representative of the domain. We also observed that CTG assigns some studies MeSH terms (as disease focus of the study) that are too broad (e.g., ‘syndrome’ or ‘disease’). We did not try to correct this misclassification. Second, when using the CTG field study_condition and assigning studies to a MeSH term, we did not try to select a single MeSH keyword for a study. We simply counted a study under each of its keyword. This double counting may be considered incorrect by some experts, however we chose to respect multiple keywords for a study as entered by trial record administrators. In other words, our chosen unit of analysis was MeSH keyword and not a study. Third, for our prediction model, we only used predictors available in CTG and picked predictors based on descriptive analysis, prior literature and expert opinion. A comprehensive prediction analysis could possibly incorporate a larger set of predictors.
Conclusion

We found that 10.8% of studies plan to share IPD data (as declared on CTG) and compared data sharing ratio by disease. The most important study features that predict future IPD data sharing are large sample size and deposition of basic summary results. As a case study, we analyzed more closely sharing rate and detailed plan description for HIV/AIDS studies.

Abstract

To overcome limitations of previously developed scientific productivity ranking services, we created the Biomedical Informatics Researchers ranking website (rank.informatics-review.com). The website is composed of four key components that work together to create the automatically updating ranking website: 1) list of biomedical informatics researchers, 2) Google Scholar scraper, 3) display page, and 4) updater. The interactive website has facilitated identification of leaders in each of the key citation statistics categories (i.e., number of citations, h-index, and i10-index), and it has allowed other groups, such as tenure and promotions committees, to more effectively and efficiently evaluate researchers and interpret the various citation statistics reported by candidates. Creation of the biomedical informatics researcher ranking website highlights the vast differences in scholarly productivity among members of the biomedical informatics research community. Future efforts are underway to add new functionality to the website and to expand the work to identify top papers in biomedical informatics.

Introduction

Citation statistics have been used to measure scholarly production of researchers since 1964, when Eugene Garfield created the Science Citation Index.1 Since then, additional measures have been developed in attempt to quantify research productivity and scientific impact independent of a researcher’s field of study and years at work, and without inflation from a small number of highly cited articles. Some services have attempted to rank research productivity, including ResearchGate,2 SciVal,3 and Highly Cited Researchers.4 However, these services have limitations, such as reliance on proprietary metrics, inclusion of only a limited number of highly ranked researchers, and requirements of organizational commitment to commercial sites.

Google created a new paradigm for citation analysis with Google Scholar,5 an online, freely available, automatically updating scientific information resource. By allowing researchers to create their own profile page,6 complete with multiple bibliometric calculations (e.g., total citations, h-index, i-10 index), Google provides a potential new method that allows comparison across researchers. Comparisons of Google Scholar with Web of Science and Scopus have found variations in citation statistics, where Google Scholar was frequently found to be considerably higher than Web of Science and Scopus due to Google Scholar’s wider inclusion of conference papers and gray literature.7,8 Despite these limitations, the format and availability of Google Scholar Profiles prove advantageous.

To facilitate comparison across researchers, we created a ranking website based on Google Scholar profiles for biomedical informatics researchers.9 This site was based on code previously developed by one author [JL] and used to create ranking sites for information retrieval,10 human-computer interaction,11 and top computer science researchers12 using a straightforward website scraping approach. These sites computed additional metrics to normalize Google Scholar’s bibliometric measures by dividing each of them by the number of years since the researcher received his or her first citation (i.e., citations/year, h-index/year, i-10 index/year).13

Design Considerations

Our goal in creating the Biomedical Informatics Researchers ranking website was to produce a freely available, automatically updating information resource based on Google Scholar citation profiles for all individuals interested in the field of biomedical informatics. Creating this resource required us to:

- Identify a set of biomedical informatics researchers with publicly-available Google Scholar profiles.
- Develop efficient methods to scrape the Google Scholar citation profiles of this list of individuals and extract key citation metrics.
- Implement a method to render the ranked list of researchers along with the means to re-order and search the list.
- Produce a method to allow new biomedical informatics researchers to add their name and google scholar profile location to the ranking site.
- Develop a method to automatically update the ranking site with the latest Google Scholar results on a periodic basis.

![Table showing the top 15 biomedical informatics researchers as of March 11, 2019](image)

**Figure 1:** Top 15 biomedical informatics researchers as of March 11, 2019
System Description

A snapshot of the ranking website as of March 11, 2019 is depicted in Figure 1. The website is composed of four key components that all work together to create the automatically updating ranking site: list of researchers, Google Scholar scraper, display page, and updater.

The first is the list of biomedical informatics researchers. The list file is in JSON (JavaScript Object Notation) format, with name / URL pairs represented as:

“Full Name [FACMI] [FAMIA] [FIAHSI] [Collen Year]”; “Google Scholar URL”

where:

- “FACMI” is an optional indicator that designates that they are member of the American College of Medical Informatics (ACMI).14
- “FAMIA” is an optional indicator that designates that they are a fellow of the American Medical Informatics Association (AMIA).15
- “FIAHSI” is an optional indicator that designates that they are a member of the International Academy of Health Sciences Informatics (IAHSI).16
- “Collen Year” is an optional indicator that designates that they are a recipient of the Morris F. Collen Award, and the year of their award.17

The FACMI, FAMIA, FIAHSI, and Collen Year components are appended to the name to be displayed on the ranked list of researchers. The list was created initially through an iterative process that began with manual searches for known biomedical informaticians using Google Scholar. After approximately 100 researchers were identified, we realized that we needed an automated method to develop a more comprehensive list. Therefore, in 2014, we used the “label:biomedical_informatics” search feature that identified all individuals on Google Scholar with “biomedical informatics” as one of their “areas of interest” and at least one publication with one or more citations. We repeated this search using “label:medical_informatics” and other common key words related to biomedical informatics, including health informatics, electronic health record, clinical decision support, and health information technology.

To facilitate new requests to be added to the list of biomedical informatics researchers, we created a Google form that allows a researcher to requested to add his or her profile to the ranking website. The Google form prompts researchers to enter his or her name and Google Scholar URL; to indicate whether they are an ACMI fellow, AMIA fellow, or member of IAHSI; and to indicate whether they have received the Morris F. Collen award and, if so, to enter the year. The input data is manually verified to be accurate by one of the co-authors to prevent errors in running the scraper, then it is added to the list of biomedical informatics researchers to be included on the site with the next update. Since then, we have periodically solicited requests for individuals to add their profiles (or create one if they had not already done so) through the ACMI listserv and other targeted e-mailings (e.g., to department listservs, through AMIA Connect). We have also manually added new profiles found through repeated Google Scholar searches of relevant labels and review of new individuals listed on ACMI, FAMIA, and IAHSI member lists.

The second component is the Google Scholar Scraper. This open-source application is written in node.js and built using commonly-available open-source libraries. It takes as input the list of researchers and then iteratively retrieves the listing of each person’s google scholar citation counts, the total number of citations, the year of first citation, the i-10 index, and the h-index. These values are extracted based on matching the relevant elements from each page’s DOM (Document Object Model) structure. This approach makes the scraper application dependent on the layout of the Google Scholar profile page, so it is not robust to changes in the layout of the profiles, and indeed, the application has broken several times since the initial development in 2014 after Google updated its site. However, no APIs (Application Programming Interfaces) that allow programmatic access to such data are available, so there are few alternatives to this screen-scraping approach.

In addition to extracting raw statistics from profile pages, the application also calculates the citations/year, i-10 index/year, and h-index/year; all computed values are written into a file in JSON format, which facilitates the display as well as downstream processing by other applications. The following is a brief definition of each of the bibliometric measures included on the ranking site:

- Total number of citations – the total number of citations to all of a researcher’s published articles
• Year of first citation – the year in which the researcher received his or her first citation, regardless of the year of publication of their first article

• i-10-index – the number of articles that a researcher has published that have received at least 10 citations

• h-index – the number of articles (n) that a researcher has published that have received at least “h” citations where n=h. In other words, if a research has published 25 articles that have all received at least 25 citations, then his or her h-index is 25.

• Citations/year – a researcher’s total number of citations divided by the number of years in which he or she has been accumulating citations (i.e., current year – year of first citation)

• i10-index/year – a researcher’s i-10-index divided by the number of years in which he or she has been accumulating citations

• h-index/year – a researcher’s h-index divided by the number of years in which he or she has been accumulating citations

The third component is the display page that renders the JSON data created by the scraper program above in HTML/CSS, (Hypertext Markup Language / Cascading Style Sheets) with the aid of JavaScript. The display lists the researchers in ranked order and allows a user to re-sort the entire list by any of the column headers (e.g., citations or i-10 index). The display page also incorporates a search feature that allows one to display a ranked subset of researchers, for example: 235 ACMI members, the 32 people associated with “Vanderbilt University”, or the 26 people with “David” in either their name or affiliation. This page also includes code that allows Google Analytics to track website traffic.

The final component is the updater, a script that periodically re-runs the scraper and pushes the updated data to the web site and Github. The updater is currently set to run twice per week. Several error conditions are periodically encountered and detected by the updater script, including instances where people delete their Google Scholar profile or make it private, network issues that prevent connection to Google Scholar or Github, or temporary blocks imposed by Google. Although Google permits scraping of Google Scholar profiles in their robot exclusion standard (robots.txt) file, they do periodically block the scraper if it is set to run too often.

**Current Status of Biomedical Informatics Researcher Ranking Website**

The Citation Statistics of Biomedical Informatics Researchers ranking website can be viewed at rank.informatics-review.com. In the nearly five years since its inception, the website has been viewed more than 18,000 times by almost 9,000 users. Of these users, 70% reside in the United States, 6% in India, 2.5% in Australia, 2.4% in Canada, 1.7% in the United Kingdom, and 1% in China. We observed apparent spikes in website traffic in several instances after listserv e-mails were sent or individual researchers mentioned the website on social media (Figure 2). For example, timepoint #1 corresponds with an e-mail sent to the ACMI listserv, and timepoint #4 corresponds with a Tweet by @allisonbmc-coy.

![Figure 2: Visitors to the biomedical informatics ranking website from Google Analytics with traffic spikes corresponding to known instances of dissemination.](image)

The list of biomedical informatics researchers contains 1,401 individuals, including 235 ACMI fellows, 62 AMIA fellows, 61 IAHSI members, and 12 Morris F. Collen award winners. Requests to be added to the site have been submitted through the Google form for 171 researchers.
Since the BMI ranking list has been available, numerous uses for the list have been identified, including:

- To create a list of members from a single university and compare the scholarly productivity of those university’s biomedical informatics departments. To our knowledge, at least three universities are currently using the website in annual department reviews.19
- To identify productive researchers for nomination to ACMI or IAHSI members.
- To identify potential recruits for academic positions.
- To help tenure and promotions committees to interpret the various citation statistics reported by candidates.
- To identify speakers for conferences.
- To identify subfields of biomedical informatics for which citations are highest.20

**Notable Statistics for Biomedical Informatics Researchers**

Table 1 shows the median, min, and max values for all biomedical informatics researchers as well as for all ACMI, FAMIA, and IAHSI members and Morris F. Collen award winners, as identified through the biomedical informatics ranking website as of March 4, 2019. As expected, the median ACMI and IAHSI members (h-index=35.5 and 41, respectively) have been publishing for 8-10 years longer than the median for all researchers (h-index: 15). The median h-index for AMIA fellows (14) is similar to the median for all researchers, which is also expected given that FAMIA recognition is based on application of informatics skills and knowledge, regardless of research productivity. Table 2 shows the values for 10 randomly chosen Nobel Prize winning scientists (median h-index: 120) as an upper extreme for comparison.22

ACMI = American College of Medical Informatics, AMIA = American Medical Informatics Association, IAHSI = International Academy of Health Sciences Informatics
In reviewing the citation ranking statistics on the website (Figure 1) and changing the primary sort order by column, we have made a number of interesting observations about the list:

- Eugene Koonin from National Center for Biotechnology Information has the most citations (166,410) and the highest h-index (199).

- Twenty-nine researchers are tied for the earliest “year of first citation” (1980). In reviewing these results, we noted that this is a limitation in the Google Scholar profile page, with no citations depicted prior to this date, though prior publication dates are listed on individual researchers’ pages (e.g., Homer Warner, 195121).

- Alex Wang from National Institutes of Health has the highest i10-index (922).

- Brian Pollack from University of Pittsburgh has the highest citations/year (9,958), h-index/year (15.6), and i10-index/year (51.3).

- ACMI members make up 55 of the top 100 researchers when sorted by both h-index and citations, and IAHSI members make up 20/100.

![Figure 3: Graph showing the relationship between h-index and total citations ($r^2=0.77$).](image-url)
To evaluate the included citation statistics, we calculated the correlation coefficient between the h-index and total citations ($r^2=0.77$) (Figure 3) and i10-index ($r^2=0.89$) (Figure 4) using Stata/IC 15.1. Overall, the statistics similarly portray researcher productivity; however, in one case a researcher has a disproportionately high total citation count compared to h-index due to a single paper with more than 100,000 citations.

Lessons Learned

Creation of the biomedical informatics researcher ranking website highlights the vast differences in scholarly productivity among members of the biomedical informatics research community. Careful inspection of the citations included on many researchers’ profile pages also highlights many of the limitations of automatically curated lists, including:

- For individuals with relatively common family names, the inclusion of articles that were authored by other researchers are often included erroneously, which can falsely inflate citation statistics and rankings. Authors can curate their own profiles to remove erroneous citations, but few do.

- Duplicate citations exist in many profiles that can also false inflate citation statistics and rankings; however, Google Scholar has implemented functionality to automatically merge some articles and combine citations when authors do not manually merge citations.

- Researchers with publications before the 1990’s, when use of the internet substantially increased, are not as well included in the various citation statistics. Most notable is that there are no citations included before 1980 in any of the counts, an important limitation of Google Scholar profile page and the scraper tool.

- Highly cited publications by large consortia, including the “Initial Sequencing and analysis of the human genome” and “Observation of a new boson at a mass of 125 GeV with the CMS experiment at the LHC” heavily skew some authors’ citation statistics.

- Not all articles included are equal, although Google Scholar often lists blog posts and slide presentations with articles from peer-reviewed scientific journals.

- Likewise, not all citations are equal, although Google Scholar counts all citations equally, whether from a website, slide presentation, or top scientific journal.

- Most indexed articles are in English, which negatively affects non-English speaking researchers.
Future Directions

While we believe the current biomedical informatics researcher ranking site is already very useful, we are continuing to identify new researchers, especially those who are highly cited, ACMI fellows, members of IAHSI, or Morris F. Collen award winners. In addition, we are reviewing profiles with a large number of incorrect or duplicate citations and requesting that the individuals curate their profile or be removed from the list. We have also identified numerous enhancements that we hope to make in the future, including:

- Adding the total number of articles included in each person’s Google Scholar profile and the year of first publication to the biomedical informatics researcher ranking website.
- Adding an indicator for other noteworthy accomplishments, including AMIA signature awards (e.g., Donald A.B. Lindberg Award for Innovation in Informatics, Virginia K. Saba Informatics Award, and AMIA New Investigator Award).
- Calculating the longest consecutive string of years in which each researcher published one or more articles that received one or more citations.26
- Calculating $h$ (universal h-index), or the h-index of an individual divided by the mean h-index of everyone in the field.27
- Evaluating and improving the usability and efficiency of the site.

Finally, we are exploring opportunities to use the current Google Scholar scraper to identify top papers in biomedical informatics for all time and in the past year. A preliminary version of this new tool retrieved the top 100 most cited publications with 100 or more citations from all profiles in the list of biomedical informatics researchers and found 7,429 papers that met these criteria. The top most cited publication had 69,812 citations total with 3,173 citations per year.28 A preliminary version of the tool to identify top papers in the last year retrieved all publications in 2018 from all profiles in the list of biomedical researchers and found 3,751 publications. The top most cited publication had 2,177 citations total.29 At present, several limitations to this new tool exist. One important limitation is the inclusion of all publication types; in 2018, the most cited publication was a textbook. Another limitation is the inclusion of papers published by biomedical informatics researchers in areas that are not directly related to biomedical informatics; for example, an American Heart Association report on which a biomedical informatics researcher played a small role related to informatics development or data analysis is the second most cited publication in 2018.30

Conclusion

We have developed an easily searchable, interactive, automatically updating, open-source bibliometric ranking website using Google Scholar citation profiles that includes over 1,300 biomedical informatics researchers from around the world. While there are limitations to both using bibliometric citation analysis to measure scientific productivity and automatically generated lists of articles and citations, the biomedical informatics ranking website has already proven to be useful for a number of important tasks. Future efforts are underway to add new functionality to the website and to expand the work to identify top papers in biomedical informatics.

FHIR OWL: Transforming OWL ontologies into FHIR terminology resources

Alejandro Metke-Jimenez, PhD, Michael Lawley, PhD, David Hansen, PhD
The Australian eHealth Research Centre, CSIRO, Herston, Queensland, Australia

Abstract
The FHIR specification provides a mechanism to access clinical terminologies using a standard API, and many existing terminologies, such as SNOMED CT, are well supported. However, in areas such as genomics, terminologies from other domains are starting to be used in clinical settings. Many of these are authored or distributed in Web Ontology Language (OWL) format. In this paper we describe a transformation between OWL ontologies and FHIR terminology resources. The results show that there are several challenges in implementing the transformation, with the major one being the lack of a modularisation mechanism in the FHIR code system resource that resembles the import mechanism available in OWL. A workaround with minimal drawbacks was successfully implemented in this solution. The availability of this transformation is significant because it enables a broad range of terminologies that are currently available in OWL to be available using the FHIR API.

Introduction
The Fast Healthcare Interoperability Resources (FHIR) standard defines a set of terminology resources that provide a mechanism to access clinical terminology in a standardised way. Many clinical terminologies are currently supported, including SNOMED CT, RxNorm and LOINC. Recently, there has been increasing interest in supporting terminologies from other domains. In genomics, for example, there is increasing use of the Human Phenotype Ontology (HPO) to capture information about rare diseases.

Many terminologies in other domains are authored or distributed using the Web Ontology Language (OWL), including HPO and NCI Thesaurus. This paper describes how to transform OWL ontologies into FHIR terminology resources and uses HPO as a case study. The challenges in the transformation are explained and a detailed overview of the mapping between OWL and FHIR is provided. The resulting transformation is generic and can be used to transform other OWL ontologies.

Having HPO available as a FHIR code system allows it to be accessed through the same FHIR-based API as SNOMED CT and other clinical terminologies, enabling OWL ontologies such as HPO to be easily supported by clinical information systems. HPO together with SNOMED CT can provide a more comprehensive set of concepts to describe clinical findings.

1 Background and Related Work
To the best of our knowledge, no other transformation between OWL ontologies and FHIR terminology resources has been published in the literature, with the exception of a paper on Ontoserver, a FHIR terminology server, that describes a preliminary version of this transformation.

In the following sections we review some basic concepts around FHIR terminology resources and OWL ontologies.

1.1 FHIR Terminology Support
The FHIR resources required to support terminology in FHIR are CodeSystem, ValueSet, ConceptMap, NamingSystem and TerminologyCapabilities. A detailed description of the FHIR terminology subsystem can be found in the FHIR specification. This work is based on FHIR R4, which is the current version at the time of writing. The transformation presented in this paper targets only the CodeSystem resource.

In FHIR, a code system represents a set of codes from a system. Each terminology is represented by a code system resource within a FHIR server. Some examples of large, standardised terminologies are SNOMED CT, RxNorm and LOINC. Note that even though the authoring and distribution formats for these terminologies are very different, its content can be accessed in a uniform way using the FHIR API. Users can also create and upload custom code systems
that are prevalent in the healthcare domain. More details about the CodeSystem resource can be found in the FHIR documentation available at http://hl7.org/fhir/codesystem.html.

1.2 OWL Ontologies

OWL is a language designed to represent complex knowledge about things. This includes properties of things, groups of things and relations between things. This knowledge, called an ontology, is meant to evolve constantly. The things described in an ontology are referred to as individuals and the relations as property assertions, which relate these individuals to each other. The groups of things are referred to as classes. An ontology is made of axioms that constrain how the individuals relate to each other through the definition of classes. This set of axioms can be interpreted by a software component, called a reasoner, that automatically infers new knowledge. An interesting example in the medical domain can be found in the work by Baadar, Lutz and Suntisrivaraporn.

There are three sublanguages in OWL 2 that support different levels of expressivity: OWL EL, OWL QL and OWL RL. These sublanguages limit the constructs that can be used when authoring an ontology, which reduces the kind of knowledge that can be expressed but facilitates the implementation of efficient reasoning algorithms. Most ontologies in the biomedical domain fall into the OWL EL profile.

2 Methods

To determine how to transform OWL ontologies into FHIR CodeSystem resources, an in-depth analysis of the key similarities and differences between both representations was conducted. Feedback about the different alternatives was also sought from FHIR experts through the FHIR community chat.

The FHIR resource that aligns more closely with OWL ontologies is CodeSystem, which is used to define codes that are relevant in the healthcare domain. This resource provides a simple mechanism to access codes in a standardised manner, deal with different versions, specify properties for each code and define filters based on these properties. However, FHIR code systems are not intended to support the formal definition and maintenance of large code systems, but rather to support standardised access to these and the creation of small, ad-hoc code systems. Many code systems supported in FHIR, such as SNOMED CT and LOINC, for example, have their own distribution formats and maintenance processes.

OWL, on the other hand, is much more complex than the FHIR terminology resources and is typically used to author ontologies with the aid of authoring environments such as Protege.

Most of the properties available in a FHIR code system can be found in an OWL ontology. Table 1 shows the properties of a code system and which ones have default values in OWL. These default values can always be overridden to use either a value passed in by the user or to use a different annotation property to look for values in the ontology.

Three filters are added by default: root, deprecated and imported.

Four properties are added by default: parent, imported, root and deprecated.

Table 1: Code system elements and their corresponding elements in OWL ontologies.

A concept in a FHIR code system typically corresponds to a class in OWL, which defines a “group of things”. Table 2 shows how the elements of an OWL class are mapped into a FHIR concept. The IRI of the class is mapped to the concept’s code by default, but this can be overridden so an arbitrary annotation property can be used instead. In HPO, the default mapping works well but in other cases the code is contained in other properties. For example, in the OWL version of the HUGO Gene Nomenclature, the code does not correspond to the IRI but rather to the HGNC_ID annotation property.

Table 2: Code system concepts and their corresponding elements in OWL ontologies.

2.1 Challenges

The are three main challenges when designing the transformation. The first is the absence of an import mechanism in FHIR code systems that is equivalent to the import mechanism available in OWL ontologies. When authoring an OWL ontology, external ontologies can be imported and existing concepts can be used to model new concepts, promoting modularity and reuse. For example, the Human Phenotype Ontology (HPO) imports 11 additional ontologies, some of which also import other ontologies. In FHIR, code systems do not support importing external code systems. The only mechanism that has been designed to include content from external code systems are code system supplements, which allow defining code systems that add designations and properties to existing code systems. However, new concepts cannot be defined in the supplementing code systems. Overall, there is no in-built mechanism to import external code systems in a way that is similar to the importing mechanism in OWL. Interestingly, the CTS2 specification, which predates FHIR and informed some of its terminology features, supports an includes attribute that does correspond to an OWL import statement.

The second challenge is determining which concepts belong to the main ontology and which ones are imported. This appears to be a simple problem but it is not straightforward for several reasons. First, an OWL class that was defined in an imported ontology can be redeclared in the main ontology with no modifications. In this case, it is clear that the class belongs in the imported ontology. However, it is also valid to do certain modifications to imported classes. In this case, the class could be considered part of the main ontology. Also, it is valid to declare classes in an ontology

---

1The IRI does resemble the id but it is formatted slightly differently, with an underscore instead of a colon, e.g., HGNC_100 instead of HGNC:100.
document with multiple namespaces, so the base namespace is not enough to determine if a class is imported or not. In certain cases, for example in HPO and other ontologies developed by the OBO Foundry, a naming convention is used, which makes it easy to determine if a class is imported or not, but not all ontologies use similar conventions so it is not feasible to rely on these in a generic solution.

Finally, FHIR code systems are meant to both support standardised access to existing code systems and the authoring of small, ad-hoc ones. The standard is not meant to support the authoring and distribution of existing code systems that use their own authoring and distribution mechanisms. For example, SNOMED CT uses RF2 to distribute its content and the FHIR standard does not describe how to process it, only the way users should access it using the FHIR terminology resources. Implementers are free to design their own mechanisms to process RF2 files and import the code system into their server. Transforming OWL ontologies into FHIR code systems breaks this assumption, because OWL ontologies can be very large. Existing terminology servers designed to deal only with small FHIR code systems might require modifications to perform well with FHIR code systems of this size.

2.2 Proposed Solutions

To overcome the first challenge, the mismatch between the import mechanism available in OWL and similar mechanisms in FHIR code systems, three alternatives were evaluated. First, each OWL ontology was created as a separate code system and the relationships between concepts that spanned ontologies were defined using a property, external-parent, of type coding. The coding type in FHIR allows referring to a code in a specific code system, while the code type does not support specifying a system and therefore assumes that the code belongs to the current code system. The main issue with this approach is that the parent and child properties available by default are of type code and therefore are not designed to reference external code systems. The main implication of using a non-standard property is that none of the subsumption features in FHIR, such as search by subsumption, will work. An additional drawback is that sometimes the ontologies that get imported into the main ontology are not complete, but rather just import modules, designed to contain only a subset of the ontology. This is typically done for performance reasons if the imported ontology is very big. Some of these import modules refer to their source ontology through the Dublin Core source property (for example, the Phenotypic Quality Ontology import module used in HPO) but some others do not (for example, the Relation Ontology import module, used recursively in HPO). When creating code systems for these, it is important to know if these ontologies represent fragments or complete code systems in order to set the content property correctly. The absence of a reference to the full ontology in import modules will result in a generated code system that claims to be complete.

The second approach creates a single code system with all the concepts in the ontology closure (i.e., all the concepts in the base ontology plus all the concepts in the imported ontologies, including recursive imports). A value set is created for each ontology so searching can be constrained to any single ontology. This approach overcomes the issue of having to use a bespoke property to build the hierarchy. Now the standard parent and child properties can be used because all the codes belong to the same code system. However, the main drawback of this approach is that the concepts’ codes need to include the namespace (i.e., they need to be the long form of the IRI) because otherwise there is the possibility of having name clashes. Also, strictly speaking, the definitions are incorrect because external codes are specified as belonging to the main system, when in reality this is not the case.

The final approach also creates a single code system but treats the concepts from the main ontology differently from the imported concepts. The property imported is created to flag if a concept belongs to the main code system or is imported from an external code system. Also, the imported concepts include the namespace in their codes, similarly to the second approach, but the concepts that belong to the main code system only use the short form of the IRI because the namespace is the system of the main code system. This approach still allows using the standard code system properties parent and child to build the hierarchy but has the advantage of clearly indicating that some concepts used in the code system are defined externally. Both the value of the imported property and the value of the code can be used to determine if the concept is imported. The main limitation of this approach is that it is possible to create redundant instances of imported concepts if multiple ontologies that import the same ontologies are used. So, for example, if both HPO and my new ontology use the Foundational Model of Anatomy (FMA), then all the concepts from FMA used in both ontologies will be created, which results in a waste of space. However, we believe the benefits
of this approach outweigh this relatively minor issue and therefore this was the solution adopted in the transformation. Figure 1 shows an example of a local and and imported concept when using this approach. The local concept, Abnormal cardiac septum morphology from HPO, uses the short form of the code and has the imported attribute set to false. The imported concept, septum from UBERON which is used in HPO, uses the long form of the code and has the imported attribute set to true.

```json
"concept": [  
  {  
    "code": "HP:0001671",  
    "display": "Abnormal cardiac septum morphology",  
    "property": [  
      {  
        "code": "imported",  
        "valueBoolean": false  
      },  
      {  
        "code": "parent",  
        "valueCode": "HP:0001627"  
      },  
      {  
        "code": "root",  
        "valueBoolean": false  
      },  
      {  
        "code": "deprecated",  
        "valueBoolean": false  
      }  
    ]  
  }]

"concept": [  
  {  
    "code": "http://purl.obolibrary.org/obo/UBERON_0003037",  
    "display": "septum",  
    "property": [  
      {  
        "code": "imported",  
        "valueBoolean": true  
      },  
      {  
        "code": "parent",  
        "valueCode": "http://purl.obolibrary.org/obo/UBERON_0000061"  
      },  
      {  
        "code": "root",  
        "valueBoolean": false  
      },  
      {  
        "code": "deprecated",  
        "valueBoolean": false  
      }  
    ]  
  }]
```

Figure 1: The FHIR representation of a local (left) and and imported (right) concept using the proposed approach.

This provides a good segue into the solution for the second challenge, determining which concepts belong in the main ontology and which ones are imported. The most straightforward alternative is to accept a user-defined list of namespaces that indicate if a concept belongs in the main ontology. Any concepts that use other namespaces will be considered imported. This strategy is implemented relaxing the definition of namespace by treating them as prefixes. In HPO, providing a list with the single element, http://purl.obolibrary.org/obo/hp_, produces correct results. If no input is provided then another alternative is to consider the classes defined in the main ontology document as local and all the others as imported. This approach does not work properly with HPO because several classes are redeclared in the main document, for example, several classes from the Chemical Entities of Biological Interest (ChEBI) ontology. Finally, a more sophisticated approach that does not require user input is to classify as local all the classes declared in the main document minus the ones declared in the imported documents. For HPO, this approach produces a result that is very close to being correct. The only issue is that some concepts are incorrectly classified as part of the main ontology because they are declared but never imported.

Finally, the third challenge involved implementing changes in our terminology server to support dealing with very large FHIR code systems. Our initial implementation assumed that large code systems would be imported using a specific component, such as the RF2 importer we use to support SNOMED CT, and that FHIR code systems would be small. Producing a FHIR representation of OWL ontologies instead of importing them directly has the advantage that the generated resources are standardised and can therefore be, in theory, uploaded to any FHIR terminology server. However, this also means that now FHIR code systems can be expected to contain thousands of concepts, as is the case with HPO.

3 Results

The transformation was implemented as an open source Spring Boot command line interface application. The OWL-API library was used to load the input OWL file and the ELK reasoner was used to classify the ontologies, because all

2The concepts are CHEBI_18183, CHEBI_17553, CHEBI_89843, CHEBI_17012, CHEBI_28875, CHEBI_132952, GO_0016265 and UBERON_0001029. The transformation was tested with HPO version 20180613.

3Available at https://github.com/aehrc/fhir-owl.
the ones selected for this project fall into the OWL EL profile\(^4\). The OWL-API library allows plugging in a different reasoner if required. The OWL ontologies are always classified before the transformation so this ensures that the is-a relationships available in the FHIR representation are inferred. The HAPI-FHIR libraries were used to generate the FHIR in-memory model and to save it to disk in JSON format.

HPO was used as an initial case study and the transformation produced a compliant FHIR code system that was loaded into Ontoserver and can be visualised correctly using Shrimp, our FHIR terminology browser. Figure 2 shows the HPO hierarchy displayed in Shrimp.

![Figure 2: The Human Phenotype Ontology in the Shrimp browser.](image)

To make sure that the proposed approach is generalisable to any OWL ontology, a set of additional ontologies that are relevant in the genomics space were selected and transformed into FHIR code systems. Table 3 shows the list of ontologies that were transformed.

4 Discussion

The original motivation for this work was to provide access to HPO using the FHIR API but the implementation evolved to become a generic OWL to FHIR transformation engine. This enables access to many existing OWL ontologies through the FHIR API. One of the benefits of having access to this content is that it is now possible to replace existing terminology servers with FHIR-compliant ones without missing out on available content. For example, REDCap\(^5\) provides autocomplete-style search over OWL ontologies through BioPortal, which only provides basic searching functionality. A new REDCap plugin\(^5\) provides an alternative implementation that uses a FHIR server that delivers more powerful searching capabilities than BioPortal, such as constraining search to value sets, i.e., to a relevant subset of an ontology. For example, if a specific field is capturing a cancer type, a value set can be used to constrain the possible values to search for the children of the cancer concept in the target ontology, instead of having to search through all the content, which will most likely include a lot of irrelevant concepts. This is very useful when trying to improve the quality of data being captured, especially when dealing with large terminologies. The OWL to FHIR transformation allows importing all the OWL content in BioPortal to a FHIR server.

The solution addresses the challenges adequately but it does have some minor drawbacks that could be solved with changes or extensions to the main FHIR specification, to allow directly referencing parents and children across code systems. This would require the parent and children properties to be of type coding and all the operations that use subsumption would also need to be updated to support search parameters of type token. We are currently exploring these potential changes with the FHIR community and assessing the possible impacts in the current implementation of our terminology server.

One limitation of this work is that it assumes that the target FHIR concepts are only OWL classes. While this is true in all the ontologies that were transformed as part of this project, it might be the case that an ontology also contains individuals and these should also be transformed into FHIR concepts. Also, anonymous classes are not supported, because in FHIR a concept's code is a mandatory field. Finally, only a set of predefined properties are created in the target code system, mostly used to build the hierarchy correctly. Arbitrary properties in the source OWL file, represented as annotation properties in OWL, cannot be mapped to the target code system with the current implementation. Some OWL constructs, such as concrete domains\(^9\), could also be represented in some simple cases as properties in the target code system, but are currently ignored.

\(^5\)Available at [https://github.com/aehrc/redcap_fhir_ontology_provider](https://github.com/aehrc/redcap_fhir_ontology_provider).
5 Conclusion

In this paper we described the implementation of a transformation between OWL ontologies and FHIR code systems. The implementation maps elements using sensible defaults and also supports many configuration parameters.

A case study that is relevant in the genomics space was conducted using HPO and this highlighted some of the challenges in the transformation. Several approaches were considered and a satisfactory solution with minimal drawbacks was achieved. The solution was then tested on a larger group of ontologies and this showed that the transformation is generic and works with arbitrary OWL ontologies. In order to overcome some of the minor drawbacks, changes or extensions to the FHIR specification are currently being considered. These would allow natively referencing parents and children across code systems to better support importing external content.

The main benefit of this transformation is that it enables access to a broad range of ontologies in OWL format through the standard FHIR terminology APIs, without requiring the implementation of a bespoke importer for each one. This supports their use in electronic data capture systems such as EMRs through a single interface.

Abstract
An informatics platform has been designed, deployed and validated around the ITCBio initiative to provide support to clinical and translational research in Andalusia. To this end, an infrastructure has been developed which, in a scalable manner, incorporates functionalities aimed to facilitate the consistent definition of information models, the data reusability from electronic health records, as well as the analysis and processing of information. All this with the purpose of providing support to the different clinical and translational research processes associated with clinical trials and research projects. This initiative is based on the creation of a suite of applications that, through using standards, incorporates open-source tools intended to support these research processes. It is currently in widespread and growing use in university hospitals in which the platform is deployed.

Introduction
Research and innovation from the discipline of biomedical informatics for clinical and translational research EHR-based faces several significant challenges. In this paper, we present the ITCBio platform that we have developed to respond to these challenges in practice. This initiative is well accepted among users due to the high capabilities offered to clinical and translational research, from the integration and improvement of a set of tools of proven effectiveness, as described in the section on methods.

Informatics oriented to Clinical Research
Currently, the development of research studies is carried out by collecting data on paper or using a computer system proposed by the promoter of the research. This working scheme turns the data collected in the Electronic Health Record (EHR) into systems that cannot be reused for research, resulting in a double collection of information by professionals. This double data collection allows errors and inconsistencies to appear in the clinical information that could be controlled if the documentation is performed in a unified manner.

To accelerate and optimize the translation of information and knowledge that occur in each phase of the clinical research process, a new discipline oriented towards Clinical Research (CR) has emerged in the field of Informatics. Such discipline proposes the development of new theories, tools and computer solutions that allow to improve the research capacity of the institutions that adopt them [1]. These tools and computer solutions must be designed to support the four phases of the clinical trial (Phase I, Phase II, Phase III and Phase IV) and the rest of the processes involved in each research study. That is why the result of the advances in CR range from the increase of the efficiency in the collection and acquisition of data to the optimization of the design of protocols and its efficient management. Likewise, the recruitment of patients and their management, the notification of adverse events, the compliance and adherence to the legal framework, as well as the storage, the transfer, the process and the analysis of research data.

Research networks based on the reuse of Electronic Health Record data
Promoters of research studies have a period of protection for their discoveries limited to 20 years for new drugs and patent molecules. Considering that the average time required by the pharmaceutical industry to introduce a new drug to the market from the start of its research is about 12 years [2], promoters of research studies will have significant benefits if the development times of these studies are reduced.

Based on the significant benefits of reducing clinical trial development time, the pharmaceutical industry promotes the reusability of EHR data to reduce patient recruitment times. At European level, the EHR4CR project [3] funded by the IMI call has developed a framework of services for more efficient clinical research. The project is developing
a framework in which interoperability solutions are integrated through the application of standards, security, data quality, data storage, organizational processes, accreditations and certifications that allow to develop pilots where studies are conducted to a European level. Associated with the results of this project, the EHR4CR Champion program has been created with the objective of creating a network and community of hospitals oriented towards the reusability of data for research. Numerous European hospitals are currently being contacted to participate in this network [4-5].

Among the benefits offered by participating in this network to healthcare providers, it is identified that by having optimized mechanisms for conducting clinical trial feasibility studies, network members are eligible to participate in a more significant number of clinical trials. The associate hospitals of this network accept the installation of a platform in their hospitals that is in charge of returning anonymized data from the patients of the center to the researchers of the pharmaceutical industry during the feasibility study phase of the clinical trial. The Swiss-based company Clinerion has also developed a system with a similar approach in which it offers to install a free system in hospitals that allows consultations by researchers from the pharmaceutical industry with the aim of encouraging the hospital to participate in a larger number of clinical trials [6].

Finally, the ITCBio platform aims to offer an alternative to avoid technological dependence on the pharmaceutical industry and to ensure the control of data through the development of independent studies that promote networking between research centers.

Security and data protection

The new European General Data Protection Regulation (GDPR (EU 2016/679) has emerged as a response to the need to ensure that security and data protection mechanisms are established in new scenarios [7]. GDPR is a step forward in clarifying how to specify patients' consents to the application of their data in research studies and also clarifies that data protection principles should not be applied to anonymous information. Thus, anonymized data allows the data subject not to be identifiable and therefore, it can be used for statistical or research purposes. Thanks to this new regulation there is finally legal certainty in areas that were not sufficiently identified in the previous regulation.

In parallel, the development of initiatives that tries to democratize and share the use of biomedical and health data through the FAIR principles guidelines is becoming popular. Such initiatives seek to establish guidelines so that resources, data and research results are easy to find, with clear rules of access, interoperable and reusable (“Findable, Accessible, Interoperable, and Reusable” [8]). The FAIR4Health project guides the future strategy of the European Commission concerning the management of publicly funded research data. This project is coordinated by the first author of this paper on behalf the Andalusian Health Service (SAS) and has 17 partners from eleven countries (Spain, Portugal, Italy, United Kingdom, Germany, Switzerland, Austria, Netherlands, Belgium, Serbia, and Turkey). Our ITCBio platform will be improved for the anonymization and implementation of the FAIR principles for the data collection that the Andalusian Health Service will bring to the FAIR4Health project.

Currently, the use of new technologies allows the establishment of new paradigms based on Dynamic Consent. Dynamic Consent takes advantage of information technologies to establish more flexible mechanisms of communication with patients and provides them greater control of their data and biological samples [9].

Interoperability

From the point of view of health care providers, due to the need to support the continuous care of patients in different health institutions, there are several initiatives currently working on the definition of specifications and computer models that allow communication between EHR systems and laboratory systems, pathological anatomy, radiology, etc.

To support the migratory flows and movements of people in Europe, the European Commission has defined a series of services focused on cross-border healthcare in our continent. These services are called Connecting Europe Facility and they are based on a European interoperability framework for eHealth that has defined the most relevant use cases in which there will be an emphasis at European level on the standardization of communications. The European interoperability framework defined identifies how to apply standards and profiles of HL7, IHE and Continua Health organizations for communication in telemonitoring scenarios, as well as the transfer of patient’s summary of records, prescriptions and drug dispensing, discharge reports, laboratories and radiology.
Besides, at national level, the Spanish Ministry of Health, Social Services and Equality has also recently defined the Minimum Data Set of Clinical Reports to support the continuity of patient care across multiple autonomous communities through the application of the HL7 CDA standard.

Moreover, the HL7 organization has recently developed the HL7 FHIR standard as a technology that enables the communication of clinical information [10]. This technology is having a great acceptance in a part of the industry, especially in the development of mobile applications, since it allows REST communications. There is a new initiative called SMART that establishes a framework for the development of mobile applications in the healthcare field using FHIR technology [11]. Based on these specifications, the Sync for Science (S4S) initiative has been established in the USA, with the participation of the leading EHR system commercialization companies (e.g., Allscripts, Cerner, eClinicalWorks, and Epic, etc.) and organizations such as the National Institutes of Health (NIH), Office of the National Coordinator for Health IT (ONC), and Harvard Medical School.

**Andalusian Health Service (SAS)**

Servicio Andaluz de Salud-SAS (Andalusian Health Service) is a public body providing all healthcare public services to the 8.4 million inhabitants in Andalusia. It is an autonomous organization, attached to the Regional Ministry of Health of the Government of Andalusia. SAS provides a wide range of healthcare services from preventive and public health activities to highly specialized services, in a system with universal coverage and funded by taxes, through a network of integrated healthcare facilities organized to ensure the accessibility of the population: 1,500 primary care centers, 49 hospitals, and over 100,000 employees.

SAS Central Service is located in Seville (Spain), including the Deputy Directorate of Information Technology and Communications (STIC), responsible for the definition and implementation of ICT policies and strategies throughout the Andalusian Health Service. The STIC is leading the process of transformation and improvement of eSystems, to facilitate and improve the daily work of public healthcare professionals and the services provided to citizens.

Diraya (“knowledge” in Arabic) is the region-wide EHR system network-based that aggregates all the health-related information as a Single Health Record. The system, integrated and accessible throughout the whole Andalusian Health Service, links patients’ information generated at any of the different care levels. The electronic health record is structured in a federated way, with some information blocks kept at a central level (such as problems, allergies, past medical history, prescriptions, lab, and imaging tests…) and local blocks that store reports (discharge summaries, care plans…) generated during local care encounters.

For research, SAS covers the performance of research and innovation activities. As part of this activity, according to data collected in 2017 [12], SAS has developed and participated in a total of 1100 projects, 49 of which correspond to international research initiatives. In terms of clinical trials, SAS carried out a total of 2,143 trials in 2017, of which 1,753 were commercial initiatives while 390 were promoted as independent trials.

In order to respond to the challenges of research in this context of Andalusia, our proposal has been to develop an infrastructure to support the translational and clinical research processes with the following features:

- Highly scalable. The infrastructure will be able to grow according to the available resources.
- Based on open-source software. The use of this kind of applications avoids dependencies with proprietary solutions, counting on a wide community of users and developers who give support and make this type of applications evolve.
- Oriented to the normalization, integration, advanced analysis and visualization of biomedical information. To support the complete process of clinical and translational research.
- Reuse of components and information resources, which makes it highly effective.

**Methods**

A suite of applications capable of integrating different open-source software initiatives to support clinical and translational research has been developed. Specifically, the current version of the platform includes the integration of the following tools:

- Data warehouse management software: i2b2 [13]
- OpenClinica [14] and RedCap [15] clinical trial and research study management software
- Advanced biomedical information analysis software: tranSMART [16]

For the integration of these initiatives with the ITCBio platform, the service bus known as Mirth Connect has been used, a free software engine developed specifically for health integrations and which natively provides the HL7 messaging standard. Mirth Connect consists of a set of tools that allows us to develop, test, deploy and monitor connection interfaces in a comfortable and intuitive way through the definition of integration channels.

Through this integration engine, it is also possible to interoperate with the clinical information present in the EHRs of the SAS for patients recruited in clinical trials and research projects. This integration is carried out through the development of specific channels that allow the on-demand reuse of patients’ clinical information in the electronic forms designed for clinical trials and research projects.

For user authentication in the ITCBio platform, as well as in the different open-source software initiatives mentioned above, the following considerations are taken into account:

- Use of corporate services for SAS user identification. The ITCBio platform makes use of connections with the SAS Active Directory server (LDAP) for the reuse of corporate credentials of SAS researchers.
- Ability to integrate with other sources of authentication external to the ITCBio platform.
- Use of an Active Directory (LDAP) server for local users to the platform who are not present in the external authentication systems discussed above.
- Mapping of user roles and permissions according to the Study/Center to which it belongs and its corresponding association in the different applications integrated within the ITCBio platform.
- After the initial authentication of the users in the ITCBio platform, the user can move freely between the different integrated applications, offering the capacity of Single Sign On within the whole platform.

The ITCBio platform implements a context management system for research. This initiative follows a scheme similar to the one proposed by the standard Clinical Context Object Workgroup (CCOW) [17-18], a Health Level Seven International standard protocol designed to enable disparate applications to synchronize in real time, and at the user-interface level. In addition, the ITCBio platform also incorporates an interoperability module based on IHE XDS [19] profiles for the management and exchange of documents with biomedical information, as well as the CDISC [20] standard, which allows the information obtained in the course of studies to be available in any other system that interoperate through these standards, widely used in the sector. On the other hand, the ITCBio platform also offers other interoperability interfaces to accept information from external systems in FHIR format. This interoperability interface makes it possible to integrate clinical information into the i2b2 clinical information repository, an initiative already pursued by other researchers in the sector [21].

Results

From a functional point of view, the ITCBio platform provides many advanced capabilities that support the main research processes present in our organization. Below there is an indicative scheme where the main aspects mentioned above can be observed:
The ITCBio platform is currently deployed in the Virgen del Rocío University Hospital, the Virgen Macarena University Hospital and the Biomedicine Institute of Seville (Seville, Spain). It is also being used in 27 research projects and six clinical trials, many of which are multicentric initiatives. These projects are framed within diverse clinical domains such as Oncology, Allergology, Thoracic Surgery, Pediatrics, Neurology, Pneumology, Gynecology or Hematology. Among all these projects, there are more than 4,500 registered patients in multiple research studies and more than 300 registered users.

Currently, we have an active innovation project around this initiative funded by the Ministry of Health of the Regional Government of Andalusia. This project aims to define, implement and evaluate a sustainable and scalable service to support clinical and translational research through the ITCBio platform. Likewise, this project intends to identify requirements to meet the needs in order to establish a sustainable service in SAS, which allows to implement and assess the impact of offering the service to support research through an evolved version of the platform. Based on the use of the service and its benefits obtained, the goal is to estimate the potential impact of the extension of this service in Andalusia and to define a strategy for the promotion of Health research activity in our region.

Discussion

One of the main milestones achieved through this platform has been to develop a common framework that integrates heterogeneous open-software initiatives to improve the processes associated with clinical and translational research. As expected, each of these initiatives uses completely different technologies and data models, which require a significant workload to achieve their correct integration. Although it has been identified diverse interoperability standards at different levels (information exchange, patients' identification or users' identification, among others) that could greatly facilitate this integration process, the various software initiatives prefer to opt for independent developments, practically on the margin of all of them. This fact emphasizes that the current development of open-software tools related to the biomedical environment is not sufficiently aligned with the specifications defined by the standardization organizations. Consequently, the development of cross-sectional solutions, such as the ITCBio platform, is challenging.
Around this situation, we have found some standards that have entirely fallen into disuse, such as the standard of exchange of clinical context information (CCOW) and others that, despite their usefulness, are not yet on the roadmap of the open-source initiatives that we have thought about in this document. On the other hand, in order to achieve interoperability between systems, the most appropriate standard for communicating information about clinical trials and research studies is the CDISC ODM. This standard allows exchanging not only the information contained within the clinical trial or research study but also a large amount of metadata associated with its research protocol. Unfortunately, the open-source initiatives oriented to data exploitation (i2b2 and tranSMART) do not have this capacity yet, so in this project, it has been necessary to implement integration mechanisms with greater complexity that directly require working at the database level.

Besides, another of the main aspects to be highlighted in the development process of this platform is the modeling and management of clinical information recorded in clinical trials and research studies. Within this process, the ITCBio platform has developed a specific module oriented to the design of the electronic data forms by using semantic mechanisms. This module, based on a previous project known as HEMIC [22], is a tool that allows the consistent definition of forms based on the main reference terminologies and ontologies in the health domain. Through this module, the integration of the different open-source tools that are part of the ITCBio infrastructure has been facilitated. Besides, it has been possible to significantly improve the processes of clinical information exchange from the registration tools to the tools in charge of the analysis and data exploitation. In this way, we believe that the incorporation of semantic techniques for the definition of electronic data forms can be very useful for this kind of open-source initiatives, such as OpenClinica and RedCap.

Conclusion

The ITCBio platform begins with competitive funding of the call for Scientific-Technical Equipment of the Spanish Ministry of Economy and Competitiveness in 2013. The design, development, and deployment of a scalable and reusable infrastructure to support translational and clinical research based on open-source software were carried out. Its objectives are the following:

- To facilitate feasibility studies and patient recruitment in clinical trials based on Real World Data.
- To provide researchers with access and management of all the information they need to carry out their research activity, including access to sources of available clinical care information.
- To promote collaboration between researchers inside and outside each organization through tools that support the management of roles and accesses in multicenter studies, complying with regulations, security information and confidentiality needs, as well as the enrichment of data collections with metadata in accordance with FAIR principles for effective reusability of the same in new collaborative research.
- To offer tools for the advanced analysis and exploitation of the data obtained in the research studies.
- To develop new lines of research on the standardization, integration, advanced analysis and visualization of integrated information with available clinical information.

The ITCBio platform is based on the integration of different modules or open source components. Thanks to this integration of components, the platform can offer a set of services to support translational research that is not able to offer the components individually or any of the competitors in the market. In particular, this platform offers the following benefits:

- At the scientific level, the ITC-Bio platform provides advanced capabilities for the management and conduct of clinical trials and research studies with cross-cutting application to the whole range of diseases and pathologies. The ITC-Bio platform accelerates this discovery process and therefore has a great impact on the research and development of new treatments, making the health and research centers that use its services more attractive to participate in clinical trials promoted by the pharmaceutical industry, enhancing the capacity to generate research results that can be transferred to the biotechnology market.
- From the scientific-academic point of view, this infrastructure boosts the scientific production capacities of translational researchers and clinicians who make use of it, also boosting the development of clinical trials and research studies.
From the technological point of view, the ITC-Bio platform presents an important advance in terms of research platforms thanks to the inclusion of functionalities that allow collaboration between users and different institutions through the possibility of integrating with multiple user management systems. The platform does not depend on any external license because it integrates different open source applications in a common framework using a Service-Oriented Architecture that allows its scalability.

On the other hand, this infrastructure will be able to support all lines of translational and clinical research that may arise in the hospital environment. Also, its deployment and implementation are leading to the emergence of new lines of research in technologies applied to health and information technology for biomedical research, among others:

- Research and development of new interfaces for the efficient and effective visualization of information and decision support systems based on personalized medicine.
- Research and development of algorithms and advanced information analysis methodologies including the application of artificial intelligence techniques such as data mining and clustering.
- Research in rapid phenotyping techniques based on the application of natural language processing algorithms on clinical information stored in free text.
- Research on the semantic representation of biomedical information and the needs of the patient.
- Finally, it is intended to incorporate FAIRification capability (provision of FAIR-compliant metadata to research data collections) that would allow universal reusability of data collections which extends the interest in the use of the platform to all actors willing to open science and the acceleration of shared biomedical research based on open data.

Abstract

Developing promising treatments in biomedicine often requires aggregation and analysis of data from disparate sources across the healthcare and research spectrum. To facilitate these approaches, there is a growing focus on supporting interoperation of datasets by standardizing data-capture and reporting requirements. Common Data Elements (CDEs)—precise specifications of questions and the set of allowable answers to each question—are increasingly being adopted to help meet these standardization goals. While CDEs can provide a strong conceptual foundation for interoperation, there are no widely recognized serialization or interchange formats to describe and exchange their definitions. As a result, CDEs defined in one system cannot be easily reused by other systems. An additional problem is that current CDE-based systems tend to be rather heavyweight and cannot be easily adopted and used by third-parties. To address these problems, we developed extensions to a metadata management system called the CEDAR Workbench to provide a platform to simplify the creation, exchange, and use of CDEs. We show how the resulting system allows users to quickly define and share CDEs and to immediately use these CDEs to build and deploy Web-based forms to acquire conforming metadata. We also show how we incorporated a large CDE library from the National Cancer Institute’s caDSR system and made these CDEs publicly available for general use.

Introduction

The use of ontologies and controlled terminologies has become pervasive in biomedicine. Dozens of large ontologies and terminologies and hundreds of specialized smaller ones have been developed to cover many biomedical domains. For example, the National Center for Biomedical Ontology's BioPortal ontology repository¹ serves over 700 biomedical ontologies and terminologies, which are used throughout biomedicine. While ontologies and controlled terminologies provide a common vocabulary to refer to biomedical concepts, additional detailed specifications are typically needed to satisfy data collection and reporting needs.² Data collection requirements for clinical studies, for example, mandate precise specifications of questions and the range of possible answers to those questions. Common data elements (CDEs), which provide the means to link the specification of the question to a range of possible answers, are increasingly being adopted to satisfy these data collection and reporting needs.²⁻⁴

A CDE is effectively an agreed-upon question specification, precisely defining how a particular question should be asked and what values should be presented to users for their selection.⁵⁻⁶ An answer is represented as a single typed value. Answers can be strings, in which case simple parameters such as string length and encoding can be specified. They may be numeric, in which case parameters such as valid ranges, units, and precision may be specified. Answers can also come from controlled terminologies, where the answer may be specified as a terminology code or an encoded value. Often a permitted value set, or value domain, is built to define the allowed answers for a question. Such value sets are often built from one or more standards or terminologies.⁷⁻⁸ CDEs are commonly used to define case report forms (CRFs) for clinical trials, though they can be used in any situation where it is important to meet rigorous data collection or reporting requirements. They have been adopted most widely in cancer research,⁹⁻¹² but they are also used in other domains, such as epilepsy,¹³ brain injury,¹⁴ stroke,¹⁵ phenotyping,¹⁶ and radiology.¹⁷

CDE definitions can provide a strong foundation for interoperation because they allow data descriptions to be recorded in a registry. Such registries can help to standardize the way data are collected, stored, transferred, and reported. One of the largest CDE registries has been developed by the U.S. National Cancer Institute (NCI) with the goal of facilitating multidisciplinary, multi-institutional cancer research. This registry is called Cancer Data Standards Repository (caDSR)⁹,¹⁸ and it contains over 60,000 CDEs that cover many aspects of cancer research. The U.S.
National Institutes of Health (NIH) are also developing a multi-discipline registry that aims to unify the range of biomedical CDEs that have been produced by a variety of NIH and other organizations (https://cde.nlm.nih.gov).

While these registries provide a strong conceptual foundation for the definition and use of CDEs, there are a number of practical challenges that must be addressed when attempting to reuse CDEs. The common structure is provided by the ISO/IEC 11179 standard,19 which is used as a basis of the caDSR and other repositories, is helpful but the standard does not specify implementation-level details. As a result, CDEs cannot be easily used across systems. Reflecting the strong regulatory requirements of the domains they are used in, and ISO standard conformance requirements, building new CDEs tends also to be a laborious task that involves complex workflows. In addition, CDEs must be fully specified before data collection forms can be built, adding additional complexity. Building data collection forms from CDEs can thus be an onerous task. An additional issue is that ISO/IEC 11179-based systems typically aim to provide faithful implementations of large parts of the standard, significantly increasing their complexity.

There is thus a technological barrier to developing and reusing CDEs in new systems that we believe is limiting their adoption by the broader biomedical community. To address this problem we extended an existing Web-based metadata management platform called the CEDAR Workbench20,21 to provide a core representation of CDEs suitable for specifying questions in a metadata acquisition system. Rather than aiming to provide CDE definitions that reflect a comprehensive implementation of the ISO/IEC 11179 standard, we instead concentrated on providing the functionality in core parts of the standard that relates to the precise specification of questions and the values used to answer those questions. A key focus is on interoperation with Linked Open Data by providing a direct mapping of CDE-described data to RDF. We describe the functionality provided by the system and show how the resulting system allows users to easily use CDEs to build and deploy Web-based forms to acquire conforming data. We also show how we incorporated the large CDE library from NCI's ISO/IEC 11179-based caDSR system and made these CDEs publicly available for general use.

Methods

Although there are no widely adopted standards defining CDEs in the biomedical domain, the ISO/IEC 11179 specification19 has been used as the underpinning of many CDE-based systems. This specification, which is formally known as the ISO/IEC 11179 Information-Technology Metadata Registry standard, is divided into six parts and covers a wide range of requirements for developing and deploying metadata registries. Part 3 of the standard describes a Data Element, which is the fundamental information component in the standard. An ISO data element is designed to support the description of an atomic piece of data. It has been adopted by many systems to model common data elements.

In addition to defining the core specification of a particular question and answer, the standard also outlines a rich model describing many aspects of a data element. Such information includes provenance information (e.g., who developed the data element, workflow (e.g., its development status, such as whether it is under development or is released), possible relationships with other data elements, and detailed descriptions about the context and the domain in which the data element is to be used. While useful in some situations, this information is generally not needed if the goal is to produce an operational implementation of a system that uses CDE-based question specifications. In this paper we, ignore these contextual metadata. Instead, our analysis and implementation restrict themselves to the core features needed to deploy CDEs in a metadata acquisition system.

To provide a detailed set of requirements for supporting the resulting types of CDEs, we analyzed a 11179-based CDE system. In particular, we used the cancer Data Standards Repository (caDSR)22,23, which was developed by the U.S. National Cancer Institute. The system was designed to support the development and deployment of CDEs in data collection forms in cancer research. It adheres very closely to the ISO/IEC 11179 Edition 2 metadata standard, with extensions to support terminologies and ontologies by data elements. It provides a rich and comprehensive implementation of that standard and has been used for over two decades by clinical-trials data management systems.

Requirements

Using the caDSR system as the source, our requirements analysis aimed to identify the core set of features necessary to support CDEs in a metadata acquisition system. In addition to faithfully representing the core requirements of a CDE itself, a system must be able to ingest libraries of CDEs, be able to use them to build Web-based forms, and, finally, to be able to deploy those forms to acquire data meeting the specifications of the CDEs used in the forms. An additional requirement is to produce an RDF representation of data collected using CDEs.

The analysis identified three main sets of requirements for representing CDEs: (1) Descriptive information about a CDE must be represented. This information includes a public identifier for a CDE, its name, and a definition. CDEs
can be versioned, allowing them to evolve over time. CDEs can also be tagged with basic provenance information, which can be used to, for example, indicate their domain or to divide them into categories. (2) CDE question specifications must be represented. The caDSR system provides a number of ways to indicate the questions presented to users when they are filling in CDE-specified fields. In addition to the primary question text, CDEs may also contain an set of alternative questions. These alternatives questions can be used to customize deployed CDEs for different domains. (3) Finally, CDE value domains must be represented. An array of complex features is provided by caDSR to define the value domain of a CDE. Broadly speaking, values may be string-based, dates, times, Boolean, numeric, or from a controlled term source. String-based CDEs support fairly simple minimum and maximum length specifications. Numeric values may come from a variety of different datatypes. Units and ranges may also be specified for numeric values. Controlled term value domains specifications are the most complex. A system must allow value sets to be built to define sets of controlled values. These value sets may be customized during deployment to allow reordering of values so that the most useful values are presented to users for particular needs. Similarly, some values from a value set can be excluded for particular deployments. Again, these features are to allow customization of CDEs to meet different deployment needs.

A final set of requirements that we identified relates to the management of CDEs in a system. Users must first be able to search for CDEs for use in forms. Searching may be by CDE public identifier, name, description, category, and value in value set. Once a CDE is found, users must be able to add the selected CDE to a form, and possibly to customize the CDE. Customizations include selecting a question from a set of alternative questions and reordering or excluding values in a value set. Web-based forms must then be generated from these form specifications to acquire data from end-users. The deployed forms must enforce the value domain restrictions specified by CDEs.

**Implementation**

We decided to provide CDE support on top of an existing platform (Figure 1), rather than to implement the required features from scratch. This platform, which was developed by the Center for Expanded Data Annotation and Retrieval, is called the CEDAR Workbench. It provides a collaborative, Web-based environment for managing metadata resources. The platform is centered on the creation of metadata templates (or simply templates) to describe biomedical experiments. These templates define the data attributes—termed template fields or fields—needed to precisely describe these experiments. For example, an experiment template may have an organism field containing the name of the organism being studied by the experiment (e.g., Homo sapiens).

![Figure 1. High-level overview of the workflow of ingesting libraries of CDEs into CEDAR. CDEs from an external library are transformed to the CEDAR model and uploaded to the CEDAR Workbench via the CEDAR REST APIs. The controlled term value sets used by these CDEs are stored in BioPortal. The biomedical community can easily access and reuse the CDEs when building Web-based metadata acquisition forms. The CDEs can also be accessed via the CEDAR REST APIs.](https://example.com/figure1.png)
numbers, and dates, field values can also be defined using standardized terms from ontologies and other sources of controlled terms. CEDAR works in concert with the BioPortal ontology repository⁴ to supply these values. BioPortal is a popular platform for accessing and sharing biomedical ontologies and hosts over 700 ontologies and 8.9 million classes. This combination of CEDAR and BioPortal provides the ability to create value set descriptions that nicely align with the requirements of CDE value domains.

A final set of features provided by CEDAR supplies the ability to deploy CDEs in Web-based forms defined by templates. These are: (1) a Template Designer, which supports interactive template creation; (2) a Metadata Editor, which allows end-users to fill in templates with metadata; and (3) a Metadata Repository, which manages the storage and retrieval of both templates and the metadata created using those templates. CEDAR defines a standardized metadata model, together with Web-based services to store, search, and share metadata.²⁴ This model is based on the JSON Schema and JSON-LD specifications. It allows users to publish their metadata as both JSON-LD and RDF, thus facilitating interoperability with Linked Open Data. Users can quickly create forms using the Template Designer and deploy the forms using Metadata Editor to produce semantically annotated data.

CEDAR thus provides a set of core features that are suited to supporting the deployment and use of CDEs. Based on the requirements outlined earlier, we identified the set of existing CEDAR features and the set of extensions that would meet these requirements. The primary extensions involved significantly enhancing CEDAR's field-level capabilities to support the rich value restrictions specified by CDEs. In addition to this field-level functionality, CEDAR must also be able to ingest a CDE library and map the library’s CDE representation to the CEDAR model. With this functionality, CDE-based fields can be added to templates and deployed to collect metadata from users using CEDAR’s Template Designer and Metadata Editor tools.

**Field Extensions** We performed a detailed analysis of the caDSR implementation of ISO/IEC 11179 standard to identify the core functionality that a CDE system must support. The first task was to find commonalities between the caDSR model and the CEDAR metadata model, as well as the limitations of the latter to support CDE-based fields. Note that, reflecting the ISO/IEC 11179 standard, caDSR stores rich provenance information and domain-level semantic descriptions for individual CDEs. Since we are aiming only to represent the relevant operational specifications of CDEs, we excluded these from our analysis. We identified four classes in the caDSR model that contain information that represents this operational information. The classes are *Data Element*, *Value Domain*, *Permissible Values*, and *Reference Document* (Figure 2).

**Figure 2.** Visual representation of the mappings between the core caDSR CDE model and the CEDAR and BioPortal models. The figure shows the subset of attributes of the caDSR model that are mapped to the CEDAR Template Model (dashed blue line) and to the BioPortal Value Set model (dashed red line). The attributes `publicId`, `version`, `preferredName`, and `preferredDefinition` from the *ValueDomain* caDSR entity are mapped both to CEDAR and BioPortal.
The core CDE entity in caDSR model is the *Data Element*, which represents the smallest unit of data that can be represented and exchanged between systems. It contains attributes that capture descriptive information for a CDE, such as its public identifier, name, and version. The characteristics of the values accepted by a data element are defined by the *ValueDomain* entity, which contains attributes to specify the data type and the different value constraints. Each data element and value domain can contain terminology references. The attribute *ValueDomainType* of the *ValueDomain* entity specifies whether the domain is enumerated—when it is specified by a predetermined list of permissible values (e.g., *male* and *female* for the element *Sex*)—or non-enumerated—when the domain is specified by a description or range (e.g., positive integers for the element *Number of Months Stayed Off Cigarettes*). When the value domain is enumerated, the accepted values are represented by the *PermissibleValue* entity, which specifies the exact names, codes, and textual labels that can be stored for the CDE.

**Table 1.** Field-level mappings between the core caDSR model and the CEDAR and BioPortal models. The table shows the core attributes of a CDE in the caDSR model and the corresponding attributes in a CEDAR model. For example, the first row shows that the attribute *PUBLICID* from the element *Data Element* in the NCI’s caDSR model file is mapped to the field *schema:identifier* in the CEDAR model. The right column shows the attributes used to represent value sets and their values in BioPortal. Fields added to the CEDAR model to support the representation of CDEs are indicated by an asterisk.

When comparing the caDSR and CEDAR models, we noticed a direct correspondence between the caDSR *DataElement*, *ReferenceDocument*, and *ValueDomain* entities and the CEDAR *TemplateField* entity. We observed that the *TemplateField* entity contained attributes to cover some of the core information for CDEs, such as name, definition, and version. However, it lacked support for some other crucial CDE features. We identified five main limitations in the CEDAR model and associated software and developed functionality to provide them:

**Public Identifiers** The CEDAR model lacked a way to store a public identifier of a field. This information complements the field CEDAR identifier and it is crucial to accurately find and refer to the CDE. As a solution to this limitation, we added the *schema:identifier* property to the model, which can now be used to store public identifiers for any CEDAR field. The Template Designer and Metadata Editor were also extended to handle this new field.
The caDSR ReferenceDocument entity makes it possible to specify, in addition to the preferred question text, alternate questions that can be presented to the user when filling out CDE-specified fields. An example of preferred question text for a CDE is Has the disease relapsed? while an alternate question is Was the status considered a disease relapse? We extended CEDAR to allow entering an alternate question text and stored it in the model using the property skos:altLabel. The Template Designer and Metadata Editor were also extended to work with alternate questions.

**Datatypes** The caDSR ValueDomain entity contains a dataType attribute that specifies the type of the value accepted by the CDE. Our analysis of a set of 60,409 caDSR CDEs revealed 190 different data types. Most of these datatypes can be directly mapped to equivalent data types supported by CEDAR. To limit the implementation effort, we decided to initially map the 10 most used datatypes (CHARACTER, java.lang.String, ALPHANUMERIC, ISO21090CDv1.0, NUMBER, java.lang.Long, java.lang.Integer, java.lang.Double, java.util.Date, DATE). These 10 types are present in 53,175 CDEs (88%). We are currently working on mappings the remaining data types to existing CEDAR types. In a few cases, we will need to extend CEDAR to support less common data types.

**Value Constraints** The ValueDomain entity contains a rich set of attributes to define some advanced value constraints, which the CEDAR model did not support. We extended the CEDAR model with fields to specify the minimum and maximum values, the number of decimal places, and the unit of measure accepted by numeric fields. We also the added fields to store the minimum and maximum length of string fields. The Template Designer and Metadata Editors were also enhanced to handle these value constraint extensions.

**Value Sets** In caDSR value sets can be used to define the range of possible values for a CDE. Value sets are versioned, first-class entities. They can be reused by several CDEs and can evolve over time. Typically, the values in a value set are selected from controlled term sources. Most value set values in caDSR come from the National Cancer Institute Thesaurus (NCIT). In collaboration with the BioPortal team, we extended BioPortal to support the representation of caDSR value sets. The enumerated value set specified by a ValueDomain is mapped to a BioPortal value set, while all the permissible values are stored as values in the value set. In CEDAR, the CDEs with enumerated values are linked to BioPortal using a URI that identifies the value set in BioPortal. We also extended the CEDAR model to support value set reordering and value exclusions. The Metadata Editor was also modified to handle this reordering and exclusion functionality.

![Figure 3](image-url). Schematic showing the caDSR CDE ingestion workflow. The cadsr2cedar tool takes an XML file with a set of caDSR CDEs and transforms each CDE to a CEDAR field. The transformed CDE fields are uploaded to the CEDAR Workbench via the CEDAR REST API. Any associated value sets and their values are transformed into an OWL and then uploaded to BioPortal via the BioPortal REST API.

**Ingestion Pipeline** We developed a pipeline to ingest the set of public caDSR CDEs into the CEDAR Workbench. The process converts XML-encoded caDSR CDEs to JSON Schema-encoded fields in the CEDAR model (Figure 3). We used a set of 60,409 CDEs that we downloaded from caDSR on August 2018. We developed a tool called cadsr2cedar to transform the CDEs in the XML file to the CEDAR model. Table 1 shows the primary mappings used.
in this conversion. The conversion process excluded currently unsupported datatypes and also excluded CDEs that were not marked as released by the caDSR system. As a result, we obtained 48,817 CDEs, which we uploaded to the CEDAR Workbench using its REST API. The cadsr2cedar tool also generated a total of 8,808 different value sets and 114,121 values used by the CDEs. We uploaded these to BioPortal using the BioPortal REST API.

Currently, we run the conversion process manually, but we plan to enhance it to run to immediately reflect CDE updates in the caDSR system. Extensions will be needed to the caDSR system to notify 3rd-party systems of such updates. The ingestion tools will also need to quickly identify the CDEs or value sets that have changed since the last update and selectively update only the corresponding CEDAR or BioPortal entities.

All the CDEs ingested are publicly available in the CEDAR Workbench (https://goo.gl/SggjQB).

Results

The main result of this work is a new version of the CEDAR Workbench that supports CDEs and that has been equipped with a large library of CDEs defined and maintained by the NCI. In addition to the field types natively available in the CEDAR Workbench (e.g., text, date, numeric, ontology values), CEDAR users can now search and select from a large number of CDEs ingested from the NCI's caDSR registry to build Web-based data acquisition forms. These forms can be used to collect data based on standard values from ontologies and terminologies, and easily share both the forms and the collected data with the broader biomedical community.

We used a CDE ingestion pipeline to incorporate 49,280 NCI caDSR CDEs into the CEDAR Workbench, as well as to upload the corresponding value sets to the BioPortal ontology repository. Our CDE ingestion pipeline can be reused to ingest new NCI caDSR CDEs into CEDAR. It can also be adapted to include CDEs from other sources.

**Figure 4.** Parallel representation of a CDE in the caDSR and CEDAR systems. The left side of the figure shows a screenshot of NCI's CDE Browser with details of a CDE, including its public identifier (3111302), version (2.0), and long name (Specimen Type Collection Biospecimen Type). The right side of the figure shows how that particular CDE can be used in the CEDAR Template Designer to build a Biospecimen template in combination with other non-CDE fields (Study Title, Organism, Cell Type, and Test Date), which were created on-the-fly. The Template Designer displays the most relevant information for the CDE, including its version, public identifier, long name, preferred question text, definition, and value set. This value set can be explored interactively.

CDEs can now be used when building CEDAR templates (Figure 4). The left side of the figure shows a screenshot of the NCI's CDE Browser (https://cdebrowser.nci.nih.gov/cdebrowserClient/cdeBrowser.html) for the CDE Specimen Type Collection Biospecimen Type. The CDE Browser provides relevant details for the selected CDE, including its identifier (3111302), version (2.0), and the preferred question text that should be used when incorporating it into a form (Sample Type). The right side of the figure shows how that CDE can be used in the CEDAR Template Designer to build a Biospecimen template, in combination with either other CDEs or with other fields that can be created on-the-fly, such as Study Title and Organism.
Figure 5 shows a screenshot of the Metadata Editor for the Biospecimen template, with the list of allowed values for the Sample Type. The right side of the figure shows the entered values in JSON-LD format. For the Sample Type field, CEDAR’s metadata contain not only the label of the value selected (Blood) but also the URI of the corresponding term in the NCI Thesaurus (http://ncicb.nci.nih.gov/xml/owl/EVS/Thesaurus.owl#C12434).

Our current implementation allowed us to transform 88% of the set of 60,409 caDSR CDEs available in August 2018. We are currently working on extending CEDAR to reach 100% coverage.

Figure 5. Screenshot of CEDAR’s Metadata Editor displaying a data acquisition form generated from the Biospecimen template shown in Figure 4. Here, the user is about to select the value Blood from the list of allowed values for the Sample Type field. The right side of the figure shows CEDAR’s JSON-LD representation for the entered values. For the Sample Type field, the JSON-LD representation contains not only the label of the selected value (Blood), but also the URI of that term in the NCI Thesaurus (http://ncicb.nci.nih.gov/xml/owl/EVS/Thesaurus.owl#C12434). CEDAR’s JSON-LD metadata also contains the values entered for the other fields, as well as provenance information such as the author and the date when the values were entered. This JSON-LD representation can be automatically transformed to RDF.

Discussion

Over the past few decades, there has been a strong emphasis on standardizing data collection and reporting requirements to facilitate data discovery, data interpretation, and data reuse. Different communities have adopted a variety of approaches to address these standardization needs. The cancer community, for example, has adopted CDEs as a mechanism for defining reusable question specifications that can be employed when collecting and reporting data in clinical research studies. Large libraries of CDEs have been built, which provide a strong foundation for interoperability. The social sciences community often uses data collection tools such as REDCap for their reporting needs. REDCap allows users to construct data acquisition forms. These forms can be built from reusable data collection instruments, which are used to standardize data-collection requirements over different studies. In the biological sciences, controlled terminologies are widely used. Many comprehensive ontologies have been developed, providing a common vocabulary to refer to biological entities.

While these solutions address the needs of their respective communities, they do not interoperate with each other, and each has shortcomings. For example, approaches such a REDCap make little use of controlled terms. The CDE-based solutions developed by the cancer community typically involve systems that are not easily reusable outside the specialized task of constructing case report forms. And, while controlled terms are useful in themselves, they do not address the full needs of specifying data-collection and reporting requirements. There is a need for an interoperable approach that meets the needs of these different communities.

We believe that the CDE-based approach outlined in this paper can provide such a solution. The system we developed supports the easy form construction capabilities of tools such as REDCap and the precise data specification advantages of CDEs, together with the central use of controlled terms. The system is built using the principled definition of CDEs provided by the ISO/IEC 11179 standard. However, the goal was not to exhaustively represent the wide array of provenance information and conceptual metadata that is specified by the standard; such information would be needed,
for example, when developing a specification-conforming metadata registry, or when trying to identify or analyze CDEs or data that are semantically related. Instead, the system restricts itself to the core parts of the standard necessary to represent standalone question specifications. This restricted interpretation of the ISO/IEC 11179 standard leverages its power while simplifying the specification of robust CDEs. We have done some preliminary testing to demonstrate the feasibility of our approach with NCI users, though more empirical testing is required to fully evaluate our claim.

Conclusion

In this paper, we describe how we extended the CEDAR Workbench to natively support CDE-based question specifications. The primary goal of this work is to provide an open platform that dramatically simplifies the use and deployment of CDEs by supplying intuitive and highly interactive Web-based interfaces. A key focus is to support interoperation, both by allowing third-party CDEs to be incorporated into the system, and by representing CDEs using ontologies and Semantic Web standards. Support for this markup was provided by extending the BioPortal ontology repository to natively facilitate the creation of value sets of controlled terms and then allowing these values sets to be interactively linked to CDE definitions. The resulting functionality supports the creation of robust, semantically rich CDE definitions that can be quickly deployed to collect data.

We ingested a library of over 48,000 CDEs and associated value sets from the NCI's caDSR CDE repository and made these CDEs available for public use. In particular, we validated that the system could present questions to users that accurately reflect a CDE specification and that it could also ensure that acquired answers fully meet the value requirements of those specifications. As outlined in this paper, we made several extensions to CEDAR to support caDSR CDEs, eventually reaching 88% coverage. We are currently developing additional features to fully represent the remaining caDSR CDEs. In addition to making the CDEs available for reuse, the goal of this ingestion task was to validate that CEDAR could faithfully represent and enforce a subset of the key elements of an ISO/IEC 11179-based CDE specification. This initial set of CDEs was developed over several decades for use in a large number of case report forms for clinical trials. They cover a broad range of cancer research. We plan to ingest CDEs from a variety of other sources to increase domain coverage. We also plan to develop additional features to support the management and search of multiple, large CDE collections.

The resulting system provides an open platform for sharing, managing, and deploying CDEs. We believe that the system lowers the barrier to the use of CDEs by leveraging existing CDE libraries and by supporting the easy creation of data-collection forms that allow these CDEs to be quickly provided to end-users.

Abstract

Maternal morbidity and mortality have gained major attention recently, spurred on by rising domestic rates even as maternal mortality decreases in Europe. A major driver of morbidity and mortality among delivering women is postpartum hemorrhage (PPH). PPH is currently phenotyped using the subjective measure of ‘Estimated blood loss’ (EBL), which has been shown to be unreliable for tracking quality. Here we present a framework for phenotyping PPH into multiple severity levels, using a combination of data-driven techniques and expert-derived clinical indicators. We validate the framework by predicting large drops in hematocrit and quantitative blood loss, finding that the framework performs better in predicting coded PPH than a hematocrit-based predictor or predictors based on other metrics such as blood transfusions, and does better in predicting quantitative blood loss, a gold standard metric for blood loss that we have for a subset of patients, than any predictor we could build using hematocrit drops alone. In all, we present a principled framework that can be used to phenotype PPH in hospitals using readily available EHR data, and that will perform with more granularity and accuracy than existing methods.

Introduction

Maternal morbidity and mortality have become a topic of great interest recently, with Centers for Disease Control reports of rising US rates (1), higher rates in the US than other developed countries, and recent attention cast on severe maternal morbidity measures by popular media such as the New York Times, Propublica, and USA Today. A major driver of morbidity and mortality among delivering women is postpartum hemorrhage (PPH). Most women bleed after giving birth, but PPH denotes excessive bleeding that can be life threatening if not recognized and treated. As of 2014, hemorrhage is the largest single direct cause of death worldwide among delivering women in both the developing and developed world, with postpartum (as opposed to antepartum or intrapartum) hemorrhage being the most prevalent type of obstetric hemorrhage, the largest individual direct cause of death in the developing world, and the 3rd largest individual direct cause of death in the developed world (2). However despite much effort and attention, PPH rates continue to rise domestically (3,4).

Prevention, improved early recognition, and optimized management are of primary areas of focus for hospitals as they work to improve outcomes for patients, but quality improvement efforts are hindered by the lack of a reliable phenotype for PPH that can be tracked in electronic health records (EHR). The standard definition of PPH is based on ‘estimated blood loss’ (EBL), by which a clinician estimates how many milliliters (mL) of blood a patient has lost after delivery. This metric suffers from basic subjectivity and reliability issues, including a recognized tendency for clinicians to both underestimate and overestimate blood loss in obstetrics (5,6). Nevertheless, EBL is used to determine which patients get the ICD-CM diagnosis code for PPH, and the PPH billing codes are used to track PPH rates for quality analyses, reimbursement, and other needs (6). As with many other diseases, ICD-9 diagnosis codes have been demonstrated to be inaccurate; in this case, ICD codes have been found to underestimate the prevalence of PPH among women undergoing Cesarean delivery (7).
Accurately phenotyping PPH is a first step in understanding causes, prevalence, and potential ways to improve care. Aside from the EBL-based definition of PPH (≥500mL blood after vaginal delivery or ≥1000 mL blood after Cesarean delivery, classically, but modified in 2017 to 1000mL EBL after either type of delivery), PPH has been phenotyped in several ways (6,8). Some guidelines cite Hematocrit (Hct) drops during pregnancy of >10% as a definition of PPH (6,8). However, Hct drops can be affected by many factors including the fluid shifts as a result of intravenous hydration routinely given during and after delivery, hemoconcentration seen in the setting of preeclampsia, as well as blood transfusions given to treat PPH itself. Hct drops are thus fairly non-specific for PPH (we analyze this explicitly in this paper). Other analyses use any transfusions of red blood cells (RBC), or in some cases 4 or more RBC transfusions, as the definition of severe hemorrhage. These definitions are incomplete, as they exclude many deliveries that have large and potentially dangerous PPH, but are dealt with through means other than transfusions (e.g., uterotonics, tamponade), or are otherwise below a severity threshold that would require transfusion. There is another method available for assessing blood loss called ‘quantitative blood loss’ (QBL) which should be considered the gold standard for phenotyping PPH, as it involves objectively measuring the amount of blood lost by a patient. However, this method is fairly new and requires specialized equipment that is not widely adopted in hospitals, and for now, its accuracy can vary depending on the training and approach used for measurement (5,9,10). Until QBL is widely adopted and its application standardized, there remains a need for an electronic phenotyping method that can judge the severity of PPH with available hospital data.

To answer this need, we here present a framework for phenotyping PPH into multiple severity levels, using a combination of data-driven techniques and expert-derived clinical indicators. We believe that a binary classification of PPH (yes/no) is less useful for quality improvement than a more gradated system, which would give a richer interpretation for hospital use, and also would align more with the actual PPH phenotype as captured by QBL: namely, a continuous variable denoting the quantity of blood loss. This suggests that a continuous measure of blood loss would be ideal, but without QBL being routinely measured and with Hct being unreliable (as will be shown), a continuous measure becomes impractical. With 2 severity levels being too few and a continuous variable being impractical (at least until QBL becomes routine), we used clinical judgement to settle on an electronic phenotype for PPH that includes 5 severity levels. The framework is derived based on aggregate Hct drops for patients with various conditions and interventions, the records of which are routinely available in the EHR, plus expert judgement (e.g., for incorporating interventions that affect Hct levels). We also derive an optimal cutoff of Hct drop for phenotyping PPH to compare in performance to our framework. Finally, we validate our method using QBL measurements from our EHR. In all, we present a principled, portable, and data-driven method for phenotyping PPH, which relies on readily available hospital data.

Methods

Cohort
The framework was developed using data from a cohort of all patients delivering babies between July 2014 and July 2017 in four hospitals within a single health system in New York City, numbering 43,657 total delivery visits. Approval to use this data for research was obtained from the Columbia University Institutional Review Board.

EHR data
Data were extracted through automated query from our institution’s electronic data warehouse, which aggregates data from the EHR, billing system, and other sources. Quality checks were performed to ensure that data were not missing, and when necessary, data were pulled directly from the EHR in order to fill gaps. For example, quality checks revealed that uterotonics data were missing in our data warehouse before a certain date from one of our hospitals; we pulled the data directly from the EHR to fill the gaps.

Hct drops
Hct measurements were taken from lab results in the EHR. Hct drops were calculated as the percent decrease between the lowest post-delivery Hct measurement and the last pre-delivery Hct measurement (with a decrease denoting a positive Hct drop).

Definition of the PPH severity framework
A PPH severity framework was built including 5 severity levels. The levels were defined as follows:

- **PPH Level 0**: No PPH
- **PPH Level 1**: Use of uterotonic medications, aside from Pitocin, as documented in the EHR (search terms: methergine, ergonovine, cytotec, misoprostol, hemabate, and carprofen).

- **PPH Level 2**: ICD-9 or ICD-10 diagnosis code for PPH (ICD-9: 66600, 66602, 66604, 66610, 66612, 66614, 66620, 66622, 66624, ICD-10: O720, O721, O722).

- **PPH Level 3**: transfusion of 1-3 units red blood cells as documented in the hospital’s bloodbank, or receipt of a Bakri balloon, which is a uterine tamponade device available across our health system, as documented in EHR notes (search term: Bakri).

- **PPH Level 4**: ≥4 units red blood cells, or hysterectomy on the delivery visit (ICD-9: 68.29, 68.39, 68.49, 68.69; ICD-10: 0UT90ZZ, 0UTC0ZZ, 0UTC70ZZ, 0UBC0ZZ, 0US90ZZ).

Each patient was placed into only one level of the PPH framework on a given visit, corresponding to the highest PPH level they qualify for. So, for example, a patient who received both uterotonics and a Bakri balloon would be placed in PPH level 3 only.

**Logistic regression analysis**

To compare performance of our PPH severity phenotyping model against other methods in predicting a large Hct drop, we built a logistic regression model that predicted ≥28.6% Hct drop (the ‘silver standard’ developed in Figure 1) based on 6 variables: uterotonic administration (aside from oxytocin), coded PPH, Bakri balloon, any transfusion, number of transfusions, and hysterectomy.

**Quantitative blood loss**

QBL readings were extracted from flow sheet data in the EHR. Readings were only available in 2 of our 4 hospitals, and only for part of the time range of the study (January 2016 – July 2017), as the technology is not yet broadly implemented in our hospital system. In quality checks, we noticed that a high percentage (44%) of all QBL readings were divisible by 50. We excluded these readings, assuming that they were actually EBLs that had been inadvertently entered into the QBL flow sheet. After this filtering, there remained 285 QBL values for distinct visits.

**Data handling & analysis**

All data cleaning was done in SQL and R, and data analysis was done in R.

**Framework validation against QBL**

As a validation of our framework, we compared its performance in predicting QBL vs. the performance of analogous, 5-level severity frameworks that are based solely on Hct % drops. We focused on the 255 delivery visits for which we had both QBL and Hct measured (excluding one outlier measurement).

Patients were split into five severity levels so that the Hct-based measure could be fully analogous to our severity framework (which also includes 5 PPH levels when counting “no PPH”). To construct an Hct-based framework, we chose 4 random Hct cutoffs to categorize patients into 5 severity groups, restricting each group to contain at least 10 patients. We did this 1000 times with random Hct cutoffs, so that we could understand how Hct-based 5-level frameworks perform versus our PPH severity framework. To assess ‘goodness’ of a given Hct-based framework, we calculated it’s R^2 value in predicting QBL levels. We present the distribution of R^2 values from different Hct-based frameworks, versus the R^2 value from the PPH severity framework that we build based on clinical records of diagnoses and interventions.

**Results**

**How best to identify PPH using Hct drops?**

Our point of departure in this study is Hct drop, because Hct is ubiquitously measured and could be used universally as a phenotype for PPH if it were sufficiently accurate. Hct drop has been cited before as a proxy for PPH, typically with a cutoff of 10%. A natural question to ask with any new phenotyping method for PPH is: how does it compare to using Hct?

To answer this, we tuned a cutoff of Hct % drops across our whole cohort of patients such that the F-measure is maximized for predicting coded PPH. F-measure balances positive predictive value and sensitivity to achieve a harmonic mean (Figure 1a). The optimal Hct cutoff for predicting coded PPH, which we consider to be silver standard,
is 28.6 percent Hct drop (Figure 1b-c). We present test statistics for this optimal cutoff, plus several other Hct cutoffs that present whole numbers, one of which (30%) performs similarly.

**Figure 1. Development of an optimal Hct cutoff to predict coded PPH.** (a) Definition of F-measure, the harmonic mean of positive predictive value (PPV) and sensitivity. (b) Hct drops across our cohort are shown for patients with vs. without coded PPH. (c) For different Hct cutoffs, test statistics are shown for predicting coded PPH. The blue cutoff maximizes F-score. (d) Test statistics are listed for 3 Hct cutoffs (NPV = negative predictive value), with arrow colors corresponding to the colors of vertical lines in panels b and c.

**Construction of a multi-level PPH framework**

To go beyond Hct drop in predicting PPH, we developed a framework to phenotype patients into different PPH severity levels. Hct drops were used in the construction of the framework to help rank the severity of patient populations receiving different interventions (Figure 2a). The reasoning behind using Hct levels in this way is that, although they are noisy on an individual patient level, the noise would cancel out over a large population and be informative on aggregate about which interventions were used on more severe patients. However, Hct drops have a fundamental limit once patients become transfused, since RBC transfusions affect Hct levels. We therefore used clinical knowledge to re-rank some of the interventions based on known severity (See ‘Regime 2’ in Figure 2a). The final PPH severity phenotyping framework has 4 levels beyond a base level of no PPH (so 5 levels total; Figure 2b). A patient was only placed into one severity level on a given visit, corresponding to the highest level that they qualify for.
Figure 2. Building a severity framework to go beyond Hct in phenotyping PPH. (a) Interventions and diagnosis of coded PPH are ordered according to median Hct % drop among patients in our cohort. Two ‘regimes’ are defined; the first denotes interventions that should be ordered by Hct drop, and the second denotes interventions for which Hct is unreliable, and thus clinical judgement is used to re-rank severity. (b) The resulting PPH severity framework, with Hct distributions shown.

Performance of the PPH severity framework vs Hct
With the PPH framework and optimal Hct cutoff in place, we are positioned to assess the performance of the framework in identifying PPH. For this, we compared several methods for predicting patients with PPH according to the criterion of having Hct drop ≥28.6%, as this was determined earlier to be the most informative Hct cutoff for denoting PPH. We built a logistic regression model using all factors composing the PPH framework (see Methods), and then compared its performance in predicting patients above the Hct cutoff versus several other predictors that were subsets of the framework (Figure 3a). We found that the full framework was more predictive than any subset component, including coded PPH, which notably was the factor that the Hct cutoff of 28.6% was tuned on. To compare the logistic regression results directly against binary factors (such as coded PPH), we report in Figure 3a the logistic regression cutoff that would maximize the F-measure; the full ROC curve for this model is shown in Figure 3b, with modest AUC of 0.68.

Factor used to predict >28.6% Hct drop
PPH framework constituents* 0.36 0.97 0.44 0.95 0.39
PPH level ≥ 3 0.24 0.99 0.64 0.95 0.35
Any units RBC transfused 0.22 0.99 0.68 0.95 0.34
PPH, ICD coded 0.25 0.97 0.39 0.95 0.30

Figure 3. Performance of PPH framework in predicting high Hct drops. (a) We compare different metrics, all of which are included in the PPH phenotyping framework, for their ability to predict Hct drop of >28.6% (see Figure 1). Test statistics are shown. ‘PPH framework constituents’ (denoted with a *) is a logistic regression model with cutoff tuned to maximize F-score in predicting the Hct drop cutoff. (b) ROC curve for the asterisked logistic regression.

Validation of framework vs. QBL
The gold standard for measuring PPH is QBL. We do not routinely measure QBL in our hospital system, although a small subset of deliveries in our cohort (0.6% of total) had QBL recorded (see Methods). We therefore re-examined our framework in light of these QBL measurements, and found that ranking interventions by median QBL recapitulates the exact ordering of interventions that occupy the levels of our PPH framework (Figure 4a). Importantly, the QBL
does not require a ‘reshuffling’ of some PPH interventions to form severity levels based on clinical knowledge (as Hct did: see Figure 2a), but rather it ranks interventions exactly in accordance with the framework. Unlike Hct drops (which cease to be informative once blood is transfused and thus show similar Hct distributions for PPH level 3, which includes <4 units RBC, and PPH level 4, which includes ≥4 units RBC), QBL distributions show a clear separation between PPH levels 3 and 4 (Figure 4b).

![Figure 4. Validation of PPH framework vs. QBL.](image)

*denominators are # visits from the 2 Hospitals from which we could query QBL.

PPH severity framework vs. an Hct-based framework with 5 levels

A final validation of our framework comes in the form of comparing its performance to Hct % drop cutoffs in a fully analogous framework. Since our severity framework contains 5 PPH levels (no PPH, PPH level 1, level 2, level 3, and level 4), we constructed predictors of QBL using Hct cutoffs that split the 285 deliveries for which we had QBL into 5 severity levels, using randomly chosen Hct cutoffs (methods). Fit of a framework was judged by its $R^2$ value in predicting QBL. The best of the 1000 Hct-based predictors is shown in Figure 5a, with an $R^2$ of 0.27. The PPH severity framework we present has an $R^2$ to predict QBL of 0.38, far surpassing any Hct-based predictor that could be generated (Figure 5b). A linear fit of Hct against QBL achieved $R^2$=0.21. These results reinforce that Hct is a noisy signal for blood loss, and the extra information embedded in our PPH severity framework is meaningful enough to boost it considerably beyond what Hct can do.
Figure 5. Performance of PPH Severity framework vs. a Hct-based framework  
(a) The set of cutoffs in Hct to form a 5-level system (i.e., to be comparable with ours: PPH0 – PPH4) that perform the best in predicting QBL.  
(b) The distribution of R^2 values from plots like on the left (from 1000 random Hct cutoff thresholds), versus the R^2 of the PPH severity framework.

Discussion

Importance of measuring

Many efforts are currently aimed at improving the quality of care for women with obstetric hemorrhage, as clinicians, hospitals, states, and national bodies work to decrease severe maternal morbidity and mortality. To understand the impact of these interventions, it is critical that organizations have reliable, easily accessible data that goes beyond using billing codes to demonstrate that a woman bled, required a blood transfusion, or had a hysterectomy. Proposed metrics such as ICU admission and massive blood transfusion are important but also rare, making them less useful as the only measures. The approach described herein provides a practical option for obtaining important clinical data that allows evaluation of process and outcome metrics for the treatment of obstetric hemorrhage. The framework allows assessment of early stage therapies and escalating clinical interventions targeted at stopping bleeding. Clinically, the hope is that as early aggressive interventions are increasingly employed, later stage morbidities associated with hemorrhage will be seen less frequently.

Strengths and weaknesses of framework

The PPH severity phenotyping framework has the weakness that it relies on outcome and process metrics as heuristics to judge whether a patient lost blood. Given, for example, rising PPH rates in a hospital, this makes it difficult to determine whether patients are bleeding more over time, versus more interventions being done on similar patients. Ways to better understand this might include assessing the underlying Hct drops for patients at a given intervention level (although Hct is especially unreliable after transfusion), or assessing potential under-treatment of PPH by looking, e.g., for cases of low fibrinogen levels as a reflection of patients developing coagulopathy in the setting of treatment delays. The most reliable way to move past these challenges will likely be broadly adopting QBL measurement.

In the meantime, the best practices for identifying PPH are woefully inadequate, with subjective measures (EBL) the dominant method. In this landscape, despite its weaknesses, our framework stands as the most principled method to date for phenotyping and analyzing severity of PPH. The framework also has the potential to utilize the EHR to reliably assess and track many process metrics that will be useful to teams seeking to identify whether best practices for treating postpartum hemorrhage are being adopted in their hospitals. Better assessment of process metrics should lead to an impact on outcome metrics for our patients.

Future Work

Planned future work based on the framework developed here includes multiple important efforts. First, we will use this framework to look at trends over time across our healthcare system. Active efforts have been underway to standardize and optimize PPH management through implementation of national and statewide bundles. Utilization of the principled framework will allow assessment of our bundle implementation by evaluating process and outcome measures for women with obstetrical hemorrhage. Only once we have this sort of data will we be able to proactively identify additional improvement opportunities and develop targeted strategies. Secondly, we intend to utilize the framework to look for any variation in PPH practice patterns across our system. Understanding how successfully we have standardized our management will similarly be invaluable to guide further system wide efforts. Finally, there are efforts underway to develop an obstetric hemorrhage dashboard that can be used to follow postpartum hemorrhage management and outcomes in an ongoing fashion. A dashboard including this level of granularity, rather than ICD coded hemorrhage, will be useful to observe the impact of ongoing PPH improvement efforts over time, as well as to ensure sustainability of the processes put into place to minimize morbidity and enhance patient outcomes.

Conclusion

The framework developed and presented in this work is a reflection of the power of collaboration between engaged clinicians, quality improvement team members, and data-analytics experts. None of these groups in isolation has the power to develop such a tool without input from the rest of the team. Individuals with the expertise to obtain this sort of data from the EHR can help drive clinically important improvement work with the potential for large-scale impact.
on patient outcomes. The presented phenotyping framework, a culmination of this tight collaboration, should provide a strong tool for future use in tracking obstetric hemorrhage.

Abstract

When deciding about surgical treatment options, an important aspect of the decision-making process is the potential risk of complications. A risk assessment performed by a spinal surgeon is based on their knowledge of the best available evidence and on their own clinical experience. The objective of this work is to demonstrate the differences in the way spine surgeons perceive the importance of attributes used to calculate risk of post-operative and quantify the differences by building individual formal models of risk perceptions. We employ a preference-learning method - ROR-UTADIS - to build surgeon-specific additive value functions for risk of complications. Comparing these functions enables the identification and discussion of differences among personal perceptions of risk factors. Our results show there exist differences in surgeons’ perceived factors including primary diagnosis, type of surgery, patient’s age, body mass index, or presence of comorbidities.

Introduction

When deciding about surgical treatment, an important factor driving a surgeon’s decision-making is the perceived risk for post-surgical complications. Spine surgery is no exception, especially considering that introduction of new surgical implants makes even more patients eligible for spine surgery¹. Moreover, significant variability is observed in the use of spine surgery, among different hospitals, as well as at the level of an individual surgeon²–³. Because risk is inherent in any procedure, reducing the number of unnecessary, or high-risk operations is an important issue in patient safety and will improve overall patient outcomes, reduce complication rates, and reduce the need for repeated surgery.⁴ Thus, the ability to correctly and consistently assess the risk of post-surgical complications plays an important role in deciding if a patient is eligible for surgery and what type of surgical procedure should be considered.

A spinal surgeon’s risk assessment is based on their knowledge of the best available evidence as well as on their own clinical experience. Commonly used risk assessment tools in spinal surgery include SpineSage⁵ and spinalRAT⁶, and we use these as baselines in this work. These tools consider patient demographics and additional attributes such as patient condition, comorbidities, pre-surgical diagnoses, surgical and complication detail, and others. Although little is known about how surgeons weigh available evidence and clinical experience, emphasis on experience is likely increased when little scientific evidence exists, the surgeon is unaware of that evidence, or the surgeon has discounted that evidence based on its quality. For these reasons, differences exist among spinal surgeons while assessing the risk of post-surgical complications for the same patient. These differences translate into uneven application of standards of care and inconsistent selection of patients eligible for surgery. Identification and analysis of differences should help mitigate these inconsistencies and is the topic of the research described in this paper.

The objective of our work is to identify how spinal surgeons weigh the importance of the variables in risk assessment tools. Towards this end we assess the differences in the way spinal surgeons assess risk by building formal models of risk perceptions of 6 spinal surgeons working in a large academic hospital in Canada. We employ a preference-learning method - ROR-UTADIS⁷- to build preference models that capture surgeon-specific perception of risk of complications. We previously used a similar approach to capture the professional opinions of physicians when evaluating the relevance of medical evidence for decision making⁸. While other research on preference elicitation involving surgeons has focused on treatment options⁹–¹², our work is more concerned with identifying the differences in post-surgical risk assessment and attempts to discover the most relevant clinical factors, and how surgeons balance them when making such an assessment.

Related Work

Surgical decision-making has evolved over time. What was once an intuitive matter for surgeons has now become a complex multi-faceted decision process¹³. Risk assessment has a substantial subjective element, thus there is a need
for objective tools and methods. Such approaches aid surgeon decision making but also provide realistic expectations for the patient, helping them make an informed decision.

Scoring systems that focus on postoperative outcomes are a common method for predicting risk. For example, www.riskprediction.org.uk, lists 12 risk assessment tools related to various procedures. Scoring tools are generally based on prognostic factors including age, disease severity and co-morbidity and procedure specific considerations are available to surgeons. For example, the well-known POSSUM system (Physiological and Severity Score for the Enumeration of Mortality and Morbidity), and its variants, compute information on the surgical risk in terms of morbidity and mortality by combining physiological parameters (e.g. age, cardiac status, respiratory status) with operative parameters (e.g. the type of operation, the urgency of the operation and the number of procedures).

Spinal surgery is a complex procedure and requires clinicians to evaluate the relative risk of several risk factors including age, gender, medical comorbidities, substance abuse, body mass index (BMI), medical comorbidity, previous spinal surgery, primary diagnosis and surgical approach. Given the large number of possible risk factors, many approaches to assessing spinal surgery risk have used statistical techniques such as regression and multivariate analysis. Although predictions from systems such as those described by can be individualized, they largely pertain to populations rather than an individual. SpineSage is a tool that attempts to individuateize the risk assessment of spine surgery by taking into consideration patient-specific risk factors, specifically a patients’ comorbidity profile as well as the invasiveness of the procedure. It utilizes a multivariate log-binomial approach. Other work has employed machine learning, for example Ehlers et al. have developed a Naive Bayes algorithm that uses 300 predictors to predict risk of adverse event or death within 90 days of different types of surgery including spine surgery. Karhade et al., compared four machine learning algorithms for preoperative prediction of non-routine discharges for elective inpatient lumbar degenerative disc disorders and found a neural network approach to be the best performing with an AUC of 0.823.

In addition to the large number of factors to be evaluated, there are other emerging issues that cause poor consistency in risk assessment for spine surgery. These include an increasing number of available surgical interventions with collateral adverse outcomes that may be traded off against each other. Furthermore, risk factors vary considerably with comorbidities and different patient populations present very specific concerns. For example, surgical risk is especially challenging in elderly patients because of their levels of frailty which is not commonly considered by risk prediction systems and scoring systems or machine learning algorithms based on population level characteristics do not generalize well to all patient groups. Our approach in analyzing the preferences of a number of surgeons for multiple and heterogeneous risk factors aims to shed light on what the important decision-making inconsistencies are among spinal surgeons. We believe this is first time such an analysis has been conducted in the spine surgery domain.

Methods

The ROR-UTADIS method

In our work we assume a preference model that captures perceptions of risk of complications and is represented as an additive value function. An additive function is the sum of marginal value functions associated with specific criteria characterizing alternatives. Here alternatives correspond to patients and criteria to variables characterizing patients that are listed in Table 1. The additive value function not only provides a comprehensive assessment of a patient (in terms of perceived risk) but also, through marginal value functions, gives insight into risk perceptions associated with individual variables which is crucial for achieving our research goals.

Most methods for building additive value functions establish parameters of marginal value functions from indirect preferential information provided by a decision maker for a subset of alternatives (so-called reference alternatives), e.g., their pairwise comparisons. Usually, there are multiple additive value functions compatible with preferential information. A simple approach involves selecting any of these functions, while an advanced one takes into account and exploits all these compatible functions for more robust results. The latter approach is known as robust ordinal regression (ROR).

In our study we employed the ROR-UTADIS method that follows the ROR principle. It aims to solve a sorting decision problem, i.e., assignment of alternatives to predefined and ordered classes (e.g., risk classes). In addition to a resulting additive value function it also establishes a set of thresholds that can be imposed on obtained quantitative assessments to translate them into class recommendations. ROR-UTADIS accepts rich and diversified preferential information, including class assignments (possibly imprecise) of references alternatives, their assignment-based pairwise comparisons, and desired class cardinalities. In our analysis we focused solely on the value function and...
ignored the thresholds. Moreover, we used only the first type of preferential information, i.e., assignment of reference (paper) patients to risk classes, as it was most relevant from a practical perspective and easiest to obtain from surgeons.

Below we briefly summarize the outline of the ROR-UTADIS method. In this description we use terminology specific for our clinical problem:

1. A set of value functions that are compatible with provided assignments of patient cases to risk classes (low, medium and high) is constructed by solving a linear programming model. If this model has no solution, it indicates that some of the provided class assignments are problematic and need to be revised, and the method proceeds to step 2. Otherwise, it skips to step 3.

2. Problematic class assignments are identified by solving a 0-1 linear programming model. Found class assignments are presented to a decision maker who needs to decrease their precision, e.g., an initial assignment of a specific patient to the medium risk class is changed into an assignment to medium or high classes (the obtained solution also points to whether the assignment should be expanded towards a lower or higher risk). Once all problematic assignments have been revised, ROR-UTADIS returns to step 1.

3. A set of compatible additive value functions established in step 1 is explored and a representative additive function is constructed. This step involves solving another linear programming model that is aimed at maximizing the differences in evaluations between patient cases assigned to different risk classes and then minimizing differences in evaluations between patients assigned to the same risk classes.

Study Design

Our study population consists of 6 staff surgeons (4 orthopedic and 2 neurosurgical surgeons) from the Division of Orthopedic Surgery at The Ottawa Hospital (TOH), Ottawa, Ontario, Canada. The participants are academic, fellowship-trained spinal surgeons, with training at Canadian, American, British, and Australian hospitals. All of the surgeons work closely in a combined orthopedic and neurosurgical spine program. This study population excluded residents and included all but one of the staff spine surgeons at TOH. While all 7 staff surgeons agreed to participate, one did not provide answers. Yet this study population represents almost the entirety of the TOH spine program and thus represents the group’s thoughts. All the surgeons were considered to have the same experience level.

Study participants were provided with a set of 15 representative hypothetical patient cases described by a set of 7 features that are available at the time of first consult. First consult is typically when surgery is planned and considered when evaluating risk of post-surgical complications (see Table 1). These features include type of the surgical procedure and how it was conducted (often called “approach”), diagnosis, features associated with comorbidities such as diabetes, hypertension, and known bleeding diathesis, age, and BMI. The patient cases were developed by an independent spinal surgeon on the basis of cases recorded in The Ottawa Hospital Institutional National Surgical Quality Improvement Program (NSQIP) database for patients undergoing spinal surgery. The patient cases were
developed based on EHR data and represent the patient population that is being treated in the academic center. This population covers different age groups, resulting in the age variation seen across patient cases.

As a starting point, we elicited individual risk assessments from surgeons asking them to assess the risk of post-surgical complications for each patient case on a low/medium/high risk scale. In the first stage of the analysis assessments were used to construct a common additive value function representing a perception of risk by all participating surgeons. The second stage of analysis focused on building a set of surgeon-specific additive value functions to highlight differences in individual risk assessment.

**Results and Discussion**

The patient cases considered in this study and the assignments to risk classes provided by the participating surgeons are given in Table 2. As summarized in the bottom portion of the table, there exists a fairly large number of disagreements among surgeons with regards to the perceived risk of post-surgical complications. Indeed, only one patient case (P6) had the same risk assessment from all spinal surgeons, while one third (5/15) of the patients had risk assessments that span the whole spectrum from low to high risk.

**Table 2.** Risk assessment of the 15 paper cases (P1-15 in columns) by the 6 spine surgeons (S1-6 on rows). The bottom part of the table reports frequency of risk classes for each patient when pooling all surgeon assessments together.

In the first stage of the analysis, we combined individual assessments to build an overall additive value function capturing common risk perception by all participating surgeons. Merging responses provided by specific surgeons resulted in imprecise risk class assignments that were provided as input to the ROR-UTADIS method. For example, patient P1 was assigned to low or medium risk classes, P2 to all risk classes, and P3 to medium and high risk classes. Figure 1a shows the marginal risk functions obtained for the combined assessments. Each marginal function describes how values of a specific feature contribute to the perception of risk with feature values being reported on the X-axis and the contribution on the Y-axis. The latter is expressed using a scale from 0 (no contribution) to 1 (maximum risk).
Figure 1. Marginal risk functions for combined assessments of all surgeons (a) and for individual surgeons (b). Functions on a single row refer to a specific feature, while columns represent either the group of all participating surgeons or individual surgeons (S1-S6).

Findings from this stage of our study align with common clinical practice and general guidelines for spine surgery. Procedure type/approach and diagnosis all emerged as contributing to the risk of post-surgical complications. The
same can be said about diabetes. Age and BMI contributions depend on values recorded for a patient. Initially for low values these two features are not contributing to risk, this starts to change after a threshold of 60 years of age and BMI of 25 (this is aligned with what clinical guidelines state), to finally become major drivers for risk of complications for high values - age greater than 85 and BMI greater than 30. Hypertension and bleeding diathesis do not impact the perceived risk of post-surgical complications.

In the second stage of the analysis we applied ROR-UTADIS again in order to discover if individual surgeons differed in the ways they evaluate the importance of specific features and their values. The method was not initially able to construct additive value functions for S3, S4, S5 and S6 and identified problematic class assignments for some patient cases (P2, P4, P7, P8, P9, P11 and P14). These assignments had to be revised by making them less precise (e.g., the risk class assignment of P2 by S3 was changed from medium to low or medium), while the remaining precise assignments reported in Table 2 were kept unchanged.

Surgeon-specific marginal value functions are reported in Figure 1b. Interestingly, surgeon-specific models highlight how the two categorical features characterizing the type of procedure type/approach and the diagnosis have different impact on risk according to individual surgeons. S6 does not attribute any additional risk to the different procedure type/approach categories used in this study; S1 and S2 consider anterior cervical surgeries to be associated with smaller risk and attribute the same risk to the surgeries with posterior approach; finally, S3, S4 and S5 consider thoracolumbar surgeries considerably more risky than cervical ones. A somewhat similar consideration is true for the diagnosis feature where S4 and S5 consider operating on patients with degenerative and traumatic lesions as associated with the same risk, while the other surgeons attribute more risk (with different intensities) to traumatic lesions. These observations are explained by the fact that procedure type/approach and diagnosis together describe the overall complexity of a patient case. However clinical experience of each surgeon and the frequency of operating on a specific group of patients (e.g. trauma) or performing a specific type of surgery (e.g. posterior approaches, or thoracolumbar) are likely to influence the risk propensity that they ascribe to individual features.

Diabetes, hypertension, and known bleeding diathesis are all well-known risk factors but the specific weighting of each of them in the risk assessment process is subjective to the individual surgeon considering both evidence and experience. This is reflected in the fact that only a subset of surgeons attribute marginal risk when any of these features is present. For example, S2, S3, S4 and S5 do not consider operating on diabetic patients riskier, while S1 and S6 attribute an important (0.30) risk contribution to having diabetes. The observed variability of weights attributed to the same feature by different surgeons (e.g. hypertension has a non-zero weight only for S6) is also an example of subjectivity as a result of surgeons’ experience and available evidence.

Features such as age and BMI are also commonly considered risk factors, but little is known as to whether the risk increases linearly, exponentially, or in a stepwise fashion at certain threshold levels. Furthermore, chronological age does not necessarily accurately reflect physiological age or general health. These considerations make the contribution to risk of factors like age and BMI very subjective in terms of cut-off points. Surgeon-specific models shown in Figure 2 reflect this variability, but still highlight the fact that age and BMI influence risk for all but one surgeon. After discussing the results with the participating surgeons, it was confirmed that for some a threshold impacting risk assessment can be set at BMI=25 while for others at BMI=30 or even more. Similarly, some surgeons will not operate on patients over 90 years old as they consider this age group to be of too high risk of post-surgical complications.

While the list of features considered in our study is small compared to existing tools such as SpineSage and spinalRAT, we can still make several observations applicable to these tools. SpineSage uses age, surgical invasiveness score, bleeding disorder, congestive heart failure, and diagnosis of spine trauma and spine infection to predict any complication and age, surgical invasiveness score, gender, chronic pulmonary disease, hypertension, previous cardiac history, and diagnosis of spine trauma and spine infection to predict major complications. spinalRAT uses age, gender, comorbidities, preop diagnosis, location of surgery, use of BMP, fusion status, and instrumentation status for predication. While these features are more comprehensive than ours, we have commonalities (age, comorbidities, diagnosis) in our feature set. These common features, and proxies for others, allow us to deduce that surgeons will perceive the importance of the features in a similar manner when using SpineSage, spinalRAT, and other similar tools.

**Conclusion**

Spinal surgeons’ decision-making process is driven by the scores reported by risk assessment tools they use to quantify post-surgical complications. However, their interpretation and weighing of the importance placed on each attribute used to calculate these scores varies. The relative contribution of each attribute is vital in making accurate predictions.
of complications and should be considered when using these assessment tools for surgical decision-making. As such, the relative importance of the attributes that make up each score, as determined by a surgeon, should be better explained to inform the construction of the surgical plan and to educate the patient.

In this work, starting from data collected from 6 experienced spinal surgeons, we built a formal additive model summarizing contribution of specific factors to the risk of complications for spine surgical patients. The overall model elicited for all surgeons aligns with available scientific evidence, highlighting variables that the majority of surgeons deemed important for risk assessment. However, significant differences were observed in the way individual surgeons assign importance to attributes used to evaluate risk. Our preference-learning-based method proved effective in discovering these differences and enabled in-depth discussion with the clinical experts involved. Results suggest that factors such as overall complexity of the surgery, presence of comorbidities, age, and BMI all play an important but highly subjective role in complication risk assessment for spine surgery and ultimately need to be carefully considered during spine surgery planning.

Our study includes several limitations that are mentioned below:

- The preference model represented as an additive value function assumes independence of different variables and does not consider interactions among them;
- The number of surgeons participating in the study is limited to 6 and all of them practice in the same institution;
- Evaluations were conducted on patient cases that, albeit realistic, constitute a simplified approximation of a real patient case;
- Patient cases evaluated by surgeons excluded day surgeries, which represents a relevant proportion of spine surgical interventions, but are intrinsically low risk.

Future research will address some of the limitations of our current approach. For example, considering rule-based preference models that are able to capture interactions between features, using richer description of patients and involving a larger number of participants. Collecting more preference-oriented data (e.g. including surgeons still in training, as well as across different sites) will result in creating a decision support tool that allows insight into the trade-offs between the different factors involved when evaluating risk.

Abstract
This study focuses on interruptions in an inpatient pharmacy setting and the impact of CPOE implementation on the types, frequency, and duration of interruptions. A cross-sectional observation study of pharmacy employees in an inpatient pharmacy was conducted. The independent variables included day of week, time of day, job position of the person interrupted, and description of each interruption. A total of 552 interruptions were observed with a mean frequency of 10.6 interruptions per hour lasting a mean (SD) duration of 1.34 (1.43) minutes. Incoming calls were the most frequent interruption type across all phases. Pharmacy employees spend almost a quarter of their time on interruptions, and pharmacists have longer interruptions than technicians. Immediately after CPOE implementation, durations tend to be one-and-a-half times longer than before. CPOE implementation did not affect the frequency of interruptions. Recommendations included redesign of work processes and job responsibilities.

Introduction
Medication error is a major cause for concern within the healthcare sector have major safety and cost implications. Such errors lead to approximately 9,000 preventable deaths per year and accrue costs due to increased lengths of stay. Hospital pharmacy accounts for approximately 15 percent of a hospital budget. Hence, understanding the root causes of medication errors and changing work processes is vital to improving safety, reducing costs and achieving higher levels of overall quality of healthcare. One type of medication-related error is a dispensing error occurring within pharmacy. Medication dispensing errors can be attributed to several causes such as staffing constraints, excessive workload on pharmacists and technicians, interruptions and distractions, lighting levels, and noise. Interruptions in physicians have been studied and have been associated with errors. Pharmacy interruptions can also impact performance, and such interruptions are a major concern especially with pharmacists and technicians working on visual tasks. Research studies indicate that interruption of an activity may have a negative impact on human performance. This is because the mean processing time is higher for a task that was interrupted than if the task was not interrupted. Further, previous work has found that physicians and nurses generate twice as many interruptions as they receive, leading to an interruptive workplace and contributing to inefficiency in work practice. Since the focus is on continuous quality improvement and value of the care provided to patients, it is important to understand interruptions and their factors, to redesign work processes and improve quality.

Hospitals are implementing new technology such as electronic medical records, Computerized Prescriber Order Entry (CPOE), electronic medication order processing, electronic medication administration record (eMAR), etc. Some authors have proposed that health information technologies ultimately increase clinicians’ access to data and thus may decrease interruptions between clinicians asking for clarification or information. However, others have observed that newly implemented health information technologies, such as electronic medical records or medication administration tools, increase complication of work tasks, disrupt work flow (including increases in interruptions), and do not support clinician information needs. They may also disrupt communication and coordination processes between various clinical personnel. Further, much of the existing work on the effect of implementing health information technologies on work flow has focused on single clinician types or a single unit or work environment. Less is known about the implications to work processes across disciplines and work areas. CPOE, in particular, has been shown to impact work flow and processes beyond physician providers. It is also important to note that computer-based health information technologies are generally not used in isolation; clinicians may regularly be interrupted while performing data entry and retrieval tasks and these interruptions have been cited as a source of increased errors following implementation of health information technology. Hence, it is important to study interruptions with respect to technology implementation beyond isolated professions/disciplines and understand trends and patterns to redesign work processes and improve quality of care.

The overall objective was to study the impact of technology implementation, specifically CPOE, on interruptions in an inpatient pharmacy. The specific research question was to study how technology implementation affects, types of interruptions, frequency of interruptions, and duration of interruptions.
Method
This study used a cross-sectional observation method to record interruption types, times, durations, and pharmacy personnel involved during three data collection periods: prior to CPOE implementation, immediately post CPOE implementation, and approximately 5 months post CPOE implementation. Since the primary focus was to study the impact of CPOE implementation, the sessions were sampled to account for pre-, immediate post and later post implementation, so that the study could capture both immediate and long term effects of CPOE implementation.

Observation sessions: Prior to data collection, the study was approved by the Institutional Review Board (IRB). All pharmacists and technicians agreed to the observers being present. Three observers spent a total of 29 sessions spanning 52.25 hours in the inpatient pharmacy of a 274-bed academic hospital. Each session had one or two observers present. The observation sessions were scheduled for up to two hours each. Sessions were included from each of the three types of day classifications (Mon-Thu, Fri, and Sat-Sun), and three different time of day classifications - morning (8 a.m. to 11 a.m.), afternoon (11 a.m. to 5 p.m.) and evening (5 p.m. to 9 p.m.). These type of day and time of day classifications were identified based on significant differences in medication orders received by pharmacy across these day and time categories. Our assumption here is that based on significant differences in medication orders received by pharmacy, interruptions would be similar within these categories and different between these categories. During each session, the observers situated themselves in pre-determined locations close to the pharmacist/technician and recorded time and duration using stopwatches, and description of the interruptions. The observers focused on behavioral cues to identify interruptions (ceasing a task to respond to external stimuli). When an interruption occurred, the observers used contextual cues to determine the root cause and classified the interruption. The duration was noted until the point in time when the employee either returned to the original task or was further distracted. For cases where the observer was unable to determine the cause of the interruption, the pharmacist or technician was prompted to provide a brief description.

Calibration and inter-observer reliability: Prior to any data collection, two observation sessions were conducted to calibrate the observation process and ensure consistency in the data collection process. During these calibration sessions, all three observers were present and recorded the same set of interruptions. After completion of the second observation session, 100% consistency in the data collection and coding was achieved. To ensure reliability, the data were tested. After accounting for when the sessions were scheduled (day of week and time of day), no significant differences among the observers were identified, thus ensuring inter-coder reliability.

Data Collection: Data from the observation sessions included CPOE phase, type of day, time of day, type of interruption, job title of the person interrupted (job position), duration and description of each interruption. The type of interruption included one of six types – incoming phone calls, outgoing phone calls, discussion, window, door and hands-on task. Incoming phone call interruptions were to clarify medications, locate missing medications, confirm that the orders placed have been received, check-up on the status of the orders placed and hurry-up the processing of the orders placed. Outgoing phone calls were primarily to change a medication due to an adverse drug interaction, allergy conflict, wrong dosage, etc. While other interruptions can be detrimental to patient safety, outgoing phone calls can be argued to improve patient safety. This study does not distinguish the type of interruption as increasing/decreasing risk of errors. Rather, the primary focus is on interruptions that disrupt the smooth flow of operations. Discussion included interruptions when a pharmacy employee had to consult another employee, for instance, a pharmacist instructing the technician to fix a computer or a technician/pharmacist consulting a pharmacist on a medication-related question. Window and door refer to interruptions at the window and door respectively. And finally, hands-on task is an interruption that required the employee to have to make a major move from their location and use both hands for another task like checking the incoming tube, using the print/fax machine, writing on the board, etc. Job position refers to the person interrupted, pharmacist or technician. The description column recorded the reasons for each interruption. This data was recorded in a spreadsheet for analyses. All data variables were coded as nominal, except for duration which was coded as a scale variable. The types of interruptions, frequency and duration were the dependent variables and the rest were independent variables. For each CPOE phase, the difference in the type, frequency and duration of the interruptions were analyzed. Further for each CPOE phase, the difference in the type, frequency and duration of the interruptions by type of day, time of day and job position were also analyzed.

Analysis: The three outcomes of interest were types, frequency and duration of interruptions. Continuous variables are described using mean and standard deviation. And, univariate differences were compared using t-test and Wilcoxon rank-sum test. Nominal categorical variables were described using frequency and percentages and
univariate difference were examined using Pearson chi-square test. Specifically, for the types of interruptions, Pearson Chi-squared test was used for both the unstratified and stratified analyses. For the frequency of interruptions, there were 29 sessions with varying session duration lengths. Therefore, for this analysis, a Poisson regression model was used where the session duration with an offset was accounted for via an offset parameter and the over-dispersed variance was scaled using the deviance. We evaluated the frequency of interruption for a given session and the factors included day of the week (Mon-Thu, Fri, Sat-Sun), time of day (morning, afternoon, evening), CPOE Phase (Pre-CPOE, Immediate Post-CPOE, Post-CPOE). In addition, the difference in the variation of the rate of interruption was assessed using the Levene’s test for homogeneity.

For the duration of the individual interruptions, which was measured in number of minutes, the data was transformed via a natural log function because the original form of the data was not normally distributed. A multiple linear regression model was used to analyze the log-transformed duration of the interruptions and the variables examined include day of the week, time of day, type of interruption, job position, CPOE Phase and all pairwise interactions. For both the Poisson regression and linear regression models, a backwards elimination method with a p-value criterion of 0.05 was used for model selection.

Avoidance of bias: The sessions in the three phases were of different total lengths, however this will not affect the percent of types of interruptions observed and the duration of interruptions observed. The different lengths may affect the frequency of interruptions observed, which was addressed by normalizing the number of interruptions in any given session using the length of the session to compute the frequency of interruptions per hour.

Results
A total of 552 interruptions were observed at a mean frequency of 10.6 interruptions per hour and lasting a mean (SD) duration of 1.34 (1.43) minutes. This translates to spending 14.2 minutes dealing with interruptions for every hour of work in pharmacy. Or in other words, pharmacists and technicians working in order processing spend almost a quarter (25 percent) of their time on interruptions. Descriptive statistics of the sessions are provided in Error! Reference source not found. below, and those of interruptions are provided in Table 2.

Types of interruptions:
When the types of interruptions were analyzed using multiple chi-squared tests, no significant differences were observed across the three phases. However, within the three phases, several significant differences were found based on type of day, time of day and the job position. The type of interruptions was significantly different by type of day only for pre-CPOE and later post-CPOE phases. Interruptions during the immediate post-CPOE phase did not have any significant differences based on the type of day, see Table 3. Incoming calls were the highest across all day
types and phases. Otherwise, changes were noted with outgoing phone call, window and discussion interruption types. Window interruptions moved from being highest on Monday-Thursday pre-CPOE to Saturday-Sunday during later-post CPOE. Outgoing phone calls moved from being highest on Saturday-Sunday and Monday-Thursday during pre-CPOE to Friday during later post-CPOE phase. Discussion interruptions moved from being highest on Saturday-Sunday pre-CPOE to highest on Monday-Thursday during the later post-CPOE phase.

The time of day was significant only during the pre-CPOE phase, see Table 3. Again incoming calls was the highest type of interruption across all times of day. Otherwise, discussion interruptions tend to be higher during mornings and afternoons, while outgoing calls tend to be higher during mornings and nights. The time of day was not significant for immediate post-CPOE and later post-CPOE phases. The types of interruptions received by pharmacists and technicians across all three phases were also significantly different, Table 3. Specifically, regardless of CPOE implementation phase, incoming calls were the highest for both pharmacists and technicians. In addition, when pharmacists were interrupted, they typically tended to have discussion or outgoing phone call interruptions. Whereas, technicians were interrupted more by incoming phone calls and window interruptions.

Frequency of interruptions:
To analyze the frequency of interruptions, the frequency was computed for each session based on the number of interruptions that occurred and the total duration of that session. When frequency of interruptions (number of interruptions per hour) was analyzed no significant relationships were identified. In other words, there is no significant evidence to suggest that frequency of interruptions were different for the three CPOE phases. On average, the pharmacy experiences approximately 10.12 (SD = 3.67) interruptions per hour during the course of its daily operations. The rate of interruptions tends to vary slightly and increases from an average of 9.51 interruptions per hour in during Mondays-Thursday to 10.84/hour in the weekends. However, this difference is not statistically significantly (p=0.7707). In terms of time of day, the opposite trend is observed where on average there are 10.92 interruptions per hour during the morning and decreases to 8.96 per hour in the evening. Similarly, this decrease is also not significant with a p-value of 0.5738. Through the three phases of CPOE, an increasing but not significant rate of interruptions per hour was observed from 9.63 per hour during the pre-CPOE phase, to 10.18 per hour during the immediate post-CPOE phase and to 10.65 per hour at the later post-CPOE phase (p=0.8028). However, significant differences in the variation of the rate of interruption was found across the three CPOE phases (p=0.0384). Specifically, the variation in the rate of interruptions increased significantly from pre-CPOE to immediate post-CPOE to post-CPOE phases. Please note that differences in variation of interruption rate across days of the week and times of the day were not significant.

Duration of interruptions:
When duration of interruptions was analyzed, there were significant differences (p-value=0.0002) between the three phases (pre-, immediate-post and later-post). The mean duration per interruption increases from 1.1 (1.16) minutes during pre-CPOE to the highest level of 1.7 (1.88) minutes during immediate post-CPOE and drops back to 1.3 (1.25) minutes during later post-CPOE. Time of day was a significant factor during the pre and immediate post
phases, with mornings having the shortest duration and evenings with the longest duration of interruptions. Another important factor affecting the duration of interruption was the job position, technician interruptions tend to be shorter than pharmacist interruptions. This was significant across pre-CPOE and later post-CPOE phases. Both pharmacist and technician interruptions increased to the highest level during the immediate post-CPOE phase. While the pharmacist interruption duration increased 58 percent, the technician interruption duration increased only 22 percent. Type of day did not have any significant effect on the duration of interruptions in any of the three CPOE phases.

711
Duration was analyzed using regression, where the durations were converted to a log scale. Based on data collection, window, door and hand-on task interruptions were aggregated to be listed as “Other.” This is both because, of the primary interest in incoming phone calls, outgoing phone calls and discussion interruptions and of the small frequency of these “other” interruptions not all of these occur in all stratifications, for instance, there are no morning hands-on tasks or evening door interruptions.

Given the sample size, the duration was analyzed using t-test. Overall, duration of interruptions showed several significant relationships. Durations of interruptions involving pharmacist are significantly longer than interruptions involving technicians (p<0.0001). Table 5 shows “Technician” as the reference for “Job Position” and the estimate is positive. Similarly, the durations of interruptions were significantly different during various phases of CPOE (p=0.0006). Specifically, the duration of interruptions in the pre-CPOE phase were significantly shorter than the interruptions immediately post-CPOE (P=0.0001) and later post-CPOE (P=0.0006). Furthermore, durations of interruptions immediately post-CPOE were found to be significantly longer than interruptions later post-CPOE (p=0.0012). Stress type by itself was not significant with regard to the duration of interruptions. However, stress type along with the time of day have an interaction effect and significantly affect the duration of the interruption (p=0.0056). Please refer to Figure 1 for the trend in interruption duration of stress type by time of day. Overall, durations shows an increasing trend as the day progresses with lot of variation in the afternoon. Further, there are different patterns for different type of interruptions. Incoming calls fairly stay the same (with a slight increase) from morning to afternoon and drastically increase into the evening. On the other hand, outgoing calls increase rapidly from morning to afternoon and stay approximately the same into the evening. And, discussions have a gradual increase through the day. Other interruptions show drastic changes, with the least duration in the morning to the maximum in the afternoon and the least in the evening.

CPOE interruptions:
Following these results, the interruption description column was also analyzed. There were a total of 22 interruptions in the immediate post and two interruptions in the later post phases respectively, that were related to CPOE. These were analyzed for differences in types and duration of interruptions. There was a significant difference (p-value=0.0002) in immediate post-CPOE phase between CPOE interruptions and non-CPOE interruptions. Discussions tend to be almost six times more likely with CPOE interruptions. Duration was significantly different (p-value=0.003) for immediate post-CPOE phase. CPOE interruptions are almost twice the length of non-CPOE interruptions.

Discussion
Hospitals have been identified as interruptive environments\(^{28}\), and as can be seen from our study, pharmacists and technicians spend almost 25 percent of their time on interruptions. This study focused primarily on the effect of technology implementation on interruptions in inpatient pharmacy. Overall, CPOE implementation disrupted order processing operations, and specifically had an impact on the type of interruptions and duration, but insufficient evidence exists with regard to the impact on the frequency of interruptions. CPOE implementation, by itself, had an impact only on the duration of the interruptions. With the type of day, it also had an impact on the types of interruptions. And, along with time of day and job position, they had an impact on both the types and the duration of interruption. Specifically, the types of interruptions were different, a) by type of day for pre- and later post-CPOE phases; b) by time of day for pre-CPOE phase; and c) by job position for all three phases. The duration of interruptions was different a) by time of day during pre and immediate post-CPOE phases; and b) by job position for immediate post and later post-CPOE phases.

Previous research has found that workers will adapt and use work-arounds to cope with disruptions in work flow following implementation of CPOE\(^{29, 30}\). Phone calls between providers have been used as work-arounds, which may have implications for changes in interruptions following implementation of health information technologies like those trends found in the current study\(^{29}\). We confirm this by noting that almost 70 percent of the interruptions were incoming phone calls and almost 80 percent are all phone-related interruptions.
CPOE interruptions in the immediate post-CPOE phase were almost twice the length of other interruptions, and tend to be six times more likely to lead to discussions. This is consistent with previous work that has shown that computer users prefer to seek guidance or help from peers or local experts instead of printed manuals or other computer-based documentation sources. Thus, post implementation of CPOE, we may see increases in interruption duration as clinicians are consulting the pharmacy not only for their normal questions, but also for technical support and guidance. This has major implications for work flow, since discussion type interruptions have a multiplier effect since they involve interruptions for other pharmacy employees. This increase in duration in the immediate post-CPOE phase may be attributed to “learning curve” phenomenon.

CPOE has been shown to have a significant impact on work processes across medical professions (including nurses, physicians, pharmacists and technicians) by reassigning tasks, reallocating decision-making or expertise, and redistribution of power. We found differences in interruptions based on job position (between pharmacists and technicians). Pharmacists more likely to have discussions and outgoing phone calls, and technician are more likely to have window interruptions. Further, after CPOE implementation, the duration increases considerably more for pharmacists, and the likelihood of discussion interruptions for pharmacists also increases. These highlight that technology implementation may be more disruptive to pharmacists than technicians. Hence, in a technology implemented era, job responsibilities and work flow need to be revisited. Further, as pharmacists assume clinical/rounding pharmacist roles, work redistribution response to interruptions needs to be further studied.

This study considered outgoing phone calls as an interruption disrupting smooth flow of operations. There is a potential argument to consider outgoing phone calls as reducing risk of error and thereby enhancing patient safety. Such a study in the future can focus on distinguishing risk-reducing and risk-increasing interruptions. Our research is based on one hospital and hence restricts its generalizability. The focus is on inpatient pharmacy and does not apply to commercial pharmacy. However, where possible, we link our work to previous research on interruptions in general and shed more light on pharmacy interruptions. The study included sampling from specific times of day; there were no night sessions. Thus, there may be different interruption patterns during time periods not included in the study. However, sessions were scheduled to cover a range of work demand periods across all days of the week and the highest work demand periods of the day. Such targeted observational studies with similar sampling methods have been successfully used to quantify system and worker responses, as well as changes to processes, during naturally occurring changes in an organization, such as the implementation of health information technologies.

Conclusion

Pharmacy employees spend almost a quarter of their time on interruptions, and pharmacists have considerably longer interruptions than technicians during all phases related to CPOE implementation. Immediately after CPOE implementation, durations tend to be one-and-a-half times longer than before, and CPOE interruptions are almost twice as long as non-CPOE interruptions. CPOE implementation does not affect the frequency of interruptions. Our research stresses on the effects of technology implementation and the significant differences in interruptions due to other related factors. Next steps should involve study of origin of interruptions and focus on redesign of work processes and responsibilities of pharmacists and technicians. Further, as the pharmacists’ roles evolve to assume clinical responsibilities as a ‘rounding pharmacist’, changes in the effects on interruptions should be revisited.

**Abstract**

Adverse event report (AER) data are a key source of signal for post marketing drug surveillance. The standard methodology to analyze AER data applies disproportionality metrics, which estimate the strength of drug/side-effect associations from discrete counts of their occurrence at report level. However, in other domains, improvements in predictive modeling accuracy have been obtained through representation learning, where discrete features are replaced by distributed representations learned from unlabeled data. This paper describes aer2vec, a novel representational approach for AER data in which concept embeddings emerge from neural networks trained to predict drug/side-effect co-occurrence. Trained models are evaluated for their utility in identifying drug/side-effect relationships, with improvements over disproportionality metrics in most cases. In addition, we evaluate the utility of an otherwise-untapped resource in the Food and Drug Administration (FDA) AER system – reporter designations of suspected causality – and find that incorporating this information enhances performance of all models evaluated.

**Introduction**

The need for post-marketing surveillance of the unintended effects of pharmaceutical products has been repeatedly highlighted by the withdrawal of drugs on account of previously undetected serious side effects¹. Notoriously, the widely utilized Cox-2 inhibitor Vioxx (rofecoxib) was removed from market five years after release as it was shown to significantly increase the risk of myocardial infarction, and was estimated to have caused between 88,000 and 140,000 coronary cardiac events in the United States alone while on market²,³. More recently proton pump inhibitors, many of which are available without prescription, have been shown to significantly increase risk of bone fracture as well as chronic kidney disease⁴,⁵. These findings are not atypical – between the years of 2001 and 2010, nearly one third of drugs approved by the US Food and Drug Administration (FDA) had a subsequent safety event in the form of a label change, safety communication or withdrawal⁶. The median time from drug release to detection of such events was 4.2 years⁶. The morbidity and mortality caused by previously undetected drug side effects could be mitigated by earlier detection, as could the societal costs of such adverse events – estimated at 3.5 billion dollars in 2006⁷. One solution to the inherent shortcomings of clinical trials in detecting adverse drug events (ADEs) is improving their identification after release to market. Consequently, post-marketing surveillance through pharmacovigilance, defined as “the study of the safety of marketed drugs under the practical conditions of clinical use in large communities”, is an essential component of drug safety⁸.

Traditionally, such safety surveillance has involved the analysis of reports of suspected ADEs submitted by healthcare practitioners, pharmaceutical companies and patients. In the United States the FDA maintains the FDA Adverse Event Reporting System (FAERS), providing a database of ADE reports from as early as 1969⁹. Adverse events in the AERS are reported by healthcare professionals, consumers, and pharmaceutical companies. Each report includes one or more adverse events that appear to be associated with the administration of a drug as well as other drugs prescribed to the patient concerned and their therapeutic indications. Of importance to the current research, reporters have the opportunity to indicate which of a set of prescribed drugs they suspect caused the ADE under consideration, by designating these drugs as primary (presumed cause) or secondary (potential cause) suspects. Large numbers of reports exist in this repository, with over a million received in the year 2014 alone¹. Consequently, automated methods of analysis are a prerequisite to the identification of actionable safety signals.
An important component of post-marketing drug surveillance is the identification of statistically significant drug/side-effect association, termed “signal detection”, and considerable research has been devoted to the development and evaluation of methods for this purpose. In order to identify meaningful associations from large and unlabeled data sets such as AERS reports, data mining techniques known as Signal Detection Algorithms (SDAs) are employed. SDAs can be subdivided into two main classes, disproportionality analysis (DPA) and multivariate modeling. DPA methods quantify the extent to which drugs and side-effects are reported together beyond what would be expected by chance. For a review of DPA methodologies, we refer the interested reader to Bate et al. Multivariate modeling can mitigate for confounding polypharmacy variables as well as the lack of a quantitative drug prescription frequency. SDAs are the most frequently utilized methods used in analyzing AERS data, and they are well documented in the post-marketing drug surveillance literature.

While SDAs have shown their utility as a means to identify safety signals from adverse event reports, they are not without limitations. In particular, they lack the capacity to draw connections between similar drugs (e.g. the entire family of selective cox-2 inhibitors) and related side-effects (e.g. myocardial infarction and other cardiac events such as stroke) as a means to enhance the strength of safety signals for relatively rare events. This situation is analogous to recent developments in natural language processing (NLP), where discrete ‘one-hot’ vector representations of words have been largely superseded by distributed vector representations, which are learned from a large unlabeled corpus such that words that occur in similar contexts have similar vectors. In the current paper we adapt skip-gram neural embeddings, a widely used representation learning technique in NLP embodied in the popular word2vec software package, to the task of representing drugs and side-effects appearing in FAERS data and evaluate their utility as a means to detect safety signals.

Specifically, this paper describes aer2vec, a novel representational approach for adverse event report data in which a neural network is trained to predict drug/side-effect co-occurrence events. The trained model is evaluated for its utility as a means to identify causal drug/side-effect relationships. Our approach leverages methods of distributional semantics to represent the AERS database as a vector space. Distributional semantics methods - such as the neural embeddings implemented by word2vec - attempt to model the semantic similarity and relatedness between words. These methods are based on the distributional hypothesis which states that words that occur in similar contexts tend to have similar meanings. A broad range of methodological approaches have been applied to learn word representations from text (for reviews see). A recent trend involves the application of neural-probabilistic models, such as the skipgram and continuous-bag-of-words architectures embodied in the popular word2vec and fastText software packages. As implied by the term “neural-probabilistic”, these models are trained to predict the occurrence of a context word given an observed term. Although generally utilized during training only, this probabilistic aspect of the model can be used to recover learned probabilities for observing one word in the context of another. It is this aspect of neural-probabilistic models that we adapt to represent AERS data in the current work.

Our primary hypothesis in conducting this work was that, at least in some cases, the capacity of distributional semantics models to generalize between similar drugs and side-effects may lead to improved performance in the task of identifying drug/side-effect relationships. A secondary hypothesis was that restricting the data considered by our models, and perhaps baseline disproportionality metrics also, to designations of primary and/or secondary suspect may improve their performance.

Methods

Disproportionality metrics: We compare the performance of our models to two widely-used disproportionality metrics, the Proportional Reporting Ratio (PRR) and the Reporting Odds Ratio (ROR). Disproportionality metrics are derived from 2x2 contingency tables (Table 1) constructed using report level statistics:

<table>
<thead>
<tr>
<th></th>
<th>ADE of Interest</th>
<th>Other ADE’s</th>
</tr>
</thead>
<tbody>
<tr>
<td>Drug of Interest</td>
<td>a</td>
<td>b</td>
</tr>
<tr>
<td>Other Drugs</td>
<td>c</td>
<td>d</td>
</tr>
</tbody>
</table>

718
From this table, we derive two disproportionality metrics, the PRR and the ROR. The PRR estimates the probability of an ADE given a drug divided by the probability of this ADE without the drug, or \( P(\text{ADE} | \text{drug}) / P(\text{ADE} | \neg \text{drug}) \). This probability can be calculated from the 2x2 table as follows:

\[
PRR = \frac{a}{a+b} / \frac{c}{c+d}
\]

In statistical terms, the ROR is the ratio of odds of an ADE occurring vs not occurring given a drug to the odds of this ADE occurring vs not occurring given other drugs. It is calculated from the 2x2 table as follows:

\[
ROR = \frac{a}{b} / \frac{c}{d}
\]

These disproportionality metrics provide a baseline for our evaluation.

Skipgram-with-negative-sampling: The skipgram-with-negative-sampling (SGNS) algorithm of Mikolov and his colleagues trains a shallow neural network to predict the probability of a context word \( c \) occurring nearby to an observed word \( w \), \( P(c | w) \). For example, given the sliding window “adverse [drug] events”, the model would be trained to optimize \( P(\text{adverse} | \text{drug}) \) and \( P(\text{events} | \text{drug}) \). While it would in theory be possible to train this model using a softmax objective in which all other unique terms in the corpus are considered as counterexamples to the observed context term in every window, this would be computationally intractable. The SGNS algorithm provides a practical way to train neural embeddings by instead considering as counterexamples a small number (usually 5-15) of negative samples, randomly drawn words that probably do not occur with the focus word within a sliding window. More formally, the optimization objective of the SGNS algorithm can be expressed as follows:

\[
\arg\max_{\theta} \sum_{(w,c) \in D} \log \sigma(v_c, v_w) + \sum_{(w,c') \in D'} \log \sigma(-v_{c'}, v_w)
\]

where \( w \) are observed words in a set of documents \( D \), and \( c \) and \( c' \) are context terms that occur with these observed terms in a sliding window or are randomly drawn as counterexamples respectively. \( v_w \) and \( v_c \) are vector representations of these terms, specifically the input weights \( (v_w) \) and output weights \( (V_c) \) of the neural network for each term in the vocabulary. \( \sigma \) is the sigmoid function, which converts the scalar product between these vectors into a value between one and zero which can be interpreted probabilistically. Training in SGNS occurs through stochastic gradient descent with a linearly decreasing learning rate. The algorithm has several hyper-parameters that have been shown to influence performance across tasks. Of importance for the current paper, the number of negative sample terms drawn as counterexamples to each observed term is a parameter of the model, and these terms are drawn with a probability derived from the frequency, \( f \), with which they appear in the corpus (i.e. \( f = \text{count} / \text{total number of non-unique terms} \)). Another hyper-parameter setting concerns subsampling – ignoring terms occurring above a predetermined frequency threshold \( t \) with probability \( 1 - \frac{2}{\sqrt{f}} \). With SGNS, the input weights are usually retained as word embeddings and used in downstream tasks, and the output weights are discarded. However, \( P(c | w) \) can be estimated by retaining these weights and calculating \( \sigma(v_c, v_w) \).

aer2vec: With aer2vec, we adapt the SGNS algorithm to estimate probabilities for drug/side-effect relations from AERS data. We derive two neural architectures, aer2vec + which estimates \( P(\text{drug} | \text{ADE}) \) and aer2vec - which estimates \( P(\text{ADE} | \text{drug}) \). Our motivation in developing distinct architectures for each of these estimates was to ensure that only information pertinent to an estimate of interest is encoded by the architecture responsible for it, eliminating one channel through which noise might be introduced. In addition we wished to determine which of these two possible neural-probabilistic estimates is of greater utility for identification of drug/ADE relationships.
These architectures are illustrated in Figure 1, which shows a simplified aer2vec architectures for 8 side effects and 10 drugs. As is the case with the original skipgram architecture, each observed term (in this case a drug) is connected to a hidden layer by input weights, which are in turn connected to a predicted term by output weights. While the output weights are usually discarded when generating word embeddings, we retain them to facilitate predicting \( \text{P} \text{drug} | \text{ADE} \) and \( \text{P} \text{ADE} | \text{drug} \) in aer2vec+ and aer2vec- respectively. When trained with negative sampling, the aer2vec architectures have the following optimization objectives:

\[
\text{aer2vec}^+: \arg \max_\theta \sum_{(\text{ADE}, \text{drug}) \in R} \log \sigma(v_{\text{drug}}^i, v_{\text{ADE}}^j) + \sum_{(\text{ADE}, \text{drug'}) \in R'} \log \sigma(-v_{\text{drug}}^i, v_{\text{ADE}}^j)
\]

\[
\text{aer2vec}^-: \arg \max_\theta \sum_{(\text{drug}, \text{ADE}) \in R} \log \sigma(v_{\text{ADE}}^i, v_{\text{drug}}^j) + \sum_{(\text{drug'}, \text{ADE'}) \in R'} \log \sigma(-v_{\text{ADE}}^i, v_{\text{drug}}^j)
\]

This is similar to SGNS with word windows, with the exceptions that (1) co-occurrence occurs at the level of a report (\( R \)) rather than a sliding window; and (2) drugs and ADEs have either input weight vectors or output weight vectors depending on the model, whereas words in neural word embeddings have both input and output weights. With aer2vec, both sets of weights are retained, permitting estimation of both \( \text{P} \text{drug} | \text{ADE} \) with aer2vec+, and \( \text{P} \text{ADE} | \text{drug} \) with aer2vec-, as \( \sigma(v_{\text{drug}}^i, v_{\text{ADE}}^j) \).

**Evaluation**

**AER data:** As data for all models, we used a standardized version of the FAERS data set released by Banda et al\(^2\). This data set contains standardized versions of the FAERS data for the years 2004 to 2013. Standardization here indicates that drugs are mapped to RxNorm concepts, and the side-effects to SNOMED-CT\(^2\). We extracted three component data sets. First, we generated an unconstrained data set (FULL), including all the drugs that were mapped to RxNorm and side effects that occur in the “pt” field of any report with them. We then use the role code variable to produce two subsets of this data set. The role codes we used were primary suspect (PS) and secondary suspect (SS). These terms denote whether a drug is the primary or secondary suspect for a side-effect, and we leveraged these to produce data subsets consisting of only drugs and side-effects in primary suspect relationships (PS), and the disjunction of primary and secondary suspect relationships (PS-SS).

**aer2vec models:** For each of the three dataset configurations, we generated aer2vec+ and aer2vec- models. All models used 500-dimensional vectors and were trained for 25 iterations across the data with five negative samples per positive example, and without subsampling of frequently occurring concepts. We did not attempt to optimize these hyperparameters in our initial experiments. During training we encoded all of the drug and ADE terms meeting the relevant constraints (PS/PS-SS/FULL), aside from a stoplist of 28 ADE terms (such as “NA”, “test”, “error”) that were identified as lacking semantic content upon inspection of the data.
**Evaluation sets:** A number of research groups have released reference standards that provide a uniform testing ground for pharmacovigilance systems. In some cases, these are manually curated reference sets of positive and negative relationships between drugs and potential ADEs\textsuperscript{23,24}. For example, the widely-used OMOP reference standard produced by Ryan and his colleagues consists of 165 positive and 234 negative examples of drug/ADE relationships, spanning four serious side-effects (such as renal failure), and developed through extensive manual review of the literature and other sources\textsuperscript{23}. These sets have been extensively curated, so there is reason to believe they are largely accurate (for positive examples in particular – some amendments have been suggested for negative controls). We evaluated aer2vec for its ability to distinguish between positive and negative controls in the reference standards produced by Ryan \textit{et al} (henceforth, OMOP) and Coloma \textit{et al} (henceforth EU-ADR) containing 399 and 94 examples respectively\textsuperscript{23,24}. For both disproportionality metrics and aer2vec models, a small number of examples were eliminated from the FULL (n=1) and PS/PSSS (n=6) configurations of the OMOP set respectively. These examples concerned the drugs “olmesartan medoxomil” (all configurations), “endopeptidases” and “alatrofloxacin” (PS/PSSS configurations), which are not present in the source data. All examples from the EU-ADR set (n=94) were retained.

**Quantitative evaluation:** For each drug/event pair in the two reference standards (OMOP/EU-ADR) under each of the three configurations (PS/SS/FULL), we calculated disproportionality metrics (PRR/ROR), as well as $P(\text{drug}/\text{ADE})$ and $P(\text{ADE}/\text{drug})$ with aer2vec+ and aer2vec- respectively. These scores were used to estimate the area under receiver operator characteristic curve (AUROC) and area under the precision recall curve (AUPRC) to provide a basis for comparison. In order to account for variance in the stochastic initialization of the aer2vec embedding weights, we retrained each aer2vec model 10 times, and report mean area under curve (AUC) across these runs.

**Qualitative evaluation:** In order to assess the likely utility of the vector embeddings generated during the course of training our models for downstream supervised machine learning, we include some examples of nearest neighbor searches amongst the input and output embeddings for the best-performing model.

**Hyperparameter settings:** Subsequent to our initial experiments, we explored the influence of two aer2vec+ hyperparameters on model performance. We repeated our initial experiments with the PS and FULL configurations at dimensionality of 100, 250, 500 (the original setting) and 1,000 dimensions; and at 100 dimensions with subsampling thresholds of $10^3$, $10^4$, $10^5$ and without subsampling (the original setting). For these experiments we used 5 (rather than the original 25) epochs of training.

**Results:**

**Quantitative evaluation:** Disproportionality metric results for all three versions of the data sets across both reference standards, are shown in Table 2. These results provide points of comparison for aer2vec. As anticipated (see for example Waller \textit{et al} \textsuperscript{23}), these metrics exhibit similar performance. Of note, both baseline metrics show an increase in performance when reducing the data set by role code. In the OMOP set, restricting to the PS-SS leads to best performance with AUROC’s of .744 for both PRR and ROR. In the EU-ADR set, best performance is obtained with the PS constraint with AUROC’s of .935 for both methods. Across both reference sets and disproportionality metrics, there is an absolute AUROC increase of approximately 10% when we reduce the full data set to the primary suspects.

**aer2vec:** Results for the two aer2vec models are shown in Table 3. These results show improvement over disproportionality metrics for both reference sets in every configuration (FULL,PS-SS and PS) by both metrics of evaluation. As was the case with the disproportionality metrics, the results show an improvement in AUC when reducing the data set by role code, with an absolute AUC increase of approximately 10% when we constrain the
FAERS data to primary suspects. While aer2vec+ and aer2vec- perform similarly to one another on the EU-ADR set, the aer2vec+ model performs considerably better on the larger OMOP set. As was the case with disproportionality metrics, performance improves by around 10% (absolute AUROC) when restricting data to primary suspect relationships only. In addition, the best aer2vec results exceed the best disproportionality metric result on both data sets, with substantive improvements in performance across all configurations with the OMOP set in particular. As indicated by the confidence intervals of these mean values, performance was remarkably consistent across iterations. Across these ten iterations, all differences in performance between PS, PS-SS and FULL configurations of the same model were statistically significant by an unpaired t-test, as were all differences between aer2vec+ and aer2vec- models in the same configuration, aside from the sole case of the PS-SS configuration with the EU-ADR set.

Table 3: aer2vec results. Mean AUROC/AUPRC ±1.96*STD across 10 repeated runs. PS-SS= primary and secondary suspects. PS=primary suspects. Best results for each metric on each reference set are in boldface. The best baseline model (ROR) is shown in the middle two rows for the purpose of comparison.

</table>

Table 4 illustrates three ways in which the trained embedding space (in this case aer2vec+ PS) can be interrogated. The first two results columns involve comparing the same types of entities – side effects (in this case input weight embeddings) or drugs (in this case output weight embeddings). Furthermore, it is possible to recover predictions for observing a particular drug given a side effect has been reported as shown in the third results column. As indicated in the accompanying comments, the results are interpretable in many cases and suggest the resulting embeddings may be of utility for downstream supervised learning models on account of the similarities they capture.

Table 4: Nearest neighbors in aer2vec+ PS space. IW=input weights, OW=output weights

| Cosine to IW(dystonia) | Cosine to OW(clozapine) | P(drug|acute myocardial infarction) |
|------------------------|-------------------------|--------------------------------|
| 1.00 dystonia          | 1.00 clozapine*          | 0.54 rofecoxib*                 |
| 0.67 tardive dyskinesia| 0.41 trimeprazine*       | 0.28 rosiglitazone*             |
| 0.65 extrapyramidal disorder | 0.39 clorazepanone | 0.23 ticagrelor                  |
| 0.59 akathisia         | 0.38 piracetam           | 0.15 prasugrel                   |
| 0.56 meige's syndrome  | 0.37 moclobemide         | 0.11 bivalirudin                |
| 0.55 dyskinesia        | 0.37 nitrazepam          | 0.08 alvimopan                  |
| 0.55 oculogyration     | 0.36 loxapine*           | 0.07 abacavir/lamivudine         |
| 0.55 respiratory dyskinesia | 0.36 perazine* | 0.04 tirosiban                    |
| 0.53 oculogyric crisis | 0.35 amisulpride*        | 0.03 valdecoxib*                |
| 0.52 neuroleptic malignant syndrome | 0.34 sulphiride* | 0.01 ziconotide_acetate          |

Other mostly movement related side effects caused by antipsychotic drugs, (*): drugs sharing rare ADEs: except Meige's syndrome, a dystonia toxic epidermal necrolysis of unknown etiology (surprising to (clorazepanone); agranulocytosis (loxapine). Removed from market for cardiac safety concerns (*). Myocardial infarction is a known side effect of abacavir. Some other results (anticoagulants and platelet inhibitors) suggest reporter misattribution of suspicion.
These results also give some insight into the possible mechanisms underlying aer2vec’s improvements in performance over established disproportionality metrics, as the estimation of \( P(\text{drug|ADE}) \) (or vice-versa) will be influenced by similarities between drug and side-effect terms. For example, \( P(\text{drug|tardive dyskinesia}) \) will be elevated for a drug reported with the term “extrapyramidal disorder”, which is a useful generalization in this case because of the hyponymic relationship between these side effects (tardive dyskinesia is a type of extrapyramidal disorder). More broadly, one would anticipate the model inferring that drugs that share some side effects may share others.

**Hyperparameter settings:** Evaluation of performance across different hyperparameter settings reveals that subsampling impairs performance (Figure 2, left) and consistency across a range of dimensions (Figure 2, right). Best performance across these settings is shown in Table 5, with improvements in OMOP set performance in particular.

**Figure 2:** Mean AUROC \((n=10)\) with 95% CI at different subsampling thresholds (left; ‘-’ indicates no subsampling) and dimensionalities (right). 0.5 baseline indicates performance with random ordering.

**Table 5:** Best aer2vec+ performance across hyperparameter settings (100 dimensions, no subsampling)

**Discussion**

Our results demonstrate improved signal detection from the FAERS data when applying an adaptation of the SGNS algorithm to represent observational data, providing a novel methodology for the identification of drug/side-effect associations. Across both reference standards and three different configurations of our source dataset, \( P(\text{drug|ADE}) \) estimates produced by the aer2vec+ model consistently result in a higher AUC than was obtained by either of the two disproportionality metrics evaluated. The aer2vec- model also outperformed disproportionality metrics in most but not all cases. Furthermore, we found that the role code information in the FAERS data can be used to subset these data in a way that improves performance. Lastly, we discovered that aer2vec+ outperforms aer2vec- in all cases. These findings have implications for the analysis of adverse event report data.

Our primary finding is that aer2vec+ outperforms the standard disproportionality metrics across two reference sets and all dataset configurations, with improvements in performance of up to 10% in absolute AUROC on the larger and more challenging OMOP set, and smaller but still substantial improvements in performance on the EU-ADR set. This supports our initial hypothesis that distributed representations (concept embeddings) derived from AERS data may be of value for pharmacovigilance. Qualitative analysis of neighboring embeddings suggests that trained embeddings capture regularities in the data. Concepts occurring in similar AER contexts have similar embeddings, permitting our
models to generalize across related drugs and ADEs, suggesting a mechanism underlying their enhanced performance. In the current work, we applied these embeddings by recapitulating the probabilistic estimates used during the course of training. However, the benefits of pre-trained distributed representations are often best demonstrated in downstream supervised learning. In our previous work we have shown that literature-derived embeddings used as a basis for supervised machine learning produce state-of-the-art performance (AUROC=.96) on the OMOP reference set\textsuperscript{26,27}. A logical next step will involve evaluating the utility of aer2vec embeddings as a complement to literature-derived embeddings for supervised machine learning. Intriguingly, best performance with aer2vec on the EU-ADR set exceeds that obtained with supervised models - both in our work\textsuperscript{26,27} and when classifiers were trained on manually engineered features derived from a range of sources including the biomedical literature, FAERS data and pharmaceutical product labels\textsuperscript{38}. One reason for this may be the limited number of training examples per side-effect available relative to the OMOP set, where recapitulating aer2vec’s neural-probabilistic learning objective does not in and of itself lead to state-of-the-art performance. In addition, prior work leveraging side-effect patterns in AERS data for drug repurposing suggests aer2vec embeddings that represent such patterns may be leveraged for this purpose also\textsuperscript{29}.

A second notable finding is that constraining the data set in accordance with human judgment of suspected causality enhances performance. The role code variable in the FAERS data set provides valuable information that has generally not been used in prior published work, and leveraging this information to constrain the occurrence events in the data resulted in substantive improvements in performance for all models evaluated. It seems likely that the mechanism in this case involves reducing the influence of confounding variables, providing a useful addition to the armament of methods that have been deployed for this purpose in pharmacovigilance\textsuperscript{30,31,32}. However, incorporation of human judgment into statistical models introduces a degree of subjectivity that warrants further discussion. One might argue that attempts to leverage these designations of suspicion would accentuate documented biases in spontaneous reporting, such as notoriety bias - a tendency toward increased reporting of adverse events that have recently appeared in safety alerts\textsuperscript{33}. A more pragmatic perspective might be to consider the cumulative independent judgments of a diverse group of adverse event reporters – who are in some cases domain experts and have access to information concerning temporality and other factors that are not explicit in reporting data alone – as exemplifying the “wisdom of crowds”\textsuperscript{34}. At a minimum, the utility of reporter designations of suspected causality as a means to improve predictive modeling performance across multiple models and two reference standards suggests a need for further investigation into the circumstances in which this information is of value for post-marketing drug surveillance.

In addition, we find that aer2vec+ performs better than aer2vec-. While both approaches outperform the disproportionality metrics in most cases, aer2vec+ is consistently better than aer2vec-, with better mean AUC scores for aer2vec+ across both reference sets in all configurations. We reason that predicting the drug given the side-effect is the more suitable approach to identifying drug/side-effect associations from AERS data, and that future research should prioritize aer2vec+ as a means to represent these data for pharmacovigilance purposes. Subsequent exploration of model hyperparameters showed subsampling of frequent terms reduced performance, which seems intuitive given the nature of the task. In addition, these experiments revealed improved aer2vec+ performance on the OMOP set in particular at a lower dimensionality than in our original experiments. Optimal performance at lower dimensionality has been observed in other distributional semantic models also, and we refer the interested reader to Yin and Shen’s recent theoretical account of the relationship between dimensionality and task performance in such models\textsuperscript{35}. Code to reproduce our experiments is publicly available\textsuperscript{i}, as are trained models for our primary and best results\textsuperscript{ii}.

Limitations
An important limitation of this study concerns the use of reference sets containing well-established side effects. More stringent evaluations using time-indexed sets are needed to determine performance with emerging side effects\textsuperscript{36}. These models were also created with standardized data. Our methods have yet to be evaluated in the context of raw FAERS data, although one might hypothesize that the capacity for generalization provided by distributed representations would offer greater advantages in the context of data that have not been normalized. Another limitation is that this data set only contains data up to 2015. We plan to address these limitations by training our models using raw FAERS data in future experiments. Finally, we compared aer2vec performance to two disproportionality metrics only. Outperforming these metrics is of practical significance because they are currently in use for regulatory purposes. However in recent work these and other statistical metrics have been evaluated for utility as features for supervised machine learning. In future work we will assess aer2vec’s utility as a basis for downstream machine learning also.

\textsuperscript{ii} https://zenodo.org/record/3283012
Conclusion

In this paper, we described how aer2vec distributed representations of AER data can be used to acquire signal for drug/side-effect associations, outperforming established disproportionality metrics on two pharmacovigilance reference standards. Considering provider designations of suspected causality resulted in further improvements in performance in both aer2vec and baseline models. As the baseline disproportionality models concerned are in current use, these results have immediate implications for pharmacovigilance practice, with the potential for broad application of the embeddings that result.

Abstract

MEDLINE is the National Library of Medicine’s premier bibliographic database for biomedical literature. A highly valuable feature of the database is that each record is manually indexed with a controlled vocabulary called MeSH. Most MEDLINE journals are indexed cover-to-cover, but there are about 200 selectively indexed journals for which only articles related to biomedicine and life sciences are indexed. In recent years, the selection process has become an increasing burden for indexing staff, and this paper presents a machine learning based system that offers very significant time savings by semi-automating the task. At the core of the system is a high recall classifier for the identification of journal articles that are in-scope for MEDLINE. The system is shown to reduce the number of articles requiring manual review by 54%, equivalent to approximately 40,000 articles per year.

Introduction

MEDLINE® is the U.S. National Library of Medicine’s (NLM) journal citation database. It contains over 25 million citations and is growing at rate of over 900,000 citations per year. The subject scope of MEDLINE is biomedicine and health, broadly defined to encompass the information needs of those working in healthcare and life sciences. A distinctive feature of MEDLINE is that records are manually indexed with NLM Medical Subject Headings (MeSH®). MEDLINE currently covers over 5,200 international journals, and the majority of these journals are indexed cover-to-cover; that is, all articles, substantive editorials, and letters are indexed. About 200 journals are selectively indexed, meaning that only articles related to biomedicine and life sciences are indexed. These selectively indexed journals are typically multidisciplinary journals, such as general science or general chemistry titles.

Between 2000 and 2017, the number of articles from selectively indexed journals has increased rapidly from approximately 13,000 to 78,000, while at the same time the fraction of articles selected for indexing has decreased from about 90% to 25%†. As a consequence, selecting articles for MEDLINE indexing is an increasing burden for NLM indexers, distracting them from their core task of indexing the biomedical literature.

This paper presents a machine learning based system that has been developed to assist indexers with the selection process. The core component of the system is a high recall classifier for the identification of journal articles that are in-scope for MEDLINE. The main inputs to the classifier are the article title and abstract, and the output is a prediction of whether the article is in-scope for MEDLINE. The classifier is used to pre-filter articles that are likely to require MEDLINE indexing and offers significant time-savings by reducing the number of articles requiring manual review. Indexers require the classifier to have close to 100% recall as they do not want to miss in-scope articles.

Related Work

We are not aware of any prior work on selecting biomedical journal articles for indexing, however triage of relevant PubMed articles is often the first step in database curation. An example of such an approach is the TREC 2004 genomics track categorization task2. This task simulated the curation of the Mouse Genome Informatics system and required the triage of articles that contain evidence supporting the assignment of a GO code to a specific gene. The goal was to limit the number of articles sent to human curators for more exhaustive analysis. A similar example is the selection and ranking of articles for the Comparative Toxicogenomics Database (CTD) in the BioCreative evaluation3. The CTD database captures chemical-gene-disease relationships and triage effectiveness was measured by gene, disease, and chemical named entity recognition performance. A different application, that also requires the selection of a subset of PubMed articles, is the identification of scientifically rigorous articles for clinicians practicing

† Statistics computed using the 2018 MEDLINE/PubMed baseline4.
evidence-based medicine. Several machine learning based approaches have been developed to solve this important problem\textsuperscript{[5,6]}. More generally, topic-based text classification has been extensively studied in many domains. A relevant and well-studied topic-based text classification problem is the automatic indexing of biomedical articles using the MeSH vocabulary\textsuperscript{[7,8]}. 

**Methods**

**Dataset**

The dataset is comprised of citation data for MEDLINE articles published in selectively indexed journals before September 2018. It was constructed using a list of selectively indexed journals (and associated start/end years of selective indexing) automatically extracted from the 2018 NLM List of Serials Indexed for Online Users file\textsuperscript{10}. Citation data was downloaded from the 2018 MEDLINE/PubMed annual baseline\textsuperscript{11} and daily update files, and articles from selectively indexed journals were filtered based on their journal and publication date. Articles published in the same year that their journal was selected or deselected for selective indexing were excluded as selective indexing may have started or ended part way through the year.

Articles from selectively indexed journals have typically been reviewed by a single NLM indexer, and whether or not an article has been selected for indexing can be determined from the MEDLINE citation status. Indexed articles are assigned “MEDLINE” status and out-of-scope articles are assigned “PubMed-not-MEDLINE” status. There are 33 journals that are known to have problematic determinations before 2015, and the affected articles were removed from the dataset. The validation and test sets only contain articles published in 2018, as we want to evaluate how the system performs on recent articles. The test set only contains articles from a subset of 132 selectively indexed journals that the indexing team are particularly interested in\textsuperscript{‡}. Some special citation types (Comment, Erratum, Expression of Concern, Republished, Retraction, Update, Reprint, and Patent Summary) are also excluded from the validation and test sets because they follow special indexing rules. The final dataset contains 1.5 million training set articles, 14,346 validation set articles, and 29,833 test set articles. As discussed previously, the fraction of articles selected for indexing has decreased over time: the training set contains articles published before 2018 and has an overall indexing rate of 64%, while the validation and test sets contain articles published in 2018 and have indexing rates of 18%.

**Classifier for In-Scope Biomedical Journal Articles**

The developed classifier combines the predictions of an ensemble of traditional machine learning algorithms and a Convolutional Neural Network (CNN). These two component classifiers are described in detail below.

**Ensemble of Traditional Machine Learning Algorithms**

The ensemble is implemented using scikit-learn\textsuperscript{\textsuperscript{[11]}v0.20.2) and uses averaging to combine the predictions of Bernoulli Naive Bayes, Logistic Regression, Stochastic Gradient Descent, and Random Forest classifiers. The model was trained on 2017 data and the input features are concatenated term frequency inverse document frequency (TF-IDF) representations of the title, abstract, and author affiliations. Model hyperparameters were optimized using a grid search for $F_2$-score and are listed in Table\textsuperscript{1}.

The individual algorithms for the ensemble were chosen by first evaluating their standalone performance on the validation set. Only algorithms available in scikit-learn, and known to perform well on natural language processing (NLP) tasks, were considered. Individual algorithms that performed well were chosen as candidates for the final ensemble model, and the best performing combination of algorithms was determined using a grid search.

**Convolutional Neural Network**

A Convolutional Neural Network is a type of deep neural network that is commonly applied to image processing tasks. Recently, however, CNNs have also been shown to be effective for various NLP problems, including text classification. The neural network architecture used in this paper (Figure\textsuperscript{1}) is based on the CNN architecture presented by Kim et al.\textsuperscript{12}. In their paper, Kim et al. demonstrate that this architecture is effective for sentence classification. The

architecture represents words as vectors and input text as the concatenation of word vectors. The network learns a set of convolutional filters that are convolved along the length of the input text to produce an activation map; filters learn to activate when they detect a specific type of feature (e.g. discriminative words or phrases) at some position in the text. The convolution operation is followed by a max pooling operation that keeps only the maximum activation of each filter. The result is a fixed length representation of the input text that is invariant to the position of the detected features. The final layer of the network is a task specific classification layer.

This paper presents a custom neural network architecture that uses a CNN to process text inputs. There are five inputs to the network: the article title, abstract, journal, publication year, and indexing year. The network generates a fixed length representation of each input and then concatenates them to construct the input to the hidden layer. The final classification layer uses a sigmoid activation function to generate a single output value between zero and one, which can be interpreted as the probability of an article being in-scope for MEDLINE. The model uses randomly initialized word vectors, dropout regularization, and batch normalization for the hidden and convolution layers.

The title and abstract inputs are processed separately using the same word embeddings and convolutional filter weights. Standard max pooling is used for the title, whereas dynamic max pooling is used for the abstract. Dynamic max pooling is implemented by first dividing the abstract into five equal length sections, and then standard max pooling is applied to each of these sections. The intention is to create a richer representation of the abstract by retaining some position information.

The journal is treated as a categorical input, and each journal is represented by a fixed length vector. Like the word embeddings, the journal embeddings are learned during training. The two year inputs are represented using the special encoding scheme shown in (Figure 2). The encoding is similar to one-hot encoding; however, positions for the year and preceding years are activated. The encoding is intended to capture the sequential nature of time and allow for
Figure 2: Illustration of the special encoding used for year inputs. The example shows how years between 2014 and 2018 would be encoded.

The model was trained on the full training set using binary cross entropy loss, the Adam optimizer, and mini-batch gradient descent. The $F_1$-score metric was monitored on the validation set, and training was stopped early when it stopped increasing. Model hyperparameters (Table 2) were chosen based on the literature and manual optimization for $F_1$-score.

Final Combined Model

The final model combines the predictions of the ensemble of traditional machine learning algorithms and the CNN. To compute the output probability of the combined model, we assume that the component model predictions are independent and take the product of their output probabilities.

The final prediction of whether an article should be selected for indexing can only be made after the selection of a decision threshold. There is a trade-off between precision and recall: a high threshold will result in high precision but low recall, whereas a low threshold will result in low precision but high recall. The classifier developed in this paper is required to have close to 100% recall, and therefore a relatively low threshold was selected on the validation set. All the code, datasets and trained models required to reproduce the results of this paper are publicly available on GitHub at [http://github.com/indexing-initiative/selective_indexing](http://github.com/indexing-initiative/selective_indexing).

Results

This section presents a performance evaluation of the developed classifier on the 2018 test set. We first compare the performance of the combined model to the standalone performance of its component models. We then breakdown the performance of the combined model by journal topic.
Figure 3 shows precision-recall curves for the ensemble of traditional machine learning algorithms, CNN, and combined models. Figure 3a is the full plot and Figure 3b is a zoomed in plot showing recall values close to 100%. Figure 3b shows that, for intermediate values of recall, the CNN is the best performing model. In this recall range, the relatively low performance of the ensemble degrades the performance of the combined model. We are, however, interested in performance at high recall values. For the high recall values shown in Figure 3b, it can be seen that the predictions of the ensemble and the CNN model are complementary and that the combined model has the highest precision for most values of recall.

After discussion with NLM indexers, it was decided that recall of about 99.5% resulted in a good balance between classifier precision and false negative error rate. After selecting a decision threshold on the validation set, the final combined model precision and recall was measured to be 38.0% and 99.4% respectively, on the test set.

In order to breakdown model performance by journal topic, each selectively indexed journal was assigned to one of four journal groups: Chemistry, Science, Jurisprudence, or Biotech. Both the compilation of the list of journal groups and the assignment of journals to groups was done based on human judgement; the MeSH terms that are assigned to MEDLINE journals were used as guidance. Figure 4 plots precision-recall curves for the combined model by journal group and shows that the model performance varies significantly between journal groups. Specifically, the model performs better on Science and Jurisprudence articles and worse on Biotech and Chemistry articles.

Discussion

At the measured precision of 38.0%, the implemented system offers NLM indexers considerable time and cost savings by allowing them to automatically discard the 54% of articles that are very unlikely to require indexing. In 2017 there were approximately 80,000 articles processed from selectively indexed journals, and we would therefore expect the system to exclude approximately 40,000 articles from manual review each year. The measured recall value of 99.4% indicates that approximately 0.6% of in-scope articles will be missed by the system, but this is considered acceptable given the expected time-savings. It is important to realize that even human indexers may miss articles or disagree on whether an article is in-scope.

In the results section it was shown that the model performance varies considerably with article topic. The reason for this variation in performance is not explored in this paper, but the analysis highlights that the model could potentially be deployed for a subset of journals for which it is particularly effective.

One of the key challenges that was faced when developing the presented classifier was the time-variance of the dataset. There are many factors that cause time-variance and these include changes to selective indexing policy, changes to the
Figure 4: Precision-recall curves for combined model by journal group.

Figure 5: Fraction of indexed articles from selectively indexed journals against publication year. Shows the actual fraction and the fraction predicted by the CNN model.

The observed time-variance is especially problematic for the training of the CNN because it requires a large amount of training data to achieve high performance. There is insufficient data from recent years, and consequently the CNN is forced to model the time-variance of the dataset and to generalize across years if possible. The publication year and indexing year inputs were added for this purpose and were found to improve performance on the 2018 validation set. Figure 5 shows that the indexing rate predicted by the CNN closely follows the true indexing rate, and this provides further evidence that the CNN is effectively modeling the time-variance of the dataset.

Conclusion

This paper presents a machine learning based system that has been developed to assist indexers with the selection of articles for MEDLINE indexing. At the core of the system is a high recall classifier for the identification of journal articles that are in-scope for MEDLINE that combines the predictions of traditional machine learning algorithms and a Convolutional Neural Network. The system is shown to offer very significant time and cost savings by allowing
indexers to discard 54% of articles that are very unlikely to require indexing.

For future work, we plan to further explore the effect of the dataset time-variance on model performance. It is claimed that new language model based text representations require less task specific training data. It may therefore be possible to achieve better performance by training models using these new representations only on recent data. We would also like to understand why the model performance varies so much with article topic. Our motivation is that the two worst performing groups (Biotech and Chemistry) make up over two thirds of 2018 articles. Any performance improvements for these two groups will result in a significant increase in overall performance.

Abstract

Healthcare organizations worldwide use quality dashboards to provide feedback to clinical teams and managers, in order to monitor care quality and stimulate quality improvement. However, there is limited evidence regarding the impact of quality dashboards and audit and feedback research focuses on feedback to individual clinicians, rather than to clinical and managerial teams. Consequently, we know little about what features a quality dashboard needs in order to provide benefit. We conducted 54 interviews across five healthcare organizations in the National Health Service in England, interviewing personnel at different levels of the organization, to understand how national (UK) clinical audit data are used for quality improvement and factors that support or constrain use of these data. The findings, organized around the themes of choosing performance indicators, assessing performance, identifying causes, communicating from ward to board, and data quality, have implications for the design of quality dashboards, which we have translated into a series of requirements.

Introduction

Dashboards are a type of health information technology (HIT) that use data visualization techniques to support clinicians and managers in viewing and exploring data on processes and outcomes of care¹. A distinction can be made between clinical dashboards and quality dashboards. Clinical dashboards provide feedback to individual clinicians on their performance compared to standards or targets, with the aim of informing decisions about, and thereby improving, patient care². For example, a clinical dashboard may seek to reduce inappropriate prescribing of antibiotics and therefore present data to clinicians regarding how their rate of antibiotic prescribing compares to that of their colleagues³–⁴. In contrast, quality dashboards show performance at the ward or organizational level to inform operational decision making and quality improvement efforts⁵. Ideally they will provide feedback that can be used at both ward and organizational levels⁶–⁷. It is thought that the visualizations provided by quality dashboards can lead to the identification of previously unnoticed patterns in data⁸, informing quality improvement initiatives, and more efficient and effective decision making⁹.

Healthcare organizations worldwide are increasingly using quality dashboards as a way of monitoring the quality of care they provide and as the basis for quality improvement initiatives. For example, use of quality dashboards has been reported in the US⁷, ¹⁰, Canada¹¹, the UK⁴, and the Netherlands¹². This is a trend that is likely to continue, with electronic health records providing a source of data to automatically populate quality dashboards¹³. Quality dashboards have been shown to have positive effects on performance indicators¹⁴ and use of quality dashboards has been identified amongst boards of high-performing hospitals¹⁰. However, empirical evidence regarding the impact of quality dashboards remains limited. In a systematic review of the evidence base for the use of quality and clinical dashboards, 11 research studies that had evaluated their impact on either quality or clinical outcomes were identified¹ but only one of these studies met the definition of a quality dashboard¹⁴. Consequently, we know little about what features a quality dashboard needs in order to stimulate quality improvement.

Research on audit and feedback provides a number of suggestions that are likely to have relevance when considering the design of a quality dashboard. For example, Contextual Feedback Intervention Theory (CFIT) suggests that the recipient of the feedback needs to perceive the standard or target as desirable (goal attractiveness) and achievable (goal expectancy) and perceive the feedback about the discrepancy between their performance and the standard as accurate¹⁵. CFIT contends that such feedback is more likely to change behavior if it is timely, frequent, cognitively simple, e.g. presented graphically, unambiguous, and provides concrete suggestions of how to improve performance. Hysong et al.’s model of actionable feedback suggests clinicians are more likely to respond to the feedback if it is perceived to be timely and non-punitive and if they receive feedback about their own individual performance rather than aggregated data about overall performance of the organization¹⁶. If they are able to customize how they view the data, this leads to active engagement in sensemaking, further increasing the likelihood that the feedback will be acted on. However, as the audit and feedback literature is largely concerned with feedback to individual clinicians¹⁷, this...
raises the question of how such recommendations can be adapted for quality dashboards, given that quality dashboards provide feedback to teams, whether clinical teams or managerial teams.

In the UK, the Healthcare Quality Improvement Partnership (HQIP) centrally develops and manages a programme of over 60 national clinical audits each year through the National Clinical Audit and Patient Outcomes Programme (NCAPOP). The National Health Service (NHS) standard contract requires all healthcare organizations that provide NHS services to participate in the NCAPOP national clinical audits and they are required to contribute to their funding. In addition, there are over 50 independent national clinical audits that are not part of the NCAPOP, funded either through subscription, by a charity or professional body, or by NHS England (the body responsible for commissioning NHS services in England). In comparison to Hospital Compare\textsuperscript{18} in the US, which provides an overall hospital rating made up of 57 measures, in the UK each national clinical audit focuses on a particular clinical area or condition, making them more comparable to national registries. Each national clinical audit produces an annual report that is made available to the public. National clinical audits aim to systematically measure the quality of care delivered by clinical teams and healthcare organizations and to stimulate quality improvement\textsuperscript{19}.

While there is evidence of positive impacts of national clinical audits\textsuperscript{20-22}, there is variation both within and between healthcare organizations in the extent to which they engage with national clinical audit data\textsuperscript{23, 24}. Consequently, national clinical audit data are substantially underutilized and the potential for national clinical audit data to inform quality improvement is not being realized. In response to this, we are undertaking a study to develop a quality dashboard for exploring national clinical audit data by both clinical teams and managers. As part of this, we undertook an interview study with clinicians, managers, and audit support staff to understand how national clinical audit data are currently used for quality improvement and factors that support or constrain the use of these data.

In this paper, we draw on the interview data to identify themes that have relevance for the design of quality dashboards. We first describe the methods of the interview study and then present our results. We conclude by discussing the implications of our findings for the design of quality dashboards which could be used across healthcare contexts, translating them into a series of requirements for future dashboard design.

**Methods**

**Participants**

Interviews were conducted across five acute healthcare organizations in England. Three were teaching hospitals and two were district general hospitals. To ensure our findings were generalizable beyond a single national clinical audit, interviews explored use of the Myocardial Ischaemia National Audit Project (MINAP) and the Paediatric Intensive Care Audit Network (PICANet), which vary in terms of clinical specialty, patient groups, and performance indicators. MINAP has been running continuously since 2000 and data are contributed by all hospitals in England, Wales and Northern Ireland that admit patients with acute coronary syndromes\textsuperscript{25}. PICANet was set up in 2002 and contains data from all NHS Pediatric Intensive Care Units (PICUs) in England and Wales\textsuperscript{26}. Examples of the performance indicators included in these audits are provided in Table 1. As the two district general hospitals did not have PICUs, use of PICANet data was investigated in PICUs across three of the healthcare organizations and use of MINAP data was investigated within cardiology services across all five organizations. As both MINAP and PICANet are part of the NCAPOP, to capture further variation, we also gathered information on use of the British Association of Urological Surgeons (BAUS) audits and the National Audit of Cardiac Rehabilitation (NACR), which are independent audits.

A combination of purposive and snowball sampling was used. In each site the clinical contact for the study (typically a MINAP or PICANet lead) was interviewed first. These contacts were then asked to identify others who were involved with national clinical audits, enabling us to map the networks of stakeholders through which data for particular audits were captured, accessed, and analyzed. We sought to interview participants at all levels of the organization, including clinical team members, Quality & Safety Committee members, and members of the Board of Directors. We also sought to interview those who commission healthcare services from the five sites.

Ethics approval for this study was received from the University of Leeds, School of Healthcare Research Ethics Committee (Approval no. HREC16-044).

Data collection

A semi-structured interview topic guide was developed by the research team. This was reviewed by the study Lay Advisory Group and revised based on their feedback to ensure that the interviews explored topics that matter to patients. Interviews began with discussion of the participant’s role, with a focus on their responsibilities for national clinical audits (e.g. collection, analysis, dissemination). Participants were then encouraged to draw on their own experiences and articulate how national clinical audit data were used, with an emphasis on the role of the data in informing quality improvement. They were asked about the circumstances that they felt constrained or supported use of national clinical audit data for quality improvement and what features they would consider important in a quality dashboard for exploring national clinical audit data. Example interview questions are provided in Table 2. Interviews were audio recorded and transcribed verbatim.

Data analysis

The interviews were anonymized and entered into NVivo 11. Framework analysis, an approach developed for analyzing qualitative data for applied policy research, was used. Informed by the interview topic guide and reading of preliminary interviews, codes for indexing the data were identified and agreed by four members of the research team. They then indexed 5 transcripts to test the applicability of the codes and assess agreement. Where there was variation in the indexing, the codes were refined and definitions were clarified. The refined codes were applied to all
transcripts. Example codes are provided in Table 3. The indexed data were summarized in a matrix display to build up a picture of the data as a whole29. In the final stage, mapping and interpretation, the matrix was used to identify similarities and differences in participants’ responses.

Results

Fifty-four interviews were conducted between November 2017 and June 2018. Interviews ranged from 33 minutes to 1 hour 29 minutes, with an average (mean) length of interview of 54 minutes. Table 4 provides a summary of participants by professional group and audit. A significant number of participants, such as members of Quality & Safety Committees and Board members, used multiple audits.

Analysis of the interviews revealed five main themes that have significance for the requirements for a quality dashboard: choosing performance indicators, assessing performance, identifying causes, communicating from ward to board, and data quality. The requirements for each theme are summarized in Table 5.

Choosing performance indicators

A key issue in the design of any dashboard is the choice of performance indicators to be displayed. In discussing this with our interviewees, they talked about wanting a dashboard that was customizable, in terms of enabling them to select what performance indicators are displayed (Requirement 1). Such an approach would enable users to select performance indicators that they perceive as important signifiers of care quality. In looking at use of national clinical audit data, we found that there was limited engagement from nursing staff in part because the national clinical audits did not capture what they considered to be important markers of care quality. For example, in the PICUs, nurses were concerned about the number of central line infections, data that are not captured in PICANet. When deciding which performance indicators should be displayed on a quality dashboard, it is important that an interdisciplinary decision is made and that the selected performance indicators have relevance to all members of the multidisciplinary team.

Interviewees also talked about wanting to have access to performance indicators from other areas of the organization, a topic we return to under ‘Identifying causes’.

Assessing performance

Quality improvement depends on using the selected indicators to make comparisons, thereby providing an assessment of performance, as this interviewee describes:

*Quality improvement is about having a process in place where you are measuring those things, whether it’s patient surveys or hard data-type audit, and comparing it against either a set national standard or your peers or benchmarking [...] and that you then have a system in place where that comparison allows you to reflect on how you are performing and make the necessary adjustments to improve performance.* (Site 2, Cardiologist 4)

We identified three key ways in which clinical teams assessed their performance, which have implications for the information that should be provided in a quality dashboard and how data should be presented. One way in which performance was assessed was comparing practice against evidence-based standards that are known to improve patient outcomes (Requirement 2):

*I do reports, like monthly and yearly, to show how we’re doing. [...] it’s the nurses’ data, but I do all the data to tell them if they’re on schedule to hit the 60% target [angiogram within 72 hours for non ST-elevation myocardial infarction (NSTEMI) patients] and stuff like that. I look at all the figures for the STEMIs [ST-elevation myocardial infarction], to see if they’re hitting the 150 minute call-to-balloon and 90 minute door-to-balloon.* (Site 4, MINAP Audit Assistant)

However, such an approach only works in clinical areas where there are evidence-based standards against which to assess performance. Additionally, research on audit and feedback interventions aimed at individual clinicians emphasizes that clinicians need to see meeting these standards as achievable.

The second way in which performance is assessed is through monitoring trends over time (Requirement 3). This type of monitoring is particularly important for clinical areas where there are no evidence-based standards against which to compare service performance, as is the case in pediatric intensive care. Consequently, we found that clinical teams would use PICANet data to monitor trends over time (month-on-month):

*We use the PICANet data to produce monthly graphs that we use at our monthly clinical governance meetings. So basically, we look at re-admissions within 48 hours of discharge, deaths, accidental extubations. So, we get graphs with month-on-month numbers, so we can monitor it and see changes.* (Site 1, Pediatrician 2)

The interviewee described how monitoring PICANet data in this way led to a quality improvement initiative to reduce the number of accidental extubations; having identified a ‘spike’ in accidental extubations, additional training was introduced for nursing staff, about how to tape the tube to keep it in position and how to check the tube position on a chest x-ray.
While such assessments of performance over time were only undertaken in those sites where they had the resources to generate appropriate graphs, particularly in terms of staff skills and time, a quality dashboard should allow easy identification of such trends. Interviewees also talked about wanting to be able to choose over what time period a particular metric was displayed (Requirement 4); for example, for metrics where you may expect to see fluctuations over a year, it would be necessary to view data for several years.

The third way in which performance was assessed was through comparison with other healthcare organizations (Requirement 5). National comparisons offer opportunities to identify high-quality services in other organizations, which could act as examples of good practice from which clinical teams can learn. Making such comparisons was important to all sites, and perhaps especially to PICUs, which do not have access to evidence-based standards and thus feel the need to benchmark themselves against other units to assess their performance.

Clinical teams, in addition to comparing themselves against the national average, may also want to be able to select particular organizations to compare themselves against, organizations that they consider similar in terms of size and/or case mix (Requirement 6). One interviewee made the following comment:

"There’s PICUs that, you know, if they had no re-admission rate, I wouldn’t be surprised because it’s not a high level PICU. So, you’d have to be stratified to a PICU, an average of a PICU who is like you. So, we have cardiac patients, we have neuro patients, we have ECMO patients, so we can only really be compared with them, otherwise we’re not comparing like with like. (Site 1, Pediatrician 2)"

**Identifying causes**

Having assessed performance, a quality dashboard should then support clinical teams to identify causes for any particular performance indicators that raise concern. Interviewees described wanting to be able to ‘drill down’ into the data to understand the reasons behind the numbers, for example, to look at a particular sub-group of patients (Requirement 7). Drilling down may also go as far as looking at details of individual patients:

"It’s looking at the complications we’ve had and how we can improve them. So it’s things like the patient’s died: was it due to the procedure or was it something else? And we look at all the pathway, you know, should they have come to us, should they have come quicker? You know, we then tweak things to improve it. Or it might be that they’ve had a dissection or a blockage while they’ve been doing the procedure, and we look at, well, what equipment was used? And again, we feed back to each individual operator on their cases. So it might be Doctor so-and-so: ‘we think you should have used this piece of kit when you got into that difficulty, we’ve tried…you know, another colleague’s tried this and it worked’. So then they’ll know next time to think it. (Site 1, MINAP Audit Support Nurse)"

Interviewees at the clinical team level also talked about wanting to see data from other clinical areas, rather than data in silos, to understand how their performance interacted with and was impacted on by other areas of the organization (Requirement 8). For example, if a PICU receives a large number of emergency readmissions from the High Dependency Unit (HDU), they may also want to look at performance indicators for the HDU.

Some interviewees at the clinical team level talked about wanting a dashboard that could support simultaneous interaction by multiple users, so as to be able to drill down into the data and discuss within a meeting (Requirement 9). The interviewees felt that, through this, a quality dashboard could enhance the ability of teams to engage flexibly and in depth with national clinical audit data:

"The potential is you could use it in further discussions or using that information to probably motivate you or stimulate you into something in an audit group, so it might be that there's an aspect of care which [...] another unit might be doing really well so you might want to say: well, how are they doing that? So having that access, that would probably be something which we’d do on a larger group, that’s what I would think. (Site 1, PICU nurse)"

This may mean making the dashboard available on large touchscreens or tabletop computers, or enabling multiple users to access it via laptops and handheld devices.

**Communicating from ward to board**

For monitoring of care quality, it is important that data such as those contained within national clinical audits move from "ward to Board". However, the requirements at these different levels of the organization vary significantly. At divisional and corporate (Board and sub-committees that report to the Board, such as Quality and Safety Committees) levels, a different set of performance indicators will be of concern, those which reflect the performance of the division or organization as a whole. For example, interviewees at these levels discussed looking at performance indicators related to mortality, never events, harms, and complaints. There may be a disconnect between the performance
indicators considered at divisional and corporate levels, which are likely to reflect national priorities, and those that are considered at the clinical team to reflect care quality.

Nonetheless, our interviewees reported that there are occasions when the national clinical audits are considered at the corporate level, particularly where a clinical area is identified as an outlier; as one Board member at Site 1 said ‘Nobody wants to be an outlier.’ One way in which a quality dashboard could support the use of such data at corporate levels is by enabling easy identification of when a clinical area is an outlier within a particular audit (Requirement 10):

*What I need is flags that tell me and direct me to things that are outliers that I need to look at and then I can interrogate them [...] all of us are so pressured that we absolutely need things that are going to say: ‘problem here, here’s how you look for it’, and then you go in and look for it.* (Site 2, Quality & Safety Committee member)

One suggestion for achieving this was the use of the ‘traffic light’ or ‘RAG-rating’ system, where red, amber or green are used to indicate performance that falls below, almost falls below, or meets required standards. This was favored by several interviewees, because it is used frequently within healthcare organizations and enables users to identify potential problems at a glance. However, several interviewees also pointed out limitations with such an approach, most notably that it does not capture nuances within data, as when a standard has not been achieved for sound clinical reasons.

While it has been suggested that high performing hospitals are those where Boards spend time discussing quality issues, we found that, at divisional and corporate levels, full agendas meant there were significant constraints on time available in meetings for discussion. Where clinical team level performance indicators are considered in meetings, they will not be considered in detail. Consequently, the level of interaction and the ability to drill down that is required at the clinical team level is not needed within divisional and corporate level meetings (although will be required outside of meetings).

**Data quality**

Data quality was a topic that was frequently discussed in the interviews, with key issues being timeliness and trust in the data. At all levels, a key constraint in use of national clinical audit data for quality improvement was lack of access to timely data, with the data contained within annual reports often being perceived as too out of date to be of use. Timely data, that reflects current performance, were considered essential if they are to inform quality improvement (Requirement 11). While organizations may have timely data about their own performance, timely comparator data are also needed.

For clinical teams to engage with data for quality improvement, it is important that they have trust in the quality of the data (Requirement 12). For example, in one of the sites, they employed a dedicated PICANet audit co-ordinator who entered data into the Access database with only a day’s delay and, with support from the clinical lead, checked the accuracy and completeness of the data. Given these resources and supports, the pediatricians had confidence in the accuracy of data reports generated from the local database and used them to inform clinical governance meetings.

Trust in the quality of national comparator data is also important for clinical teams. Inconsistent or inaccurate coding was reported to have a negative impact on interviewees’ trust in MINAP data and on their ability to make meaningful comparisons with other organizations. Indeed, owing to inconsistent coding, one interviewee likened such assessments to ‘comparing apples and oranges’ (Site 3, Cardiologist).

**Discussion**

Quality dashboards are increasingly being introduced into healthcare organizations as a tool to support quality improvement, yet limited empirical research on use of quality dashboards means that we know little about what features a quality dashboard should have in order to provide the desired benefits. We have drawn on the experience of a range of professional groups who have experience of working with national clinical audit data in the NHS in England to understand what supports and constrains the use of such data for quality improvement. The findings suggest a number of requirements for a quality dashboard, which we have summarized in Table 5.

A number of the findings echo findings in the audit and feedback literature concerning the characteristics of feedback that are most likely to trigger a change in behavior. For example, the need for feedback to be timely is described in CFIT and the model of actionable feedback, and is also highlighted more generally in the literature. Similarly, credibility of the information is also noted as an important characteristic. The desire of interviewees to be able to select the performance indicators displayed can be seen as contributing to the ‘goal attractiveness’ that CFIT describes as...
influencing the likelihood of action because it enables users to select performance indicators that they perceive as important signifiers of care quality. It also enables them to select performance indicators that are consistent with established goals and priorities, another feedback characteristic that has been highlighted in the literature. Similarly, comparing performance against evidence-based standards, those that are known to lead to improved patient outcomes, may also contribute to enhancing goal attractiveness.

However, the findings also highlight some differences that have relevance when designing HIT to provide feedback to a team, rather than to an individual. For example, selection of performance indicators needs to be agreed through an interdisciplinary approach and it is necessary to ensure that they have relevance to all members of the multidisciplinary team. To support in depth engagement and discussion as a team, support for simultaneous interaction by multiple users is likely to be required and there are also implications for the hardware on which the dashboard is displayed. Literature on audit and feedback suggests that feedback should be constructed through social interaction, which is hard when it is an individual clinician interacting with a clinical dashboard but which can and should be facilitated by a quality dashboard. We also see differences between the requirements when providing feedback to an individual clinician about their performance and when providing information to managers about the performance of a clinical area. Here what becomes important is easy identification of when a clinical area is not meeting particular targets or standards.

We have described a number of ways in which clinical teams assessed performance: comparing performance to a standard, assessing change over time, and comparing performance to performance of other healthcare organizations. While which of these is most effective remains to be determined, we did identify that the choice of approach and
choice of organizations against which to compare will depend on the clinical area. Specifically, comparison against a standard is only likely to be effective if there is evidence to demonstrate that the standard is associated with improved patient outcomes. Existing literature on audit and feedback suggests that only one method of comparison should be used, to avoid the risk of conflicting messages, e.g. if performance is shown to be improving over time but does not meet the desired standard. However, we would argue that both comparing performance to a standard and assessing change over time are important because, depending on the organization’s starting point, the standard may take years to achieve yet it is appropriate for clinical teams to see that progress is being made.

Limitations

For healthcare organizations that are looking to develop quality dashboards, a prioritized list of requirements would be helpful, particularly if resources might be limited. While we have described how the relevance of the requirements will vary according to the user and the clinical area, the qualitative approach to data collection that we have undertaken does not allow us to provide a prioritized list. In a workshop with representatives of 22 national clinical audits, Requirements 2, 4, 7 were categorized as essential by all participants and scoring of requirements identified Requirements 1, 4, 7, and 11 as top priorities. However, the perspectives of the national clinical audits who participated in the workshop may differ from the perspectives of clinical teams and staff at divisional and corporate levels, and thus it would be beneficial to repeat the exercise with them.

A limitation of this research is that data were collected through interviews. Thus, while we have identified requirements for a quality dashboard that our interviewees perceived as important in order to support quality improvement, we do not have empirical evidence to demonstrate that a quality dashboard that meets these requirements will lead to quality improvement. In later phases of this study, we will be introducing a quality dashboard into the five organizations and evaluating its impact, allowing us to assess the importance of the requirements identified.

This research was conducted in the UK, which has an established mechanism for collecting data nationally for quality improvement purposes. However, while it might be UK focused, the findings regarding the implications for developing quality dashboards are relevant across healthcare organizations and contexts.

Conclusion

This study has explored how national clinical audit data are currently used for quality improvement and factors that support or constrain the use of these data. The findings, organized around the themes of choosing performance indicators, assessing performance, identifying causes, communicating from ward to board, and data quality, provide a number of requirements to inform the design of quality dashboards. Future research will explore the extent to which the described features support engagement with national clinical audit data and stimulates quality improvement.

A Health System’s Pilot Experience with Using Mobile Social Knowledge Networking (SKN) Technology to Enable Meaningful Use of EHR Medication Reconciliation Technology

Pavani Rangachari, PhD¹, Kevin C. Dellsperger, MD, PhD², R. Karl Rethemeyer, PhD³
¹Augusta University, Augusta, GA, USA; ² AU Health System, Augusta, GA, USA; ³ University at Albany, State University of New York, Albany, NY, USA

Abstract
In fall 2016, a two-year grant was secured from AHRQ, to pilot a mobile Social Knowledge Networking (SKN) system on Electronic Health Record (EHR) Medication Reconciliation (MedRec), to enable Augusta University (AU) Health System, to progress from “limited-use” of EHR-MedRec technology, to “meaningful-use.” The rationale is that an SKN system would enable knowledge exchange on practice issues related to EHR-MedRec, across diverse provider subgroups and settings-of-care, which, in turn, is expected to increase provider engagement, promote inter-professional learning of best-practices, and provide a foundation for practice change (e.g., Meaningful Use of EHR-MedRec technology). Over a one-year period, 50 SKN Users (physicians, nurses, and pharmacists from outpatient-and-inpatient-medicine services), participated in discussing issues-related-to-EHR-MedRec, moderated by 5 SKN Moderators (senior administrators). This paper describes the health system’s experiences with this pilot initiative; and discusses lessons learned, in regard to the potential of a mobile SKN system to enable Meaningful Use of EHR-MedRec technology.

Introduction
Over the past two decades, there has been a proliferation in the use of mobile technology to improve healthcare delivery, including a dizzying array of applications targeted toward promoting patient self-management of chronic disease, and provider-to-patient communication of treatment and lifestyle management, to improve outcomes and strengthen the patient experience¹ ². By comparison however, there is limited understanding of the potential of mobile technology to enable knowledge exchange and learning across a continuum of care providers, for promoting Meaningful Use of Electronic Health Record (EHR) technology, coordination of care, and patient safety³.

Similar to issues faced in health systems across the U.S., Augusta University Health System (AU Health), based in Augusta, Georgia, faced a scenario of low physician engagement in, and limited-use of its EHR Medication Reconciliation (MedRec) technology, which translated to high rates of medication discrepancies and low accuracy of the patient’s active medication list, during transitions of care. In fall 2016, a two-year grant was secured from the U.S. Agency for Healthcare Research and Quality (AHRQ), to pilot a mobile Social Knowledge Networking (SKN) system pertaining to EHR MedRec, to enable AU Health to progress from “limited use” of EHR MedRec technology, to “meaningful use.” An SKN system refers to an online platform for enabling moderated discussions on select topics among professionals within an enterprise, to foster professional engagement and learning on those topics. Details related to the design and implementation of the SKN system at AU Health, are provided in the section below on “Methods for Implementing SKN.”

The theoretical rationale behind an SKN system on EHR MedRec (which emanates from professional complex systems and social network theories), is that it could provide a platform for tacit knowledge exchange on practice issues related to EHR MedRec, across diverse provider subgroups and settings-of-care, to highlight adverse consequences of gaps in practice for patient safety (e.g., not using the electronic medication history function resulted in an error in recording dosage upon admission, which resulted in adverse event for the patient). This, in turn, is expected to increase physician (provider) engagement in addressing issues related to EHR MedRec; and promote inter-professional learning of best practices related to EHR MedRec (e.g., using the electronic medication history to generate the current medication list during each encounter), to provide a foundation for practice change, e.g., Meaningful Use of EHR MedRec technology ⁴ ¹⁵.

This paper describes AU Health’s experiences with novel use of mobile technology to pilot an SKN system on EHR MedRec. It also discusses lessons learned in regard to the potential of an SKN to enable inter-professional learning and Meaningful Use of EHR MedRec technology; and identifies practice implications for healthcare managers.
Problem of Interest

Healthcare delivery and payment reform efforts are increasingly focused on improving quality and safety during transitions of care, when patients are most vulnerable to medical errors. Transitions of care (from outpatient to inpatient, and back to outpatient settings), are commonly experienced by patients with chronic conditions (e.g., heart disease, diabetes, and stroke). Medication errors in particular, are common at hospital admission and discharge, and are a major contributor to adverse patient outcomes and increased spending associated with transitions of care. According to the Institute of Medicine, medication errors injure over 1.5 million people and cost billions of dollars each year. Additionally, the average hospitalized patient is known to experience at least one medication error per day. The risk of medication errors is heightened during care transitions because, clinicians, and in some cases, patients, do not have access to accurate up-to-date medication lists. This can result in the inadvertent addition, omission or duplication of medications, resulting in “unintended discrepancies” between what patients should be prescribed, and what they are actually prescribed. To help prevent medication errors and discrepancies during transitions of care, patient safety advocates have long promoted the use of Medication Reconciliation.

Medication reconciliation (MedRec) is a formal process for creating a complete and accurate list of a patient’s current medications during transitions of care. The process of MedRec comprises several key steps: (a) develop a list of the patient’s current medications; (b) develop a list of the medications to be prescribed; (c) compare the medications on the two lists; (d) make clinical decisions to update the medication list, based on the comparison; and (e) communicate the updated medication list to both the patient/family and the next providers of care. The goal of MedRec is to reduce medication errors and discrepancies during care transitions, and provide an accurate active medication list to patients and their next providers of care, to promote patient safety and quality of care.

MedRec has been a part of the Joint Commission hospital accreditation requirements since 2005, and with the introduction of the HITECH Act in 2009, it has become part of the Electronic Health Record (EHR) Meaningful Use requirements. Meaningful Use (MU) of EHR MedRec technology refers to effective use of the EHR MedRec system by providers, to complete the MedRec process (outlined above), to reduce medication discrepancies and promote medication-list accuracy, during transitions of care.

Despite the regulatory impetus towards MU of EHR MedRec however, hospital adherence has been found to lag due to low physician engagement in EHR MedRec, stemming in part, from lack of professional consensus about which physician (e.g., hospital vs. community physician) is responsible for managing a patient’s medication list, and the value of MedRec as a clinical tool for promoting patient safety. Additionally, within the hospital context, the assignment of MedRec responsibilities among provider subgroups—multiple physicians, nurses, and pharmacists, —is often unclear, leading to inefficiency and potential for error. Consistent with these findings, several recent studies have found that although hospital EHR vendors have been enhancing MedRec functionality over time, numerous hospitals still use partially paper-based processes during care transitions. In other words, there is “limited use” of EHR MedRec technology, in health systems across the U.S, as opposed to “meaningful use.”

Rationale for SKN

Based in Augusta, Georgia, Augusta University’s Health System, AU Health, is a health care network offering comprehensive primary, specialty and subspecialty care in the region. Facilities include a 478-bed AU Medical Center, more than 80 outpatient practice sites, a Critical Care Center housing a regional trauma center and a 154-bed Children’s Hospital. The health system averages approximately 21,000 inpatient discharges and 90,000 emergency room visits per year. Medicare and Medicaid together account for over 50% of the patient care revenues.

In 2016, AU Health faced challenges with the use and implementation of its EHR MedRec system (which is powered by Cerner Inc., a federally certified EHR vendor). Although MedRec was often marked as “complete” on the EHR, before patient discharge from the hospital, AU Health leadership estimated the patient’s active medication list to be inaccurate (with discrepancies between patient’s home and hospital medication lists, in regard to drugs, dosages, and frequencies), for a majority of discharged cases. Importantly, there was consensus among health system administrators, that the EHR MedRec system was not being used effectively to communicate changes in the patient’s active medication list across the provider continuum and to patients/families. This challenge was ascribed to the general reluctance of physicians to discontinue medications that they did not originally order from the active medication list, which led to not only discrepancies in the active medication list during care transitions, but also to frustrations associated with inaccurate and incomplete medication lists, among patients and providers alike, across the continuum of care.
As such, AU Health faced a scenario that was reflective of national concerns related to use and implementation of EHR MedRec technology in hospitals and health systems, i.e., low physician engagement, translating to limited-use of EHR MedRec technology. In fall 2016, a two-year grant was secured from AHRQ, to pilot-test an SKN system on EHR MedRec, for the purpose of enabling AU Health to progress from “limited use” of EHR MedRec Technology, to “meaningful use” \(^{31,32}\).

The rationale is that an SKN system would enable tacit knowledge exchange on practice issues related to EHR MedRec, across diverse provider subgroups and settings-of-care, which, in turn, is expected to increase provider engagement, promote inter-professional learning of best-practices, and provide a foundation for practice change or improvement (i.e., Meaningful Use of EHR MedRec technology) \(^{4-15}\).

Methods for Implementing SKN

The pilot implementation of the SKN system on EHR MedRec was conducted over a one-year period at AU Health, i.e., April 1, 2017-to-March 31, 2018 (Q2 2017-Q1 2018), among diverse provider subgroups and settings-of-care, i.e., physicians, nurses, and pharmacists, based in outpatient and inpatient medicine settings at AU Health. The SKN system implemented at AU Health, consisted of several components:

- **SKN Reporting Tool**: an online form that allowed participating providers (SKN Users) to report practice issues related to EHR MedRec (e.g., challenges in obtaining complete information at admission for compiling the patient’s current medication list). The form allowed users to provide a brief description of the issue and indicate the care settings and patient conditions it applies to.

- **SKN Discussion Tool (Microsoft Yammer)**: an online platform separate from the SKN Reporting Tool, to enable moderated discussions on issues related to EHR MedRec. Microsoft Yammer is an example of an enterprise SKN system. This pilot project used the basic version of Yammer, which was available to AU as part of its Office 365 package.

- **SKN Lunch-and-Learn Sessions**: A total of 5 SKN Lunch-and-Learn sessions were held over the one-year SKN period, for participants to meet and discuss lessons learned from exchanges on SKN Yammer, in person. Advance invitations to these sessions were sent to all SKN participants.

- **SKN Periodic Email Updates**: Approximately 15 periodic progress update emails were sent by the Principal Investigator (PI) to all SKN participants, over the one-year SKN period.

Additionally, there were two types of participants in the SKN system:

1. **SKN Moderators**: included a group of 5 senior administrators who played a key role in moderating discussions on issues related to EHR MedRec among participants (SKN Users) over the one-year SKN period. The 5 SKN Moderators included the Chief Medical Officer (CMO), Chief Medical Information Officer (CMIO), two hospitalist chiefs, and the Principal Investigator (PI). A key responsibility of SKN Moderators was to bring issues related to EHR MedRec reported by individual SKN Users on the SKN Reporting Tool, for discussion by all SKN Users on Yammer. As such, a majority of threads-of-discussion on Yammer began with an issue-report (problem statement) brought to Yammer by SKN Moderators. Another responsibility of SKN Moderators was to proactively initiate discussions on topics relevant to EHR MedRec (e.g., best practices identified in the literature), and bring lessons learned from the SKN system, for discussion at regular health system meetings, including the Hospital Quality Council.

2. **SKN Users**: included 50 practitioners, i.e., physicians, nurses, and pharmacists based in outpatient and inpatient medicine services at AU Health, who agreed to participate in the SKN system. Key responsibilities of SKN Users were to 1) report issues related to EHR MedRec on the SKN Reporting Tool on an ongoing basis; 2) participate in moderated discussions on SKN Yammer, over the one-year period; and 3) share lessons learned from their ongoing participation on the SKN, with colleagues in the health system. However, SKN Users were not allowed to initiate new threads-of-discussion directly on SKN Yammer. This ability was restricted to SKN Moderators, to enable coordinated discussions of issues related to EHR MedRec on the SKN system.

Participant recruitment to the SKN system, began after the project received IRB approval from Augusta University. All practitioners in three professional subgroups, i.e., physicians, nurses, and pharmacists, within five inpatient and outpatient medicine service lines at AU Health, including Cardiology, Internal Medicine, Family Medicine, Emergency Medicine, and Hospitalist service lines, were approached by the PI for recruitment using the IRB-approved informed consent process. Cardiology was the only medicine subspecialty included in the project. A total of 50 practitioners were recruited to participate as SKN Users, including 15 physicians, 15 nurses, and 20 pharmacists, from outpatient and inpatient medicine settings. All participating physicians from Cardiology, Internal
Medicine, and Family Medicine, practiced in both inpatient and outpatient settings. Only Hospitalists were exclusively inpatient practitioners.

Participants received a detailed orientation to the SKN system, prior to its launch, including steps for accessing the SKN Reporting Tool and SKN Yammer, both of which were made available to participants through separate links within the EHR at AU Health. Both tools were also accessible through the enterprise employee web portal and through mobile devices. Additionally, Yammer was downloadable as an App. Figure 1 provides screenshots of the SKN Reporting Tool and SKN Yammer.

Figure 1. Screenshots of SKN Reporting Tool and SKN Yammer.

Of the 50 practitioners who signed up to be SKN Users, 25 were active users of SKN Yammer, with 10 or more posts over the one-year SKN period. Active users of Yammer came from all professional subgroups and care settings represented on the SKN, including 8 physicians, 8 nurses, and 9 pharmacists. Additionally, 3 of the 5 SKN Moderators (including the CMO, CMIO, and PI), each posted 40 or more messages on Yammer.

Over the one-year SKN period there were a total of 485 posted communications on Yammer, divided into 62 threads-of-discussion. Of these, 45 threads had 3 or more posts; among which, 12 threads had 10 or more posts; of which 3 threads had 25 or more posts, including 1 thread with 45 posts. There were a total of 32 issues related to EHR MedRec reported on the SKN Reporting Tool, over the one-year period. Of the 45 threads with 3 or more posts, 32 began with issues reported on the SKN Reporting Tool, brought in to Yammer by SKN Moderators. As such, all issues related to EHR MedRec that were reported on the SKN Reporting Tool, were used to launch threads-of-discussion on Yammer. All threads-of-discussion on Yammer, were open and available to all SKN Users, without restriction. Yammer recorded the name, date, and time associated with each posting.

Health System Experience

Thematic analysis of the content of inter-professional knowledge exchange related to EHR MedRec on SKN Yammer over the one-year period, revealed six broad themes that were repeated across several threads-of-discussion, in the chronological order outlined below 33-35:

1) Problem Statements
2) Problem-Solving Statements (“The How-To”)
3) IT System Education (“The What”)
4) Best-Practice Assertions (“The Why”)
5) Culture Change Assertions (“The Way-To”)
6) Collective Learning (“Aha”) Moments

Figure 2 provides an example of a discussion thread (THREAD 1) on a practice issue related to EHR MedRec on Yammer, for which inter-professional discussions progressed through the full spectrum of themes from “problem statements” to “collective learning (aha) moments,” to lay a foundation for practice change (improvement), during
the one-year SKN period. In essence, this practice issue pertained to the “Importation of the External Rx History during Patient Encounters,” which pertained to the broader theme of improving communication related to the patient’s active medication list, across the continuum of providers. “External Rx History Import” refers to the electronic importation of the patient’s medication history filled at their pharmacy, by the provider (at the start of the patient encounter), by activating the Rx History button on the EHR, which would access the Surescripts system to pull the patient’s Rx history. Surescripts is an IT company that supports e-prescription, the electronic transmission of prescriptions between healthcare organizations (HCOs) and pharmacies. According to the US DHHS, in 2014, 96% of US pharmacies used the Surescripts network. At AU Health, it was determined that 90% of patients fill their prescriptions at pharmacies that participate in the Surescripts system.

Discussions related to “External Rx History Import” began with a problem statement from an Emergency Department (ED) Nurse, in regard to the challenge of obtaining the correct medication history from the patient upon arrival, to formulate the current medication list for reconciliation. In response, an outpatient nurse suggested use of the “External Rx History Import,” functionality within the EHR, for obtaining a current medication list for reconciliation. However, this suggestion was initially met with resistance. For example, the ED nurse argued that the External Rx History was not completely accurate, and therefore could not be trusted, and another provider, a Cardiologist argued that relying on the External Rx History when the patient does not have all the ‘pill bottles,’ could create errors. These disagreements were met with problem-solving statements from other providers. For example, a hospitalist physician argued that even if an electronic list of medications cannot be fully trusted, it could provide a starting point for discussing with patients what they are actually taking. Such statements were then followed by IT system education, e.g., clarifications related to the External Rx History functionality on the EHR by the CMIO/SKN Moderator, which was followed by best-practice assertions from pharmacists, i.e., articulations of the benefits of adhering to and consequences of not adhering to the best practice of External Rx History Import. For example, a pharmacist argued that importing “External Rx History,” preferably as close to admission as possible, is essential, since it includes 90% plus of what actually occurred in the community. While there may be some gaps, it would at least allow providers to know what the patient has been prescribed and help them question why they are not taking certain medications. The CMO/SKN Moderator then helped to reinforce these best-practice assertions, by providing examples of recent cases where dosing errors could have been averted, if the External Rx History option had been used. Another pharmacist then put forth a culture change assertion, urging participants to not allow ‘perfection to become the enemy of the good,’ arguing that, when prescribers do not act to reconcile a medication owing to insufficient information, they are making a decision to ‘do nothing.’ The CMO/SKN Moderator helped to reinforce this message by arguing that ED patients and hospital-to-hospital transfers have little ability to provide medication history, making the importation of External Rx History, all the more important. These discussions culminated in a collective learning (aha) moment summarized by the PI/SKN Moderator, in that, “incremental efforts to improve the accuracy of the current medication list, by leveraging the External Rx History Import function, could go a long way in reducing medication discrepancies during care transitions.” The second SKN Lunch-and-Learn session (held in July 2017), provided an opportunity for SKN Moderators to meet face-to-face with several SKN Users. The essential purpose of this session was to summarize lessons learned from Yammer on the topic of External Rx History Import; and reinforce the collective learning (aha) moments on this topic.
Figure 2. Dynamics of Inter-Professional Knowledge Exchange on External Rx History Import (THREAD 1).
The aforementioned inter-professional learning dynamics in turn, coincided with a distinct improvement trend in the Aggregate Proportion of External Rx History Import among all Congestive Heart Failure (CHF) patient encounters in the 5 participating medicine service lines at AU Health, during and beyond the SKN period. This measure may be regarded as a “measure of Meaningful Use (MU) of EHR MedRec technology” (or a measure of best practice in EHR MedRec), because a higher proportion, reflects better use of the EHR MedRec system by providers, to obtain a current medication list, for reconciling with new prescriptions, to reduce medication discrepancies and improve accuracy of the active medication list, during transitions of care.

Figure 3 depicts the trend in this measure over a 6-quarter period (Q1 2017-Q2 2018). The vertical dotted line on the graph represents the point-in-time of the second SKN Lunch-and-Learn session, which was conducted (at the start of Q3 2017), after several weeks of inter-professional discussion on SKN Yammer. Essentially, this session served as a culminating point for collective learning on the topic of External Rx History Import. As indicated in the figure, substantial improvement (increase) of over 140% was noted in the measure, during and beyond the SKN period, including a discernible increase from Q2 to Q3 2017 among the SKN participating medicine service lines. On the other hand, the comparative data for the Neurosurgery service line at AU Health (which did not participate in the SKN system), shows a relatively stable trend in the same measure, with the aggregate proportion of “External Rx History Import” for this service line, remaining at an average of ~45%, throughout the same timeframe. These dynamics in inter-professional learning and practice improvement suggest that the distinct improvement trend noted in this measure of MU of EHR MedRec technology among the 5 participating medicine service lines, may have emanated from the inter-professional learning associated with this topic, on the SKN system.

Lessons Learned and Practice Implications

The health system’s pilot experiences suggest that a mobile technology-enabled SKN system could be a valuable tool for engaging providers to share knowledge on practice issues and promote inter-professional learning of best-practices, to create a foundation for practice change/improvement, i.e., EHR Meaningful Use. The experience also suggests that the SKN system enabled progress towards MU of EHR MedRec, by addressing EHR implementation-challenges in the correct sequence, i.e., by facilitating collective learning of the value of best-practices in EHR MedRec and a shared understanding of the system-level EHR MedRec workflow among providers (i.e., the “big picture”), before IT-training of providers to address socio-technical challenges of EHR implementation (e.g., differing system-views across provider subgroups). Results also suggest that an SKN system may be a particularly valuable tool for institutions where practice change (e.g., MU of EHR technology) needs to occur with existing resources, through workflow changes; as opposed to new resource outlays, e.g., dedicated pharmacy techs in each and every unit within the health system. Importantly, the experience suggests that the health IT components of the SKN system, e.g., SKN Yammer and the non-health-IT components, e.g., SKN Lunch-and-Learn sessions, served to not only complement, but also reinforce each other synergistically, to enable inter-professional learning, and provide a foundation for practice change (MU of EHR MedRec technology).
From a broader perspective, the experiences with this SKN pilot initiative at AU Health, help to identify the following evidence-based management strategies for the creation of “learning health systems,” for enabling successful change implementation in HCOs.

- At the start of the effort, create a knowledge sharing and learning mechanism (e.g., SKN) among a critical mass of providers, expected to implement practice changes. The mechanism should facilitate tacit knowledge exchange on issues experienced with current practices, as well as possible resolutions to those issues.
- Conduct proactive, periodic communications (from senior leadership) on benefits of adhering to best practices and consequences of not adhering to them.
- Create shared understanding of the value of best practices (i.e., the link between practices and outcomes) or the “why,” to gain provider engagement in practice change, before embarking on IT-training of providers to address sociotechnical (health IT) challenges.
- Develop capacity to collect, analyze, and disseminate data on best-practice measures among providers to promote a scientific (research-based) approach to learning and improvement.
- Enable champions for change to emerge from among providers, to voice the need for culture change for enabling successful best-practice implementation; and reinforce these messages with proactive, periodic communication from senior leadership.
- Create a “learning health system,” by synthesizing lessons learned to facilitate “collective learning (aha) moments” across provider subgroups and care settings; and encourage providers to spread the learning within the broader institution.

The aforementioned set of strategies, represents a significant contribution to healthcare management practice, particularly in the context of a growing body of literature that has argued for health IT initiatives to be evaluated using a “health system” lens, i.e., from a broader perspective of achieving health system goals. In other words, hospital IT initiatives should be able to be integrated into existing health system functions and complement health system goals to avoid being perceived as silo or stand-alone solutions. This paper provides a meaningful example of a pilot hospital IT initiative that was integrated into a broader health system goal of developing a “learning health system,” to enable Meaningful Use of EHR MedRec technology. To this effect, this paper is also directly aligned with the AMIA 2019 Annual Meeting Theme: “Informatics: From Data to Knowledge to Action.”

Conclusion

The health system’s experience with this pilot initiative suggests that an SKN system could be a valuable tool in enabling inter-professional learning to promote complex practice change (e.g., MU of EHR technology). Future research could help to evaluate the generalizability of experiences in this case, through large-scale controlled experiments to investigate causal relationships between SKN use and Meaningful Use of EHR technology, across a wide variety of HCOs. These types of research endeavors in turn, would help to generate a systematic evidence-base of strategies for promoting Meaningful Use of EHR technology, which, in turn, could be used to prompt federal EHR vendors to incorporate SKN features into EHR systems.

Abstract
With the increased adoption of electronic health records, data collected for routine clinical care is used for health outcomes and population sciences research, including the identification of phenotypes. In recent years, research networks, such as eMERGE, OHDSI and PCORnet, have been able to increase statistical power and population diversity by combining patient cohorts. These networks share phenotype algorithms that are executed at each participating site. Here we observe experiences with phenotype algorithm portability across seven research networks and propose a generalizable framework for phenotype algorithm portability. Several strategies exist to increase the portability of phenotype algorithms, reducing the implementation effort needed by each site. These include using a common data model, standardized representation of the phenotype algorithm logic, and technical solutions to facilitate federated execution of queries. Portability is achieved by tradeoffs across three domains: Data, Authoring and Implementation, and multiple approaches were observed in representing portable phenotype algorithms. Our proposed framework will help guide future research in operationalizing phenotype algorithm portability at scale.

Introduction and Background
As the proliferation of electronic health records (EHRs) has increased the secondary use of healthcare data, it has also catalyzed the establishment of collaborative research networks where multiple institutions are working on large studies to increase their sample size and diversity of the study population. This has been demonstrated via multi-site prospective clinical trials and large-scale observational studies, where participant eligibility criteria queries - which, typically take the form of phenotype algorithms (i.e., structured selection criteria designed to produce research-quality phenotypes)1,2 - are run at each participating institution to identify the study cohort. More recently, large collaborative networks such as the Health Care Systems Research Network (HCSRN, formerly the HMORN)3, Mini-Sentinel4, the electronic Medical Records and Genomics (eMERGE) Network5, the National Patient-Centered Clinical Research Network (PCORNet)6, the Accrual to Clinical Trials (ACT) Network7, the Observational Health Data Sciences and Informatics (OHDSI) program8, and the Electronic Health Records for Clinical Research (EHR4CR) European project9 have shown different models for how a single phenotype algorithm may be run across heterogeneous EHRs and database systems. A desired state from many of these networks is to have “computable phenotype algorithms” that are portable, and can be executed in a high-throughput manner10.

In our observations, across both clinical trials and research networks, two primary models have emerged for the implementation of phenotype algorithms at multiple sites: 1) sharing a human-readable narrative of the algorithm that is re-implemented at each site (e.g., clinical trials, eMERGE), and 2) using a pre-coordinated common data model (CDM) which allows sharing of machine interpretable executable code (e.g., OHDSI, PCORnet, HCSRN). The first approach often reduces the burden on the algorithm authoring institution, as they may describe the phenotype algorithm logic and required medical vocabulary codes in a more generic manner or in a manner that meets their local institution-specific settings (e.g., local, non-standardized laboratory measurement codes). This algorithm logic can then be disseminated widely via public repositories - the eMERGE Network uses the Phenotype KnowledgeBase (PheKB)11, and clinical trial criteria are made available on ClinicalTrials.gov12. Sites implementing the phenotype algorithm then interpret and convert the written description to an executable format that can run against their local data, which often requires iterative communication with the original author(s) to ensure accuracy. Local validation is an important component to ensure the implementation is correct, and that the phenotype algorithm implementation is sufficiently sensitive and/or specific (depending on the specific study needs) when implemented across multiple sites13. To this end, phenotype algorithms may be easily shared as a narrative document, but this limits scalability as each algorithm must be transformed from a narrative to local queries. This has been shown to be a cumbersome, resource-intensive and error-prone process14.
The second approach, the use of a CDM, uses a pre-coordinated structure for the data such that the phenotype algorithm – represented as a database query – may be directly shared and executed at different sites using the same CDM. Several CDMs have been defined, including Informatics for Integrating Biology and the Bedside (i2b2)\textsuperscript{13}, PCORNet\textsuperscript{6}, Mini-Sentinel CDM\textsuperscript{16}, OHDSI’s Observational Medical Outcomes Partnership (OMOP)\textsuperscript{17}, the Clinical Data Interchange Standards Consortium (CDISC) Study Data Tabulation Model (SDTM)\textsuperscript{18}, and the HCSRN’s Virtual Data Warehouse (VDW)\textsuperscript{19, 20}. CDMs by their nature are optimized for a specific set of uses and data sources (e.g., clinical vs. research, claims data vs. EHR data)\textsuperscript{21}. Furthermore, no CDM is “universally common,” meaning that translation and reimplementation are required when crossing CDM boundaries. A more recent project led by the Food and Drug Administration, “Harmonization of Various Common Data Models and Open Standards For Evidence Generation”\textsuperscript{22}, is developing mappings from several of these CDMs to the BRIDG\textsuperscript{23} domain analysis model to address this need. In addition, local adjustment of the phenotype algorithm is still sometimes needed to account for differences that may not be addressed by a CDM, such as different numeric ranges for abnormal lab results across sites. Similar to the first approach, sensitivity and specificity still need to be assessed to ensure the phenotype algorithm is complete (e.g., includes all relevant vocabulary codes). Because of this, portability of phenotype algorithms is not solved solely by a CDM, although a CDM provides many advantages\textsuperscript{10}.

The Phenotype Execution and Modeling Architecture (PhEMA) project has proposed an architectural model\textsuperscript{24} that supports the authoring of standards-based EHR-based phenotype algorithms, and their subsequent execution across multiple CDMs. This is done by the use of a canonical, standard representation of the phenotype algorithm logic and value sets (collections of standard medical vocabulary codes). PhEMA then automates the translation steps to convert these pieces to computable phenotype algorithms for individual CDMs. Most recently, PhEMA was used to execute a benign prostatic hyperplasia phenotype algorithm across multiple institutions’ data warehouses and i2b2 instances\textsuperscript{25}, demonstrating a basis for a single representation of a phenotype algorithm that can span multiple data models. In addition to crossing data model boundaries, we recognize that many other facets of portability exist. In this work, we build on the reported experiences of collaborative research networks, as well as our experiences in implementing PhEMA across three academic medical centers, by further exploring the considerations needed for cross-site portability of phenotype algorithms.

**Methods**

We identified large research networks published in the health and biomedical informatics literature that have focused on building or leveraging infrastructure to support cross-site execution of EHR-based phenotype algorithms. Identification of the networks was done from a cursory search of PubMed for consortia describing EHR-based phenotyping, supplemented by the authors’ collective experience. Within this paper, we are broadly considering an “EHR-based phenotype” as a definition of a disease or trait that is ascertained primarily from data stored in an EHR. We limited consideration to only those networks describing a distributed model, in which participating institutions retain access to their respective data, and those that have an established infrastructure to demonstrate portable phenotype algorithm execution. In total, we selected a purposive sample of seven collaborative networks: ACT Network, EHR4CR, eMERGE, HSCRN, Mini-Sentinel, OHDSI, and PCORnet. We reviewed the literature published by the respective networks, as well as documentation available online regarding CDMs and technical architecture. This was supplemented by the authors’ experience from participation in some (but not all) of the networks, and personal communication with members in other networks. From this, we created maps showing the elements used to compose a phenotype algorithm, the methods by which phenotype algorithms are shared across sites, and how they are executed at each site. Multiple approaches may be used within a single network; however, as our objective was to evaluate the distinct approaches, we did not exhaustively document all possible permutations across all networks. These models were consolidated into a final framework to capture and model the considerations needed for portable EHR-based phenotype algorithms.

**Results**

From review and consolidation of the respective research network models, we developed a framework for phenotype algorithm portability that has three main components: 1) a phenotype algorithm workflow model, 2) a portability tradeoff model, and 3) a portability representation model.

**Phenotype Algorithm Workflow Model**

The phenotype algorithm workflow model is comprised of 8 steps across 3 broad domains that we identified as being involved within the phenotype modeling and execution process, and that have potential impact on portability (Table 1). As described, these steps identify the core work needed to establish a portable phenotype algorithm, and are part...
of an iterative process.

</table>
Data Collection - A reality for any research network is that if a particular data element is not collected as part of an institution’s care process, it will never be available to a phenotype algorithm. Similarly, if a data element is available within a source system but is not made available to a site’s integrated data repository (IDR) in a way that it can be queried, a phenotype algorithm will not be able to include it. This may be observed with data collected as clinical narratives or images, as opposed to structured data. We note that even with a common data model that is capable of representing all medical concepts, these potential barriers would keep the data not represented in the CDM from being provided. This remains a consistent barrier across all networks.

Data Preparation - We observed that many networks adopted a CDM to aid with portability. This requires those involved with the Data Preparation step to spend additional time “data wrangling” (i.e., cleaning, mapping and translating their source EHR data into the CDM). This reduces the downstream effort on both authors and implementers. There are variations in the pre-coordination of vocabularies within the CDMs, however. For example, within i2b2 (used in the ACT network), each site may have a local ontology specified for their data elements. This allows for custom data elements (e.g., status within a biobank or clinical trial), as well as individual site selection of the vocabulary to use (e.g., NDC codes for medications instead of RxNorm codes). Other networks, such as OHDSI, provide stronger guidance on the vocabularies to use, potentially requiring additional time and effort in the data mapping process. They still allow flexibility by preserving the source system’s native vocabulary code, and allow phenotype algorithms to be defined using those codes. Some CDMs account for processing steps to convert data between modalities, such as the NOTE_NLP table within OMOP to store structured results from natural language processing (NLP). This requires additional effort to perform NLP on clinical text, but produces structured data that is more amenable to processing. Depending on the amount of effort needed, not all sites adopting a CDM may perform this pre-processing, or may do it on an ad hoc basis as new categories of data are needed for a study (e.g., processing just echocardiogram reports). On the other hand, it was pointed out that existing NOTE_NLP table lacks flexibility to store relations between medical concepts.

Defining Value Sets - In networks where a pre-coordinated set of vocabularies have been implemented (as described in Data Preparation), time and effort are reduced within the authoring process as the phenotype algorithm author can write the phenotype algorithm for just those vocabularies. For example, within OMOP, diagnoses may be represented entirely using SNOMED CT. Within networks such as eMERGE where sites re-implement the phenotype algorithm locally, additional effort is needed by the author or implementation site to expand a value set. For example, an existing phenotype algorithm developed using just ICD-9-CM codes only would need to be updated for an implementer wishing to include ICD-10-CM codes (ICD-10 codes were used in the US only after October 2015). We note that the reduced authoring time in networks having a pre-coordinated vocabulary does not necessarily guarantee portability across research network boundaries. For example, an HSCRN query representing a medication value set with NDC codes would require mapping to RxNorm to support execution in ACT.

Defining Logic - Research networks use three general approaches to make their phenotype algorithms portable. The first is the use of a specific programming language to represent the query (e.g., SAS within HSCRN, R and SQL within OHDSI). A second approach is the use of a system-specific intermediary representation for the logic, agnostic to underlying implementation. For example, the ATLAS JSON format within OHDSI, the XML query definition in i2b2, and the Eligibility Criteria Language for Clinical Trial Investigation and Construction (ECLECTIC) within EHR4CR. The third approach is the development of a written narrative and/or visual flowchart to describe the phenotype logic (e.g., phenotype logic posted to PheKB for eMERGE). This last format is based on a computable implementation at the authoring site, which may be done against any data model and using any technology the authoring site chooses. The description of the phenotype algorithm may be easier for the author to provide as it can convey the intent of the logic without prescribing specific tables or fields to be used, but requires each implementing site to read, evaluate and map the intent of the logic to their local institutional data model.

Distribution – Phenotype algorithms were distributed manually or automatically, and the choice of distribution method often depends on how the logic was represented as well as constraints within the research network. Within the eMERGE network, the author will manually publish a phenotype algorithm to PheKB, and inform implementing sites when it is ready. Similarly within OHDSI, phenotype algorithms may be tracked within a central GitHub repository, where they can be reviewed and manually imported into a local OHDSI instance. The HSCRN and PCORnet have infrastructure to electronically share the phenotype algorithm to implementing sites, where it may be reviewed from a worklist before execution. Federated architectures, such as EHR4CR’s Orchestrator, ACT’s use of the Shared Health Research Information Network (SHRINE) on top of i2b2, or the ARACHNE system within OHDSI, allow phenotype
algorithms to be automatically distributed. Within this step, automation can reduce burden on implementers, and also reduce burden on authors if a technical solution exists to link authoring to distribution.

**Translation** - Varying levels of transformation are needed across the networks, driven by technical capabilities. Within HSCRN (where SAS files were directly shared) and within OHDSI (where SQL and R code are shared), some manual translation may be needed to configure the code to run locally. As an example, SQL code for OHDSI may require specifying a local database schema name before it can be run. Within OHDSI where the JSON representation of a phenotype algorithm is shared from the ATLAS system, the translation is done automatically. Similarly, within ACT, SHRINE performs real-time mapping of ontology terms in the XML message to the local i2b2 instance, and i2b2 itself manages translation of XML to local SQL queries.

**Execution** - This step is consistent across all research networks, as all translations have been completed and the phenotype algorithm is now in an executable format for the local data repository. During the execution phase, considerations for portability are driven largely by the results of the execution. A phenotype algorithm may be appropriately translated to SQL code, but requires a significant amount of time or resource to run. This may be to the point where the SQL code is unable to complete before a system-level timeout causes it to halt; thus, it is not truly executable and is no longer viewed as a portable implementation. Likewise, a phenotype algorithm may have execution paths that are entirely dependent on a category of data that is not present due to considerations from steps in the Data domain. Although a syntactically valid definition of the phenotype algorithm exists, it is also not viewed as portable given that it returns no records when some records are expected to be found.

**Validation** – This step is carried out in multiple ways across the different research networks, often depending on the technical approach used to perform actual execution. Usually the first pass of the execution is a simple cohort count (“how many cases and controls with X?”), which may be supplemented with a demographic breakdown. An initial face-validity check of the result can be used to ascertain if the results seem feasible, given expected prevalence of a condition. To perform more in-depth validation, or to troubleshoot why a phenotype algorithm is returning an empty cohort, access to the underlying data model is typically needed. As this is a manual process, it requires additional coordination and time across implementation sites by the author site to conduct chart reviews. Automation of this type of analysis can be done in the Execution step, although this increases overall execution time.

**Portability Tradeoff Model**

The second component of our proposed framework is a portability tradeoff model that represents the interlinked nature of the three domains in the workflow model. Across the seven reviewed research networks, we observed that different weights are given to Data, Authoring and Implementation. Within the portability tradeoff model, we consider a higher weight in a domain as having an increased overall cost (although we note that a high cost is not inherently “good” or “bad”). These costs are in turn linked to the “iron triangle” of project management: time, features and resource. This results in what we have termed the “nested iron triangle of phenotype algorithm portability” (Figure 1). For example, OHDSI and PCORnet put additional weight on the Data domain, such that more up-front work is needed at each institution to adhere to the CDM. This reduces the time spent on Authoring, as the author only needs to consider a single data model and a limited set of vocabularies. Similarly, less effort is then needed at each site for Implementation, as less localization is needed during the Translation step. As a second example, sharing phenotype algorithms as narratives (employed within the eMERGE network) allows flexibility in the data model, often leveraging existing data warehousing infrastructure (decreased weight on Data). However, additional time may be required during Authoring, if the author is considering portability and thoroughly investigating comprehensive value sets. Furthermore, more weight is given to steps in the Implementation domain, as each site must put more effort into the Translation step to arrive at an executable definition.

![Figure 1. Portability tradeoff model: the “nested iron triangle of phenotype algorithm portability”.](image-url)
**Portability Representation Model**

During our review, we observed how the seven research networks approached the representation of the phenotype algorithms, and the impact this representation had on portability across steps in the Authoring and Implementation domains. This is defined in its own model given the additional considerations needed. Four general approaches were identified (Figure 2), with their own benefits and limitations.

**Unchanged** – This approach is the ideal state of portable representation, as a single definition (the originally developed phenotype algorithm) may be distributed for use at the implementing sites. Technically this approach is currently available in our reviewed networks, with the exception of the non-computable narrative phenotype algorithms in the eMERGE network.

**Criteria Relaxation** - This approach allows making a phenotype algorithm more general by reducing or removing constraints, while monitoring and balancing sensitivity and specificity for the intended use case. This results in a single phenotype algorithm that is distributed, and only includes the logic known to be runnable at each implementing site. We observed this as being universally available across all of the research networks from a technical standpoint. All reviewed systems across the research networks allow criteria to be removed entirely (if overly-exclusive), or constraints broadened (if insufficiently inclusive). This requires creating a revision of the phenotype algorithm with the modified logic and/or value sets. This may result in a phenotype algorithm with overall lower sensitivity and higher specificity across multiple sites, but allows the phenotype algorithm to remain a singular entity that eases distribution, as the same phenotype algorithm is shared universally.

**Multi-Label Specification** - This approach involves implementing a single version of the phenotype algorithm, but allowing different labels to be applied to the cohort, depending on quality of evidence (e.g., “gold standard” and “silver standard”). Unlike criteria relaxation, this allows the single phenotype algorithm to be run at each site and produce results, but may increase overall complexity of the phenotype algorithm depending on the number of logic paths. This is not directly supported outside of narrative descriptions (eMERGE phenotype algorithms) and executable implementations (e.g., HSCRN SAS, OHDSI SQL and R). In networks that provide an intermediary platform to author phenotype algorithms (ACT’s i2b2 and OHDSI’s ATLAS), no solution was observed. Instead, authors must create multiple versions of a phenotype algorithm - one for each label. This causes duplication of logic, which must now be maintained across multiple phenotype algorithms, and these platforms do not provide a way to group the disparate phenotype algorithms together to show they are related.

**Site-Specific Customizations** - In this approach, the implementing site changes the logic or translates executable code of the phenotype algorithm so that it will run and produce acceptable results. This may be done at the discretion of the implementing site, or done in conjunction with the original author to assess tradeoffs. The result is multiple versions of the phenotype algorithm, which are (at best) loosely linked together. This approach is also universally available across all of the research networks. We note that while it provides flexibility to implementers (at the tradeoff of additional work), it severs provenance to the original phenotype algorithm. This makes subsequent changes by the original author difficult or impossible to incorporate automatically, as well as changes from the implementers that may be useful to the author and other implementers.

Discussion
Here we have presented a framework of phenotype algorithm portability based on the reported experiences of seven research networks. It is comprised of three interlinked models, which together provide researchers and system evaluators with a comprehensive framework against which to consider barriers and solutions to the portability of EHR-based phenotype algorithms. The framework demonstrates that the concept of phenotype algorithm portability is multi-faceted, as shown by the number of steps and potential impact points, and by the observation that the approaches within each model are not necessarily mutually exclusive within a single network. For example, within the portability tradeoff model, an institution adopting a CDM such as PCORnet may put less up-front investment in the Data domain (reducing it compared to other sites), which then would increase Implementation resource needs for that site. Similarly, within the portability representation model, multiple approaches may be observed within the same network. Within OHDSI, an ATLAS-authored phenotype algorithm may be shared across sites as unchanged, but a SQL script written for a specific database vendor may require site-specific customization to port the syntax to another vendor system. While in our framework and respective models we consider automation and computability, we note that the concept of portability is not dependent on them. For example, several of the research networks that we evaluated require the manual review of a phenotype algorithm before it could be executed (driven by that network’s operating policies). We recognize that this mandated manual review step impacts how scalable that portability solution is to a large number of phenotype algorithms.

Our proposed framework is supported by previous studies reported in the literature, but to our knowledge, no previous study has considered all aspects of portability. Our framework supports the ongoing need for localization of phenotype algorithms, which was also identified within a previously reported desiderata33. We believe the need for localization will remain for the foreseeable future, given the number of disparate CDMs that exist, and the complexities of data collection and representation within the EHR34. As CDMs continue to evolve, and as more work is done to harmonize CDMs35, that need will lessen. However, previous studies have demonstrated the impact of data heterogeneity on phenotype algorithms36, 37, which we believe will be an ongoing issue. Recognizing this, we propose adjusting the view of a phenotype algorithm as a single, immutable object. This view is currently reflected in practice, as demonstrated by three of the four approaches in our portability representation model (criteria relaxation, multi-label specification, and site-specific customization). No system to date has fully addressed how to represent this in a computable way, although we note systems like PheKB provide a communication hub to centralize storing multiple site implementations for a phenotype algorithm.

Instead, as more phenotype algorithms are made computable, they should incorporate localization considerations centrally, regardless of the approach needed. For example, criteria relaxation allows for a central computable definition, as it involves changing a single definition. The inclusion of version tracking (an approach used by PCORnet’s ADAPTABLE trial38 and OHDSI39) would also allow tracking changes to the phenotype algorithm as criteria are relaxed, and allow documentation of the tradeoff decisions considered over time. The resulting phenotype algorithm would then be a single repository with the full history available. For multi-label specification, a computable phenotype algorithm should provide a means by which the label may be assigned during authoring, and automatically tracked during implementation. This will require adjusting tools and specifications used in the authoring and execution processes. We note that within the PhEMA project, work is ongoing to develop a representation that meets these requirements. The final approach, site-specific customization, may benefit from lessons learned in version control systems for source code management. Based on a single, original phenotype algorithm, implementers may make a copy (“branch”) which retains a link back to the original. The implementer may propose changes (via “pull request”) or the author may review localized copies of the phenotype algorithm to determine if changes could be incorporated into the original definition.

With particular respect to controlled medical vocabularies, a previous review noted the overlap in available terms across vocabularies, although no clear rationale was ascertained as to why different vocabularies (with incomplete mappings observed in some instances) were used in a phenotype algorithm14. We posit, based on our experiences, that this is in part due to the availability of data at a local institution (the Data phase of our proposed model). That is, the rules developed or features learned in the creation of a phenotype algorithm are driven by the data collected and mapped to an IDR or CDM. While some phenotype algorithm authors do consider the most comprehensive value set definition up-front, and CDMs such as OMOP use a prescribed set of vocabularies to obviate the need for heterogeneous vocabulary mapping, they are not singular solutions. This further highlights the importance of
implementing and evaluating phenotype algorithms at multiple institutions, which will naturally uncover gaps in the original definition. Portability, in turn, becomes a critical consideration.

Although our review primarily considered rules-based phenotype algorithms, similar parallels can be drawn with respect to machine learning (ML)-based data-driven algorithms. ML-based approaches have demonstrated potential to achieve high-throughput phenotyping by learning relevant features of the EHR data (including features derived from narrative text), thereby reducing the time to establish a phenotype algorithm as opposed to manually curated, expert-driven rules-based phenotype algorithms at each institution. Additional considerations for portability within the phenotype algorithm workflow model would include an expansion of our proposed Translation and Execution steps. This is because collection of a relevant corpus and re-training of the algorithm is needed locally before the phenotype algorithm may perform optimally. For the portability tradeoff model, we believe our proposed criteria relaxation and site-specific customization approaches would apply to ML-based phenotypes, as features used within the model may be removed (relaxed) from the model for all implementers, or require other local changes depending on factors such as data availability. More recent advances in ML have included the concept of “federated learning,” whereby predictive models may be trained across disparate data sources that are not centrally available to the model developer (e.g., to preserve privacy). This has been demonstrated in the healthcare space, and future work in this area will be an important consideration for portable ML-based phenotype algorithms that can automate the evolution of phenotype algorithm by iterating through all sites’ data.

We do acknowledge some limitations of this work. Although we are proposing our framework as a global one, we recognize that this is not based on a systematic literature review, and is focused on the health and biomedical domain. As our reconciliation of the network-specific models was based on multiple permutations, and we reached a saturation of new permutations during the review, we do believe the model represents the current state of the field. Similarly, as new knowledge is gained within the health and biomedical domain and beyond, the model can (and should) be adjusted accordingly. We also recognize that no evaluation of the reviewed research networks is presented using this framework. In development of the framework, we observed that heterogeneity within each network can and does exist (as previously mentioned). This precluded us from classifying each network as a whole, and instead requires formal study within and across the respective networks. We believe this is important future work to be undertaken, but was outside of the scope of this paper. Given current knowledge, this model provides health and biomedical informatics researchers with a framework by which to formally evaluate and further study aspects of portability of EHR-based phenotype algorithms.

Conclusion
Based on a review of seven multi-site research networks, we have identified multiple steps and considerations that impact how an EHR-based phenotype algorithm may be made portable. We have provided a more comprehensive definition of phenotype algorithm portability by proposing a framework with eight steps across three domains (Data, Authoring, Implementation). Within these domains, we have also identified and illustrated how optimizing one can result in more or less effort required in another, and how multiple representations for portable phenotype algorithms have been used. We believe this framework will help guide future research in the area of phenotype algorithm portability.

Abstract

As healthcare organizations continue to grow and evolve, migrations from one commercial electronic health record (EHR) system to another are likely to become more common. However, little is known about front-line clinicians’ and staff’s perceptions of such changes. Our study addresses this gap through an organization-wide survey of employees immediately prior to the transition to a new commercial EHR. We found that almost all front-line clinicians and staff were aware of the upcoming migration, and that most felt positive or neutral about the change, with only about 11% indicating that they were uncomfortable with the migration. Reasons for discomfort included the beliefs that the new EHR will be more time consuming to use and that moving to a new EHR is too costly, as well as concerns about the migration process. Attitudes differed by demographic characteristics and satisfaction with the current EHR. We discuss the implications of these results.

Introduction

While the investments made through the 2009 HITECH Act have resulted in significant progress in the adoption of electronic health record (EHR) systems in the U.S. over the last decade, this progress has come with some growing pains.1,2 Many healthcare organizations have now not only implemented an EHR but have also migrated from one EHR to another. The extant literature suggests that these migrations have met numerous challenges and that these challenges can put patient safety at risk.3 For instance, studies have found that technical issues (e.g., converting data to a new format) can create new work for users and result in continued parallel reliance on the old system.4–6 In addition, physicians often perceive such changes negatively, for example, reporting that the new EHR is less efficient.5–7 In fact, Hanauer et al. reported that, even up to two years after migrating to a popular commercial EHR system, many physicians’ attitudes towards the new EHR were surprisingly negative.5

Existing studies have largely focused on migrations from locally developed, “homegrown,” EHRs to commercial systems.6–7 In these cases, healthcare organizations are switching from an EHR that has been designed specifically for their particular context, but that may not be a comprehensive system with the more advanced functionalities offered by a mature commercial tool (e.g., clinical decision support). However, in recent years, it has become increasingly common for healthcare organizations to migrate from one commercial EHR to another commercial system. Like the aforementioned transitions, these migrations may be motivated by the need for a commercial tool with more advanced functionalities. In other cases, though, healthcare organizations have come to realize that the comprehensive commercial tool that they adopted is not optimal for their situation, prompting them to switch to a more suitable comprehensive commercial EHR.

Less is known about commercial-to-commercial migrations, especially how front-line clinicians and staff perceive the change.8,9 Our study addresses this gap through a survey assessing the attitudes and beliefs of employees at a large academic health system immediately prior to such a transition. The results of this survey have important implications for the migration at the study institution, as well as those considering or planning for a similar transition.

Methods

Institutional Setting

University of California, Irvine Health (UCI Health) is a large academic health system. In November 2017, UCI Health migrated from their existing comprehensive commercial EHR, Quest (Allscripts, Chicago, IL, USA), to another comprehensive commercial EHR, Epic (Epic Systems, Verona, WI, USA). UCI Health prepared clinicians and staff for this change in a number of ways such as in-person and online trainings.
**Survey Development and Deployment**

We developed a short survey to understand clinician and staff perceptions related to the upcoming migration from Quest to Epic. Specifically, we included structured questions to understand their satisfaction with Quest, awareness of and comfort with the upcoming migration to Epic, and reasons for their attitudes. Respondents were also able to provide unstructured (free-text) responses to several of the questions. The technology acceptance model (TAM) was used to guide survey development.

To minimize the burden on participants, we designed a skip pattern that ensured that they were only asked to respond to questions that were appropriate based on their previous answers. For instance, if a participant indicated that they did not know what Quest was, they were not asked to complete any additional questions. After the survey instrument was finalized, the questions and survey logic were entered into REDCap. The initial invitation email was sent through REDCap to 7,361 UCI Health employees on September 12, 2017. Two reminder emails were subsequently sent to non-respondents over the five weeks the survey remained open.

**EHR Account Status and Demographics**

In addition to the survey results, we also had an EHR account status dataset and a demographics dataset for all UCI Health employees. The former dataset included an identifier, Epic account status (active or inactive), date of last access, and provider type. The latter included the following variables: an identifier, department, years at UCI Health (as of the date they took the survey or, for non-respondents, September 18, 2017), FTE, shift, job title, and job family (i.e., job type).

UCI Health categorizes career opportunities into the following job families: (i) administrative/clerical (e.g., clerks, administrative assistants), (ii) clinical professional (e.g., case managers, social workers), (iii) executive (e.g., directors), (iv) finance/information technology (e.g., programmers), (v) management (e.g., administrative nurses), (vi) nursing (e.g., clinical nurses), (vii) professional (e.g., administrative analysts), (viii) support services (e.g., medical assistants, admitting workers), (ix) technician/technologist (e.g., anesthesia technicians), and (x) trades and services (e.g., mechanics). We separated out clinical support service (e.g., medical assistants) and other support service (e.g., medical records admin) jobs to better align with the other job families and because we believed that those with a patient care role may have a different perspective than those with a more administrative role. In addition, 2,881 records were missing the job family field, including all physicians, as well as those with a professor or instructor job title. Therefore, we created two new job families: physician and non-clinical professor/instructor. The latter category only included professors or instructors without an active EHR account, indicating that they are not practicing clinicians. After doing this, only 472 were missing the job family field. These were categorized into the existing job families as appropriate. For example, 98.8% of job titles that included the word ‘supervisor’ were associated with the management job family; thus, if the job title for a record without a job family included this term, it was categorized as management.

In addition to the existing variables, we also created a new variable, which we refer to as job level. We categorized employees into one of five different job levels based on their job title and/or job family: (i) trainee (e.g., ‘resident’ or ‘intern’ in job title), (ii) early-career/entry (e.g., ‘i’ or ‘ii’ in job title as in ‘clinical nurse ii’), (iii) mid-career (e.g., ‘iii’, ‘iv’, or ‘v’ in job title as in ‘biller iv’), (iv) senior (e.g., ‘lead’ in job title), and (v) leadership (e.g., ‘executive’ job family).

**Data Analysis**

We combined the three datasets for analysis. Structured data were analyzed using R v.3.5.1. After conducting univariate analyses, we assessed the representativeness of our sample. We then conducted bivariate analyses to evaluate whether survey responses varied by Epic account status and/or the demographic variables, as well as to determine whether responses to certain survey questions were associated with other survey responses. For instance, we hypothesized that satisfaction with Quest would be inversely related to comfort with the migration to Epic. In other words, those dissatisfied with Quest would be more likely to be comfortable with the migration to Epic than those satisfied with or neutral about Quest (and vice versa).

For categorical independent variables we used chi-square tests for independence of all factors. We then used adjusted standardized residuals to identify where the significant differences occurred. To correct for multiple comparisons, we applied the Bonferroni p-value correction method. In addition, for continuous independent variables we performed pairwise comparisons using t-tests with pooled standard deviations, and the Holm-Bonferroni p-value correction method to account for multiple comparisons.
Free-text survey responses were analyzed with NVivo v.12.2.0. We employed an inductive qualitative analysis approach and the constant comparison method to identify emergent categories and then to classify participants’ comments.10,11 We continued this process until no new categories emerged (theoretical saturation).12 This was a quality improvement study and was, thus, exempt from institutional review board review.

**Results**

Of those invited, 1,674 responded to the survey (22.7%). Nine did not fill out the first question; and 47 indicated that they did not know what is “Quest.” These 56 individuals were excluded from the analysis. Unsurprisingly, among those excluded, the majority were not active EHR users (60.7%, N=56). In addition, a relatively high percentage of respondents in non-clinical jobs were excluded from analysis, including non-practicing clinical professors/instructors (Excluded: 20%, N=20) and trades and services jobs (Excluded: 14.3%, N=14). On the other hand, responding physicians (0%, N=222), finance professionals (0%, N=45), executives (0%, N=26), and nurses (0.7%, N=401) were least likely to be excluded.

Relative to the entire population of UCI Health employees, physicians are underrepresented in the analyzed sample (Analyzed: 13.7% vs. Overall: 20.6%), while nurses (Analyzed: 24.6% vs. Overall: 18.9%) and managers (Analyzed: 10.4% vs. Overall: 5.0%) are overrepresented. Furthermore, while the percentage of respondents in early-career or entry-level, mid-career, and senior positions are similar to the overall population, a relatively lower percentage of trainees (e.g., residents) were included in the analysis (Analyzed: 5.1% vs. Overall: 10.8%).

**Satisfaction with the Current EHR**

Among the analyzed sample (N=1,618), most were satisfied with Quest (45.9%), the EHR system currently used at UCI Health, or were neutral (31.0%). However, there were differences in satisfaction based on the respondent’s job type ($\chi^2=133.41$, df=16, p<0.001). Figure 1 presents a summary of these results. Upon examining the results of the post-hoc analysis ($\alpha_{adj}=0.002$, $z$ criteria=-3.11), we found that significantly more physicians were dissatisfied with Quest than would be expected if there was no association between the two variables, and significantly fewer were satisfied than expected (N=222; Dissatisfied: 50.5%, $r_{adj}=10.46$; Satisfied: 24.8%, $r_{adj}=-6.81$).

![Figure 1. Satisfaction with the current EHR, Quest, by job type.](image-url)
There was also a statistically significant association between satisfaction with Quest and job level ($\chi^2=41.61$, df=8, p<0.001). Specifically, the results show that significantly more trainees (e.g., residents) were dissatisfied with Quest than expected and significantly fewer were satisfied than expected ($\alpha_{adj}=0.003$, z criteria=-2.94; N=82; Dissatisfied: 48.8%, $r_{adj}=5.69$; Satisfied: 22.0%, $r_{adj}=-4.48$). Along these same lines, we also found that, on average, those satisfied with Quest had been employed at UCI Health longer than those who were dissatisfied with Quest (Satisfied: Mean=10.2 years, SD=7.98 vs. Dissatisfied: Mean=8.78 years, SD=7.74; p= 0.016).

### Awareness of the Migration

The vast majority of respondents, 98.5%, were aware that UCI Health would soon replace the current EHR, Quest, with Epic, another electronic health record system (N=1,612). The high level of awareness was fairly uniform across demographic variables, with only negligible differences.

### Attitude Toward the Migration

When asked about how they feel about UCI Health’s plan to replace Quest with Epic, most respondents indicated that they were comfortable with the migration (54.4%, N=1,601), with only 10.9% saying that they were uncomfortable. The remainder indicated that they felt neutral about the migration (34.7%).

There was some variation in responses based on demographic variables, including type of job ($\chi^2=78.6$, df=16, p<0.001) and job level ($\chi^2=66.15$, df=8, p<0.001). The post-hoc analysis showed that, for job type ($\alpha_{adj}=0.002$, z criteria=3.11), significantly more management/executives were comfortable with the migration than expected and significantly fewer than expected were neutral (N=190; Comfortable: 69.5%, $r_{adj}=4.44$; Neutral: 17.9%, $r_{adj}=-5.19$). In addition, significantly fewer physicians were neutral about the migration than expected (21.8%, N=220, $r_{adj}=-4.33$), while significantly more technicians/technologists were neutral about the migration than expected (53.8%, N=104, $r_{adj}=4.23$).

For job level ($\alpha_{adj}=0.003$, z criteria=-2.94; See Figure 2), we found that the results for the leadership category were very similar to the management/executive job type category. We also found that significantly fewer in mid-career were comfortable with the migration than expected (44.2%, N=231, $r_{adj}=-3.38$). On the other hand, significantly more trainees were comfortable with the migration than expected and significantly fewer than expected were neutral (N=81; Comfortable: 74.1%, $r_{adj}=3.65$; Neutral: 11.1%, $r_{adj}=-4.58$).

![Figure 2. Attitude toward the Epic migration by job level.](image-url)
There was also a statistically significant difference in attitude toward the Epic migration based on satisfaction with Quest ($\chi^2=110.79$, df=4, $p<0.001$). These results are highlighted in Figure 3. Perhaps unsurprisingly, the post-hoc analysis ($\alpha_{adj}=0.006$, $z$ criteria=-2.77) revealed that there were significantly more participants who were dissatisfied with Quest and comfortable with the migration than expected (73.4%, $N=368$, $r_{adj}=8.32$), while there were significantly fewer individuals satisfied with Quest and comfortable with the migration than expected (43.5%, $N=738$, $r_{adj}=-8.10$). In addition, participants who reported being satisfied with Quest and uncomfortable with the migration were observed significantly more than expected (15.3%, $N=738$, $r_{adj}=5.28$) and those neutral about Quest and uncomfortable with the migration were observed significantly less than expected (5.5%, $N=495$, $r_{adj}=-4.66$).

Figure 3. Attitude toward the Epic migration by satisfaction with the current EHR, Quest.

Those who felt comfortable with migrating to Epic ($N=871$) were asked to provide a reason(s) for this perception (see Table 1). Among the 858 participants that selected at least one of the options, over half indicated that they believe that Epic will better support their clinical work (60.4%), will be less time consuming to use (58.7%), will make it easier to retrieve data (57.6%), and that Epic’s user interface is easier to learn and use (54.1%).

Those who felt uncomfortable with migrating to Epic ($N=174$) were also asked to provide a reason(s) why they felt this way (see Table 1). Although none of the response options were selected by fifty percent or more of the 153 participants that chose at least one reason, the four most commonly reported attitudes were that Epic will be more time consuming to use (41.8%), that moving to a new electronic medical records system is too expensive (38.6%), that Epic’s user interface is more difficult to learn and use (29.4%), and that Epic will not support their clinical work as well (24.8%).

In addition to the structured questions, participants had several opportunities to share unstructured comments. These free-text responses revealed additional insights into participants’ attitudes towards the migration to Epic and fell into two main categories – attitudes towards (1) the technologies (Quest and/or Epic) and (2) the migration process. First, as suggested by the quantitative results, many participants were positive about transitioning to Epic. This was generally either due to negative perceptions about Quest or positive perceptions about Epic. For instance, one person with little knowledge about Epic stated, “It couldn't be any worse [than Quest].” Other participant comments focused on their positive beliefs or expectations about Epic, including that it will improve coordination and communication; has better system design, functionality, or usability; offers a process efficiency or otherwise better supports their work; or will improve outcomes such as increased patient safety (see Table 2). Participants indicated that their positive beliefs about Epic were largely based on their knowledge of the EHR market (e.g., “it is an industry standard”), personal experience with Epic at another institution, co-workers’ experiences with Epic, or organizational trust (e.g., “I am sure UCI has done enough research, and if it shows medical record improvement with Epic, why not”).

Second, while some participants were not actually opposed to migrating to Epic, they did feel that certain aspects of the migration process had been problematic, including training, planning, communication, and leadership (see Table 2). Of these, insufficient training and the perception of poor planning were the most commonly mentioned. Several respondents felt that they were not adequately trained to use Epic and, thus, felt ill prepared for the upcoming change. For instance, one participant stated, “training end users with incomplete workflows that can impact patient care patient's financial status. I do not feel we are ready for Go Live…” In addition, issues with the migration plan, especially the timeline, were also relatively common. For example, one person stated, “Concept is good, but timeline is too aggressive…” Finally, some respondents cited insufficient communication and negative perceptions of the migration leadership as sources of uncertainty or concern. For example, one participant stated, “EPIC’s functionality and how it differs from Quest has not been made known to us…” Another respondent commented, “The consultants that were hired to direct this project are ineffective.”

• “I believe Epic it's from this century, not like Quest.”

### Positive Perceptions about New EHR

**Improves Coordination and Communication**
- “Will have access of patient medical records chart across EPIC system”
- “Epic will make coding easier in regards to work assignment…”

**Better System Design, Functionality, or Usability**
- “better reporting - real time”
- “Epic gives more control to the user by more versatile”
- “better and faster note template and loading”

**Offers Process Efficiency or Otherwise Better Supports Work**
- “Automatically generates cost vs me having to manually input billing”
- “Epic does not use the same Script as QUEST and the interface is set up like a Word document as opposed to the windows seen in QUEST so multitasking by writing notes and looking up labs is easier and more efficient”

**Improve Outcomes**
- “After Epic implementation, Epic alone will include these 3 to 4 systems to where nursing and radiology are using the same system, decreasing duplication of work, and increasing patient safety.”

### Migration Outcomes

**Insufficient Communication**
“EPIC’s functionality and how it differs from Quest has not been made known to us…”

**Insufficient Training**
“the training had an incomplete buildout and still a lot of unanswered questions. We need more training than is supplied in the on-line modules and the single face to face session.”

**Negative Perceptions about Migration Leadership**
“The consultants that were hired to direct this project are ineffective.”

**Problems with Planning**
- “I think the push to meet a target date is a little foolhardy. We should make sure the system works first, not worry about the calendar.”
- “Why does administration think that the conversion from Quest to Epic will not impact our clinical practice and that we do not need to adjust patient volumes?”

### Discussion

Through a large survey of front-line clinicians and staff at UCI Health, we found that almost all were aware of the upcoming migration to a new comprehensive commercial EHR, and that most were fairly positive about this change. However, there was some variation in attitudes towards the migration based on satisfaction with the current comprehensive commercial EHR. In addition, we found that satisfaction with the current EHR varied based on job type, with a higher proportion of physicians being dissatisfied compared to other types of jobs. Qualitative results provided additional insights showing that positive attitudes towards the migration tended to either be based on dissatisfaction with the current EHR or on positive beliefs or expectations about the new system, while negative attitudes were not always related to the technology but, rather, sometimes stemmed from dissatisfaction with the migration process.

Overall, our results are more positive than the findings from studies that have focused on migrations from homegrown EHRs to commercial systems, e.g.,[4-7] This may suggest relatively lower levels of clinician and staff resistance to transitions from one comprehensive commercial EHR to another. There could be a number of explanations for this. For instance, in homegrown-to-commercial migrations, clinicians’ loyalty to the homegrown system that was created specifically for their context e.g.,[6] and/or a general preference for simpler EHRs without advanced features e.g.,[13,14] could lead to resistance to the migration. While in the case of comprehensive commercial-to-comprehensive commercial
transitions, on the other hand, clinicians and staff may not have the same loyalty to the existing system and have already adjusted to a comprehensive EHR, which could result in lower levels of resistance to change.

With that said, however, our results suggest that more could have been done to facilitate a smooth transition to the new EHR, including (1) supporting key clinical activities; (2) addressing commonly cited reasons for discomfort, and (3) improving training. These findings have implications for other healthcare organizations that are considering or planning for a similar change.

First, both among those who felt comfortable with migrating to a new EHR and those who felt uncomfortable with this change, most of the commonly reported reasons were related to day-to-day clinical practice as opposed to larger institutional goals such as supporting quality improvement. Others have suggested that misaligned clinical and organizational needs can contribute to clinician dissatisfaction with EHRs. However, thus far, such migrations to be successful, the new EHR needs to adequately support key clinical activities, and clinicians and staff need to be reassured of this fact (e.g., through trainings and other communications).

Second, healthcare organizations should also specifically address the commonly reported reasons that clinicians and staff feel uncomfortable with a migration. For instance, clearly communicating the differences between the current EHR and new EHR and why the investment in the new EHR is necessary, as well as incorporating clinician and staff suggestions to improve the migration process, could help to mitigate many of the concerns. In addition, it may be necessary to tailor messages about the migration to different groups who may be more resistant to the change (e.g., those who are more likely to be satisfied with the current EHR).

Finally, and as many others have noted, adequate end-user training and on-going support is essential when implementing a new EHR. However, many of our participants perceived the training they had received thus far as insufficient—their participants wanted more personalized sessions and more opportunities to interact with the new EHR. Although there are some published training programs that end-users have found satisfactory, more research is needed to understand which components are most helpful and how trainings can be effectively adapted for different contexts.

Although this survey was conducted at a single institution, it included a number of different perspectives, including physicians (from both inpatient and ambulatory care), nurses, other clinical professionals, and staff. Further research is needed to validate our findings across other institutions. In addition, future studies should consider a longitudinal approach to understand how front-line clinician and staff perceptions change once they have used the new comprehensive commercial EHR in practice. Existing research suggests that, in order to see physician satisfaction rise above baseline, follow-up may need to occur more than two years after migrating from a homegrown EHR to a commercial system. However, it remains to be seen if that will be the case for comprehensive commercial-to-comprehensive commercial migrations.

Conclusion

We found that, immediately prior to the transition, front-line clinicians and staff were more positive about the migration from one comprehensive commercial EHR to another than had been reported in the literature on migrations from homegrown EHRs to commercial systems. However, there were still some employees who were uncomfortable with the migration. Addressing the reasons for this discomfort could reduce resistance and increase satisfaction with the new EHR once it is implemented. Further research is needed to understand how clinician and staff perspectives change after this type of migration.

Public Attitudes Toward Direct to Consumer Genetic Testing

Grayson L. Ruhl1, James W. Hazel, PhD, JD1, Ellen Wright Clayton, MD, JD1, Bradley A. Malin, PhD1
Vanderbilt University, Nashville, Tennessee, USA

Abstract
Direct to consumer genetic testing (DTC-GT) is an emerging service that allows individuals to have their DNA tested without having to consult a healthcare provider. DTC-GT can provide insight into various aspects about an individual, including their health and ancestry. However, testing may pose privacy risks and yield distressing results. Despite the growing popularity of DTC-GT, public attitudes toward such services remain largely ill-defined. Using Amazon Mechanical Turk, we administered a web-based survey to over 1,000 individuals to obtain intuition into public attitudes about DTC-GT. Survey questions were grounded in a literature review of people’s views about DTC-GT. The results of the survey indicated that respondents were interested in DTC-GT as a possible way to gain insight about health, ancestry, and family relationships, as well as advance research. Despite this, respondents were concerned that DTC-GT companies and other users of their DTC-GT data would infringe upon their privacy.

Introduction
Advances in genome sequencing technology have enabled rapid growth in genomics research since the first sequencing of the human genome. As the price of genome sequencing has dropped over time, and the technology has become more accessible to the public, direct-to-consumer genetic testing (DTC-GT) has emerged as a new service. DTC-GT, also known as at-home testing, entails genetic testing services that are marketed directly to consumers and enable individuals to obtain personal genetic information without having to consult a healthcare provider. For example, 23andMe.com sends test kits to consumers’ homes to collect DNA samples in the form of saliva. Consumers then send the kits to a laboratory and receive results online after about six to eight weeks.

Research studies in this area, which are largely focused on well-established and popular DTC-GT companies such as 23andMe.com and Ancestry.com, have indicated that there are several factors that directly influence consumer decisions to undergo testing. While DTC-GT can offer insight about a wide variety of topics, many people are particularly drawn to DTC-GT services that claim to provide information about personal health (e.g., informing participants about genetic health risks and carrier status), wellness, ancestry, and personal traits. Some consumers have been found to trust DTC-GT companies more than academic medical centers for the purpose of obtaining personal genetic information. Some services, however, are more controversial than others. Some companies offer tests that purport to assess children’s athletic potential, covertly determine paternity, and discover infidelity by testing surreptitiously-gathered biological material. Such practices have raised a variety of concerns among the ethical, legal, and scientific communities. This new market for genomics services has stirred debates about genetic privacy and identity, as there are potential risks and ethical issues associated with DTC-GT.

The current literature about DTC-GT indicates that potential consumers are, to some degree, concerned about a variety of risks. Concerns include, but are not limited to, the following: (a) lack of certainty regarding how much control they have over data, (b) worries about privacy invasion, (c) tests that reveal health complications, determine paternity, or expose infidelity may disrupt family relationships or otherwise cause distress, and (d) misunderstandings due to inability to understand results. Despite these worries, this space is largely unregulated, except by the Food and Drug Administration (FDA) for health-related results. Recent studies of companies offering DTC-GT testing demonstrate that their privacy policies often fail to meet transparency guidelines concerning privacy and secondary use.

In light of these concerns, consumer enthusiasm for DTC-GT can be difficult to rationalize. The privacy paradox is a commonly observed phenomenon wherein one’s behavior concerning privacy risks does not reflect his or her privacy concerns. Consumers often succumb to this paradox when weighing the utilities of having personal genetic testing against the entailed risks, and they are often unaware of potential consequences. Furthermore, preferences and actions vary by the individual, complicating our understandings of what drives people to pursue or avoid testing. Due to a lack of public understanding about this new arena of genetic testing, this market lacks policies that would meet consumers’ needs while ensuring the delivery of useful results and mitigating the problems that testing could cause.
Insight into how individuals react to the influences surrounding personal genetic testing will be useful in forming policies to create an optimal environment for participation in DTC-GT. This would be mutually beneficial to consumers and genetic testing companies. Specifically, consumers would experience the benefits of personalized genetic testing while facing low associated risks. Additionally, DTC-GT would become a more popular and transparent service industry. Informed by a review of the literature surrounding DTC-GT and a comprehensive analysis of DTC-GT company advertisements, we created a survey to understand public attitudes toward DTC-GT in greater depth.

**Methods**

**Goals and Literature Review**

The overarching goal of this study was to decipher what individuals perceived as the utilities and risks of having DTC-GT performed. To realize this goal, we 1) codified a grounded theory about public attitudes toward DTC-GT, which was inspired by the literature surrounding the DTC-GT landscape; 2) designed and administered a survey based on these observations; and 3) tested the survey results against the grounded theory. The study was approved by Vanderbilt University’s Institutional Review Board (Protocol #180172) and data collection took place in November 2018.

To gain an understanding of the DTC-GT environment, we searched for studies that explored the DTC-GT landscape. Having collected and examined a comprehensive set of studies that specifically assessed public attitudes toward DTC-GT services, we developed theories about the motivators that contribute to peoples’ opinions, as described below. We also researched DTC-GT advertisements by visiting the websites of various companies known to the investigators and by viewing commercials aired by companies. After conducting the literature review, our grounded theory was formulated as follows:

a) People view DTC-GT as a useful means for managing their health and learning about their ancestry, but also utilize it for altruistic purposes (e.g., helping a family member or advancing research).6,19

b) Peoples’ most prevalent concerns surrounding DTC-GT are 1) privacy risks;12 2) the interpretability and emotional impact of results;19,20 and 3) the familial disruptions that various types of results would cause.13

c) People are more comfortable sharing their DTC-GT results with academic institutions than with third parties, including governmental, commercial, or foreign entities.7

Gauging privacy concerns required deliberation: privacy is a vague concept that is difficult to articulate and can embody various meanings. To determine public attitudes about the privacy risks while avoiding confusion, we separated privacy into three applicable concepts: confidentiality, anonymity, and solitude.21 Confidentiality entails keeping one’s information restricted to certain entities. Anonymity entails protecting one’s identity. And solitude entails respecting one’s right to be left alone, shielded from unwanted solicitation. We designed questions that would measure respondents’ concerns that DTC-GT companies would breach these three aspects of privacy. We were also interested in how social relationships influenced in consumers’ decisions. We assessed this by asking respondents about how motivated they would be to undergo testing if certain social connections (e.g., their parents, children, and friends) thought it was a good idea.

**Survey Creation**

Our survey instrument was created using the Research Electronic Data Capture (REDCap) platform22 and was administered on the Amazon Mechanical Turk (MTurk; discussed below). The REDCap survey consisted of various types of multiple-choice questions regarding DTC-GT, 15 in total. Respondents were also asked to provide voluntary demographics information (see Table 1). To measure respondents’ attitudes, we used the 3-point Likert scale answers, “A lot,” “Somewhat,” and “Very little” (the phrasing of some of our questions required slight wording variations for these Likert scale options). Several questions within our survey addressed topics using multiple choice inquiries, but not through a Likert scale, which allowed us to investigate connections between the Likert scale scores and the factors that potentially contributed to respondents’ attitudes. To verify participation and facilitate compensation, the survey also contained a field wherein respondents entered their MTurk worker IDs.

To determine the validity of workers’ responses before sending out our final survey, we gathered responses from a sample of 50 individuals. The responses from this sample demonstrated that certain questions contained wordings that resulted in misinterpretation, which prompted efforts to clarify the meanings of each question. To achieve face validity, we solicited feedback on the design and content of our survey from colleagues within Vanderbilt’s Center for Genetic Privacy and Identity in Community Settings (GetPreCiSe), a diverse interdisciplinary working group consisting of scholars from the law, medicine, psychology, history, and humanities fields. As further validation, and to ensure clarity
of our questions after these extensive refinements, we conducted cognitive interviews with a small group of undergraduate students at Vanderbilt University. During these interviews, participants were asked to read aloud each question and provide their assessment of its intent. In response to this feedback, we concluded that the survey questions were unambiguous and comprehensible.

**Study Population**

The population for this investigation consists of respondents who took our survey, according to our guidelines, through the Amazon Mechanical Turk (MTurk) online crowdsourcing platform. MTurk is Amazon’s online marketplace for individuals, often called workers, to complete various tasks (e.g., transcribing a speech, determining if a video contains explicit material, or answering surveys), usually for some money in return. MTurk served as a portal to prompt respondents about our survey and to compensate them $0.50 for their participation. On MTurk’s interface, we provided background information about DTC-GT, as well as a consent form, and provided respondents with the link and code necessary to access our REDCap survey.

**Survey Dissemination and Data Analysis**

We then released our survey, making it available to workers who resided in the United States for four days. After requesting 1,050 responses through MTurk, we gathered 1,090 surveys on REDCap. Ultimately, 1,026 submissions were deemed viable. We removed 64 from consideration for the following reasons: 34 submissions were unique to the REDCap system and thus did not coincide with MTurk Worker IDs; 24 submissions contained duplicates; and 6 submissions contained responses with no variance in their Likert scale answers, which strongly suggested that these workers did not consciously participate in our survey.

We exported the raw data files from REDCap containing the responses of all respondents mapped to a numerical format and derived general summary statistics about the results. For instance, answers for Likert scale questions showed up as a “1” to represent “A lot,” a “2” to represent “Somewhat,” and a “3” to represent “Very little.”

**Results**

**Respondents’ Participation in DTC-GT**

Of all respondents, 178 (17.3%) had undergone DTC-GT, 821 (80.0%) had not, and 27 (2.6%) were unsure (See Figure 1). Of the 178 respondents who had testing done, 117 (65.7%) did so to learn about their ancestry, 66 (37.1%) were curious about their personal traits, 58 (32.6%) wanted help managing their health, 19 (10.7%) wanted to determine the paternity of a child, and 5 (2.8%) took a DTC-GT test to discover infidelity (See Figure 2). Of the 821 respondents who had not undergone testing, 346 (42.1%) said they were likely to have testing in the future, 247 (30.0%) said they were unlikely to, and 228 (27.8%) did not know whether they would or not.

**Perceived Utilities of DTC-GT**

Of all respondents, 90 (8.8%) knew more than five friends or family members who had undergone DTC-GT, 471 (45.9%) knew at least one such person, 256 (25.0%) knew none, and 209 (20.4%) did not know. When asked about the extent to which certain social connections would motivate them to get testing (i.e., if these individuals or groups

---

a Here we described the purpose, approximate duration (five to ten minutes), expected costs, risks and benefits, content, and expected compensation of our study.

b We removed these 34 submissions after having deleted duplicates and incomplete submissions. Furthermore, a few of the MTurk entries had no REDCap submissions to match them. These respondents were not paid.

c We encountered repeated cases of Worker IDs within the exported REDCap dataset, suggesting that workers took the survey twice. In these cases, we removed all surveys that an individual submitted after their first submission.

d Every question required an answer so that we could conduct thorough and consistent analysis; surveys that were either exited or not completed were not considered, and we did not pay respondents who submitted such results.

e We were able to determine the legitimacy of MTurk worker responses by inspecting the relationship between average Likert scale scores and their standard deviations. We assumed relatively high standard deviations indicated that respondents were answering questions thoughtfully.
thought it was a good idea), respondents’ spouses or partners were most influential (362 [35.3%] said “A lot”), followed by their children (282 [27.5%] said “A lot”), parents (197 [19.2%] said “A lot”), and friends (170 [16.6%] said “A lot”) (See Figure 3). There were 401 (39.1%) respondents who said that their friends’ positive opinions of DTC-GT would motivate them very little.

Of all respondents, 707 (68.9%) said that they would be strongly motivated to have DTC-GT done if it would help them in combating their own illness, and 664 (64.7%) would be strongly motivated if it would help someone in their family with a healthcare issue. When asked how motivated they would be to pursue testing if it would help advance medical research, 430 (41.9%) respondents said “A lot,” and 372 (36.3%) said “Somewhat.” There were 538 (52.4%) respondents who answered that reports in the news or social media that made DTC-GT seem like a good idea would influence them very little (See Figure 4).

When asked how much they thought DTC-GT could provide useful or interesting information about certain topics, 568 (55.4%) said “A lot” about their ancestry, 471 (45.9%) said “A lot” about family relationships (e.g., paternity), 404 (39.4%) said “A lot” about managing their health, 281 (27.4%) said “A lot” about their personal traits, and 172 (16.8%) said “A lot” about infidelity (See Figure 5). More than half (526 [51.3%]) thought that DTC-GT could provide very little information about infidelity.

**Concerns about DTC-GT**

When asked how much control individuals should have over who may use their DTC-GT data, 809 (78.8%) respondents answered “A lot,” 177 (17.3%) said “Some,” and 40 (3.9%) answered “Very little.” Figure 6 illustrates respondents’ concerns about anonymity breaches, confidentiality breaches, and infringement upon solitude. Of all participants, 507 (49.4%) were very concerned that DTC-GT companies would fail to protect their identity, 489 (47.7%) said the same about sharing information without their consent, 428 (41.7%) said the same about providing unsolicited advertisements or emails, and 391 (38.1%) said the same about providing unsolicited health information.

**Figure 3.** Responses to the question, “How motivated would you be to have DTC genetic testing if your ___ thought it was a good idea?”

**Figure 4.** Responses to the question, “How motivated would you be to have DTC genetic testing if…”
Respondents also reported concerns about how downstream users (e.g., pharmaceutical companies or university research centers) might use their data. Of the respondents, 429 (41.8%) were very concerned, and 468 (45.6%) were somewhat concerned, that these users of their DTC-GT results would fail to protect their privacy (See Figure 7).

When asked whether users of their DTC-GT data should report new results (i.e., results generated beyond their initial testing) back to participants if such results indicated health concerns (e.g., an increased risk of developing breast cancer or an increased risk of addiction), 606 (59.1%) said “Always”, 378 (36.8%) indicated that they should report only serious health risks back, and 42 (4.1%) said “Never” (See Figure 8).

Respondents generally felt fairly confident that they could understand the results of DTC-GT. When asked to assess their ability to comprehend results, 275 (26.8%) said that they would accurately understand their results without any help from an expert; 558 (54.4%) said that they would understand some of their results but would prefer help from an expert; 134 (13.1%) said that they would need an expert or genetic counselor to help them understand their results; and 59 (5.8%) respondents were unsure about their capabilities to understand DTC-GT results.

Respondents were also asked how concerned they were that DTC-GT would reveal to them that they had a greater chance of developing an incurable disease, such as Alzheimer’s disease. Of all respondents, 180 (17.5%) were very concerned, 466 (45.4%) were moderately concerned, and 380 (37.0%) were not very concerned.

Given various types of DTC-GT results, respondents were then asked how concerned they were that they would disrupt their family relationships. Such concerns were generally low: 150 (14.6%) said “A lot” for health results, 105 (10.2%) said “A lot” for ancestry results, 98 (9.6%) said “A lot” for results about their personal traits, 100 (9.7%) said “A lot” for paternity results, and 93 (9.1%) said “A lot” for infidelity results (See Figure 9).
Use of DTC-GT Results

Respondents were asked with which groups they were comfortable sharing their DTC-GT results (e.g., to support research, for their personal care, or some other purpose). They were asked to mark all that applied: 646 (63.0%) respondents felt comfortable sharing results with academic institutions, 371 (36.2%) with third party companies required to provide the same privacy protections as the DTC-GT company, 147 (14.3%) with the government, 63 (6.1%) with commercial entities like Google or IBM, and 57 (5.6%) with people outside of the U.S. (see Figure 10).

When asked whether or not they would be willing to allow the results of DTC-GT to be used in research, 241 (23.5%) respondents said yes, even if their results were fully identified as theirs; 646 (63.0%) said yes, but only if their results were stripped of any identifying information; and 139 (13.5%) said “Never.”

---

**Figure 9.** Responses to the question, “How concerned are you that genetic test results about the following would disrupt your family relationships?”

**Figure 10.** Responses to the question, “With which of the following groups are you comfortable sharing your DTC genetic testing results?”

**Figure 11.** Responses to the question, “To what extent are you concerned that law enforcement can access peoples’ DTC-GT test results?”

**Figure 12.** Responses to the question, “To what extent should law enforcement have access to people’s DTC genetic test results to use for investigative purposes?”
Respondents were asked about their concerns surrounding law enforcement access to DTC genetic testing results. Of all respondents, 375 (36.5%) reported “A lot” of concern, 413 (40.3%) were “Somewhat” concerned, and 238 (23.2%) reported “Very little” concern (Figure 11). Respondents were also asked about the extent to which they felt law enforcement should have access to people’s DTC genetic test results to use for investigative purposes, either before or after a crime has been committed. Respondents appeared to be much more permissive of law enforcement accessing DTC genetic tests results to solve a crime than to prevent a crime: 734 (72.4%) of respondents said that law enforcement should have “very little” access to DTC genetic test results before a crime had been committed, while only 270 (26.3%) said that law enforcement should have “very little” access after a crime had been committed (Figure 12).

Table 1. Demographic information of the 1,026 MTurk survey participants.
Discussion

Most of the research on the impact of genetic testing to date has taken place in the context of clinical care or medical research and has demonstrated that people are often motivated by health care concerns and have a variety of worries about how the data are used.\textsuperscript{23, 24} The views of individuals regarding DTC-GT,\textsuperscript{25} which by definition is not mediated through the health care system and which is discretionary, provide additional perspectives on the public’s opinions about genetic testing. One critical observation is that, despite increasing advertisement of these services and the growing numbers of people who have enrolled,\textsuperscript{26} these highly computer-literate individuals largely have not pursued DTC-GT and do not know many people who have. The latter fact is particularly important since they report that the views of relatives and close friends would be more important in shaping their interest than social media. This observation underscores the need to learn more about the impact of social factors on the uptake of genetic testing, influences that to date have been under examined.

These respondents stated that they would be most interested in obtaining ancestry information from DTC-GT, which is consistent with the fact that genealogy and ancestry are the second most common hobby and reason for internet searches in the United States.\textsuperscript{27} They ultimately would be driven to use these services, however, to address their own and their relatives’ health issues. This is concerning given the limited amount of FDA-authorized genetic health reports currently on the market\textsuperscript{4} and early indications that much of this information may be of questionable utility to consumers.\textsuperscript{28, 29}

Like many others, these respondents overwhelmingly seek to control their data and express a variety of concerns about who would get access to their data. Given the wide variation in the data privacy policies adopted by DTC-GT companies\textsuperscript{8} and the efforts of some companies to monetize their consumers’ genetic data, these respondents’ desires to have control and to be protected are not likely to be met. At the same time, these respondents were quite willing to permit data to be used for research, especially if they were de-identified, as has been observed in many previous studies.\textsuperscript{23, 30} Their greater preference to allow data about them to be used by academic researchers than by companies, the government, and people outside the United States is concordant with what has been observed in earlier studies.\textsuperscript{31, 32} Respondents also expressed varying degrees of concern about law enforcement access to DTC-GT test results in the context of criminal investigations. Respondents overwhelmingly believed that law enforcement should have very little access to DTC-GT data in context of crime prevention, but were much more permissive of law enforcement use of such data to solve crimes.

These members of Amazon Mechanical Turk, like many research participants, generally would want to obtain additional health-related results as they became available.\textsuperscript{33} Yet only a quarter say that feel confident that they can interpret these data without assistance, with more than 50% saying that they would appreciate expert assistance and the remainder saying that they would require that help. Since DTC-GT companies generally do not provide counseling, these results will place additional burdens on a health care system that already has insufficient numbers of geneticists and genetic counselors to meet the needs of patients who need clinical care. Indeed, reports indicate that many consumers are beginning to seek guidance on DTC-GT results from their primary care physicians, who may also be ill-equipped to interpret the results. Furthermore, emerging evidence suggests that returning results may, in some cases, lead to health care interventions of unclear value.\textsuperscript{34}

Limitations

Although a small cohort of undergraduate students at Vanderbilt University was able to correctly interpret our survey questions, this does not rigorously demonstrate that the broader MTurk population found all questions thoroughly understandable. MTurk has been shown to offer a diverse population that includes significant ranges of age, education level, and socioeconomic status. But while demographically diverse in some respects, we note that MTurk workers tend to be predominately white, and are generally younger and more highly educated when compared to the entire U.S. population (See Table 1).\textsuperscript{35} Potential distinctions within our survey population remain largely unexamined. For example, non-white respondents may not share similar concerns with white respondents relating to law enforcement’s involvement with DTC-GT. Furthermore, young respondents may generally have less experience regarding the social pressures inherent in having children. It is also worth noting that because the majority of our respondents reported that they had not undergone DTC-GT, most questions were hypothetical for them. Nonetheless, our results provided intriguing signals about areas that require further study.
Conclusion

DTC-GT is a source of individual genetic information that is particularly fraught with incomplete and often misleading results. Despite concerns about the validity and utility of DTC-GT, it appears as though at-home genetic testing is here to stay for a host of purposes. In particular, as consumers attempt to decipher their health risks using such services, increasing numbers of people will turn to clinicians, seeking understanding of their results and guidance about managing their health. This has led to increasing debate about how providers and DTC-GT companies should respond to this influx.

The American College of Medical Genetics and Genomics (ACMG) claimed that DTC-GT companies should be more transparent by indicating their laboratory’s accreditation, clearly communicating privacy policies, demonstrating the validity and utility of their testing options, and providing consumers with access to genetics experts. It is evident that there is a growing demand for reliable interpretation of DTC-GT results, which neither providers nor DTC-GT are prepared to fulfill. While it would be beneficial to minimize the inappropriate use of healthcare resources based on DTC-GT results, it is crucial to educate providers about DTC-GT so that they may help patients who have concerns about their testing results. The medical informatics community should take charge of this issue by developing decision support for clinicians to handle such situations.

Abstract  Computational representations of the semantic knowledge embedded within clinical practice guidelines (CPGs) may be a significant aid in creating computer interpretable guidelines (CIGs). Formalizing plain text CPGs into CIGs manually is a laborious and burdensome task, even using CIG tools and languages designed to improve the process. Natural language understanding (NLU) systems perform automated reading comprehension, parsing text and using reasoning to convert syntactic information from unstructured text into semantic information. Influenced by successful systems used in other domains, we present the architecture for a system which uses NLU approaches to create semantic representations of entire CPGs. In the future, these representations may be used to generate CIGs.

1 Introduction
Clinical practice guidelines (CPGs) — documents designed to assist in diagnosis and treatment of disease, developed by professional organizations through systematic review of the literature, and usually distributed in a natural language (e.g., English) — form the foundation of evidence-based medicine. It is well known that compliance with paper guidelines is lacking, but that compliance improves greatly with the introduction of clinical decision support systems (CDSS), which implement guideline recommendations and are integrated into electronic health record (EHR) systems (see, e.g., [1]). Were the semantic content of the CPGs represented computationally as Computer Interpretable Guidelines (CIGs) the task of building CDSS would be eased.

Over the past two decades, methods and formalisms have been developed for representing guidelines computationally as CIGs (see [2]), but there are still few actively maintained CIGs since the process of creating them is extremely time-consuming and burdensome. If the creation of CIGs were a one-time effort perhaps the burden of manual curation could be overcome, but guidelines change frequently (often annually) in complex ways which would require ongoing effort. Therefore we believe that effort should be placed on automatically generating CIGs from their paper counterparts. In order to do so accurately and comprehensively, we believe it is necessary to represent the semantic content of CPGs to the greatest extent possible. This semantic representation may then be used to create the associated CIG. Here we present a framework and proof of concept based on natural language understanding (NLU) techniques to automatically represent the semantic content of the CPG. We leave rigorous evaluation and CIG generation from the semantics for future work.

Natural language understanding is a subtopic of natural language processing in which the goal is to build a computer system which performs reading comprehension on a given input text. These techniques are currently not widely used in the biomedical informatics community in part because the language used is complex, presupposing a significant amount of implicit knowledge. There is also a need for high precision due to the safety-critical domain. Implementing custom tools to perform the NLU task while addressing these issues requires wide-ranging expertise (biomedicine, computational linguistics, and knowledge representation and reasoning) and can be labor intensive.

The framework presented here adopts its high-level design from a previous NLU system, Tractor, designed for understanding short intelligence messages in the counter-insurgency (COIN) domain [3, 4, 5], and adapts it to the clinical domain. The Tractor system was successful in its task — it converted input text to a knowledge base (KB) containing over 92% semantic relations using rules that fired correctly nearly 98% of the time [4]. In internal evaluation not yet published we found the transformation to be on par with what a human is capable of performing. Our new system, currently under active development, is dubbed Clinical Tractor.

The remainder of the paper is organized as follows. First we aim to convince the reader that adopting portions of the Tractor architecture is appropriate while also showing where the differences lie. Clinical Tractor’s architecture is detailed in Section 3 along with a worked example in Section 4. As it is helpful to have an understanding of Clinical
Tractor when considering related research on language processing with CPGs, we save the discussion of related work for (Section 5), where we also discuss the future of the Clinical Tractor project.

2 A Comparison of the Domains of Tractor and Clinical Tractor

Tractor was initially developed for the COIN domain, requiring a large portion of reality to be modeled. Persons about whom intelligence messages are written are usually performing the activities of daily life – shopping, driving, making phone calls, interacting with other persons, carrying items, etc. The persons and items are described in varying amounts of detail. Problematically, it is unknown in advance which of these activities or attributes will be important when the messages are combined to form a complete picture of what is happening in an area. This uncertainty forced Tractor to be developed in a highly general way, so as to model a large number of activities and attributes at once, modeling specifics only where the general models were insufficient.

In this regard the domain of clinical medicine is significantly simpler. In general there is only a single person being discussed, the patient (though discussions of family history may also be present). In guidelines there is another person, the clinician, who is asked to perform some actions. The attributes of import and the actions that are or should be taken encompass only those related to health, not all of reality. A significant advantage to working in the clinical domain is the existence of a wide variety of controlled vocabularies, terminologies, and ontologies, which allow the identification of a large number of these actions and attributes. The strategy to model these actions and attributes can be adopted from Tractor with little modification. In fact, the general rules used for modeling many activities and attributes at once can be used with little or no modification.

Clinical guidelines have the advantage of containing, in general, grammatical text. Intelligence messages, like medical records, do not share this property – they often contain sentence fragments, semi-structured components, and unconventional punctuation/abbreviations. The Tractor system was built to be somewhat resilient to these issues, using only surface features where possible, working around mistakes made by the linguistic parsers in non-grammatical portions of text, and containing a system for specifying the components of semi-structured text. With CPGs we do not anticipate significant issues of this form, except perhaps in inclusion criteria where it is present, but it will be significant in planned future extensions of the work to include EHR data. Guidelines do contain some structured components in the form of document structure, which we account for.

Whereas intelligence messages are a record of what has happened, CPGs suggest what is to happen in the form of recommendations. This is significant as recommendations in CPGs often contain modal verbs, qualifying action phrases with words such as “should”, “may”, “might consider”, and so forth, in general covering the modalities of likelihood, ability, permission, and obligation. These, importantly, provide a weight to the recommendation. Weights also may be derived from the degree of evidence upon which the recommendation is based, usually provided on a scale somewhere in the guideline.

Intelligence messages and individual CPG recommendations are both similar in that they are short, avoiding issues such as topic shift and rhetorical/discourse relations. On the other hand, CPG recommendations often have temporal semantics dictated by their order. Within sections of the narrative of a guideline topic shift is generally avoided, and some discourse relations that arise in storytelling are eschewed. There is the potential for sections to exhibit rhetorical relations such as narrative strengthening [6], though we do not believe this requires any architectural additions.

3 Clinical Tractor

Because of the domain differences, the architecture of Clinical Tractor is different from that of Tractor, with more of a focus on extraction of data based on document structure, and making use of background knowledge. The architecture, seen in Figure 1, consists of four main components: text processing using various processing resources (PRs) operating within the open-source General Architecture for Text Engineering (GATE) [7]; converting the GATE output to a syntactic KB consisting of propositions in a first order logic; aligning terms in the KB with background knowledge and importing relevant data; and mapping syntactic relations to semantic relations using both domain-neutral and domain-specific mapping rules informed by the background knowledge.¹

¹We outline the framework making use of tools we have selected, but these tools could be swapped for others which perform the same tasks.
3.1 Input Data

Guidelines are distributed in several formats. In order to standardize them for our pipeline, we manually convert the guidelines of interest to an XML format capturing the document structure such as headings, tables, and inset boxes. We also include graph structures in figures and algorithms (as in the NCCN guidelines). No guideline-specific semantic features are included. The XML format used [8] is based on a combination of the Journal Article Tag Suite (JATS) [9] and GraphML [10]. In the future this transformation would either be an automated process, or, in a more ideal future, guidelines would be distributed in (possibly one of several) standardized format(s).

3.2 Text Processing in GATE

Each input CPG is processed by a set of PRs operating within GATE. Most of these PRs are from the ANNIE (a Nearly-New Information Extraction System) suite [7]. Shown in Figure 1 are: the ANNIE English Tokenizer and Sentence Splitter that divide the input into linguistic units; the Stanford Dependency Parser, for part-of-speech tagging and parsing (discussed further in Section 3.2.1); the GATE Morphological Analyser for identifying root forms of inflected nouns and verbs; a group of named-entity recognizers – list based, ontology-based, rule based, and MetaMap (discussed further in Section 3.2.2); and a group of PRs that perform co-reference resolution. GATE uses a plugin architecture allowing for the use of many other PRs as well as the creation of custom PRs. It also allows customization of each of the selected PRs according to the domain.

3.2.1 Dependency Parsing

The notion of dependency relations in language is ancient, going back to Pāṇini’s grammar in the 5th century BCE. Phrase structure grammar which is more commonly covered in introductory linguistics courses, on the other hand, is a modern invention. Dependency grammars represent syntactic structure as (often binary) relations between tokens in the text. These relations are known as dependencies. The Universal Dependencies [11] used in the Stanford Dependency Parser contain mostly syntactic relations, but also relations consistent with a shallow semantic parse. This apparently semantic information makes the task of developing syntax-semantics mapping rules to determine semantic roles somewhat easier.

---

2 There are purely algorithmic transformations from phrase structure parses to dependency parse (e.g., [12]), meaning there isn’t inherently more semantic information present in the dependency parse – the information is simply organized in a more useful way.
### 3.2.2 Named Entity Recognition

Named entity recognition (NER) is a component often associated with information extraction (IE) systems in which structured data is extracted from free text for one or more classes of entities. These classes often include the names of persons, locations, and organizations, but also dates, addresses, quantities, etc. As discussed above, the person entities in a guideline are fairly straightforward. In contrast, there are very large classes of entities such as drugs, procedures, diseases, symptoms, and anatomical locations. There are also a significant number of entities related to measurements and temporal relation. Guidelines also include evidence levels represented in various forms. NER can be used to identify the text spans representing an instance of a class of entities, and can also assist in unifying the the multiple ways of expressing a concept (e.g., anatomical location) in natural language. We make use of several forms of NER:

- **List-Based NER** GATE contains a “gazetteer” PR for identifying entities from lists. Lists may contain complete named entities such as names or locations, or words (keys) which given context can indicate that a named entity begins with or ends with the key (e.g., “Hospital” in a hospital name or “Jr.” in a person’s name). A key type of great importance in CPGs is that which indicates the current sentence, paragraph, or section is or contains recommendations. Gazetteer items have a major and minor type, allowing for a shallow ontology.

- **Ontology-Based NER** Related to list-based NER is ontology based NER. Terms and their synonyms are identified in the text through simple matching. We have developed tools [13] which extract this data from ontologies to store them in gazetteer lists for matching. By storing them in lists, additional synonyms can easily be added without modifying the underlying ontology.

- **MetaMap** Probably the most popular method for recognizing terms from medical vocabularies in text, and making use of the UMLS, MetaMap is sometimes criticized for its precision/recall. In combination with other approaches, it can be a useful addition to a complete NER suite.

- **Rule-Based NER** Rules allow identification of named entities through regular expressions over annotations using the Java Annotation Patterns Engine (JAPE). These rules allow for recognition of complete entities for which keys were noted in the list-based NERs. Entities with semi-structured formats such as prescription drugs may also be recognized. Rules provide an opportunity for a first pass at disambiguation and the removal of over-matches given the context available in word orderings.

Downstream processing in the syntax-semantics mapping rules makes use of the dependency parse to perform the bulk of the NLU task. One source of confusion in designing an NLU system of this type is how much NER to do using rules and lists, and how much to do later using the dependency parse. Dependency parsing captures structural relationships (dependencies) well, but recognition based on word order given a dependency parse is quite difficult. Therefore we limit ourselves to recognition which is word-order dependent at this stage.

### 3.3 Propositionalizer

The result of GATE processing is a set of annotations, each consisting of an identifier, a start and end position within the CPG’s text, a type, and a set of attribute-value pairs. Each of GATE’s PRs produces these annotations, so the set consists of information about XML document structure, tokens, sentences, paragraphs, dependencies, named entities, etc. The propositionalizer converts the set of GATE annotations into a set of logical propositions.

Given the input from GATE, the propositionalizer merges annotations which have the same start and end positions (e.g., a token and one or more results from the NERs). The result of this is a set of annotations each with unique start and end positions, and each with a unique identifier. The propositionalizer re-constructs the hierarchy of document-related XML tags and produces logical assertions in a form subsuming that of DoCO, the Document Components Ontology [14]. In addition to what DoCO offers, head words of sentences (found via the dependency parse) are attached to the sentences for use in the syntax-semantics mapper.

The propositionalizer produces a KB consisting of a set of propositions (expressions which may have a truth value assigned to them), in the logical language of the CSNePS knowledge representation and reasoning (KRR) system [15, 16, 17]. CSNePS is used to represent and perform reasoning on all of the KBs created by Clinical Tractor from the English CPGs. CSNePS is simultaneously a logic-, frame-, and graph-based KRR system [18]. It is the latest member of the SNePS family of KRR systems [19].
A CSNePS proposition may be “asserted” meaning it is taken to be true in the KB. Propositions need not be asserted to exist in the KB; CSNePS can consider propositions of unknown truth. When we discuss “asserting a proposition” we mean to add it to the KB as an assertion, and when we discuss “unasserting a proposition” we mean to remove the assertion from the KB. CSNePS uses a term logic, in which all expressions are terms – even those that in first order logic would not be. This means that propositions may have propositions as arguments (allowing for meta-knowledge). This is especially useful for representing the source of knowledge. The arguments of a proposition are terms that could denote words, tokens, syntactic categories, entities and events, and classes or properties of these entities and events.

Relations and the propositions in which they occur may be categorized as either: syntactic, taking as arguments terms denoting words, tokens, and syntactic categories; or as semantic, taking as arguments entities and events in the domain and their classes and properties. A KB is syntactic to the extent that its assertions are syntactic, and is semantic to the extent that its assertions are semantic. The KB produced by the propositionalizer is mostly syntactic, and therefore is referred to as the syntactic KB.

3.4 Background Knowledge Alignment

The syntactic KB is enhanced by a background knowledge alignment system (BKAS). This system matches spans of text against lexical resources such as WordNet and VerbNet, and locates ontological terms based on the results of NER in SNOMED (via MetaMap CUIs) and biomedical ontologies. The matched data is imported into the KB. Where the data is hierarchical as in the WordNet hypernym hierarchy, the VerbNet hierarchy, and ontological subsumption hierarchies, relevant hierarchies are imported into the KB. Where other logical relations are present, those are imported as well. Background knowledge allows mapping rules to be written more generally – for example, instead of operating only on a specific verb or list of verbs, a rule might operate on classes of related verbs by using a higher level concept.

Clinical Tractor is designed to operate in an ontologically heterogeneous environment, in which a single concept in the text may be annotated with multiple ontological terms from different sources. That said, we make heavy use of the OBO Library ontologies which have been co-developed to be inter-operable, as the more entirely separate sources there are, the more complex downstream processing in the mapping rules becomes.

The BKAS is meant to be generic, allowing for the easy addition of resources as needed. In future work, we intend for this to include knowledge extracted from other materials such as journal articles and other guidelines. As the BKAS system enhances the syntactic KB with background knowledge, we refer to the result as an enhanced syntactic KB.

3.5 Syntax → Semantics Mapper

The enhanced syntactic KB is operated on by mapping rules, converting the mostly syntactic KB to a mostly semantic representation. Whereas IE approaches aim to identify “within text instances of specified classes of entities and of predications involving these entities” [20, emphasis added], we aim to convert the entire syntactic content of the guideline into semantic content, doing true automatic reading comprehension. This includes understanding all parts of the text, not only verb relations or noun phrases matching some pre-specified patterns as other systems do (see Section 5). The mapping rules are represented in the CSNePS rule language and are executed within the CSNePS KR system.

The mapping rules, designed to be generic, come in two major types – those that convert syntactic representations to more easily processable syntactic representations, and those that convert syntactic representations to semantic ones. The left side of Figure 2 shows a rule that simplifies syntactic representations, transforming phrases in the passive voice to the active voice. This rule fires (i.e., is executed) when an nsubjpass (passive nominal subject) relation is identified in the dependency parse. This relation occurs between a verb and its passive subject. It converts this into a dobj (direct object) relation and unasserts the nsubjpass relation. The rule also looks to see, in a subrule, if the verb is in a case relation with the word “by”, and makes the nominal subject of the verb the object of the prepositional relation. This rule would transform the parse of “morphine should be prescribed by the clinician” to the parse of “the clinician should prescribe morphine”. In building NLU systems, the number of rules can quickly grow out of hand; rules such as this simplify the problem somewhat by requiring no special rules to be written for handling passive phrases.
The right side of Figure 2 shows two syntax-semantics mapping rules. The first of these, dobjAction, would make morphine the theme of the ‘prescribe’ action in the previous example. The relation theme reflects one of the linguistic thematic relations [21, 22, 23], often used to express the action of a verb. This rule fires when the verb, prescribe in this case, is a member of the class Action. This is derivable from background knowledge sources. The dobjPerception rule fires when the verb is a Perception action, a more specific case than dobjAction. A verb would be known to be a perception by making use of imported data from the BKAS, such as VerbNet. In this case the topic thematic role is used. For example, a guideline might contain the text “... when complications are discovered.” Here complication is the topic of discover. Determination of the thematic roles to use is done by making use of the Unified Verb Index [24] wherever possible.

Background knowledge sources play an important role in the mapping rules. The lexical relations available from WordNet and VerbNet allow the creation of general rules which are specific to the kinds of things discussed in guidelines. While an above example makes use of the “prescribe” verb, many others could be used (e.g., receive, take, be given). In general, these verbs have some medication or treatment as their direct object, and indicate a transference of ownership. Verbs of this type are covered by a small set of upper-level concepts in the lexical resources, which may be used in the mapping rules. While our goal is to use general rules wherever possible, we will use more specific rules as discussed here when necessary. Using this technique, the rules can identify many of the “Action Palette” [25] action types used in guidelines.

As Clinical Tractor is still under development, the principal effort is in building suitable mapping rules. Development involves the creation of new domain-neutral rules and many more domain-specific rules. We aim to understand noun phrases, including those that otherwise might be given only a single code by an NER system. Using a common, consistent, semantic structure exposes the relation between long expressions which may not have a code, such as “cellulitis of left hallux” and shorter expressions (e.g., “cellulitis”) and other long expressions that do have codes, such as “cellulitis of toe of left foot”. Negation may also be understood using mapping rules.

The mapping rules also must handle verb phrases, these include condition-action phrases, the Action Palette items, and discussions of choices and decision making. These often include evidence in the form of in-text citations, statements of evidence level, and modality. Guidelines also provide plans for treatment, or give guidance on creating such plans which must be handled. The result of applying the mapping rules is a semantic KB.

4 A Worked Example

Consider the following recommendation from the ADA Standards of Medical Care in Diabetes 2017 [26]: “Patients found to have elevated blood pressure should have blood pressure confirmed on a separate day.” To illustrate the pipeline, this was processed through an early prototype of the system with limited NER (using only MetaMap), only
MetaMap Tagging (GATE): Patients found to have elevated blood pressure should have blood pressure confirmed on a separate day.

Dependency Parsing

CSNePS Syntactic Graph for “Patients found to have elevated blood pressure”

CSNePS Semantic Graph after mapping rules applied

Figure 3: A small example using a prototype implementation of Clinical Tractor, with some by-hand augmentation. MetaMap matches and the dependency parse for a single recommendation are shown at the top, with a subset of the CSNePS syntactic KB after propositionalization, and semantic KB after the mapping rules have been applied shown for the phrase “Patients found to have elevated blood pressure.”

The processing results are shown in Figure 3. Identified concepts in MetaMap are shown on top, with the Stanford dependency parse directly underneath. The propositionalizer converted the GATE output to a CSNePS KB, and we’ve visualized it as a propositional graph. Portions of the KB for the text “patients found to have elevated blood pressure” are shown. Each token can be seen attached to its identifier (beginning with n). Dependency relations may be seen in the graph. The string representation of the multi-word expression “elevated blood pressure” and its decomposition into single words can be seen at the bottom right of the syntactic graph. MetaMap CUIs and concept names for some of the tokens are also shown. This graph excludes many additional relations that are in the KB for easier readability.

The result of applying the mapping rules is shown at the bottom of the figure in the semantic graph. A subtle change that has occurred is that n terms that originally denoted syntactic entities now denote semantic entities. Previously n40 denoted a token with the text “patients”. Now it denotes a group of entities, each of which is of the type patient. n17 was a token with the text “pressure”, adjectivally modified by “elevated” but now denotes an entity of type pressure, with the modifiers elevated and blood. The MetaMap concept Increase in blood pressure applies to this entity instead of the string “elevated blood pressure” as it did in the syntactic graph. This entity is possessed by n40. In sum, this graph represents the group of patients possessing elevated blood pressure.

Only two changes to the semantic graph were handled manually for this example. Two MetaMap concepts were identified for “elevated blood pressure” - a disorder (hypertensive disease), and a finding (increase in blood pressure). We manually selected the finding concept, though the process for selecting the correct one is already well defined: “found” is past tense of “find”, a member of the verb frame for “discover” (using VerbNet) which indicates a clinical observation; a finding. Second, we moved MetaMap concepts for multi-word expressions to the head noun.
Clinical Tractor shares characteristics with many systems used in biomedical informatics for language processing tasks. Guideline-focused work tends to be centered on the task of aiding the creation of CIGs by performing IE tasks to retrieve, and possibly restructure, salient portions of the CPG. Several examples make use of semantically informed patterns over the text. Wenzina and Kaiser [27] use patterns over UMLS semantic types to identify condition-action sentences. They observed recall of 75% and precision of 88% on a small evaluation set. In other work, Kaiser, et al. worked to identify treatment activities in guideline text [28]. Here they used the UMLS semantic network types and relations to generate semantic patterns for activities such as performing, using, and analyzing. They made use of lists of verbs corresponding to the relations and a dependency parse to determine which MetaMap identified concepts in the sentence fit the the subject and object of the relation.

Serban and colleagues [29] presented an ontology-driven method for pattern matching on frequently recurring linguistic patterns, mapped to the control structures (e.g., sequencing, if-then, action-effect) of the target CIG formalism. Medical thesauri have been used [30] to enhance the ability to identify portions of guideline text which map to reusable building blocks, useful for guideline formalization.

Machine learning techniques have also been applied to the recommendation identification task. Preliminary work extracting regular-expression-based heuristic patterns has shown some promise [31], but the inclusion of semantic data is needed. Other work has used part of speech tags as features to extract action sentences from CPGs [32], but again, without the use of semantic data. Neither of these approaches were specifically tailored to the CPG domain. While not using machine learning approaches, Taboada et al. [33] provide evidence for the need to tailor systems to the domain at hand. They used several off-the-shelf tools to extract descriptive knowledge about therapeutic and diagnostic procedures, finding that adaptation of the tools to the task improved results, though their paper doesn’t make tailoring vs. non-tailoring directly comparable.

It’s important to note that in isolation each of the above systems cover only a small subset of what is necessary to derive the complete semantics of the recommendations of a CPG, let alone an entire CPG. In considering the approach taken by Clinical Tractor, there are similarities to the pattern-matching approaches. The primary difference is that instead of using UMLS resources combined with mostly surface structure, Clinical Tractor aims to make significant use of the dependency parse, other kinds of NER, additional background knowledge resources to enhance generalization, and rules applied in multiple steps to move toward a completely semantic representation. This goal of a complete semantic representation appears to be unique to Clinical Tractor in the domain of CPGs.

In relying on, at least in part, a more “standard” NLP pipeline, Clinical Tractor also shares some characteristics with systems such as cTAKES [34], CLAMP [35], HITEx [36], and HTP-NLP [37]. The domain in which these tools are most commonly used is slightly different: information extraction for electronic health records (EHRs). While these domains have many similarities such as including some narrative structure, mentioning many of the same kinds of named entities, and being patient-centric, there are differences in content and appearance of the language. Medical records tend to contain more non-standard abbreviations, sentence fragments, and non-standard English. While only occasionally appearing in guidelines themselves, clinical protocol eligibility criteria do often share the property of being made up of sentence fragments. Work on ERGO [38] discusses many of the challenges involved in eligibility criteria, including acronyms, Boolean operators, and comparison statements. We have in-progress work addressing these issues mostly during the rule-based NER stage of Clinical Tractor. Even given the challenges of this type of text, we don’t believe there’s a need to go as far as to use IE components which are meant explicitly to account for such problems, such as NegEx, which appear frequently in EHR-focused pipelines using the above tools.

6 Conclusion

We have presented an architecture for an NLU system meant to perform, as near as possible, complete reading comprehension of CPGs. The early stages of our architecture use a fairly standard NLP pipeline, comparable to what many NLP systems in biomedicine perform, though with enhanced NER capabilities. It is unique in the attention paid to aligning background knowledge with the textual contents and going a step further than pattern matching rules over text, making use of a KRR system and syntax-semantics mapping rules to transform a syntactic KB into a semantic one utilizing NLU techniques. This approach is built upon that taken by Tractor, which has shown to be successful in
Clinical Tractor is currently under active development as part of a larger system for the automatic generation of CIGs from CPGs. Our hope is that this systems proves useful to people working in and researching biomedicine, and that over time we can build a compendium of semantically represented knowledge. Our even longer term goal for Clinical Tractor is to generalize it to work wherever there is text in biomedicine, whether it be in guidelines, EHRs, journal articles, or clinical trial protocols. Moreover it is important to us that what we build be free for the world to use; as components of our system reach a usable state they will be released open source, under a non-restrictive license.

Abstract

Surgical Site Infection surveillance in healthcare systems is labor intensive and plagued by underreporting as current methodology relies heavily on manual chart review. The rapid adoption of electronic health records (EHRs) has the potential to allow the secondary use of EHR data for quality surveillance programs. This study aims to investigate the effectiveness of integrating natural language processing (NLP) outputs with structured EHR data to build machine learning models for SSI identification using real-world clinical data. We examined a set of models using structured data with and without NLP document-level, mention-level, and keyword features. The top-performing model was based on a Random Forest classifier enhanced with NLP document-level features achieving a 0.58 sensitivity, 0.97 specificity, 0.54 PPV, 0.98 NPV, and 0.52 F0.5 score. We further interrogated the feature contributions, analyzed the errors, and discussed future directions.

Introduction

Healthcare-associated infections (HAIs) affect 10% of patients undergoing surgical procedures in the United States and contribute a significant amount of morbidity to patients1. For patients, the development of an HAI can be associated with increased risk of mortality, longer length of stay, and increased risk of readmission2. Given the significance of HAIs to healthcare utilization, several surgical quality improvement programs have been designed to aid in the surveillance of HAIs. These programs include the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) and the Centers for Disease Control (CDC) National Healthcare Safety Network3. The backbone of these programs is the ascertainment of clinical data through a manual chart review processes4. These processes, while providing high-quality information, are inherently limited by the cost and effort of chart review5. Additionally, these processes are under high risk of underreporting HAIs6, 7, caused by biased interpretation of guideline or data, use of different criteria, insufficient training, etc. To account for these limitations, the programs rely on a sampling methodology either by selecting specific procedures or by a random sampling of procedures, thus limiting the scalability and generalizability of the manual chart review process.

Surgical site infections (SSI) are the most common type of HAI occurring after surgical procedures2. According to the CDC, an SSI is an infection in the surgical wound occurring within 30 days of the operative procedure and can be classified as superficial, deep, or organ space SSI depending on the location of the infection with the surgical wound8. One important distinction for classification of SSIs is to identify the cases with an infection present at the time of surgery (PATOS) as PATOS infections significantly increase the risk of a recurrence of an SSI after the procedure. The diagnosis of SSI can occur through multiple pathways, including provider diagnosis, provider-initiated treatment, or isolation of organisms from a microbiology culture. Given the heterogeneous nature of diagnosing SSIs, manual chart review is currently required to verify or exclude diagnoses9.

Over the past ten years, in response to the Health Information Technology for Economic and Clinical Health Act, there has been rapid adoption of Electronic Health Records (EHR) in US hospitals9. As of 2017, 96% of federal acute care hospitals have adopted a Certified EHR capable of computerized decision support, computerized provider order entry and electronic physician documentation. The almost universal adoption of certified EHRs has to potential to leverage the secondary use of EHR data for quality assurance programs and reduce or depreciate the effort of the manual chart review for surveillance of SSIs.

In previous work, several groups have leveraged electronic health care data to create automated surveillance systems
for SSIs. Hu et al. used EHR data from a single institution along with machine learning models to detect the occurrence of HAIs after surgical procedures. They used International Classification of Diseases (ICD) Codes, laboratory results, microbiology orders and results, medication administration, radiology orders, and vital signs to develop logistic regression models, using manually chart reviewed data as the gold standard. Overall, the area under the curve (AUC) for the classification of SSI was 0.91. The most predictive features included microbiology results and imaging orders. The limitation of this study is the lack of clinical text information in the development of the classification models. Given that the diagnosis of SSI is mainly dependent on physician diagnosis that is usually described in clinical notes, the inclusion of text information may improve the performance of the classification model.

Grundmeier et al. expanded upon this work to include limited text information to build classification models for SSI. Pre-specified keywords related to SSI that had been identified from clinical narratives were added using regular expression matching. The overall performance of the classification model significantly improved with the addition of keywords (AUC 0.97 vs. 0.94). Their best model performed with a 0.9 sensitivity and 0.28 positive predictive value (PPV). The most informative keyword features they found included: “pain,” “infection,” “warm,” “drainage.” While the inclusion of keywords improves the model performance, ignoring the context of keywords is a significant limitation of this approach, which we elaborated further in the discussion.

Other groups have focused exclusively on natural language processing methodology. FitzHenry et al. developed a rules-based NLP system using SNOMED-CT concepts from free text notes in the Veterans Affairs Healthcare system. They developed rules for classifying ten postoperative complications after surgical procedures, including SSI. The performance of the system for detection of SSI was modest, with a sensitivity of 77% and specificity of 63%. The advantage of this approach is the inclusion of text-based features for SSI classification. However, they did not include other structured data into their algorithms, such as medications and laboratory values.

In the present study, we aim to build upon previous work on automated detection of SSIs using EHR data. We combine machine learning techniques with a rules-based natural language processing system. We hypothesize the inclusion of NLP-derived features in structured data-based machine learning models will improve the classification performance for detection of SSIs after surgical procedures. To aim at real-world use, we target our cohort to all surgical patients without any complication code filtering.

Methods

In this study, we applied a rule-based natural language processing (NLP) to extract the information related to surgical site infections (SSI) from the clinical notes, and infer the infection status for each document. Then we combined the keywords or the NLP derived features with structured EHR data to build machine learning models to classify the patients’ SSI status.

Machine learning data set development

The patient data was collected through the University of Utah Health Enterprise Data Warehouse (EDW), including patients from the University Hospital and Clinics, the University of Utah from July 1st, 2013 to August 31st, 2017. The inclusion criteria were patients whose surgical course underwent review by a trained surgical clinical reviewer (SCR) as part of the ACS-NSQIP program. Patients were excluded if they expired within 30 days of the operation. For patients included in the present study, we obtained the following structured EHR data from their records between 2-30 days after their operative procedure: hospital encounters, ICD 9th/10th Edition Diagnosis Codes, medication administration, radiology orders, laboratory and microbiology results, and vital signs. A total of 5,795 patients were included, among which 291 patients were labeled as SSI positive by manual chart review performed by an SCR. For the text data, we created a full corpus by obtaining all clinical notes from 0-30 days after the operative procedure of the following note types: admission notes, history and physical notes, discharge notes and progress notes. We excluded notes that were incomplete or not signed by a credentialed provider (Physician or Advanced Practice Provider).

Structured EHR Data Feature Engineering

For each category of features from the structured EHR data, we performed feature engineering for the development of machine learning models. ICD codes were mapped to the Agency for Healthcare Research and Quality Clinical Classification software and treated as a binary variable. Medications were mapped to RxNorm, and the number of
days of each medication class was used as features. For radiology orders, we grouped common orders and used the number of orders for that particular group as a feature. Laboratory results and vital signs were grouped based on clinical meanings. For example, Potassium levels from both serum or plasma were grouped. Due to the temporal nature of laboratory and vital sign measurement, we used only the minimum, median, and maximum values of each group as features. Groups with greater than 25% missing elements were excluded. For groups with <25% missing values, we imputed using the median of the group. For the microbiology results, we created binary features based on the culture type and organism isolated.

Development of NLP Annotation Guidelines

Based on the ACS NSQIP definitions and clinical expertise, we developed an annotation guideline to perform iterative manual annotation of the NLP development corpus. We defined a mention-level annotation type \textit{Evidence of SSI} and a document-level annotation type \textit{SSI Status}. The \textit{Evidence of SSI} was used to annotate the sentences that explicitly or implicitly mentioned any evidence of infection of a surgical wound. Infection mentions without explicitly referring to an incision were not annotated. For instance, we ignored “he doesn’t have signs of infection.” The \textit{Evidence of SSI} had two attributes: \textit{Infection Status} and \textit{Temporality}. The \textit{Infection Status} was used to clarify if an SSI statement was affirmative, probable, or negated. \textit{Temporality} was used to distinguish current and past SSIs. The document-level annotation type \textit{SSI Status} has one attribute \textit{Infection Status} with the same three eligible values above: affirmative, probable, or negated. At this step, we did not distinguish between SSI and SSI PATOS.

Creation of Gold-Standard NLP-Development Corpus

We created an NLP-development corpus for manual annotation from a random sample of 78 patients from the ACS NSQIP flagged SSI positive cases. The notes were selected using the same criteria mentioned above and cut off at total 2000 notes. We elected to only include SSI positive cases in our NLP development corpus due to the low prevalence of SSIs. Sampling data from positive patients improved the efficiency of both annotation and NLP rule development. In addition, because SSIs develop over the postoperative course, clinical notes from patients with SSIs contain a combination of SSI positive and negative documents.

These clinical notes were pre-annotated using Knowledge Author\textsuperscript{13} with broad vocabularies consolidated based on CDC and NSQIP definitions and using vocabulary expansion from the Unified Medical Language System (UMLS). The corpus was then split into 50 document batches and imported into the annotation tool: eHOST (The Extensible Human Oracle Suite of Tools)\textsuperscript{14}. Two surgeons with expertise in SSI (LCCP, CLL) were trained using the annotation guidelines and evaluated using inter-annotator agreement. After training on five batches, the inter-annotator agreement reached over 80\% for mention level and over 90\% for document-level annotation. A third reviewer (BTB) checked the disagreements and performed adjudication. We subsequently performed a single-person annotation on the remaining 1750 documents with 10\% overlap between the annotators to ensure consistent agreement. On the overlapped notes the annotators had an inter-annotator agreement of 70\% at the mention level and 85\% at the document level. The annotated gold-standard NLP-development corpus was split 50\% for NLP pipeline training (1000 documents) and testing (1000 documents) corpus.

NLP Pipeline Development and Evaluation

The NLP pipeline was developed using a rule-based tool, Easy Clinical Information Extractor (EasyCIE)\textsuperscript{15}. The main components of EasyCIE are listed in Table 1. These rule-based components were built on an optimized rule processing engine\textsuperscript{16} to allow high-speed processing of large rule sets and data sets. The rules for section detector, sentence segmenter, and negation context detector were imported from previous projects with minor tuning. The rest of the rules were developed based on the 1,000 NLP pipeline training documents. The developed pipeline was assessed on the training set for its rule coverage and then evaluated against the NLP pipeline test corpus (1000 notes). Because the rule-based NLP system used more granular and additional mention types to infer document-level conclusions, its mention-level annotation types did not match with the reference standard. Thus, we did not evaluate the mention-level performance, and only document-level F1 scores are reported.

Machine Learning Model Development and Evaluation

After the NLP system was developed from the NLP corpus, we processed all the text data in the machine learning

corpus to develop NLP features. These features included two binary feature sets: an NLP document feature set (ND) and an NLP mention feature set (NM). The document feature set included two features: \( ND_{SSI\ POS} \) to cover whether a patient’s documents contain any positive SSI note; and \( ND_{SSI\ PROB} \) to represent whether a probable SSI note was included. The mention feature set includes 28 features corresponding to the 28 mention-level annotation types generated by NLP. For instance, \( NM_{ABDOMEN} \) represents the feature describing if there is any mention that can indicate the abdomen body site; \( NM_{INCISION} \) represents the feature describing if any incision mention exists.

In addition, two numeric feature sets were also created from NLP document-level results. Frequency (\( FRE \)): the total number of the positive SSI notes or the possible SSI notes of a patient during the observation time window. Normalized frequency (\( NOR \)): the \( FRE \) divided by the total notes of that patient during the observation time window. In total, we obtained six document-level features. We performed the same conversion to mention-level annotations, resulting in 84 mention-level features. As another baseline comparison, we simply used the named entity recognizer without any context detection and inferences to extract the keywords in the notes. The extracted mentions were used to generated keyword features (\( KW \)). For readers’ convenience, we listed the abbreviations of different feature sets in Table 2 below.

Note: Each of these abbreviations represents a set of features instead of a single feature. *: All the above feature sets include structured data features.

We performed a Chi-Square feature selection to select the top performing variables. Logistic regression, support vector machines (SVM), and random forest (RF) models were developed. We applied nested cross-validation to the data set to avoid overfitting17. Because the data set was highly imbalanced with relatively sufficient positive cases, we performed down-sampling rather than up-sampling to avoid overfitting. We used three folds in the outer loop and five folds in the inner loop. We used a grid search for parameters in the inner loop. The best estimators from the inner loop were selected based on \( F_1 \) score because the data used for inner loop cross-validation were down sampled. Then these best estimators were evaluated on test sets of the outer loop (without down-sampling). We used the following performance metrics for evaluation: sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), plus \( F_{0.5} \). We choose the F measure with \( \beta =0.5 \), because we prefer to weight precision higher than recall for
practical surveillance consideration. Due to the imbalanced data set, we elected not to use the area under the receiver operating curve (AUC) in the assessment. We compared the sensitivity and specificity of each model to the NO_NLP baseline machine learning model using McNemar’s test. In addition, we used bootstrapping with 1000 replications to obtain the distribution of $F_{0.5}$ score and compared the distribution of each model to the NO_NLP baseline machine learning model.

**Results**

Once the rule-based NLP solution was developed, we assessed the rule coverage by calculating the performance on the training set. Our final micro-average of precision, recall, and F1 scores were 0.83, 0.83, 0.83 on the training corpus, respectively. Then we evaluated the NLP system on the 1000 blind test notes. The micro-average of the precision, recall, and F1 scores were 0.75, 0.75, 0.75 in the testing corpus, respectively. Next, we used the developed NLP solution to process all the text data of our full corpus to generate NLP features for machine learning. To demonstrate the value of the NLP-derived features, Figure 1 plots the frequency of selected NLP-derived features in patients with and without SSI. There are significantly more SSI-related NLP features in SSI positive compared to SSI negative patients ($p<0.01$).

![Figure 1: The means and standard deviations of example frequency features within SSI positive and negative cohorts](image)

We subsequently used the NLP-derived features to develop the machine learning models for patient-level classification of SSI. We evaluated models using the features described in Table 2 and compared the performance of each model to the baseline structured data model without NLP-derived features. The results are shown in Table 3. The RF models with document features have the highest average Specificity (0.97) and significantly improved compared to the baseline RF NO_NLP model ($p<0.001$). The best PPV (0.54) and best $F_{0.5}$ (0.52) comes from the RF models enhanced with binary document features ($ND_{BIN}$). Compared with the RF models with structured data features alone ($NO_{NLP}$), the PPV significantly improved by 8% and $F_{0.5}$ improved by 7% ($p<0.001$). The addition of mention-level features or keyword features did not significantly improve the $F_{0.5}$ compared the baseline RF model with structured data alone. Although the logistic regression models and the SVM models have higher NPV values (0.99), their $F_{0.5}$ scores are lower than the corresponding RF models, because they are lower in PPV. The SVM models with binary mention features ($NM_{BIN}$), all mention features ($NM_{All}$) and all NLP features ($ND_{NM}$) also have the highest sensitivity, but much worse $F_{0.5}$. The highest $F_{0.5}$ of all the models enhanced with keywords features is 0.480, which is not significantly different from the models with structured data alone.

**Discussion**

*The value of NLP in SSI detection*

In previously reported studies of surgical site infection surveillance, structured variables (e.g., ICD Codes, laboratory results, microbiology orders and results, medication administration, etc.) are commonly used to generate machine

*: The abbreviations of feature sets are explained in Table 2, NO_NLP, structured data features alone.
ND, NLP document-level features; NM, NLP mention-level features; BIN, binary features;
FRE, frequency features; NOR, normalized frequency features; ALL, use all document or mention features.
#: Computed against the models using structured data alone.
learning features for disease classification. These variables can reflect a significant amount of information related to SSIs, including diagnostic information as well as treatment modalities for SSI. However, given the complex nature of SSI diagnosis, without the inclusion of textual information, these models are inherently limited in performance. For example, the documentation of SSI may only be located in the clinical notes if the infection did not result in any change of laboratory orders, vital sign or medication administration, e.g., a mild surgical wound infection. Also, laboratory results or medication administration may not exist in the structured database if a patient has received emergent care outside the index hospital. This type of missing information varies a lot across different health organizations; it is especially prevalent in tertiary medical centers where patients commonly travel a long distance to receive care.

Previous studies have investigated incorporating free text into machine learning models using keywords; however, without contextual information the use of keywords does not maximize the potential of NLP. In this study, we observed that it is common that clinical notes mentioned the keywords related to SSI but not in the way of demonstrating evidence of an SSI. For example, surgical procedures in the past medical history or any medical conditions mentioned as patient education for future precautions. Of all the mentions (980,045 mentions) that we extracted using our NLP systems, 7.3% are negated concepts (e.g., “Midline incision well approximated with staples, no erythema, no drainage”), 1.5% are within irrelevant context (e.g., “Stay away from people with infections”), 3.5% are about other infections other than abdominal SSIs (e.g., “septic arthritis of the bilateral wrists”), and 0.5% are historical concepts (e.g., “Sepsis 05/2011”). Ignoring the context of these mentions adds in a significant amount of noise (12.8% in total) to machine learning models. Additionally, a document-level conclusion of an SSI may not stem from the explicit mention of SSI, but instead from inferencing multiple mentions of other different concepts. For instance, a note with mentions of “post-op s/p” and “intraabdominal infection” in separated sentences. Neither of these two concepts alone can conclude SSI, while together, they suggest a positive SSI. These cases require additional inference from mention-level information to draw document-level conclusions, whereas the simple keywords approach is incapable of.

The results of the comparative experiments above (Table 3 suggest that handling these subtle contexts and logic correctly does provide additional information gains in the development of machine learning models. The best F0.5 score using structured data alone is 0.48 (Logistic regression model). Adding keywords features improves the performance on the RF models compared with RF models using structured data alone, but the best F0.5 of all keywords enhanced models is still 0.48. Using NLP features, the best F0.5 score reaches 0.52 – an 8.3% improvement (p<0.05).

NLP error analyses and indications for future directions

The NLP errors occur at two levels: mention level, document level. The most common mention-level errors are from the context not seen in the training set. For instance, “site color red” is mentioned in a list of description of a surgical incision. Our NLP solution did not capture the earlier context about the incision, thus failed to detect the “red” as a sign of infection. In the document-level errors, the most common cause is that our developed rules do not capture all the logic at the document level. For instance, we did not observe the rare co-occurrence of other healthcare-associated infection, such as pneumonia or urinary tract infection (UTI) in the NLP training set. In these cases, it is common to refer to pneumonia or UTI as “infection” in general. Within a context of abdominal condition description, NLP tends to interpret these general infection mentions as possible abdomen infections. However, in the NLP test set, these cases were more prevalent. Among all the 180 false negative SSI notes, 35 of them have a diagnosis of pneumonia, and 64 notes have other infections without an explicit mention of an anatomical site. These are the errors that we will address in future studies.

Additionally, we also found some annotation errors in the reference standard. Often these errors happened within the notes where doctors use templates or copy a section of text from other notes, while changing a few words that support different document conclusions. The annotators tended to skip the snippets that they have seen before, and these slightly modified text pieces become difficult to identify. On the other hands, it suggests that pre-annotating these notes using developed NLP solutions might improve the human review accuracy and reduce the workload. Implementing these into real practice workflow could speed up the human chart review process, reduce errors and human labor, even if a completely automated surveillance system is not available.

Machine learning models analyses and indications for future directions
As the results show, NLP features do provide additional value to the machine learning models. Notably, our champion RF models using NLP document features not only scored better than the others but also have statistically significant differences compared with the models using structured data alone.

The logistic regression models generated sub-optimal results among the three classifiers. We examined the best performing models built from NLP document frequency features (ND_FRE). Because we used nested cross-validation, we trained 15 logistic regression models enhanced with the ND_FRE feature set (5 models in each outer loop). Then we got three best models (one per each outer loop). We identified the common features among these three models, by using the average of the corresponding coefficients and ranked them in descending order (see Table 4). The results rank the NLP derived document-level feature — the frequency of SSI positive documents, as the No. 1 weighted feature.

We also examined the Random Forest classifier by estimating the importance of features (See Table 5). It shows that the NLP document feature is ranked as the most important feature. We chose one of the decision trees within the RF classifier to visualize its tree structure. Figure 2 visualizes a decision tree’s root from one of the top RF models, which identified the NLP binary document feature stands as the tree root. 56.7% of the test cases are classified as positive, and 43.3% are classified as negative. Moreover, 80% of the cases on both sides are correctly classified. Other trees show similar functions to these features. These visualizations indicate that NLP does play an essential role in our champion RF models. Because of the overall performance of SVM models (they are the lowest among the three classifiers in this study), and the difficult nature of feature interpretation for SVM, we do not present the SVM models analyses here.

Additionally, we investigated the errors predicted by machine learning models and NLP. We found a significant number of errors are caused by misclassifying the patients who admitted with infections present at the time of surgery (PATOS), e.g., perforated appendix or cholecystitis. Among these patients, some patient went on to develop infectious complications after surgery and are labeled as SSI PATOS. Others do not develop infectious complications and are not labeled as SSI or SSI PATOS. Our structured data features neither include any temporal information such as when a
Figure 2: Visualizing the root of a decision tree from one of the best Random Forest models enhanced with document binary features. “samples” means the percentage of cases reaching the node. “value”: left is the percentage of true negative cases, right is the percentage of true positive cases. “class” is the conclusion from the parent node.

lab was ordered, lab values were collected, nor anti-infection treatments were administrated. Also, our current NLP system does not discriminate the infection status at the time of surgery or later in the postoperative course. Thus our machine learning models and NLP system have difficulty correctly classifying these patients. Since these patients are not rare in general surgery, we will address the issue in future studies. This barrier might be overcome either by integrating temporal features into machine learning models or adding higher level inferencer of NLP from document-level conclusions to patient level conclusions.

Compared with previously published studies\textsuperscript{10,12}, our methods are inherently different. The reported scores are not directly comparable. FitzHenry et al. used manipulated input data (patients with complications mixed with 10% of the ones without complications) to develop and evaluate their system. Thus the reported performance does not reflect the system’s real performance on real-world data. Hu et al. compared several different models using data without any manipulation, but only reported AUC. Because both of our data are highly skewed with negative cases, only a small portion of ROC AUC can effectively reflect true performance. For this reason, we did not report ROC AUC. Hu et al. did not report the exact AUC scores for SSI detection other than a plot. Our several models (e.g., SVM enhanced with document binary features, Logistic regression with all document features or mention features) reach 0.92 in AUC, which seems comparable to their best model. However, they are not the best model that we choose using $F_{0.5}$ score. Because we built and evaluated our models on a real-world data set, these models can be more practically used in the real environment.

Conclusion

We assessed the value of applying NLP to enhance machine learning models for SSI detection. The results show improved performance of the NLP enhanced models compared with the models using structured data alone or models enhanced with keywords features. A close investigation of these enhanced models confirms that NLP features play an important role in classification. Our error analysis suggests that future studies should include temporal status into consideration to further improve the performance.

Have ICD-10 Coding Practices Changed Since 2015?

Srikanth Sivashankaran, MS, John P. Borsi, MS, Amanda Yoho, PhD
IBM Watson Health, Cleveland, OH

Abstract

Usage of ICD-10 codes in administrative data has continued to shift since mandatory adoption in 2015. Identifying changing patterns in coding behavior is imperative in producing reliable analyses and robust conclusions. We examined the granularity of ICD-10 coding over time in a cohort selected from the IBM Explorys Therapeutic Dataset, which contains the records of over 60 million patients. Our seasonality-aware trend model identified patterns of interest, such as increased use of laterality codes for pain and increased use of codes denoting concepts novel to ICD-10 for screening encounters. Those relying on these codes should adjust for these ‘learning curve’ effects. This work should be extended to additional modalities of terminology usage and represents a starting point for researchers working with dynamic clinical ontologies.

Introduction

The Tenth Revision of the International Classification of Diseases (ICD-10) represented a “thorough rethinking” of the World Health Organization (WHO) terminology. Specifically, the clinical modification of ICD-10 (ICD-10-CM) in use in the United States included a four-fold increase in the number of available codes over the ICD-9 version, intended to dramatically increase the applicability, specificity, and usability of the code system. The migration to ICD-10 in the US proved controversial: on the one hand, the conversion to ICD-10 promised improved understanding of patient outcomes, reduced fraud and abuse, and increased extensibility. On the other, the increase in complexity and structural changes threatened to incur implementation costs and cause headaches for practitioners.

We should expect the disruption surrounding the 2015 transition to have an observable impact on the resulting ICD-coded data. A 2001 report from the CDC highlighted the statistical disruption produced by ICD-10 coding for mortality data, and reviews from the 1998-99 Australian and 2002-07 Canadian ICD-10 transitions showed noticeable changes in coding volume and prevalence of some disease categories. And, indeed, US studies in the wake of the cutover have shown under- and over-reporting of important clinical categories. Substance abuse, self-harm, HIV and Alzheimer’s coding were subject to significant alterations in perceived population prevalence across the ICD-10 boundary.

The impact of the conversion to ICD-10 is not limited to the immediate transition period, however. In the wake of Switzerland’s 1998 ICD cutover, for example, ICD usage continued to shift for years as coders acclimated to the new system. The idea of a coding ‘learning curve’ is supported both by anecdotal and experimental evidence. A South African controlled study demonstrated that ICD coding behavior can noticeably shift as a result of training and familiarization. Early reviews of US ICD coding post-cutoff show that we might expect a significant learning curve; as of 2016 there remained significant opportunities to improve the accuracy and relevance of coding.

Although learning curve effects may contribute substantially to coding variation immediately following a transition, there are other factors that might impact coding patterns over time. Coders may respond to risk adjusted payment incentives or different auditing regimes. There are potentially any number of systemic factors that could have subtle influences on subsequent data analyses. Understanding and revalidating ICD-10 coding patterns is an important step towards having confidence in analyses using ICD-coded data moving forward.

We provide a unified structure for assessing temporal coding patterns over the years 2015-2018 and present results from applying it to a large administrative data set. We examine both seasonal and long-run trends for related families of codes. For this work, we focus primarily on codes which were newly introduced in ICD-10, to best capture the relevant shifts in usage following the ICD-10 transition period.

Data and Methods

We employed the General Equivalence Mappings (GEMs) from the Center for Medicare and Medicaid Services (CMS) to identify novel concepts in ICD-10-CM. These bidirectional mappings, between ICD-9-CM and ICD-10, are accompanied by a series of flags, one of which indicates whether the mapping between concepts in the two
terminologies is approximate. We identified novel ICD-10 codes by applying all of the following conditions in the ICD-10 to ICD-9 segment of the diagnosis terminology GEMs:

1. The “approximate” flag had the value TRUE
2. The ICD-10 term did not describe a “not elsewhere classified” or “other” concept
3. No other ICD-9 term mapped to the ICD-10 term under consideration
4. The ICD-9 term in the GEM entry describes an “other” concept – a catch-all for terms not explicitly enumerated in that terminology

These criteria identify, for example, the ICD-10 code for Salmonella pyelonephritis (A02.25) as describing a concept not listed in ICD-9:

<table>
<thead>
<tr>
<th>ICD-10 Code</th>
<th>ICD-10 Description</th>
<th>Approximate mapping?</th>
<th>ICD-9 Code</th>
<th>ICD-9 Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>A02.25</td>
<td>Salmonella pyelonephritis</td>
<td>TRUE</td>
<td>003.29</td>
<td>Other localized salmonella infections</td>
</tr>
</tbody>
</table>

In order to provide a baseline against which to compare the use of novel codes, we organized the concept space of ICD-10 into groups consisting of codes sharing a header. Headers in ICD-10 are grouping artifacts defined by CMS as “not valid” but “included as a convenience for other uses”, to capture related sets of terms. For this study, we considered every concept group meeting the following conditions:

1. The group contained an ICD-10 term identified in the previous step
2. The membership of the group remained constant over the study period (fiscal years 2016, 2017, and 2018 to align with the ICD code update cycle)
3. The group contained at least one term describing an “other”, “unspecified”, or “not elsewhere classified” concept – one to be used where the medical record lacks adequate granularity or describes a condition not otherwise enumerated -- against which to compare the novel ICD-10 term(s)

These criteria situate the novel ICD-10 concept of Salmonella pyelonephritis, for example, within the following concept group:

<table>

</table>

We then obtained unique patient counts per month for each ICD-10 code in the selected groups over the fiscal years 2016, 2017, and 2018 from the IBM Explorys Therapeutic Dataset. These data are comprised of the clinical and claims records of over 60 million unique patients from over 39 healthcare systems; see Table 1 for demographic information about the study cohort selected from those patients. In order to more precisely consider the behavior of professional medical coders, we limited the study to administrative data alone. To ensure sufficient sample size, we limited analyses to the 20 header groups with greatest overall patient counts.

In order to surface patterns in the assignment of ICD-10 codes over time, we measured the difference between novel codes and other codes. We decomposed the observed variation in differences into level, trend, and seasonality components using the R forecast package, which selects an exponential smoothing method for each component that minimizes the value of Akaike’s Information Criterion (AIC) of the whole\textsuperscript{26}. We assessed the explanatory significance of the AIC-minimizing model components by comparison to the fit obtained when using no exponential smoothing for the relevant subcomponent (trend or seasonality) when holding all other methods identical. We also calculate the seasonal and non-seasonal variants of the Mann-Kendall test for trend, whose tau statistic provides a guideline as to the direction of trend where applicable\textsuperscript{27}. For consistency between groups, we used the measure of patient count relative to all patients with any diagnosis record in the filtered dataset.

**Results**

We identified 11 statistically significant coding trends that were deemed to be of practical interest. These trends are summarized in Table 2. Each of the novel ICD-10 codes identified in the reported trends can be categorized in one of two ways. First, novel codes may relate specifically to body site laterality – left knee or right shoulder, for example. Alternatively, novel codes may represent an increase in granularity over similar ICD-9 codes.

Table 2. Summary of coding trends, by novel ICD-10 code and corresponding header. Code type describes our categorization of what makes this code distinct from related ICD-9 codes. Percent change is the absolute change in the relative patient share of the novel code(s) over the entire study period.

</tr>
</tbody>
</table>
Although this work is primarily focused on changes in the usage of novel ICD-10 codes, our modelling approach also detected the tradeoff between non-novel codes closely related to codes of interest. In Table 2, we indicated this coding pattern as ‘other/unspec.’ to indicate that the calculated statistics typically reflect differential usage of the other and unspecified code types, rather than changes in usage of the new, more specific codes. For example, within the header grouping D50, ‘Iron deficiency anemia,’ the new more granular code of interest is D50.1, ‘Sideropenic dysphagia.’ Despite the relative consistency of D50.1 coding over the study period, there was a significant alteration in the comparison baseline of D50.8 and D50.9 (other anemia and unspecified anemia, respectively). We present this trend because decreased usage of ‘unspecified’ codes in favor of ‘other’ codes may indicate an area where the clinical content coverage of ICD-10 is lacking.

One of the most common types of coding pattern identified through our analysis was the increased use of laterality codes over time. For example, Figure 1 provides a clear example of reduced usage of unspecified laterality over time for the code header M25.51, pain in shoulder. This increased uptake of laterality codes is most pronounced for pain related codes; we observed increases in laterality-specific coding within the code groups describing pain in the shoulder, hip, knee, and limbs. We did also note a decrease in usage for M17, osteoarthritis of the knee.

![Figure 1. Use of laterality codes for M25.51 header (pain in shoulder)](image)

Generally, the novel codes for laterality behaved similarly to one another over the study period. There was more diversity among the trends identified for novel codes that were more specific than their ICD-9 counterparts. Of the five identified trends involving more granular ICD-10 codes, three were for increased usage of the novel codes and two were decreases in usage.

We also identified certain trends that had a dramatic seasonality to the relative usage of novel ICD-10 codes. An example of a highly-seasonal trend is provided in Figure 2. For the most part, our analysis is not susceptible to the underlying seasonal trends of disease and healthcare utilization because we are primarily interested in the relationships among codes that share similar underlying temporal attributes. However, in cases where there are clearly different month-to-month behaviors for the different codes under a single header, our analysis will include artifacts from that
seasonality. After correcting for this seasonal behavior, there remains a more subtle trend which we still present as a valid shift in coding patterns.

![Figure 2. Seasonal coding patterns for R09.8 (respiratory symptoms)](image)

**Discussion**

We expected to see an increase in novel ICD-10 code usage over time as a result of increased familiarization. The increased uptake of laterality information is an excellent example of such a positive learning curve. Initially, coders may have been unaware of the increased documentation possibilities or were using ICD-9 crosswalks which would map to unspecified laterality codes. The adoption of these laterality codes represents a positive development: usage of these new ICD-10 codes is likely to improve care and reduce fraud.

The discrepant laterality trend, M17 - osteoarthritis, was the single reported decline in usage of the laterality codes. We suspect that this trend is due to a data artifact that does not represent actual coder behavior. Over a 3-month period in early 2017, there was a substantial jump in the raw number of unspecified laterality variant of arthritis codes. This coincided with an overall increase of arthritis codes in our analysis and is likely due to a newly-introduced data contributor to the overall dataset. Contributors are deliberately concealed in this deidentified dataset, and the only proxy for determining such effects is through analysis of changes in geographical distributions of patients in the data. Although such increases in raw numbers was rare, further work will be required to fully understand the impact of such distributional shifts.

Apart from the usage of laterality codes, the perceived trends for new ICD-10 codes were of mixed magnitude and direction. Some of the reported trends were straightforward increases in adoption of more specific codes: Z12 added details about mammograms, I25 added a code for cardiomyopathy, and R09 included increased symptom specificity. However, some of the trends moved in the opposite direction: the header groupings for drug therapy and complicated type 2 diabetes (T2DM) saw shifts in usage away from novel codes and towards more unspecified or other codes. For example, in the T2DM header E11.6, the usage of the newer more granular code E11.65 (hyperglycemia) decreased and the generic, unspecified code E11.69 became more popular. See Figure 3 for the patient shares of these codes over time. There are a number of possible explanations for this type of trends: they may be explained by an evolution of diagnostic practice that ICD-10 fails to cover.
In addition to the temporal anomaly observed in the distribution of the osteoarthritis codes mentioned previously, there were some other data fluctuations on short timescales. For example, the coding for breast cancer screening experienced a noticeable discontinuity in August 2017, where the use of the novel mammogram code Z12.31 increased about ten percent among patients receiving any code for such a screening. There are several potential explanations for such a shift; to our knowledge no new screening guidelines were issued around that period, but hospital systems might have been adopting 2016 guidelines at that time. Alternatively, coders may have been responding to reimbursement pressures around screening codes. No other trend experienced a short-term shift as large as that of the breast cancer screening header, and the others may be attributable to random noise.

**Conclusion**

Understanding the uptake of ICD-10 codes is critical to the accuracy of ICD-based analyses. Our work has identified several broad categories of coding patterns that should be corrected for or excluded from retrospective studies. The introduction of laterality codes in ICD-10 represents an opportunity for more detailed study of the specific body sites of given conditions. However, researchers need to be aware of the learning curve effects present in these codes after the ICD-10 transition. Similarly, the increased specificity for screening encounters available in ICD-10 enables enhanced study of utilization and health system effects but may be affected by the trends identified here. Finally, the cases of decreased uptake of novel codes may indicate areas where revisions or additions to ICD-10 are necessary and should be tracked in future ICD-10 implementation studies.

There are several opportunities for more in-depth analysis of key coding trends revealed by this work. Throughout our trend modelling, we restricted code groupings to the header codes provided by CMS. Although sufficient for our purposes, there are higher level groupings that might reveal broader shifts in coding practice. Looking at coding practices across higher-level ICD-10 groupings or other clinically significant clusters would present highly relevant patterns to coding and informatics professionals. Additionally, novel features of ICD-10 can be spread across many different code groups. Analyzing the usage of cause of injury details or overlapping site codes would provide useful learning curve information. Another factor to be considered in future work would be the “grace period” that CMS applied only to the first fiscal year (2016) of ICD-10 implementation, which allowed for a degree of imprecision in Medicare fee-for-service claims; the freedom from audit that it promised in that year could help to explain some of the variation in coding patterns observed between that year and fiscal years 2017 and 2018. Finally, this work focuses
mainly on novel ICD-10 codes but, as we move further away from the ICD-10 transition, that novelty may prove less relevant to coding practice and our analysis should be expanded to other properties of ICD-10 codes and the relationships among them.

For future coding system updates, including both structural and incremental changes, this type of coder uptake analysis is vital to understanding the impact of various incentives on reported outcomes. This knowledge of coding practices is important not just to coders and researchers; it suggests important features of the inner workings of our health care systems.

Abstract

Introduction: 169 U.S. health systems now engage in OpenNotes: a movement to share clinical notes with patients. Few studies have focused on releasing notes during hospitalization, pediatrics, or parents/caregiver perspectives.

Methods: A focus group was conducted with eight parents with experience caring for a hospitalized child at a Midwest children’s hospital. In the 2-hour session, parents were asked about their perspectives of the idea of sharing inpatient doctors’ daily notes with parents during their child’s hospitalization. Qualitative analysis was conducted to elicit themes related to the potential benefits and challenges of sharing inpatient notes. Results: The most mentioned benefits included notes providing information as a reference for improved family education/understanding, communication/continuity, and advocacy/empowerment. Challenges were primarily related to note content, impaired communication and negative impact on families. Conclusion: Participants identified multiple potential benefits of and challenges to sharing notes with parents during their child’s hospitalization but also acknowledged the impact on healthcare professionals who work alongside them.

Introduction

The OpenNotes movement, launched in 2010, advocates “fundamental change in the way visit notes are managed”, by making visit notes available to patients.1 The objective of this overarching study was to identify stakeholder perspectives on the idea of sharing inpatient doctors’ daily notes with parents during their child’s hospitalization using an inpatient portal, MyChart Bedside (Epic Systems). We conducted five focus groups composed of different stakeholders at a quaternary children’s hospital in the Midwest: (1) parents (Patient and Family Advisory Council members with experience caring for a hospitalized child); (2) nurses (pediatric bedside nurses working on general medical/surgical units); (3) pediatric intern and resident physicians; (4) attending physicians; and (5) representatives from the departments of hospital administration, information services, risk management and patient relations. Findings from this study will be used to inform design requirements for optimally implementing and evaluating OpenNotes for hospitalized patients and caregivers using an inpatient portal. This paper reports on some of the findings from the Parent focus group.

Background

In 1973, the psychiatrists Shenkin and Warner published an editorial in the New England Journal of Medicine proposing that patients should be given complete copies of their medical record and routine issuing of new copies as information changed. This ignited a firestorm of dialogue among healthcare professionals.2 It has been called the “pioneering” work in the field of patient access.3 Alan Westin, a pioneering advocate for consumer data privacy, ascribed the patient access initiative to a developing “consumer” theory of health care.4 This theoretical lens saw patient access as beneficial for patients and the larger healthcare system alike by improving content, patient education, and patient-physician communication. Patient readers could correct erroneous information found in the record, thus ultimately enhancing the quality of care.4 Record access could also be a part of continual patient self-education, enabling smarter health consumerism and better client-physician relationships.5,6 Patients could be “more active partners” if they were allowed more information about their treatment.2,4 Further, medical record access could result in a “realignment of power.”7 Objections to such access by physicians fell into dominant themes, which Westin called...
the “doctors’ judgment model.”4 Opponents located their objections in the nature of the clinical documents themselves. In terms of content, it was argued that reading medical records could result in actual harm to the patient through causing confusion;8 of education, that the amount required to teach a patient to understand what they read placed a burden on the physician;4 and that communication between physician and patient would be negatively affected by medical record access.9

The question of how much, if any, of their medical records patients and/or their caregivers should be able to see has also been a longstanding debate in healthcare. It is no accident that the first published study of the effects of access, which appeared the same year as Shenkin & Warner’s editorial, was done in a context of Problem-Oriented Medical Record development.10 Health informatics technologies have the potential to greatly affect the balance of power between physician and patient simply by providing the patient with more information, which requires attention to knowledge representation for new readers as well as re-education of the writers.

In 2010, a movement called OpenNotes began as a collaborative experiment between hospitals in Boston, Pennsylvania and Seattle. Twenty thousand patients were given the opportunity to read their clinical notes – textual summaries of their doctor visits – using their patient portals. In two of the study sites – Pennsylvania and Boston – 82% of patients opened the notes, while in Seattle only 47% did. The response from patients was overwhelmingly positive. A very high proportion (77-87%) agreed that the notes helped them feel “more in control of their care”. By self-report, 60-78% reported increased adherence to their medications.11 As a result of this early success, as of March 10, 2019, 169 health systems in the U.S. “and a couple in Canada” are now engaging in OpenNotes.12

Themes consistent with the consumer movements of the 1970s continue to arise in the 21st century research literature of OpenNotes. Benefits include enhanced communication (text supplements to verbal instructions about care plans and appointments),13 improved patient knowledge and potentially improved self-care (understanding of diagnosis and care plans; patient activation; error correction),13,14 and greater patient participation (medication adherence, monitoring and follow-up with physician).13,14 Challenges include concerns about security,15 stress induced by reading notes,13 information overload,15 confusion induced by terminology,13,16,17 unintentionally offensive language,13 and technical issues.13

The research literature explicitly referencing the OpenNotes initiative is growing with the movement, but a PubMed search reveals only 20 published studies in which patients were involved and patient feedback sought. Of these, 15 were online surveys or analysis of secondary data from surveys, for example.18 The remaining five studies used qualitative methods, such as semi-structured interviews or focus groups. Surveys have been done of 13 patients in primary care;19 28 patients living with mental health conditions;20, 21 20 oncology patients;22 and 14 patients seen at a university health service.23 One of the numerous My HealtheVet studies examined the patient experience using focus groups of patients inside and outside the VA.24 Of note, only two studies have involved caregivers of patients. Bell ET al.14 reference unpublished studies of focus groups conducted during the early years of OpenNotes that included caregivers. Wolff et al. comment: “Family members and friends are frequently involved in the care of patients who are more vulnerable and may facilitate access and use of a patient portal. However, the longitudinal experiences of patients and families who share formal access to a patient’s portal account has, to our knowledge, not been examined.”

Nowhere is the involvement of caregivers clearer than in the domain of pediatrics. OpenNotes reported that 76 healthcare systems were sharing pediatric notes with patients, parents, or both.26 However, Sarabu et al. call attention to the complexities posed by pediatric care, “unique because additional caregivers ... are almost always involved and generally have legal decision-making capacity for most medical decisions that involve the patient.”27 The objective of this study was to identify parent perspectives of the idea of sharing doctors’ notes with parents during their child hospitalization. Qualitative research is required to understand the diverse and nuanced perspectives of stakeholder participants. This is especially important when considering changes within complex healthcare systems, like the implementation of OpenNotes in the pediatric hospital setting. This paper reports the findings from a focus group composed of important pediatric participants: parents.

Methods

Setting and participants. In the overarching study, focus groups were conducted with each of the 5 stakeholder groups at an academic children’s hospital in the Midwest during October and November 2018. The study reports on findings from the parent focus group which met once. Eligible parent participants were members of the hospital’s Patient and Family Advisory Council and were invited by email. Respondents were provided an information sheet describing the
study, risks and benefits, and contact information, and informed consent was obtained. Participants were not reimbursed for their participation. The institution’s Institutional Review Board approved this study.

**Study procedures.** The parent focus group was conducted in a private hospital conference room. The facilitator was a research specialist trained in qualitative methods (AT). A semi-structured facilitator guide was developed and refined after piloting with stakeholder representatives. A hybrid approach was used integrating both open-ended and targeted questions. Focus group sessions started with a description and definition of inpatient doctor’s daily progress notes and followed with open-ended probes to explore participant perceptions of the idea of and benefits of and challenges to sharing notes with parents during hospitalization through the inpatient portal. At the end of the session, the facilitator provided a summary, offered an opportunity for revisions or clarifications and administered a short demographic survey to participants. The facilitator guide can be found at: www.hipxchange.org/InpatientPortal.

**Data analysis.** Audio-recordings were transcribed by a professional service. A ‘cleaning’ process was then performed to ensure accuracy, fill in text that the transcriptionist could not discern, and delete any identifying information inadvertently collected. To ensure anonymity, recordings were destroyed after transcription. Transcribed data were transferred to Dedoose© (https://www.dedoose.com), software used to facilitate the organization and coding of qualitative data.

Three researchers trained in qualitative methods participated in thematic content analysis of the focus group transcript (AT, CAS, MK). Data was organized into themes related to benefits and challenges and the analytical approach was based on this framework. Two researchers (AT, CAS) first independently reviewed the transcript, identifying themes and concepts emerging from the data related to benefits and challenges to share inpatient doctors’ notes with parents during hospitalization. With a third researcher (MK), they developed and iteratively refined a codebook of identified themes, their definitions and exemplar quotes. Two researchers (AT, CAS) then independently coded the transcript. During this process, all three researchers continued to meet together to review the coding and reach consensus over any discrepancies, always referring back to the transcript.

**Findings**

The Parent focus group discussed here had 8 participants and lasted 2 hours. All but 1 participant was female, and ranged in age from 35 to over 55 years old. Half had a college degree, 75% (N=6) were White and 25% (N=2) Asian. All reported that they spent time on the Internet, using a computer, a tablet, or smart phone. The majority (N=6, 75%) more than 15 hours a week, 12% (N=1) between 6 and 10 hours a week, and 12% (N=1) between 1 and 5 hours a week.

The most mentioned themes related to potential benefits focused on notes as a means of information provision: serving as reference for improved family education/understanding, communication/continuity and advocacy/empowerment. These themes and examples are shown in Table 1.

</thead>
<tbody>
<tr>
<td><strong>NOTE CONTENT</strong></td>
<td></td>
</tr>
<tr>
<td>Medical jargon</td>
<td>It's not just the language, there just needs to be somebody that people can ask questions. Because it isn't even just medical words. It's like Q4HPRN, you know, every four hours, PRN. Does everybody know what that means? So that's not a word. That's just medical abbreviations. Maybe everybody in this room has had enough experience that they know what that is, but I would venture to guess that there are a lot of people that that would just be a jargon for.</td>
</tr>
<tr>
<td>Discussion of sensitive diagnoses (e.g., eating disorder, mental health, abuse) or private topics (e.g., sexual health, social issues, family dynamics) in notes</td>
<td>The other challenge I was wondering about is if there are certain things a patient wants to keep private… I think this came up several times about use of birth control. Personally, I don't think it's my personal opinion as a parent that if my child is on birth control, I need to know. But I would respect the law, whatever it is. So now does this open the door that like if it goes in the notes, then now someone has access to that?</td>
</tr>
<tr>
<td><strong>IMPAIRED COMMUNICATION</strong></td>
<td></td>
</tr>
<tr>
<td>Release of information (e.g., abnormal tests, diagnosis) before face-to-face communication or without translation by provider</td>
<td>I suspect that notes will also reflect comments between providers that parents are not yet aware of. I'm thinking it may not just be what happened at rounds that we know already, but after rounds, a consultation was had or some discussion was had, and that's going to show up in the notes, and we have not yet become privy to that, so the whole timing issue … brings that issue up again.</td>
</tr>
<tr>
<td>Physicians inhibited from communication with each other</td>
<td>If I really trusted my kids' doctors, I want them to go in that room without me and to play with their creative, sciency brains and go, “It could be this, it could be that.” I don't want to hear that. … I want them to figure it out and then say, hey, we're strategizing this. … I would hate for them to somehow stifle that part of their collegiality, because, oh, mom is going to read it.</td>
</tr>
<tr>
<td><strong>IMPACT ON PATIENT OR FAMILY</strong></td>
<td></td>
</tr>
<tr>
<td>Negative parent emotion induced by information in note (e.g., frustration, confusion)</td>
<td>We got called into a conference room with, what, like four doctors, four nurses, a couple social workers. I mean, we had the whole squad there, you know, and they basically told us we had a 5% chance of survival, and that we could take our daughter home and put her on hospice. If I would have read that in a doctor's note, no matter good I am at absorbing this stuff, I think would have probably freaked out then too, because it was not a good day.</td>
</tr>
<tr>
<td>Parents/families are different</td>
<td>Other parents are going to handle [access to notes] differently. We might be, you know, more professional, or we might be upset but then like keep that poker face on. But some families would probably create quite a bit of static over certain things and stifle that.</td>
</tr>
</tbody>
</table>

Some comments did not fall neatly into the Benefit or Challenge themes. On numerous occasions parent participants seemed concerned about the impact of inpatient OpenNotes on other stakeholders:

“I'd be shocked if the doctors really wanted it.”

The central theme of these comments was concern for healthcare professionals’ time – time that parents wanted to be spent on caring for their children and communicating with other healthcare professionals:

“I don't want to make their jobs more difficult as doctors, and I don't want to burden the nurses and other medical staff with all the questions that this could bring up. I mean, I'm very sensitive to the nurses' time.”

“I don't ever want to interfere with them being able to do their job.”
Discussion

This is the first study to evaluate parent perspectives of the potential for OpenNotes in the pediatric inpatient setting. There is a striking resemblance between these parents’ perceptions of sharing notes and the potential of such sharing enunciated almost 50 years ago at the dawn of the patient access initiative, a focus on content, education, and communication. These themes are echoed in recent studies evaluating patient perspectives of ambulatory OpenNotes and a pilot study assessing inpatient note sharing with 10 hospitalized adults.

These results also highlight multiple potential benefits and challenges that may be unique to sharing doctors’ notes in pediatrics and in the hospital setting. Parents mention characteristics of the child or family that may make note sharing more challenging, such as with hospitalized children approaching adolescence where it is vital to ensure that their information is kept private. Parents’ worry and anxiety may be heightened in the fast-paced, high acuity inpatient setting. Participants suggest this anxiety may be worsened with access to notes, particularly if information is shared prior to face-to-face communication with physicians. On the other hand, note sharing may facilitate parent communication with their child’s inpatient physician. For example, one parent suggests that the information found in notes may support parent engagement in communication with physicians during daily bedside rounds. Another mentions that access to notes may help parents act as “a second set of eyes” to ensure information accuracy and continuity specifically during inpatient care transitions, such as during staff change of shift. These results suggest that there may be differences in the implementation, use and impact of OpenNotes in the inpatient setting, which will be important areas for future research.

The opinions of parent participants in this focus group also reflect parents’ awareness of the potential impact of note sharing on the rest of the healthcare team. They identified potential benefits for parents during their child’s hospitalization, but also acknowledged the potential impact on healthcare professionals. In fact, one of the most frequently expressed ideas during the focus group session by these parents included comments about the potential effects of note sharing for providers. One benefit, for example, was “ensuring continuity of care/information between providers,” and a challenge was the possibility that “physicians [would be] inhibited from communication with each other.”

These results will inform efforts to design, implement and evaluate OpenNotes in pediatric inpatient settings. Potential benefits identified by parent focus group members here will be used to define meaningful outcomes for families. Example outcomes may include improved parent-physician shared understanding upon discharge and family identification of medical errors. Challenges will also be considered proactively and efforts made to mitigate potential negative consequences prior to the wide-scale implementation of inpatient OpenNotes. Parents in this focus group highlight the rapidly changing nature of inpatient care and risk of discordance between the information communicated to parents and updated and shared in notes. Organizations may need to set expectations for parents regarding the fluidity of care plans and who to contact if and when questions arise. Strategies such as these are necessary for hospitals to jointly support the work of patients, caregivers and their healthcare teams.

This study has limitations. Results reflect the perceptions of a small number of parent participants from an academic children’s hospital who may represent a more engaged population of parents. Consistent with the intent of exploratory research, the findings of this qualitative study were not intended to be generalizable, but instead lay the groundwork for future research evaluating the growing use of inpatient portals and expansion of the OpenNotes movement into the inpatient setting.

Conclusion This is the first study assessing the potential to share inpatient doctors’ daily notes with parents during their child’s hospitalization. Parents anticipated multiple potential benefits and challenges of inpatient note sharing, including the impact of note sharing on healthcare providers who work alongside them. Some themes from this parent focus group are consistent with the benefits and challenges described in the literature on outpatient notes sharing, but others highlight concepts that may be unique to pediatric and inpatient note sharing. Findings from this study will inform the design and implementation of BedsideNotes, an intervention and implementation strategy to share inpatient doctors’ daily notes with families to support their engagement in hospital care.

Comparing Deep Learning Models for Multi-cell Classification in Liquid-based Cervical Cytology Images

Sudhir Sornapudi, Ph.D. student¹, Gregory T. Brown, M.D., Ph.D.², Zhiyun Xue, Ph.D.², Rodney Long, M.A.², Lisa Allen, B.S., CT³, Sameer Antani, Ph.D.²

Abstract

Liquid-based cytology (LBC) is a reliable automated technique for the screening of Papanicolaou (Pap) smear data. It is an effective technique for collecting a majority of the cervical cells and aiding cytopathologists in locating abnormal cells. Many methods published in the research literature rely on accurate cell segmentation as a prior, which remains challenging due to a variety of factors, e.g., stain consistency, presence of clustered cells, etc. We propose a method for automatic classification of cervical slide images through generation of labeled cervical patch data and extracting deep hierarchical features by fine-tuning convolution neural networks, as well as a novel graph-based cell detection approach for cellular level evaluation. The results show that the proposed pipeline can classify images of both single cell and overlapping cells. The VGG-19 model is found to be the best at classifying the cervical cytology patch data with 95% accuracy under precision-recall curve.

Introduction

Cervical cancer is the second most common cancer in women living in under-developed regions. Nearly 570,000 new cases were recorded in 2018 and about 311,000 women died from cervical cancer worldwide¹. In the United States (2019) it is estimated that about 13,170 cases will be diagnosed for invasive cervical cancer and about 4,250 women will die from cervical cancer². Fortunately, cervical cancer can be treated successfully if detected at early stage. LBC³ for Pap (Papanicolaou) test is the gold standard for cervical cancer screening and has significantly contributed to reducing mortality. However, manual examination for detecting abnormal cells in a cervical cytology slide is a tedious process even for an expert cytologist. Expedient secondary reviews are conducted in areas marked by the pathologist or cytotechnologist with an ink marker by hand. There is a need for automated and computer-assisted technique for fast and efficient screening.

Though, generally abnormal cells have a relatively higher nuclei to cytoplasm ratio within a cell body⁴, it is very time consuming and requires significant training and expertise to manually locate these abnormal cells under a microscope. While there are some automated approaches such as Becton-Dickinson’s FocalPoint⁴ and Hologic’s ThinPrep⁵, both manual and automated cytology are challenged by the high variability in cell size, shape and color, and complex morphology due to overapped or crowded cells. In recent years, computer-assisted automatic approaches have shown promising results in cell classification⁶. The current deep learning era has vastly improved the performance and the classification accuracy in various biomedical applications. While some methods avoid pre-segmentation step, much work in the literature shows considerable research in the direction of cell segmentation of cervical cytology images and single cell classification. Segmentation using superpixel-wise convolutional neural network with dynamic shape modelling was employed by Tareef et al.⁷ Watershed⁸ and contour-seed pairs learning-based framework⁹ were some of the successful approaches in segmenting overlapping cells. However, accurate segmentation of cervical cells is impeded by overlapped and clustered cells. Cell classification is the next step after segmentation. Pixel-level classification was employed by extracting traditional features and training an SVM classifier¹⁰. Similarly, block-level classification with SVM classifier was studied¹¹. DeepPap¹² proposes CNN based cell classification on cell image patches, which are handpicked, cropped and centered at nuclei. All these approaches consider images containing only single cell or slightly overlapped cells, which are far from the real-world conditions. Traditional and machine learning

---

methods were reviewed and discussed\textsuperscript{12} for automated cervical screening from the pap-smear images. Our work lays foundation based on the stages involved in automated pap-smear analysis as mentioned in the literature review\textsuperscript{12}. The stages for analysis typically comprise of image acquisition, preprocessing, identifying abnormal regions, feature extraction and finally classification.

**Figure 1. Framework of the proposed approach**

The main objective of our study is to classify and locate the abnormal cervical cells. Understanding the challenges and limitations of the previous approaches, we aim to extract cell image patches from microscopic images under realistic conditions where cells may overlap; we evaluate different CNN models toward classifying the image patches.

**Materials and Methods**

The objective of the study is to generate clean labeled image data from the multi-level microscopic whole slide images to classify the cell image patches into normal and abnormal. First, raw cytology slide data (both clean and inked data) is preprocessed to obtain regions containing abnormal cells. The preprocessing comprises alignment of inked image data with respect to the clean image data through feature-based image registration. Lower resolution image levels (level 7) were used to speed up the process. Next, these lower resolution image levels were analyzed to obtain the ROI bounding box coordinates. This is accomplished by simple image processing techniques like image subtraction, thresholding, applying morphological operations and skeletonizing ink identified masks to detect and refine bounding boxes. Then, annotated image data is generated from the high resolution (level 1) images through accurately drawn abnormal cell boundaries on the ROIs. Finally, the labeled data was combined with Herlev Pap smear dataset\textsuperscript{13} to train and test various CNN architectures and later evaluate the results to choose the best CNN model that classifies cytology data. A novel graph-based cell detection model was also proposed to identify the cell boundaries even under overlapping cases in the high-resolution image regions. The approach includes over segmenting the image with superpixels and connecting the centroids to create a graph and then identifying sub-graphs (cell regions) with respect to nuclei nodes obtained by applying appropriate graph cuts in the graph. The flow of this proposed approach is illustrated in Figure 1.

**Datasets**

The study uses two datasets. The first set comprises 25 cervical liquid-based cytology slides provided by Becton-Dickinson (BD) Corporation using their Sure Path technique\textsuperscript{14}. In the case of abnormal slide data, there are a pair of slide images from each patient. One image contains only clean slide and the other image contains blue ink marks annotated by an expert cytotechnologist to indicate the regions containing abnormal cells (later, abnormal cells from
these regions are identified by an expert pathologist). The ink marks can be easily cleaned with an alcohol swab. The glass slides were scanned both with the marks, and after their removal, using a Hamamatsu NanoZoomer 2.0-HT whole-slide scanner, producing digitized slides in a pyramid tiled format with the file extension ndpi. The NDPI files resulting from the scanning are large in size (100’s of megabytes of size data). The second dataset is the publicly available Herlev Pap Smear dataset (http://mde-lab.aegean.gr/downloads) where specimens are prepared via conventional Pap smear. The dataset contains 917 single cervical cell images. Table 1 shows the characteristics of the data used for the study.

**ROI Detection**

While the entire cytology slide sample contains thousands of cells, just a few abnormal cells are sufficient indicators of abnormal screening. These abnormal cells may be surrounded by a large number of normal cells. Relative morphological, nucleic, or cytoplasmic appearance differences between cells helps pathologists to identify them. These regions are marked in ink on the glass slide. We use these markings on scanned slide image as region of interest (ROI) indicators. It is important to note that not all regions containing such abnormal cells were marked nor were individual abnormal cells identified within inked regions.

The NDPI format is organized as a pyramid structure with multiple levels of down-sampled subimages. A low-resolution image of level 7 is found suitable for easy preprocessing for detecting ROI bounding box coordinates. We correct any uniplanar misalignment problems between the blue ink-marked and ink-removed slides using image registration through feature based image alignment. The clean slide image is considered as a reference image, and stable ORB (Oriented FAST and Rotated BRIEF) feature points along with descriptors are obtained. These key point features are mapped with the features in the inked slide image (target) as shown in Figure 2. Homography is calculated based on the mapping information using Random Sample Consensus (RANSAC) estimation technique. The transformation is finally applied on the target inked slide image to map it to the reference clean image.

The preprocessing step also includes subtraction of blue (ROI ink) color space from red color space, which makes it easy to create a threshold ROI binary mask in lower resolution image. Skeletonizing and refining boundaries generated accurate ROIs. The coordinates of these ROIs were normalized and recorded. These ROIs are then cropped out from the high-resolution clean slide image (level 1) using the normalized bounding box coordinates data. Figure 3 shows the resultant intermediate output images.

**Figure 2.** Matching keypoints in a low resolution image to align annotated slide image to the reference clean slide image

**Figure 3.** The resultant intermediate output images.
We propose two methods for cell data generation from the extracted ROIs: Graph-based cell detection and patch-based data generation.

**Graph-Based Cell Detection:**
We chose this method to generate one cervical cell image (Herlev-like dataset). Initially the ROI image is over-segmented by generating superpixels through QuickShift approach\(^\text{\scriptsize 17}\). The pixel intensities are averaged over each superpixel region. The resultant image is converted into a graph with centroid of superpixels as nodes, line connecting the adjacent nodes as edges and absolute difference of L2 normalized color intensities at the respective adjacent nodes as edge weight. Graph cut is used at an empirically determined threshold of 59. The resultant image is a binary mask for the nuclei present in the ROI image which form the graph nodes. The novelty of the proposed approach lies in generation of subgraphs out of this graph structure to detect cell body boundary. Figure 4 shows the intermediate image outputs.

**Patch Based Data Generation:**
This approach is used to create images with real-world conditions from the high-resolution ROI regions where each image may contain multiple cervical cells along with overlaps. We use sliding window technique with stride 64 to create 128x128 patch images. The cells in the slide data are widely dispersed and contain more background. The patches containing more than 75% of background are discarded so that we get images with more cell information. The ground truth labels for the patch data are generated using the abnormal cell mask that is accurately and manually created with the help of an expert pathologist. Figure 5 shows how the abnormal cells were manually located. A patch image is labeled as abnormal if the object area in the abnormal cell mask is greater than 20% of the patch area (128x128). All the remaining patches are labeled as normal. Figure 6 shows examples of the final 128x128 labeled patch data used for the classification task.

---

**Figure 3.** ROI detection from low resolution image

**Data Generation**

We propose two methods for cell data generation from the extracted ROIs: Graph-based cell detection and patch based data generation.

**Graph-Based Cell Detection:**

We chose this method to generate one cervical cell image (Herlev-like dataset). Initially the ROI image is over-segmented by generating superpixels through QuickShift approach\(^\text{\scriptsize 17}\). The pixel intensities are averaged over each superpixel region. The resultant image is converted into a graph with centroid of superpixels as nodes, line connecting the adjacent nodes as edges and absolute difference of L2 normalized color intensities at the respective adjacent nodes as edge weight. Graph cut is used at an empirically determined threshold of 59. The resultant image is a binary mask for the nuclei present in the ROI image which form the graph nodes. The novelty of the proposed approach lies in generation of subgraphs out of this graph structure to detect cell body boundary. Figure 4 shows the intermediate image outputs. This approach could, in the future, automate segmentation of single cell images even where cells overlap.

**Figure 4.** (from left to right) Original image; Averaging pixel intensities over superpixel regions; Nuclei mask; Graph structure connecting cellular regions

**Patch Based Data Generation:**

This approach is used to create images with real-world conditions from the high-resolution ROI regions where each image may contain multiple cervical cells along with overlaps. We use sliding window technique with stride 64 to create 128x128 patch images. The cells in the slide data are widely dispersed and contain more background. The patches containing more than 75% of background are discarded so that we get images with more cell information. The ground truth labels for the patch data are generated using the abnormal cell mask that is accurately and manually created with the help of an expert pathologist. Figure 5 shows how the abnormal cells were manually located. A patch image is labeled as abnormal if the object area in the abnormal cell mask is greater than 20% of the patch area (128x128). All the remaining patches are labeled as normal. Figure 6 shows examples of the final 128x128 labeled patch data used for the classification task.
Figure 5. Manually locating abnormal cells in high resolution ROI regions.

Figure 6. 128x128 patch image data from high resolution ROIs; Class labels: Abnormal (top-row) and Normal (bottom-row).

Classification

We consider images generated from patch based approach for the binary classification task. The patch data is completely randomized and split into train, validation and test data for training different CNN models. The abnormal patches are few in number compared to the normal patches. There were 2,060 abnormal cell patches generated, which are taken into the dataset and 2,060 normal cell patches were randomly selected to be a part of the dataset. The training and validation data sets consist of the entire Herlev Pap data and a part (75%) of the patches. The training and validation data split (65-10) with remainder of the patches forming the test data. This facilitates a balanced data distribution for image classification without any bias. Table 2 shows the data distribution among training, validation and testing datasets.

We used various well-established CNN classifiers in order to determine the best performing CNN model for the classification of cervical cytology patch data. Models VGG-19\(^{18}\), ResNet-50\(^{19}\), DenseNet-121\(^{20}\), and Inception_v3\(^{21}\) were fine-tuned whose weights are initialized with pre-trained ImageNet weights. In the training phase, all the layers are trained, and layer weights are updated for each epoch, and the model is trained with batch size of 32, learning rate 0.005 and momentum 0.9 (chosen empirically). This is a bi-classification task, so we employ cross entropy loss along with stochastic gradient descent optimizer. Each model is targeted to train for 500 epochs and ultimately the best weights are saved.

**Results and Discussion**

A total of 5,037 images (4,120 patch data + 917 Herlev data) were considered for the study. 1,200 patch data (660 normal, 660 abnormal) are utilized for testing and the CNN models are trained with remaining data. Pytorch deep learning platform is used to run the models on Nvidia DGX-1. The results tabulated are as shown in Table 3.

The results indicate that ResNet-50 and VGG-19 models performed better when compared to DenseNet-121 and Inception_v3. DenseNet-121 has 0.9152 precision (PREC) value but has poor recall (REC) of 0.8015 with 131 false negatives. On the other hand, Inception_v3 has best recall (0.9136) compared to others, but poor at precision with 231 false positives. F1-score which presents balance between precision and recall is the best measure to evaluate the model performance. The F1-score of VGG-19 being 0.8896 votes VGG-19 as better model compared to ResNet-50 (0.8865). ResNet-50 is better at precision and VGG-19 is better at recall. In the field of biomedical image analysis higher recall value is always preferable, that is, lower false negatives are always recommended. Matthews correlation coefficient (MCC) provides much balanced measure by considering true and false positives and negatives. MCC for VGG-19 at 0.7773 makes it the best model compared to ResNet-50 (0.7742). Also, accuracy (ACC) wise VGG-19 is better than ResNet-50. The relatively small differences make both the models good competitors. To better understand the performance of the models at various classification thresholds, we plot the receiver operating characteristic (ROC) curve. Figure 7 shows the ROC plots for all the four models.

The best operating Q-point for the models in the cervical cytology image classification is the point where the curve has high sensitivity (true positive rate) and high specificity (1 – false positive rate). VGG-19 and ResNet-50 performed similarly with their best Q-points compared to other models. The accuracy under the ROC curve (AUC) was found to be 0.95 for both the models.

ResNet-50 and VGG-19 are good at generalizing the cervical cytology data with the pre-initialized ImageNet weights. VGG-19 is a shallow network compared to models under study and uses 3x3 convolutional layers stacked up along the depth of the network has proven to be a better model for the cervical cytology classification task in our study. ResNet-50 being a 50-layer deeper network, addresses its vanishing gradient problem through their residual learning blocks. This makes it a good competitor against VGG-19. Each layer in DenseNet-121 is fed with the outputs from the previous layers which improve the feature propagation and alleviate the vanishing gradient problem. Although DenseNet-121 is more efficient on some image classification tasks, it could not outperform the VGG-19 model on the cytology image classification. The 42-layer deep Inception v3 model factorizes convolutions and aggressively reduces dimensions which reduces the computational cost but could not maintain the quality in classifying the cytology image data.
Figure 7. ROC curve of the four CNN models

We have further explored the performance of our best model, VGG-19, on the 128x128 abnormal cell patch data extracted with respect to the centroid of each object in the abnormal mask. 203 abnormal image patches were obtained and tested with VGG-19 model. We achieved an accuracy of 0.8778 upon prediction on these 203 abnormal image patches. This indicates that the VGG-19 model is better at classifying the cytology cell images, even under challenging cell-overlapping conditions.

While this work is preliminary, it demonstrates the capability of deep learning to recognize abnormal cells in cervical cytology specimens. With further refinement this work could be incorporated into a production level tool to assist pathologists with pre-screening and quality assurance, thereby improving a pathologist’s efficiency and accuracy.

Conclusion

We have successfully developed and evaluated a prototype pipeline for the classification of cervical cytology slide images. The process automatically generated cleaner labeled patch image data for training and testing convolution neural networks. Our approach considers realistic conditions of overlapping cells which is superior to state-of-the-art classification techniques that rely on segmented cells. We investigated various CNN models for successful classification of cytology image data, and found VGG19 and ResNet-50 were similar best performers with our data. A novel graph-based cell detection technique was also proposed which may be used for developing cell analysis techniques. Our work represents a novel approach for classifying cytopathology image data, using real-world samples.

Why Patient Portal Messages Indicate Risk of Readmission for Patients with Ischemic Heart Disease

Lina Sulieman, PhD, Zhijun Yin, PhD, Bradley A. Malin, PhD
1 Vanderbilt University, Nashville, TN

Abstract

Online portals enable patients to exchanging messages with healthcare providers. After discharge, patients message providers to ask questions and report problems. Care providers read and respond accordingly, which requires a non-trivial amount of human effort and is unlikely to scale up as portals become more popular. Automatically detecting when a message indicates a worsening in a patient’s condition can assist providers to identify patients at risk of readmission. We investigated the association between messages that patients, diagnosed with ischemic heart disease, sent after discharge and the risk of readmission. We studied 4,052 messages sent after discharge for 1,552 patients. We represented messages using inferred latent topics, linguistic features (e.g. emotions, activities), and clusters of medical terms. Our analysis indicates that mentioning medication dosage and additional procedures are associated with readmission. Moreover, patients who were readmitted rarely mentioned leisurely activities or described their insights about their health information.

Introduction

Patient portals are secure online websites that healthcare organization provide to grant patients 24 hour access to their health records. Portals include a wide range of health information, including discharge summaries, medications, immunizations, and laboratory tests. One of the popular functionalities of patient portals is their support of secure messaging between patients and care providers. Messaging allows patients to keep their healthcare providers informed about their clinical status outside of visits to the clinic and stays in the hospital. Moreover, The use of messaging has been shown to be associated with improved chronic disease management and medication adherence. It has been shown that discussions about laboratory test results, reporting new symptoms, and requesting prescription refills are the most common topics in patients’ messages. The popularity of these topics demonstrates that patients utilize the portal messages for seeking information from healthcare providers when they are outside of the clinical environment. In addition, patients communicate different needs in their messages, which can be roughly partitioned into logistical (e.g., location of clinic), social (e.g., thanking care providers), informational (e.g., asking about intervention), and medical (e.g., informing physician of a health problem). Notably, it has been shown that more than 70% of messages originating from patients included medical needs.

There has been limited research into the identification of the symptoms and events that patients communicate through their messages, and their relationship with outcomes such as medication discontinuation or readmission. This may be due, in part, to the fact that the information relevant to a patient’s clinical status in a message is not explicitly indicated, but rather is in an unstructured form. This makes it essential to first identify potential factors that are indicative of health issues in portal messages, so that healthcare providers can assess and evaluate the health status of a patient. This need is further exacerbated by the rapid growth in the adoption of this technology and the number of patient messages as an artifact. Hence, healthcare organizations would benefit from automating the process of detecting a message that can indicate the risk of a negative outcome, such as readmission.

In this study, we aim to identify the contents and textual features in patient messages that can indicate the possibility of negative outcomes. Specifically, we analyzed the content of messages sent by patients who were diagnosed with ischemic heart disease and hospitalized at Vanderbilt University Medical Center (VUMC). We analyzed the content of messages sent after discharge and within 31 days for two types of patients: 1) those who were readmitted due to an unplanned hospitalization and 2) those who lacked an unplanned hospitalization. We extracted linguistic and textual features, along with patients’ demographics, and applied a generalized linear model to learn their association with readmission risk.

Related work

Several studies have analyzed the content of messages sent through patient portals. Some of these investigations relied upon manually review, while others applied machine learning and statistical analysis to automatically extract patients’ needs and assess the association between the messages and an event of interest. Certain studies focused on the volume or content of messages and with respect to outcome. For instance, Sulieman et. al. investigated the post-
discharge factors that are associated with readmission risk\textsuperscript{19}. They found that the number of messages that patients sent after discharge was one of the top predictors of readmission. Yin et. al. extracted the patterns of messaging with healthcare providers, the volume of messages and the content of messages sent by breast cancer patients\textsuperscript{15}. The authors combined these features to find associations between messages and the potential for discontinuing hormonal therapy\textsuperscript{15}. They observed that mentions of side effects and surgery-related topics were associated with an increased risk of discontinuation. By contrast, they further observed that expressions of gratitude and mentions of drugs prescribed to treat side effects were associated with a decreased risk of discontinuation. North et. al. reviewed and assessed the content of patient messages and its association with the risk of death within 30 days and the risk of hospitalization within 7 days following the message\textsuperscript{17}. They found that patients mentioned high risk symptoms in 3.5% of messages and that six hospitalizations (0.09% of messages) were related to a patient message.

**Methods**

**Cohort**

We extracted data from the VUMC Synthetic Derivative (SD), a de-identified version of the electronic health record (EHR). We focused our analysis on patients who exhibited ischemic heart disease during an inpatient visit and sent a message through the MyHealthAtVanderbilt (MHAV) patient portal after discharge. We identified the patients who were readmitted within 31 days. We excluded patients who did not send any messages after discharge. We also retrieved patients’ age at discharge, gender, race, and ethnicity.

There were 96,044 patients who were diagnosed with ischemic heart disease, with admissions between 1990 and 2018. 6,448 of these patients sent a message using MHAV between 2003 and 2018. The cohort for this study consisted of the 1,552 patients who sent a message within 31 days after the discharge. As shown in Table 2, approximately two-thirds of the patients were male and with an average age of 63. The patients were 93% Caucasian and 98% non-Hispanic.

**Message Extraction and Analysis**

We extracted the messages exchanged between patients and their healthcare providers, regardless of who initiated the message. For patients who were readmitted, we extracted the messages they sent after discharge and before readmission. For patients without a readmission, we extracted the messages sent within 31 days after the discharge. For patients with multiple admissions, we included the earliest readmission event only.
Text analysis

We grouped the messages sent by each patient after their discharge into a single document. To profile the content of each patient’s message, we preprocessed the messages, performed topic analysis, extracted linguistic features, and defined medical term clusters, as outlined in Figure 1.

Topic Analysis

To extract topics from messages, we applied Latent Dirichlet Allocation (LDA) as implemented in the Mallet Java package (version 2.0.8). LDA is a popular topic modeling method that allows a group of documents to be explained by latent topics, each of which can be further explained by the words in the documents. After running LDA, we obtained a topic distribution for each document (e.g., the probability that a document can be explained by each topic), and a word distribution for each topic (e.g., the probability that a topic can be explained by each word). Based on these distributions, together with the lengths of the documents, we calculated the topic distribution across the corpus by combining all the documents into a single large document. LDA has proven effective at summarizing a large amount of text. Since it is an unsupervised machine learning method, we relied on the coherence score to determine the best number of topics. The coherence score is used to measure the extent to which the most probable words in every topic appear together in either the current documents or some external data source (e.g., Wikipedia). A higher coherence score suggests a better topic modeling result. We learned LDA models with 2 to 26 topics (with a step size of 1) and chose the number of topics that exhibit the largest coherence score. To mitigate word sparsity and ensure interpretability, we replaced each term with its lemma form and retained only nouns, verbs, adjectives and adverbs. We also generated the bi-grams of terms using the genism python package (version 3.6.0) to capture more meaningful phrases.

Linguistic Features

We applied Linguistic Inquiry and Word Count (LIWC, version 2015) to extract the cognitive, emotional, and social aspects in the messages. LIWC is an effective tool to summarize linguistic features from online generated content. The LIWC package generates approximately 90 linguistic variables, including general descriptor categories (e.g., words per sentence), standard linguistic dimensions (e.g., percentage of pronouns in the message), word categories tapping psychological constructs (e.g., affect, cognition, biological processes, and drives), personal concern categories (e.g., leisure, work, and home), informal language markers (e.g., assents and swear words), and punctuation categories. In our text analysis, we focused on psychological constructs, personal concerns, and informal language. Table 1 shows the 45 features that LIWC extracted.

We applied

Medical Term Clusters

We used Clamp (version 1.5.0) to extract the medical terms from the messages, including treatments, clinical problems, and laboratory tests. Given the large number of clinical terms that were extracted, we reduced the dimensionality to represent features more efficiently by grouping terms that shared similar meanings. To do so, we first trained a word2vec model using the clinical communications in the entire SD. We did not use the pretrained word2vec model (e.g., the Google word2vec) because there are many terms (e.g., abbreviations) that do not exist in the pretrained documents. Word2vec generates a vector (or embedding) for each word, where similar words exhibit high semantic similarity based on a cosine function. We trained word2vec using the genism python package with a minimum word count of 50, window size of 15, and 100 hidden units.

We retrieved the words’ vectors (i.e., word2vec embedding) for each medical term in the messages extracted by Clamp. For the cases where a medical term consists of more than one word, we retrieved the word2vec embeddings for each word and calculated the mean. We applied agglomerative hierarchical clustering with complete linkage, according to a cosine distance, in the sklearn python package (version 0.20.0) to cluster the word embeddings. To obtain the most efficient number of clusters, we adopted a metric that generates a number of clusters that is 1) large enough to create efficient and interpretable semantic clusters and 2) small enough to avoid partitioning one cluster into two or more clusters with similar words. This was accomplished through the approach introduced by Yin et. al. Specifically, we construct clusters where the number of clusters range from 2 to 100 clusters (with a step size of 1). We use the standard deviation of the cluster sizes to determine when to stop the clustering process. Heuristically, the standard deviation tends to become small as the number of clusters increases. To identify the optimal number of clusters, we followed the elbow principle to locate the cluster number where the marginal gain of increasing cluster size begins to diminish.

Content Analysis

We applied logistic regression to evaluate the associations between the content of messages that includes 19 topics, 45 linguistic features, and 35 word2vec clusters and demographics, and the readmission risk. Specifically, we used the Generalized Linear Model (GLM) library in R (version 3.5.2) to learn three association models:

1- Demographics-Only model: This includes age (rescaled to 0-1 range), gender, race, and ethnicity;
2- Message content model: The learned topics (rescaled to [0,1] range), LIWC linguistic features (rescaled to [0,1] range), and medical term clusters; and
3- Demographics and message content model: A combination of models 1 and 2.

For each model, we identified the features with coefficients that were statistically significant at the 0.05 level, their associations, and the Akaike information criterion (AIC) values. The latter is an estimate of the relative quality of statistical models, which is obtained by estimating the amount of information loss in the model. A higher AIC value indicates a lower amount of information loss and thus a better quality.

Results

The patients sent 4,052 messages either before readmission or within 31 days after the discharge (for those without a readmission). Figure 2 illustrates the distribution of messages sent by patients according to their readmission status. From the figure, it can be seen that around 60% and 80% of the patients who were readmitted and lacked a readmission, respectively, sent only one message. The average (median) number of messages sent by patients with and without a readmission was 1.75 (1) and 1.87 (1), respectively. We ran Mann-Whitney to evaluate whether the numbers (e.g.,
number of messages, number of words in messages) were statistically different for patients with readmission and patients without readmission. The difference between the number of messages sent by those two groups was not found to be statistically significant (Mann-Whitney U: statistic=28120, p-value = 0.2). Among the readmitted patients, 20% sent two messages, while only 10% of the non-readmitted patients sent two messages. On average, the messages sent by patients consisted of 700 words overall (median = 381 words), while the readmitted and non-readmitted subgroups consisted of 667 words (median = 546 words) and 700 words (median = 376 words), respectively. The difference between the number of words in messages from patients with and without a readmission was not found to be statistically significant either (Mann-Whitney U: statistic = 27291.0, p-value = 0.15).

More than 50% of readmitted patients sent a message within the first five days after discharge, while 30% of patients who were not readmitted sent a message within 5 days, as depicted in Figures 2(b) and 3(a). Only 10% of patients sent a message five days before the readmission. The mean of the day of the first message sent by a readmitted and non-readmitted patient was 7.8 (SD = 6.3 and median = 5) and 12.9 (SD = 9 and median = 12), respectively. The difference between the day of the first message sent by readmitted patients and non-readmitted patients was statistically significant (Mann-Whitney U: statistic = 20478.0, p-value = 0.002).

(a) Patients not readmitted within 30 days  
(b) Patients readmitted with 30 days

*Figure 3.* First day a message was sent after discharge by a patient (a) without and (b) with a readmission.
Message Topics

We identified 19 topics in post-discharge messages. Each topic includes a set of words that patients invoked to discuss a particular topic. For instance, when patients ask about, or reschedule, appointments, they use relative phrases such as the day of the week, time, schedule, confirm, or reschedule. Table 3 lists the most relevant words in each topic ranked by the LDA model. It can be seen that the topics primarily covered appointments, vitals, checking laboratory tests, medications (including prescription and time), and logistics (including discharge locations and communications).

Readmission Risk Associations

The demographic model achieved an AIC of 379; however, none of the features (i.e., age, gender, race, and ethnicity) were statistically significant. In the message content model, we applied 19 topics, 45 linguistic features, and 35 clusters. This model achieved higher quality with an AIC of 462 and contained six features that had a statistically significant association with the readmission risk (as shown in Table 4). We report the statistically significant features. The swear linguistic category was significant and positively correlated with the readmission event. By contrast, both insight and leisure were negatively correlated with the readmission event. Moreover, the words in three clusters listed in Table 5 were significantly associated with readmission. Each cluster includes the words that are similar to each other based on their Word2Vec similarity scores. The words in Clusters 2 and 29 were positively correlated with readmission, while those in Cluster 11 were negatively correlated. It should be noted that removing correlated values from the model did affect the significance of the features. When combining demographic features and content features, we obtained a model with an AIC of 468, which was slightly higher than the message content model. In this combined model, only one feature, Cluster 2 was significant. The demographic features were still insignificant in this model.

Table 5 shows the words for each significant word semantic cluster: Cluster 2, Cluster 11, and Cluster 29. We ranked the words in each cluster based on their cosine distance to its centroid (i.e., the mean of the word2vec for the words in the cluster). As Table 5 shows, the most relevant words in Cluster 2 primarily correspond to the medication dosage that was prescribed for the patient. The top words in Cluster 11 are laboratory test names, while Cluster 29 includes the mentions of another clinical event, such as a procedure, laboratory test, and medication.

Table 3. The 30 most relevant words in each of the topics extracted from the messages.

Discussion

This investigation yielded several notable findings. First, the message patterns for patients who were readmitted were different from patients who were not readmitted. Specifically, patients who were readmitted tended to send messages earlier than other patients. This might indicate that these patients were experiencing problems or complications after discharge that they communicate to their healthcare providers. Identifying the relevant words, topics, or signals in the message may assist healthcare organizations to identify patients who are at higher readmission risk and, thus, address such complications in a timely manner.

Second, patients’ messages included indications regarding patients’ health status, health concerns, and social context after discharge, which may be useful for predicting readmission. While conventional features, such as patient demographics did not exhibit a significant association with the readmission status, the model performance was improved by incorporating the message content. We believe this is because it includes patients’ activities and concerns. For instance, social information that patients communicated about their leisurely activities, insights, and feelings were statistically significant. The analysis demonstrated that readmitted patients were less likely to write sentences about leisure activities or describe patients’ intuitions and insights (e.g., think or know) as the coefficients of the model indicated. For example, patients who were not readmitted tended to send similar questions, seek feedback or answers, such as “I think my main concern is how the H/H was trending down at the time of discharge”. One of the messages exchanged between a provider and a patient included a mention of hunting, walking (e.g., “gone deer hunting”, “I walk about half a mile to get my hunting school”, “restricted to walking a half hour daily instead of an hour”). This suggests that the readmitted patients might be experiencing unfamiliar symptoms or feelings, thus limiting their ability to enjoy some social or leisurely activities. Moreover, readmitted patients tended to use swear words in their messages, which may indicate their frustration after discharge.

Third, the medical terms in the model had a significant association with the status of the patient after discharge. Mainly, the messages that have information about the dosage of patient medications and the laboratory tests were significantly associated with readmission. These medical information types exhibited opposing directionality in their association with a patient’s outcome. Specifically, the medication dosage had a positive association with readmission, which might indicate that the readmitted patient asked about their medication dosages or explained some side effects with the prescribed dosage. By contrast, the existence of laboratory values in the message had a negative association with readmission. Another significant medical feature is the request to repeat or perform another clinical test or another medication. For example, the mention of an additional clinical event such as another MRI, another CT scan, another UTI have a positive association with readmission. Hence, the necessity of ordering another scan or another test can imply that the patient had complications after the discharge, which increased the probability of readmission.

At the same time, there are several limitations worth noting. First, this a study of a specific population at a single medical center, which calls into question the generalizability of our findings. Second, the dataset size was relatively small. Expanding this analysis to include more phenotypes and a large number of messages could provide more intuition into the associations. Third, we combined the messages sent by a patient, which masks the temporal changes in the topics. Fourth, our text analysis did not handle the negation which we will address in our future work. Fifth, our analysis focused on identifying the indication of readmission in patients messages. We did not evaluate the capability of predicting the readmission using the model. In our future work, we will focus on evaluating the ability of predicting the readmission using the model. Finally, there was a low readmission rate in our dataset. Sending MHAV secure
messaging might indicate that the patients used online patient portal to seek advice/information regarding their health, which might explain, in certain degree, the low rate of readmission in MHAV cohort who seeks information in the portal.

**Conclusion**

Online portals provide a secure channel that allows patients to interact with their healthcare providers. Patients use portal messages to communicate their needs, requests, and questions. While the number of patient portal messages is increasing, analyzing the patient reported information in their messages is still limited. Identifying the signals in portal messages that indicate the risk of readmission can help providers apply interventions to avoid adverse events. This study showed the messages sent by patients with ischemic heart disease after a hospital discharge can be leveraged to predict readmission. The findings specifically showed that leisure activities, intuition (e.g., think), and swear words, as well as medical terms in the messages are associated with readmission events. We believe that future research will benefit by evaluating the capability of our model to predict the readmission using patients message and expanding on the analysis to include other diseases.

Abstract

Clinical decision support system (CDSS) plays a significant role nowadays and it assists physicians in making decisions for treatment. Generally based on clinical guideline, the principles of the recommendation are provided and may suggest several candidate medications for similar patient group with certain clinical conditions. However, it is challenging to prioritize these candidates and even refine the guideline to a finer level for patient-specific recommendation. Here we propose a method and system to integrate the clinical knowledge and real-world evidence (RWE) for type 2 diabetes treatment, to enable both standardized and personalized medication recommendation. The RWE is generated by medication effectiveness analysis and subgroup analysis. The knowledge model has been verified by clinical experts from the advanced hospitals. The data verification results show that the medications that are consistent with the method recommendation can lead to better clinical outcome in terms of glycemic control, compared to those inconsistent.

Introduction

Type 2 diabetes (T2DM) is a chronic disease that often leads to different types of complications and causes serious health problems. According to the eighth edition of International Diabetes Federation (IDF) diabetes atlas\textsuperscript{1}, in 2017, China has more than 114 million diabetes patients, accounting for 27\% of the whole diabetes population worldwide. In addition to this challenging situation, China faces severe shortage of experienced physicians, especially in the large rural area. According to China Statistical Yearbook (2018)\textsuperscript{2}, 41\% of Chinese population lives in the rural area, but only consumes 21\% of national medical resources. As stated in China Health and Family Planning Statistical Yearbook (2017)\textsuperscript{3}, comparisons of health workers were observed between rural and urban areas for health professionals (4.0 vs. 10.8), doctors (1.6 vs. 4.0), Registered Nurses (RNs) (1.5 vs. 5.0) per 1,000 population. In this background, a robust clinical decision support system (CDSS) for type 2 diabetes treatment is of high importance in China’s market. Given the T2DM patient’s information, the CDSS can recommend the medications and provide the evidence of why the recommendation is made. It not only assists inexperienced physicians in prescribing the appropriate medications for T2DM patients, but serves as a tool for physician education.

CDSSs have been widely applied for reducing medical errors and increasing health care quality and efficiency\textsuperscript{4,5}. There are two types of approach for CDSS: knowledge-driven and data-driven. In the context of medication recommendation, the knowledge-driven approach is to develop an expert system based on clinical knowledge (such as clinical guidelines and consensus)\textsuperscript{6,7,8}, while the data-driven one is to apply the data mining techniques on electronic health records (EHRs) to build the mapping between patient’s information and medications\textsuperscript{9,10,11}.

The advantage of knowledge-driven approach is that the recommendations are always consistent with the guidelines, which is critical to a CDSS. However, the limitation is that the knowledge provided in clinical guideline could be too general to provide fine-granular personalized recommendation\textsuperscript{12}. For example, an if-then rule for knowledge-driven CDSS could be: if one has been taking biguanides (MET) for about 3 months and his HbA1c is between 7\% to 9\%, then he needs to switch to dual therapy by adding another type of oral antidiabetic drug (OAD). However, the OAD includes a number of drug classes such as sulfonylureas (SU), glinides (GLN), and alpha-glucosidase inhibitors (AGIs) etc. The physician may still have the problem to decide which drug, often a product name in a drug class hierarchy, to be prescribed.

With the large amounts of EHRs, data-driven CDSS can be developed to provide personalized medication recommendation. Recently, Liu et al. proposed an algorithm to group the patients based on the similarity metric learnt from the real-world clinical data\textsuperscript{13}. Likewise, Chen and Altman reported a Bayesian conditional probability model for
recommendation of clinical orders through the data mining of EHRs\textsuperscript{10,11}. Although data-driven approach provides personalized result, the recommended results could violate the guideline, which degrades the physicians’ trust to use the system.

In this study, we propose a method to integrate the clinical knowledge and real-world evidence (RWE), for enabling the standardized (i.e., consistent with knowledge) and personalized (i.e., referring to the RWE of similar patients) medication recommendation for T2DM patients. In our approach, the clinical guideline provides the principles of the recommendation\textsuperscript{14} and may suggest several candidate drugs/drug combinations for the patients with certain clinical conditions. The RWE is generated for prioritizing these candidates and even refining the guideline to a finer level. Specifically, we represent the clinical guideline as a decision tree, in which each leaf node is a decision point with recommended modifications and the path from the root to the leaf node defines the clinical conditions of the corresponding subgroup of T2DM patients. Then the medical data are fed via the root of tree so that each leaf node is associated with a set of data samples. For each leaf node with multiple medication options, we perform the drug effectiveness analysis\textsuperscript{15} and subgroup analysis\textsuperscript{16} on the data samples, and associate the results as the evidence. These results of the leaf node can be applied to prioritize the corresponding candidate medications, or once confirmed by domain experts, to refine the clinical guideline, i.e., to further split the leaf node into a sub-tree. We have realized such an approach and developed a CDSS for T2DM treatment. We build our knowledge model based on the national clinical guideline for T2DM 2017\textsuperscript{17} and integrate it with RWE extracted from 119236 records of T2DM patients in a Chinese city. The knowledge model has been verified by clinical experts from the advanced hospitals.

Methods

Knowledge model for standardized medication

The knowledge model was built based on Chinese guideline for prevention and treatment of type 2 diabetes (2017), and had been verified by clinical experts from the advanced hospitals. An extracted rule contains information of related feature conditions and corresponding medication recommendation. According to the guideline, the glycemic control target could be set as the glycosylated hemoglobin (HbA1c) goal of less than 7.0% or fasting plasma glucose (FPG) goal of less than 7.0 mmol/L. If the target is not achieved without any therapy or after about 3 months of therapy, it should proceed to clinical treatment or adjustment of original treatment. So the treatment could be suggested by current blood glucose level, previous treatment and its duration.

</tr>
</tbody>
</table>

Drugs commonly used for type 2 diabetes treatment include seven categories of OAD: biguanides (MET), sulfonylureas (SU), glinides (GLN), alpha-glucosidase inhibitors (AGIs), thiazolidinediones (TDZs), glucagon-like peptide-1 (GLP-1) and dipeptidyl peptidase IV (DPP-4). Since SU and GLN have the same cellular mechanism called insulin secretagogues, they can be regarded as one category of “SU/GLN”.

For each extracted rule for treatment, we set a group ID according to its corresponding therapy based on knowledge model, including Lifestyle Management, Monotherapy, Short-term Intensive Insulin Therapy, Continued Therapy, Dual Therapy, Triple Therapy, Combination Injectable Therapy. Each group contains several treatment options, as shown in Table 1.

For example, information like “if lifestyle alone fails to achieve blood glucose control, monotherapy should be initiated” in guideline would be converted to a rule like: if \( \text{HbA1c} \geq 7.0\% \) and \( \text{HbA1c} < 9.0\% \) or \( \text{FPG} \geq 7.0\,\text{mmol/L} \) and \( \text{FPG} < 11.1\,\text{mmol/L} \), then initiate Monotherapy (MET or SU/GLN or AGIs). Metformin (MET) should be the first priority when initiating therapy.

**Real-world evidence integration for personalized medication**

Based on the knowledge model, the clinical guideline provides the principles of the recommendation and may suggest several candidate drugs/drug combinations for the patients with certain clinical conditions. The RWE is generated from real-world data to suggest the priority of these candidates and even refine the guideline to a finer level. Evidences mainly include feature statistics that describe a group of similar patients, usage percentage of candidate medications in the patient group and their corresponding outcome of glycemic control. When physicians face several options, RWE data (e.g. outcome or effect evaluation) become very important for identifying the optimal and personalized treatment. Figure 1 shows our methodology of integrating clinical knowledge and real-world evidence for type 2 diabetes treatment. First, we represent the knowledge model derived from clinical guideline as a decision tree, in which each leaf node is a decision point (corresponding to each GroupID) with recommended modifications and the path from the root to the leaf node defines the clinical conditions of the corresponding group of T2DM patients. In step 1 of Figure 1, the medical data are fed via the root of tree so that each leaf node (GroupID) is associated with a set of data samples. In step 2, by knowledge model, the data samples could be divided into two parts of guideline-concordant and guideline-not-concordant samples depending on its prescription, and we perform data-based evaluation of standardized medication and its relationship with effectiveness. In step 3 and 4, for each group at leaf node with multiple guideline-concordant medication options, we perform the drug effectiveness analysis and subgroup analysis on the data samples, and the results can be associated as the evidence. These evidence of the leaf node can be applied to prioritize the corresponding candidate medications, or once confirmed by domain experts, to refine the clinical guideline, i.e., to further split the leaf node into a sub-tree.

1. Applying medical data into the knowledge model and evaluating

Applying medical data into the knowledge model, we obtained seven groups. A group corresponds to a leaf node and contains data samples with similar features and different medication patterns in their prescriptions. Comparing the medication in physician’s prescription with standardized medications from knowledge model, data samples in each group can be divided into two kinds: “guideline-concordant” or “guideline-not-concordant”. Data samples were categorized to the guideline-not-concordant cohort if their prescription is not in any of standardized medications of this group. The standardization degree for medication and its relationship with effectiveness were evaluated by guideline adherence of prescriptions and the rate of achieving glycemic control goal.

![Figure 1. Methodology of integrating clinical knowledge and RWE for T2DM treatment.](image)
To reveal the relationship between guideline-concordant medication and its effectiveness indicated by glycemic control goal achieving rate, multivariate logistic regression model was applied to adjust for confounding factors. Given that the glycemic control goal achieving rate could be affected by the baseline blood glucose level, the baseline FPG was identified as a confounding factor. Adjusted odds ratios (ORs) of achieving glycemic control goal could be obtained via multivariate logistic regression. The same analysis was applied for each group.

2. Medication effectiveness analysis and subgroup analysis

Our approach enables the guideline adherence and personalization recommendation. In each group, we first compared the effectiveness of all guideline-concordant medication options at the whole data samples of the group, where the guideline-not-concordant medications were excluded. Similarly, adjusted OR, P-value in multivariate logistic regression model were used to reveal the relationship between medication options and glycemic control goal achievement. Here, we identified confounding factors by selecting the features that were associated with the medication options, from the basic information, physical measurement and history of diseases.

If the result of the medication comparative effectiveness analysis was not statistically significant at the group level, we would apply Model-based recursive partitioning approach (MOB) on the leaf node to further “grow” the tree for subgroup analysis.

The basic idea of MOB is that each node is associated with a single model. The datasets are split into different subsets based on partitioning variables to make the model parameters stable and the distributions of the response values are most different. That means a precision cohort fitted well or with strong evidence may be found after further partitioning and the drug effectiveness result of the subgroup determines the final recommended prescriptions.

The based parametric model in our MOB tree is logistic regression in which medication option (pairwise or multiple options) is as independent variable and glycemic control goal is as dependent variable. For instance, binary medication options: MET or SU/GLN, glycemic control goal: FPG<7.0mmol/L.

The iterative steps of MOB method are as below:

1) fitted the logistic regression with glycemic control goal as response variable and binary medication options as independent variable on all observations. Given n observations \( Y_i (i = 1, 2, ..., n) \), the model can be fitted by minimizing some objective function \( \Psi(Y, \theta) \) yielding the parameter estimate \( \hat{\theta} \). Maximum likelihood method or least squares method can obtain the solution of \( \hat{\theta} \).

\[
\hat{\theta} = \arg\min_{\theta \in \Theta} \sum_{i=1}^{n} \Psi(Y_i, \theta), \quad \text{where} \quad Y_i = \begin{cases} 1, & \text{FPG} < 7.0\text{mmol/L} \\ 0, & \text{FPG} \geq 7.0\text{mmol/L} \end{cases}
\]

2) test the parameter instability on partitioning variables (age, gender, historical diseases and other demographic or medical characteristics).

3) if significant parameter instability (i.e., the smallest P values) is detected, split the sample with respect to the partitioning variable into two subsets.

4) repeat step (1) ~ (3) until there is no significant parameter instability on each node.

MOB is a recursive algorithm, since each subgroup will be further split until recursive end condition is reached.

Results

Data Set

We demonstrate the effectiveness of our method using a dataset that is a collection of type 2 diabetes patient records across multiple hospitals in a city of China with time spanning from 2015 to 2017. In total, there were 119236 records with the main diagnosis as type 2 diabetes, corresponding to 50061 unique patients. Each sample in the medical data recorded one visit of T2DM patient, which consisted of basic information of the patient, diagnosis made by the physician, blood glucose level (FPG), and the medication prescription. The distribution of age centered around 60 to 80 years old. Females accounted for 61% of the whole data. Patients with BMI more than 24 accounted for 42%. Those demographic characteristics described from data agree well with the fact that obese people are more susceptible to type 2 diabetes.

Medication Pattern Mining

Here we used association rule mining method (Aprior algorithms) to identify the frequent sets of medications with a support threshold of 0.01%. As shown in Table 2, top 10 medication patterns identified for type 2 diabetes treatment
were all consistent with the instruction from the knowledge model. Among all prescriptions, the most popular one was MET only, which accounted for about 46% of all samples. This is in consistent with the fact that MET is the first priority in T2DM therapy except for special cases. In addition, a combination of MET and SU/GLN was very common in Dual Therapy, which accounted for about 15% of all samples.

Applying medical data into the knowledge model and evaluating result

Applying medical data into the knowledge model, we obtained seven groups. As shown in Table 3, by comparing the medication in physician’s prescription with standardized medications from knowledge model, the standardization degree for medication in each group was described by guideline-concordant number, guideline-concordant ratio and main guideline-not-concordant medication.

In summary, the majority (63.57%) of medications were concordant with the guideline. Especialy in “Continued Therapy” group whose instruction is maintaining previous treatment, the guideline-concordant ratio was up to 97.83% because prescriptions always follow previous prescriptions in the data. However, in “Dual Therapy” group, the guideline-concordant ratio was as low as 1.62% since 97.50% patient visits supposed to add a new drug category according to guideline were still prescribed with previous single drug category.

There were 67493(57%) records with FPG after about 3 months’ therapy. Based on these samples we evaluated the relationship between guideline-concordant medication and glycemic control goal achieving rate, as shown in Table 4.

* Items in bold are statistically significant at P<0.05 and OR>1.
According to the evaluation result, we found that guideline-concordant treatments was associated with better clinical outcome in FPG control than guideline-not-concordant ones. The contrast of FPG-goal achieving rates show that patients with guideline-concordant prescriptions acquire higher FPG-goal achieving rate next visit time. For total samples, the FPG-goal achieving rate for guideline-concordant prescriptions was as high as 80.52%, while the FPG-goal achieving rate for guideline-not-concordant prescriptions was just 53.30%, with P value <0.001 (SS) and a rather high adjusted OR=3.62.

As mentioned before, to reveal the relationship between guideline-concordant medication and glycemic control goal achieving rate, multivariate logistic regression model was applied to adjust for confounding factors. Here base FPG was regarded as a confounding factor, which stands for the baseline level of blood glucose and has effect on FPG goal achieving rate. The mean value of base FPG was also shown in Table 4. For example, in “Dual Therapy” group, by descriptive statistic a contrary finding was that patients with guideline-concordant prescriptions acquire lower FPG-goal achieving rate (40% vs 50%). By adjusting of confounding factor, such as the base FPG (mean base FPG for guideline-concordant: 9.67mmol/L vs guideline-not-concordant: 8.70mmol/L), the adjusted P-value shows the no significant difference between guideline-concordant medication and glycemic control goal achieving rate.

For the “Triple Therapy” and “Combination Injectable Therapy” groups, the sample size is greatly unbalanced, with much fewer samples consistent with the guidelines than those inconsistent with the guidelines. The results in these groups were considered with no significant difference.

**Medication effectiveness analysis and subgroup analysis result**

Our approach enables the guideline adherence and personalization recommendation. First, the clinical guideline often suggests several candidate drug classes/drug-class combinations for similar patients with certain clinical conditions. Then the real world evidence would serve as the information for prioritizing multiple candidates and even refining the guideline to finer subgroups via drug effectiveness analysis. It helps physicians make informed decisions. In each group, we need to compare the effectiveness of all guideline-concordant medication options based on the data samples of the group.

Taking the group of “Monotherapy” for example, the usage number of each guideline-concordant medication and its effectiveness (FPG goal achieving rate) was shown in Table 5 with descriptive statistic. Since the number of using AGIs is quite small, we give the comparative effectiveness analysis just between MET and SU/GLN. The result shows that the adjusted P value=0.34 and OR=0.895, which means there was no significant difference in effectiveness between MET and SU/GLN. Here BMI, age and history of hypertension were identified as the confounding factors to adjust OR, because they were associated with medication options or glycemic control goal achievement significantly.

If the result of the comparative effectiveness analysis for medication options is not statistically significant at the group level, we apply recursive partitioning approach on the leaf node to further “grow” the tree for subgroup analysis. Here we grow a MOB tree on “Monotherapy” group to perform subgroup analysis, as shown in Figure 2. We set stopping condition: significant parameter instability P value<0.5, maximum depth of MOB tree maxDepth=3. The partitioning variables are detected after parameter instability test, they are BMI (kg/m²) and age (year). The partitioning point for BMI is 23.34 kg/m², 58 years for age variable. As shown in Figure 2A, Monotherapy group were split into three subgroups (cluster) according to BMI and age. Three single logistic regression model fitted on each cluster, and regression coefficients and adjusted ORs of treatment options are shown in Table 6. Finally, we compared the FPG goal achieving rate using MET or SU/GLN respectively, as shown in Figure 2B. Although it is not significant due to the small number of patient samples, SU/GLN can lead to better outcome in cluster 1. In cluster 2 and 3, MET can lead to better outcome which is consistent with the guideline (Improper use of SU may cause hypoglycemia especially
in elderly patients and also cause weight gain). According to the results of subgroup analysis, patients in cluster 1 (BMI≤23.34 kg/m², age≤58 years) are recommended to SU/GLN; patients in cluster 2 (BMI≤23.34 kg/m², age>58 years) are recommended to MET; for patients in cluster 3, recommendations are with no preference currently.

**RWE-integrated CDSS**

A CDSS for type 2 diabetes treatment is built with real-world evidence. After collection of patient data including basic information, lab or examine results, previous treatment, historical diseases like comorbidity or complication, the CDSS system can recommend the medications and provide the evidence of why the recommendation is made, according to the knowledge model and data-based evidence of similar patients. As shown in the top area of Figure 3, the system provided comprehensive medications for T2DM patients including blood pressure management, blood glucose management, blood lipid management and blood platelet management respectively. And each kind of medication recommendation includes class name, generic name and product name. For patients with certain conditions, there could be more than one treatment options in every management module. Physicians can switch the treatment by clicking the drop-down menu. After clicking the evidence icon next to the medication options, both the data-based evidence and knowledge-based evidence are showed at the bottom. In the bottom-right area of Figure 3, for the data-based evidence in “similar patients” tab, feature statistic, using percentage and glucose control rate of medication options in similar patients are showed in the table, the pie chart and the bar chart respectively. As shown in the bottom-left area of Figure 3, the path in the decision tree is highlighted, indicating why the recommendation is made for this individual patient according to the clinical guideline. In the real application, the physicians can turn to the CDSS for 1) reasonable medication options according to our knowledge model and 2) more detailed evidence from similar patients’ data to prioritize the corresponding candidates. After choosing the medication treatment, the physician could further customize the treatment. He or she could select/unselect the drug class by the check box, and choose the drug with specific generic name and product name. Till now, we have performed the pilot testing on the CDSS system in several hospitals in China.

**Discussion**

In this study, we proposed a method and system by integrating clinical guideline and RWE for T2DM treatment. The clinical guideline provides standardized medications and RWE is generated to prioritize the corresponding candidates.
such as effectiveness in similar patients. For similar-patient group that is not statistically significant in effectiveness, we apply recursive partitioning approach to further “grow” the tree for subgroup analysis.

The strengths of this study include the integration of the clinical knowledge and real-world evidence, the achieving the standardized (i.e., consistent with knowledge) and personalized (i.e., referring to the RWE of similar patients) medication recommendation for T2DM patients, the medication effectiveness analysis and subgroup analysis, and finally the CDSS system realization and application.

The limitation of the current work is that evidence was based on drug categories in treatment. In fact, a physician need to decide which generic name or product name of drug can be most appropriate. Moreover, we only evaluated short term glycemic control goal achievement rather than long term outcome improvement such as the occurrence of complications. When more data are accumulated with longer time span, we can refine the recommendation and evidence to generic or product level and evaluate long term outcome improvement of the patients, so that the system will be more helpful and practical for physicians. Another limitation is that the outcome used to evaluate the glycemic control has been discretized as goal-achieving and goal-not-achieving, ordinal regression model for continuous outcome can be applied with more comprehensive evaluation.

Our approach is tested with type 2 diabetes patients’ data. The method can be generalized to other chronic diseases based on its guideline. By customization of medication pattern, features, effectiveness, and related parameters, our approach can be applied in different scenarios.

Figure 3. Screen shot of the RWE-integrated CDSS
Conclusion

In this paper, we proposed a method and developed a CDSS by integrating clinical knowledge and real-world evidence for T2DM treatment. We built our knowledge model based on Chinese clinical guideline for prevention and treatment of type 2 diabetes (2017) and integrated it with RWE extracted from more than 110,000 records of T2DM patients in a Chinese city. The knowledge model has been verified by the clinical experts from the advanced hospitals. The data verification results show that the medications that are consistent with the method recommendation can lead to better clinical outcome in terms of glycemic control, compared to those are inconsistent. Furthermore, the method and system enabled the personalized medication recommendation by comparing the effectiveness of treatment options in terms of the clinical outcomes like glycemic control goal achieving rate.

Abstract

The goal of this study was to investigate the application of machine learning models capable of capturing multiplicative and temporal clinical risk factors for outcome prediction in patients with aneurysmal subarachnoid hemorrhage (aSAH). We examined a cohort of 575 aSAH patients from Emory Healthcare, identified via digital subtraction angiography. The outcome measure was the modified Ranking Scale (mRS) after 90 days. Predictions were performed with longitudinal clinical and imaging risk factors as inputs into a regularized Logistic Regression, a feedforward Neural Network and a multivariate time-series prediction model known as the long short-term memory (LSTM) architecture. Through extraction of higher-order risk factors, the LSTM model achieved an AUC of 0.89 eight days into hospitalization, outperforming other techniques. Our preliminary findings indicate the proposed model has the potential to aid treatment decisions and effective imaging resource utilization in high-risk patients by providing actionable predictions prior to the development of neurological deterioration.

Introduction and Background

Aneurysmal subarachnoid hemorrhage (aSAH) is a grave medical condition, affecting over 30,000 individuals a year in the United States1. Despite advances in medical care, it remains a major cause of premature mortality, accounting for 27% of all stroke-related years of life lost before the age of 652. Mortality is estimated at 30%, and up to 40% of survivors have long-term neurological deficits resulting in significant loss of quality of life and increased burden and cost on the healthcare system3. Delayed cerebral ischemia (DCI) and cerebral infarction are major complications of aSAH, occurring in 19-46% of patients, and account for a large burden of aSAH-related morbidity4,5. Cerebral arterial vasospasm (CVS) is another major complication of aSAH, seen in up to 70% of patients, and is often associated with DCI and cerebral infarction6. For this study, CVS is defined as arterial narrowing documented on imaging, specifically computed tomography angiography (CTA) and/or digital subtraction angiography (DSA). As DCI is often difficult to diagnose and predict, the strong association between the DCI and CVS has led to the clinical practice of using CVS detection as a means of early detection of DCI, in an effort to guide early treatment to prevent cerebral infarction. However, less than half of patients with CVS ultimately develop DCI, thus definitive prognostic and therapeutic decision based solely on CVS screening is not ideal and may lead to overtreatment and treatment-related morbidity. Furthermore, while less common, DCI also can occur in the absence of CVS further complicating timely diagnosis and treatment7,8.

There are a variety of imaging studies used to diagnose CVS, each with its own distinct advantages and pitfalls, including transcranial doppler ultrasound (TCD), computed tomographic angiography (CTA) and CT perfusion (CTP). However, there is conflicting evidence in the literature regarding sensitivity, specificity, and prognostic efficacy. In particular, TCD has been deemed both effective8,10 and ineffective11,12 in predicting both vasospasm and poor neurologic outcomes, using a variety of imaging parameters and outcome definitions. CTA and CTP are additional imaging modalities used to diagnose vasospasm and define brain tissue at risk for DCI. These imaging modalities have been shown to have a higher sensitivity for detection of vasospasm and DCI and have generally been found useful for prognostication13,14. However, the radiation exposure from these techniques must be considered. DSA is considered the gold standard for determination of angiographic vasospasm, but it is an invasive and resource intensive modality with a small, but significant risk of neurologic compromise. A review of the literature to evaluate the diagnostic value of DSA for detection of DCI revealed few studies14. Furthermore, a recent study found that screening asymptomatic patients with DSA was ineffective, although this remains useful in patients that are either symptomatic or difficult to assess clinically due to poor neurologic status15.
A wide variety of clinical signs and risk factors for developing both CVS and DCI have been described, including smoking\textsuperscript{16, 17}, hypertension\textsuperscript{16, 17}, hyperglycemia\textsuperscript{16, 17}, old age\textsuperscript{18, 19}, and level of consciousness\textsuperscript{20, 21}, as well as image-based scoring systems such as modified Fisher score (MFS)\textsuperscript{22, 23}. However, much of the literature is difficult to interpret as outcomes are often poorly defined\textsuperscript{24}. In fact, the terms CVS and DCI are often used interchangeably, further complicating study comparison. Variations in study design and differing outcome definitions underscore the need for a robust, reproducible predictive model with clearly defined outcomes. Additionally, the complex pathophysiology of aSAH, diagnostic challenges of DCI, and risk of poor neurologic outcome emphasizes the need for a prognostic tool to aid in the early identification of aSAH patients at risk for vasospasm, ischemia and stroke prior to neurologic deterioration.

In clinical research, conventional statistical techniques such as linear and logistic regression are the dominant techniques used for clinical decision support models. These techniques are hypothesis driven and simple to interpret, yet overly simplistic statistical assumptions about data distribution and model fitting, as well as inability to identify higher order interactions among the input variables, limit their applicability in complex data sets. Notably, logistic regression has been used to evaluate the contribution of TCD to predicting outcomes in aSAH patients, and the literature reveals conflicting results, with TCD shown to be both contributory\textsuperscript{11} and noncontributory\textsuperscript{11, 25}. These findings reinforce the need for an alternative approach to data modeling in aSAH patients.

Machine learning is a branch of artificial intelligence that has been employed in a variety of applications, including medicine, to analyze complex datasets\textsuperscript{26}. While the complexity of clinical problems such as aSAH outcome prediction provides an opportunity for machine learning techniques, the smaller datasets available in healthcare compared to other industries provide a significant challenge to machine learning techniques\textsuperscript{27–29}.

There have been a few preliminary studies of machine learning models to predict vasospasm in patients with aSAH, which outperformed their respective logistic regression models\textsuperscript{30–32}. However, two of the models were trained on less than 100 patients, limiting generalizability. Additionally, focusing on vasospasm as an outcome, rather than a measurable clinical outcome, limited the clinical utility of these models. The third model, while trained on a large dataset from multiple sites, did not include several important variables previously identified as prognostic for poor outcome, such as smoking status\textsuperscript{32}.

The superior performance of artificial neural networks (ANN) on complex datasets make them well-suited for clinical applications including longitudinal data and multiplicative risk factors. A Recurrent neural network (RNN) is a special type of ANN tailored towards finding predictive patterns in longitudinal multivariate data, due to their use of internal states (or memory) to process sequences of inputs. This internal memory, and the ability to model trajectories, make RNNs a powerful tool for monitoring of patients staying in hospitals to prevent adverse events\textsuperscript{33}.

In this work, we compare three predictive modeling approaches, namely a logistic regression model, an ANN model, and an RNN model, to test the hypothesis that multiplicative risk factors (or interaction terms), and temporal features in the data can improve prediction of outcomes in aSAH patients. The rest of this paper is organized as follows. We start with a description of our aSAH patient cohort and the utilized machine learning models, results, and significance of our findings and future directions.

Data and Methods

This investigation was conducted according to Emory University Institutional Review Board approved protocol 66,389. Our preliminary dataset identified approximately 4,191 patients with confirmed aSAH by DSA dating back to January 1998. We used a subset containing 575 patients dating back to January 2009 for this preliminary study. The Emory Healthcare Clinical Data Warehouse (CDW) was queried for the 575 patients in our data subset, with data extraction query for demographic, clinical and imaging data identified in our literature review as associated with aSAH outcome in prior prognostic models. Associated clinical imaging studies and reports included in the CDW retrieval are: TCD, non-contrast head CT head CTA, head CTP, and DSA. Two board-certified neuroradiologists also reviewed each patients presenting head CT to determine MFS. Individual chart-review supplemented clinical factors not expected to be captured in the CDW retrieval, including level of consciousness, and World Federation of Neurosurgeons grade. The specific model features extracted were: hypertension\textsuperscript{16, 17}, smoking status\textsuperscript{16}, hyperglycemia\textsuperscript{16}, diabetes mellitus\textsuperscript{16}, increased intracranial pressure\textsuperscript{19}, leukocytosis\textsuperscript{34}, level of consciousness\textsuperscript{20, 21}, weight\textsuperscript{17}, World Federation of Neurosur-
geons grade\textsuperscript{35,36}, and blood transfusion\textsuperscript{37}, MFS\textsuperscript{22,23}, aneurysm treatment (surgical clipping or endovascular coil)\textsuperscript{38}, presence of perfusion mismatch on CTP\textsuperscript{13,14,39}, TCD vessel elevation $> 140 cm/sec$\textsuperscript{11}, CVS on CTA\textsuperscript{14,15}, CVS on DSA\textsuperscript{14,15}, aneurysm location, number of aneurysms and aneurysm size\textsuperscript{37}. Inclusion criteria are patients 18 years of age or older with documented aSAH at admission based on the results of head CTA or DSA. Exclusion criteria are causes of SAH other than aneurysm including but not limited to trauma, infection, vascular malformation, vasculitis, post surgical complication, reversible cerebral vasospasmodic syndrome, and Moya Moya.

Two general types of variables are included in the model; time-variant features which includes laboratory values, vital signs and imaging exams, and time-invariant features which contains the information regarding demographic and patient history. Some variables such as vital signs and laboratory values are updated more frequently comparing to imaging exams. Each patient information was binned with 24-hour time intervals. Sample-and-hold technique was applied on the data. If there were more than one value for imaging exams, we took the median and if there were more than one value for vital signs and laboratory results, we took the mean of the available values. Missing values were imputed with the mean or median of the corresponding feature. Then, numerical features were normalized and transformed if needed.

The outcome labels for this study were the modified ranking scale (mRS) which is a commonly used scale for measuring the degree of disability or dependence in the daily activities of people who have suffered a stroke or other causes of neurological disability. The mRS score ranges from zero to six, where an mRS of zero corresponds to having no symptoms of disability while an mRS score of six indicates that the patient has expired. We dichotomized the mRS scores into binary outcomes\textsuperscript{24}, corresponding to poor (mRS = 4, 5, 6) and favorable (mRS = 0, 1, 2, 3) outcomes. This measure was used as a surrogate of DCI and cerebral infarction, as this measure is a common secondary outcome used as a surrogate for DCI\textsuperscript{40}.

In order to predict patients mRS each day, the data was binned based on 24 hour time intervals. Therefore, for each patient we had a sequence of daily information starting from the end of the first day of ICU admission. In this cohort, each patient had only one outcome which was assigned 90 days after being discharged from the hospital. In order to make daily prediction for each patient, the outcome was replicated\textsuperscript{41} and assigned to every day that patient was hospitalized in the ICU.

Our initial model consisted of logistic regression with L1 and L2 regularization (also known as an Elastic Net model) with 10-fold internal cross-validation to optimize the penalty term. We hypothesized that both a neural network model and a recurrent neural network model with long short-term memory (LSTM) would provide more robust prediction in patients with aSAH when compared to logistic regression.

Traditional ANNs were not designed to analyze sequential data, which complicates analysis of longitudinal data sets in clinical settings. An RNN model can be thought of as multiple copies of the same network, each passing a message to a successor. This chain-like structure and the associated memory make the RNN models ideal for use with longitudinal data. To make daily predictions of the outcome of aSAH patients, we utilized a Long Short-Term Memory (LSTM) network, which is capable of learning long-term dependencies in time series data\textsuperscript{42}.

The RNN model includes input layer containing sequential data, a LSTM layer with 50 hidden units, a fully connected layer followed by a Softmax layer and a classification layer. Number of hidden units was experimentally assigned, and a fully connected layer is added to capture all the interactions and nonlinear relationships among the features. To train the RNN model, mini batch technique was incorporated with mini batch size of 250, almost the maximum value possible. Adam optimizer was applied and the rest of the parameters in training process are initial learning rate=0.01, Gradient threshold=1, and Learning rate drop period=20. Moreover, a validation set was assigned to apply L2 regularization and prevent overfitting.

In order to make a fair comparison between the RNN model and the artificial neural network, we kept the same setting to train ANN, and only the LSTM layer was excluded from the model.

**Results**

Three predictive models were applied, namely an Elastic Net model, a feedforward ANN model with a fully connected layer and an LSTM-type recurrent neural network. To present the predictive power of LSTM, we compared the results
Figure 1: (a) AUC-ROC of applying the feedforward Artificial Neural Network on the training and testing sets (10-fold cross-validated). All patient time series were aligned at admission and risk scores were calculated on a daily basis for up to 15 days. (b) Performance of the L1L2 regularized Logistic Regression model (aka, Elastic Net).

The greatest risk of morbidity and mortality occurs during days 2-15 following initial aSAH hemorrhage. Therefore our model prediction focused on days 2-15 for outcome prediction. The performance measure we selected was area under the receiver operating curve (AUC-ROC or AUC) which is useful for comparing binary outcome classification models. The result of applying the trained models on different days of patient stay to predict the associated mRS is presented in Table 1 and Figure 2. Figure 2 demonstrates the average AUC of applying 10-fold cross-validation while predicting mRS on each day of patient stay in the ICU using the LSTM model. The vertical dotted lines present the error bar which is reasonably bounded. According to Figure 2, the overfitting is negligible and the LSTM model is performing well on both training and testing subsets. This model is capable of capturing non-linearity and temporal information in the data, and therefore in general we see an improvement in performance with inclusion of additional days of data. The best performance of the LSTM model is from day 8 to 13 in which AUC of 0.89 was achieved on testing set. Figure 1 (a) presents the average AUC from applying a NN model with 10-fold cross-validation to assess generalization performance of the model. The feedforward neural network models do not consider the temporal information in the data, but are capable of modeling non-linearity and interactions among the input features. The best performance of the NN model is on days 8, 11, and 12 which is 0.84. Figure 1 (b) shows the AUC of the ElasticNet model, which performed poorly compared to the NN and LSTM models. The main reason is that ElasticNet can neither capture temporal information nor non-linearity in the dataset. As a result, while this model is a regularized version of logistic regression model, ElasticNet is not capable of making meaningful predictions after day 5. In fact, the ElasticNet model severely overfits to the training data and performs poorly on the testing data, which is likely due to the smaller number of patient records available after day 5.

The details of predictive performance associated with the LSTM model, neural networks and ElasticNet model are presented in Table 1. The LSTM model constantly achieved better AUCs compared to the other models. Day 8 has the first best prediction performance for the LSTM model, so by testing the information on day 8 of the patient stay at ICU, we can obtain 0.89 prediction AUC. Time-dependent and time-independent features were employed in training the models. We performed sensitivity analysis in order to find the features which contributed most significantly to the AUC of the LSTM model. This analysis indicated that MRI and DSA features from imaging exams, INR, Phosphorus, white blood cells, Bilirubin, and PaO₂ from laboratory results, admission status, gender, and etiology category were the top features that contributed to the AUC achieved with the LSTM model.
Discussion and Concluding Remarks

Our results confirm our hypothesis that machine learning models can outperform traditional logistic regression in patients with aSAH. We believe that nonlinear interactions between variables, as well as the temporal relationships in longitudinal data are important to incorporate into a prediction model for this complex patient population. Our machine learning model design incorporates daily outcome prediction, which would theoretically allow physicians to more closely monitor patients at highest risk for poor outcome when used prospectively. Additionally, by focusing on an outcome related to DCI, our model does not solely rely on imaging features to potentially guide patient treatment decisions.

While this study was limited to a single institution and will require further validation, our results supports future exploration of the use of multivariate time-series prediction models such as LSTM neural networks on a larger, multi-institutional aSAH dataset. Further work could also explore the incorporation of live patient vital monitoring systems, which provide rich real-time datasets, as well as additional clinical outcomes such as mortality or cerebral infarction on follow up imaging. To eliminate the need for manual image annotation in a real-time implementation, one may build separate machine learning models to automatically annotate the images or use multimodal data fusion using a combination of convolutional neural networks for image feature extraction and recurrent neural networks for analysis of temporal information in time series data. The clinical implications of a successful predictive model for aSAH are profound, with the potential to reduce unnecessary radiation from inappropriate imaging, reduce hospital stay in low risk patients, and reduce morbidity in high risk patients. Further work in this area is warranted.

The results of this preliminary analysis demonstrate that a RNN with LTSM architecture provides robust evidence for clinical outcome prediction in patients with aSAH compared to traditional statistical techniques. We believe this supports further exploration with our full dataset, as well as expansion into a multicenter trial with a more diverse patient population.
Table 1: AUC-ROC of applying the trained LSTM, neural network and ElasticNet models to the training and testing sets. 10-fold cross-validation was applied, and the mean AUC across all folds is presented. Number of Samples denotes the available number of training and testing records as the number of days included in the analysis increases (note the drop in the number of records is due to death or discharge).

Abstract

De-identification of clinical text, the prerequisite of electronic clinical data reuse, is a typical named entity recognition (NER) problem. A number of state-of-the-art deep learning methods for NER, such as Bi-LSTM-CRF (bidirectional long-short-term-memory conditional random fields), have been applied for de-identification. Neural language models used for language representation bring great improvement in lots of NLP tasks when they are integrated with other deep learning methods. In this paper, we introduce Bi-LSTM-CRF with neural language models for de-identification of clinical text, and evaluate it on the de-identification datasets of the i2b2 2014 and the CEGS N-GRID 2016 challenges. Four neural language models of three types individually integrated with Bi-LSTM-CRF are compared in this study. Bi-LSTM-CRF with neural language models achieves the highest “strict” micro-averaged F1-score of 95.50% on the i2b2 2014 dataset and 91.82% on the CEGS N-GRID 2016 dataset, becoming new benchmark results on these two datasets respectively.

Keywords: De-identification, Named entity recognition, Bidirectional long-short-term-memory, Conditional random fields, Neural language models.

Introduction

Clinical records as an important information source for medical research and investigations have been attracting more and more attention of medical professionals. A prerequisite for clinical records sharing is removing individually identifiable health information, known as protected health information (PHI). In the United States, the Health Insurance Portability and Accountability Act (HIPAA)[1] defines 18 different types of PHI. In clinical records, there is plenty of PHI embedded in clinical text, which cannot be identified directly like PHI recorded in structured table according to table fields.

The process of finding and removing PHI is called de-identification. As removing PHI is easy to implement, de-identification mainly focuses on finding PHI, and is usually recognized as a named entity recognition task. In the last decades, a variety of methods have been proposed for de-identification. These methods can be classified into two categories: rule-based methods and machine learning methods. Rule-based methods rely on manually constructed regular expressions and domain dictionaries, which are challenging and time-consuming to develop. They are easy to implement and do not require any labeled data. The main disadvantage of rule-based methods lies in that they are not easy to replant from one domain to another. To prevent disadvantages of rule-based methods, researchers have attempted machine learning methods for de-identification of clinical text, especially since several challenges about de-identification were organized, such as the i2b2 2014 challenge [2],[3] and the CEGS N-GRID 2016 challenge[4]. Classical statistical learning methods, such as decision trees [5], support vector machines [6], conditional random fields (CRF)[7] and structured support vector machines [8], have been applied for de-identification. Among them, CRF is one of the most state-of-the-art methods. All these methods require time-consuming feature engineering.

In recent years, deep neural networks, which have the ability of learning effective features from large-scale unlabeled data instead of feature engineering in traditional statistical learning methods, have been widely used in various tasks in natural language processing, such as language representation, NER, parsing, text classification, question answering and machine translation, and have shown promising results. For de-identification, deep neural networks also achieve state-of-the-art results [9],[10]. The representative method is Bi-LSTM-CRF (bidirectional long-short-term-memory conditional random fields)[10-15]. Bi-LSTM-CRF takes as input the sequence of word embeddings
and uses Bi-LSTM [16] for sentence representation and CRF for label sequence prediction. The input sequence of word embeddings learnt by neural language models on large-scale unlabeled data is an important influencing factor of Bi-LSTM-CRF. The neural language models may be classified into the following three types: 1) The common neural language models such as CBOW[17], Skip-gram[18] and GloVe[19] are usually used to obtain representations of words. Each word learnt by these models has only one representation, denoted by word embedding. However, a great percentage of words have different meanings when appearing in different context. 2) Recently, several neural language models that determine the embeddings of a word according to its context at each time dynamically, such as ELMo[20], GPT[21] and BERT[22], have been proposed and have brought significant improvement to existing methods. 3) Another way to improve existing methods using neural language models is optimizing neural language models and existing methods simultaneously. For example, Liu L et al.[23] introduced a character-level Bi-LSTM to predict each word of the input sentence, which was optimized together with Bi-LSTM-CRF. In this way, Bi-LSTM-CRF obtained improvement on a number of NLP tasks.

In this paper, we investigate Bi-LSTM-CRF with neural language models of the above-mentioned three types on de-identification and compare four neural language models, that is, Skip-gram[18], ELMo[20]. BERT[22] and LM[23]. Experiments conducted on the de-identification datasets of the i2b2 2014 challenge and the CEGS N-GRID 2016 challenge show that Bi-LSTM-CRF with neural language models achieves state-of-the-art performance. Bi-LSTM-CRF(BERT) is the best one with a “strict” micro-averaged F1-score of 95.50% on the i2b2 2014 de-identification dataset and 91.82% on the CEGS N-GRID 2016 challenge dataset, which is higher than that of the current best system[9] by 0.39%.

Methods

We start with the basic Bi-LSTM-CRF, and then the variants when different neural language models are added separately. Figure 1 shows their overall architecture.

Figure 1. Overview architecture of Bi-LSTM-CRF with neural language models

Bi-LSTM-CRF

It consists of three main components, called “layers” here, that are input layer, Bi-LSTM layer and CRF-layer. The input layer converts an input sentence $s=w_1w_2...w_n$ into a sequence of word embeddings $x=x_1x_2...x_n$. The Bi-LSTM layer further obtains two sequences $h_f=h_{f1}h_{f2}...h_{fn}$ and $h_b=h_{b1}h_{b2}...h_{bn}$, which represent context information of each
word of interest at every position from forward and backward directions respectively. The CRF layer finally predicts a label sequence $y=y_1y_2…y_n$. For detailed information, please refer to [13].

**Bi-LSTM-CRF with Neural Language Models**

There are two ways to integrate neural language models into Bi-LSTM-CRF: at the input layer and at the CRF layer. At the input layer, there are two types of representations for input sentences: word-level and sentence-level. At the CRF-layer, the input sentences should be also produced by neural networks like autoencoding.

Skip-gram is a model for word-level representations, the idea of which is to use a word of interest to predict words around it. Given large-scale unlabeled data, Skip-gram produces one embedding for each word. Then any input sentence can be represented by replacing each word by its word embedding, which is a process of dictionary lookup.

ELMo is a model for sentence-level representation. It uses stacked bidirectional LSTMs to encode input sentences, each word of which is predicted by the forward LSTM and the backward LSTM based on the two subsentences before and after it respectively. The same word in different sentences may have different meanings and should have different representations.

Similar to ELMo, BERT is also a model sentence-level representation. It adopts neural networks based on transformer to encode input sentences, where some of the words from input sentences are randomly masked, and are predicted based only on its context. Other than that, it further introduces a “next sentence prediction” task for text pair representation.

LM is a task-aware neural language model, which predicts each word based on character-level context and is optimized together with a label sequence task in a multi-task framework. When LM is integrated into Bi-LSTM-CRF at the CRF layer, another neural language model such as Skip-gram is also integrated at the input layer. In this study, we only consider the case of Bi-LSTM-CRF(Skip-gram+LM).

**Experimental Settings and Results**

**Datasets**

We compare different Bi-LSTM-CRF variants on the de-identification datasets of the i2b2 2014 challenge and the CEGS N-GRID 2016 challenge, which are publicly available. The i2b2 2014 dataset includes a training set of 790 records with 17,045 PHI instances and a test set of 514 records with 11,462 PHI instances. The CEGS N-GRID 2016 dataset includes of a training set of 790 records with 20,845 PHI instances and a test set of 400 records with 13,521 PHI instances. All PHI instances are classified into seven main categories with subcategories. The number of PHI instances in each category is listed in Table 1, where NA denotes no subcategory, and categories defined in HIPAA are marked by *.

**Experimental Settings**

**Evaluation:** The performance of all models is measured by standard micro-averaged precision (P), recall (R) and F1-score (F1) under different criteria, namely “token”, “strict”, “relaxed”, “HIPAA token”, “HIPAA strict”, “HIPAA relaxed”, “binary token”, “binary strict”, “binary HIPAA token” and “binary HIPAA strict”, where “token” and “strict” correspond to exact matching at token-level and instance-level respectively, “relaxed” allows at most two characters mismatched at the end, “HIPAA” corresponds HIPAA-defined categories, and “binary” only considers the boundaries of PHI instances no matter their categories. “strict” is the primary criterion. We use the same preprocessing as our previous work [9] in this study.

**Parameters:** We adopt the same settings as [9] for Bi-LSTM-CRF(Skip-gram) except that all categories of PHI instances are recognized by Bi-LSTM-CRF(Skip-gram) in this study, while some categories of PHI instances are recognized by rules in [9]. We use the pretrained ELMo (https://s3-us-west-2.amazonaws.com/AllenNLP/models/elmo/2x4096_512_2048cnn_2xhighway/elmo_2x4096_512_2048cnn_2xhighway_weights.hdf5) and BERT-Base (https://storage.googleapis.com/bert_models/2018_11_03/multilingual_L-12_H-768_A-12.zip) for neural language model initialization and they are fine-tuned during Bi-LSTM model training. The hyperparameters used in our study are listed in Table 2 in detail.

Experimental Results

The comparison results of the Bi-LSTM-CRF with different neural language models on the two datasets are shown in Table 3 and Table 4 respectively, where the highest P, R and F1 are highlighted in bold. The Bi-LSTM-CRF with the two neural language models, namely ELMo and BERT, for sentence-level representation achieves higher F1-score than the Bi-LSTM-CRF with the one neural language model, namely Skip-gram, for word-level representation. Bi-LSTM-CRF(BERT) achieves the highest “strict” F1-score of 95.50% on the i2b2 2014 dataset and 91.82% on the CEGS N-GRID 2016 dataset, outperforming LSTM-CRF(ELMo) by 1.54% and 1.12% respectively.
brings an improvement of 0.72% in “strict” F1-score on the i2b2 2014 dataset and 1.19% on the CEGS N-GRID 2016 dataset, when it is added into Bi-LSTM-CRF(Skip-gram). LSTM-CRF(ELMo) and Bi-LSTM-CRF(Skip-gram+LM) shows comparative performance.

The results of the best Bi-LSTM-CRF variant, Bi-LSTM-CRF(BERT), on the main seven categories are shown in Table 5. On the i2b2 challenge dataset, Bi-LSTM-CRF(BERT) performs best on DATE with a “strict” F1-score of 98.75% and worst on PROFESSION with a “strict” F1-score of 82.78%, while on the CEGS N-GRID 2016 dataset, Bi-LSTM-CRF(BERT) performs best on DATE with a “strict” F1-score of 97.03% and worst on ID with a “strict” F1-score of 59.70%.

We also compare other state-of-the-art methods with Bi-LSTM-CRF(BERT) as shown in Table 6, where only “binary token” P, R and F1 are reported as the P, R and F1 under other criteria are not complete. “Bi-LSTM-CRF(BERT)” shows better performance than the other methods for comparison.

Discussion

It is easy to understand that Bi-LSTM-CRF(ELMo) and Bi-LSTM-CRF(BERT) perform better than Bi-LSTM-CRF(Skip-gram) since ELMo and BERT can dynamically give more detailed representation of each word according to its context. For example, “Brigham Young” is usually a name, but an organization in “Father is supervisor. College (Brigham Young, community college in TX, UCSD, Baylor), still working on bachelor’s, major sociology.”, which is correctly recognized by Bi-LSTM-CRF(ELMo) and Bi-LSTM-CRF(BERT), but wrongly recognized as a doctor’s name by Bi-LSTM-CRF(Skip-gram). Similar to previous studies in other domains[19], Bi-LSTM-CRF(BERT) shows better performance than Bi-LSTM-CRF(ELMo). As LM has ability to predict sentences regarding a specific task, Bi-LSTM-CRF(Skip-gram+LM) can fit de-identification here.

Although Bi-LSTM-CRF(BERT) shows promising overall performance, there are still some errors. Taking the results on the CEGS N-GRID 2016 dataset for example, the effect of boundary errors or category errors on overall F1-score is around 2.0% (the “strict” F1-score of 91.82% vs the “token” F1-score of 93.81% or the “binary strict” F1-score of 93.66%). The “strict” F1-scores of Bi-LSTM-CRF(BERT) on PROFESSION, LOCATION and ID are much lower than other categories as shown in Table 4. We look into the errors in these three categories and find that: 1) Lots of instances in PROFESSION are not detected as they are not mentioned directly like PHI instances in other categories, for example, “danced” is not a word to denote PROFESSION directly, but we can infer that the patient is a dancer from “She danced with MBT for 10 years;”. 2) Boundary errors widely exist in LOCATION, for example, in “video editing (DiC Entertainment Affiliate) in broadcasting Financial Stress: Yes”, “DiC Entertainment Affiliate” is recognized as an ORGANIZATION instance instead of “DiC Entertainment”. The “binary strict” F1-score on LOCATION is 89.13%, higher than the “strict” F1-score on LOCATION (i.e., 85.33%) by 3.80%. Other than that, there are also more category errors on LOCATION than other categories because of more subcategories in LOCATION. 3) The reason why Bi-LSTM-CRF(BERT) performs bad on ID is that the number of ID instances is too small. From Table 1, we can see there are only 44 ID instances in the training set of the CEGS N-GRID 2016 challenge, in particular, only 2 instances in IDNUM.

For the future work, there may be two directions for further improvement: 1) using BERT pretrained on large-scale clinical data; 2) integrating LM and BERT into Bi-LSTM-CRF at the same time since they work at different layer.

Conclusion

In this study, we introduce Bi-LSTM-CRF with neural language models for de-identification of clinical text. The Bi-LSTM-CRF variants achieve the highest “strict” micro-averaged F1-score of 95.50% on the i2b2 2014 de-identification dataset and 91.82% on the CEGS N-GRID 2016 de-identification dataset, constituting new benchmarks for de-identification.

Abstract

Background: To assess the current state of clinical data interoperability, we evaluated the use of data standards across 38 large professional society registries.

Methods: The analysis included 4 primary components: 1) environmental scan, 2) abstraction and cross-tabulation of clinical concepts and corresponding data elements from registry case report forms, dictionaries, and / or data models, 3) cross-tabulation of same across national common data models, and 4) specifying data element metadata to achieve native data interoperability.

Results: The registry analysis identified approximately 50 core clinical concepts. None were captured using the same data representation across all registries, and there was little implementation of data standards. To improve technical implementation, we specified 13 key metadata for each concept to be used to achieve data consistency.

Conclusion: The registry community has not benefitted from and does not contribute to interoperability efforts. A common, authoritative process to specify and implement common data elements is greatly needed.
**Introduction and Background:**

Clinical data interoperability, or the capacity to exchange high-quality, clinically relevant information as data from one system to another, has largely failed. Proprietary processes and custom solutions are required at each point of data exchange to extract, transform, and load data from one system to the next. While healthcare ontologies have been developed to support interoperability, these ontologies are positioned as secondary encoding schemas and are not usable natively as clinical vocabularies. While electronic health record (EHR) systems are now ubiquitous, healthcare continues to largely capture clinical information as analog text requiring data abstraction for computational purposes. The transformation and movement of clinical data from one system to another is expensive, labor intensive, and prone to semantic inaccuracy.

The capture of clinical data for submission to registries is illustrative. Clinical registries collect baseline and longitudinal data to evaluate outcomes, assess care performance and processes, and facilitate process improvement in cohorts of patients defined by a disease state, condition or exposure to a medical product. Registries have been positioned as a critical source of real-world evidence to advance clinical and regulatory science. A common source of data for clinical registries is the EHR. However, the submission of data to registries depends largely on the manual abstraction of data from the EHR and manual re-keying of data into registry data collection systems, termed “swivel chair interoperability”.

To assess the current state of interoperability with respect to registries, we evaluated the adoption and use of data standards by 38 national clinical registries in a project termed “Improving Healthcare Data Interoperability” sponsored by the Pew Charitable Trusts. The hypothesis was that data liquidity had not been achieved in the registry domain, and that native data interoperability spanning clinical documentation systems and registry database systems would provide the best pathway to accomplishing data liquidity. Specifically, we evaluated the current status of the adoption of data standards by clinical registries and created technical (database programming) specifications for a set of more than 50 clinical concepts commonly shared across registries. We evaluated these clinical concepts in the context of existing work including the federal Common Clinical Dataset and the draft 2018 US Core Data for Interoperability, HL7 Fast Healthcare Interoperability Resources, the work of standards organizations such as LOINC, and common data models including OMOP, PCORnet, and SENTINEL. The presentation will share the results of this project and identify suggested next steps.

The project had 3 Aims:

1) Evaluate registry case report forms, registry dictionaries, and / or registry data model artifacts from clinical professional society registries representing a minimum of 20 clinical specialties and patient populations, identifying the core (shared) common clinical concepts collected across the majority of registries

2) Compare the data elements used by the registries to capture the core common clinical concepts in the context of the ‘big 5’ healthcare data standards (SNOMED-CT, LOINC, RxNorm, ICD-10, CPT), developing the minimum metadata needed by database developers to natively implement a consistent technical representation of the concepts

3) Develop a roadmap for the transformations needed to achieve native data interoperability of a common clinical dataset across EHR systems, registries, and national data models

**Methods:**

We solicited participation in the project through broadcast communications to registry members of two registry associations (National Quality Registry Network of the PCPI and the Council of Medical Specialty Societies) and personal communications to a small (<10) number of professional societies. Approximately 75 registries were solicited on our behalf by the two associations (we did not manage the mailing lists per se), with our personal appeals overlapping the association-managed solicitations. Participation was voluntary; all who agreed to participate were included in the analysis. All registries were solicited several times. There were no declinations – the only exclusion was for failure to respond to our invitation. Registries agreeing to participate submitted blank registry case report forms (CRFs), data dictionaries, and / or registry data model representations to the Informatics Group of the Duke Clinical Research Institute, Durham, NC. For national data models, artifacts were sourced from publicly
available content in May-June, 2018. All artifacts were anonymized and kept confidential for purposes of analysis and reporting.

The process we followed is illustrated in Figure 1. We first analyzed the registry artifacts. Clinical concepts were tabulated and the corresponding data elements abstracted from the registry artifacts. We pre-selected for concepts that might be expected to be found in multiple registries (e.g., patient demographics, physical exam findings, procedures, medications, major outcomes). We identified those found across multiple registries as the candidate concepts. Data elements unique to a specific disease or procedure were intentionally excluded from the analysis. From this work, we determined that the data elements of interest could be grouped into the following domains: identifiers / demographics, comorbidities, common physical exam findings, procedure information, medications, lab results and patient outcomes. Attributes assigned by each registry to each data element were recorded in a cross-tabulation. Within each domain, the similarities and differences in data elements across registries were evaluated and a ‘match status’ (degree of concordance) was assigned (identical, nearly identical, no match). Identical concordance was defined as an exact match of data element label and permissible values. Nearly identical concordance was defined as representation of the concepts (particularly permissible values) in identical semantics without an exact match of permissible values (e.g., true / false versus yes / no). Similar concordance reflected variability in the representation of the concept and / or permissible values such that complete translation was not possible (e.g., yes / no versus yes / no / not available). No match indicated the inability to completely translate in terms of semantic meaning from one representation to another. Identical and nearly identical were grouped as “concordant” (i.e., semantically interoperable), while any disagreement was classified as “discordant” (i.e., not concordant).

A similar approach was applied to data elements from the federal Common Clinical Dataset along with national data models including the Observational Medical Outcomes Partnership (OMOP), the FDA SENTINEL initiative, and Patient Centered Outcomes Research Network (PCORnet). Again, similarities and differences in data type, semantic meaning, permissible values, etc., were noted and a concordance status was assigned per the definitions above.

With identification of the set of core common clinical concepts, we next developed metadata (e.g., clinical definition, data type, permissible values, coded permissible values, and terminology bindings) for each of the concepts, focusing on only the metadata required to fully qualify each clinical concept for the purposes of building the concepts as interoperable data in databases. To the greatest extent possible, we relied and prioritized published clinical data standards along with the corresponding HL7 FHIR resource for specific metadata content.

We socialized both the Methods and Recommendations via two stakeholder webinars, an in-person meeting held at the Pew Charitable Trusts headquarters in Washington, DC, and an electronic survey (Qualtrics). Feedback from each was incorporated into the final project artifacts. Additional feedback received from direct communications between the project team and stakeholders was also incorporated. Proceedings from the webinars and in-person meeting were analyzed using NVivo (QSR International), summarized, and incorporated where possible. Recordings and transcripts, along with project work products, are available online at: https://dcri.org/registry-data-standards.

**Results:**

Of the registry owners solicited, 38 agreed to participate. There were no declinations (only non-responses). The artifacts (case report forms, data dictionaries, and / or data models) provided by the 38 registry owners were sufficient to perform the analysis across all 38 registries. Approximately 50 data elements were identified as candidates for the comparative evaluation and metadata development. The original intent was to identify clinical concepts common to 50% or more of the participating registries, however, a very limited number of clinical concepts (sex, date of birth, medications, laboratory results) met this criterion. We therefore elected to use a much lower threshold (20%), deriving the following concepts to be explicitly developed: Patient Name, Date of Birth, Sex, Race, Ethnicity, Procedures, Unique Device Identifier, Vital Signs (height, length, weight, blood pressure, pulse), Lab Results (via a separate model), Medications (via a separate model), Care Team (physician only), Smoking Status (via a separate model), Alcohol Use, Substance Use, and Vital Status (Table 1).
Surprisingly few clinical concepts were collected with precisely the same data element representation from any one registry to the next; there were no concepts captured exactly the same way (i.e., concordant) across all 38 registries. Similarly, common data elements in the national common data models were also surprisingly discordant, with the technical (database) representations appearing to be derived from convenience rather than conformance with a particular data standard. An illustrative example is the clinical concept of sex. Of the 21 registries capturing this information, all intended semantically to reflect the biological concept of birth sex (not the social construct of “gender”). Yet one third (n=7) of registries assigned “Gender” or “Patient Gender” as the data element label. Despite a reasonably well-established value set, there were 6 primary variations of the value set across the registries: Male | Female, 3 sub-variations of Male | Female | Unknown, Male | Female | Other | Unknown, Male | Female | Undifferentiated, Male | Female | Unknown/Missing, and unspecified text (Table 2). Another example, tobacco use, is illustrated in Table 3. For this concept, not one of the 11 registries was concordant with another, despite the federal quality measure and resulting value set regarding same, and only 1 of the registries referenced SNOMED.

Most clinical concepts could be captured in a unidimensional manner (i.e., as a label : value pair). For these clinical concepts, 13 key metadata were specified for each data element, with the priority given to metadata with specific relevance to either (or both) clinicians and database developers (Table 4). Metadata describing the context in which data are collected (i.e., past medical history, within specified timeframe of procedure) were not included in this framework as the implications are different for each use case. Priority values for recommended metadata was given to values from predicate work, particularly the ONC USCDI, the NIH National Library of Medicine (NLM) Value Set Authority Center (VSAC), and HL7 FHIR profiles and resources (especially content listed in the FHIR Detailed Description tabs and FHIR Implementation Guides).

Critical discoveries identified during the specification of metadata included that 1) there was no single source or set of sources where all metadata could be identified – developing the metadata for each concept required the use of multiple sources; and 2) often there was not an obvious, single ‘correct’ choice, particularly for reference ontology bindings. Additionally, many common data elements and corresponding allowed values lacked explicit, unambiguous clinical definitions; in fact, the metadata with greatest variability and the least consistency were clinical definitions and definitions of clinical allowed values.

Two clinical concepts required multiple data elements to capture the semantics required by registries: medications and laboratory results. Medication and laboratory data elements were collected by most registries; 78% collected medication data, while 100% captured laboratory results data. Medication data elements from registries were compared to the AHRQ Health Information Technology Standards Panel model and models from HL7, ICD, NCI, LOINC, SNOMED CT, RxNorm (including RxClass), NDF-RT, NDC and UNII. While over 20 classes of medications metadata were identified in the environmental scan, for the representation of medications in registries, only 4 contexts were identified – the need for a complete list of a patient’s medications by name, medications by therapeutic domain, medications by pharmacologic class, and medications administered in the context of a given procedure. Capture of laboratory data also was multidimensional, typically as a series of observations with multiple prompts related to timing and units of measure. Standards contributing to the laboratory result models include LOINC, SNOMED-CT, and UCUM. Proceedings from two federal multi-agency sponsored public workshops were factored into the recommendations of the laboratory results recommendations.

Conclusions:

Collectively, the registry community is not aligned with and does not contribute to interoperability efforts. The inability to exchange data between EHR systems and registries and the inability to share standardized data across registries are barriers to interoperability and achieving the goal of generating real-world evidence. The project further noted that the specification of data elements in federal initiatives such as the USCDI are not oriented toward clinical workflow and utility. A prime example is the representation of tobacco use per SNOMED-CT codes, rather than reflecting how questions about tobacco use are actually prompted in the clinic, used for clinical purposes, or evaluated in the medical literature.

The technical output of the project was a recommended technical implementation of core common clinical data elements for database programmers of electronic health information (including registry) systems. Should all parties
conform to the implementation, data liquidity and native data interoperability for the project concepts will have been achieved. The artifacts of the project are publicly available at www.dcri.org/registry-data-standards. Socialization efforts are underway. Next steps include first the acceptance and implementation by the registry community, and second the execution of projects that demonstrate the interoperable exchange of data between health care providers (via their electronic health information systems) and registry owners.

The work products also include a white paper that lists details of the project, recommendations for federal partners, registry owners, healthcare organizations, and standards development organizations. The environmental scan found that the current landscape lacks a single, authoritative approach to advance interoperability within and across the registry community. Key recommendations include identification of a common authoritative process to identify, define and specify standards for common clinical data elements and an agreed upon process for governance thereof. Also needed is a common data element repository or common clinical data element library to support the technical adoption of standard common data elements. Similarly, common data element, model tooling, and terminology repositories for candidate data elements are needed.

Collectively, we can leverage many opportunities that will elevate our health care ecosystem to one where the capture of clinically relevant data at point of care also serves the needs of care delivery, outcomes evaluation, quality/performance measurement, and medical product evaluation/surveillance. Doing so increases the availability of real-world data to create real-world evidence, contribute to knowledge generation and translate knowledge into practice to improve public health.

Abstract

Nocturnal hypoglycemia is a serious complication of insulin-treated diabetes, which commonly goes undetected. Continuous glucose monitoring (CGM) devices have enabled prediction of impending nocturnal hypoglycemia, however, prior efforts have been limited to a short prediction horizon (~ 30 minutes). To this end, a nocturnal hypoglycemia prediction model with a 6-hour horizon (midnight–6 am) was developed using a random forest machine-learning model based on data from 10,000 users with more than 1 million nights of CGM data. The model demonstrated an overall nighttime hypoglycemia prediction performance of ROC AUC = 0.84, with AUC = 0.90 for early night (midnight–3 am) and AUC = 0.75 for late night (prediction at midnight, looking at 3-6 am window). While instabilities and the absence of late-night blood glucose patterns introduce predictability challenges, this 6-hour horizon model demonstrates good performance in predicting nocturnal hypoglycemia. Additional study and specific patient-specific features will provide refinements that further ensure safe overnight management of glycemia.

Introduction

Hypoglycemia – typically defined as a blood glucose (BG) below <70 mg/dL – is one of the acute complications of diabetes in patients treated with insulin (1). Over half of hypoglycemic episodes occur during nocturnal sleep with a higher prevalence for insulin-dependent diabetes patients that include patients with type 1 diabetes (i.e., insulin dependent) more so than type 2 diabetes (2, 3). Although the definition varies, nocturnal hypoglycemia is usually defined by a predetermined time window for which the international consensus recommendation is from midnight to 6 am, a period that usually includes the duration of nighttime sleep and the longest interprandial interval (1, 4).

Nocturnal hypoglycemia is often asymptomatic due to a sleep-induced effect that shifts the counterregulatory activation to hypoglycemia to a lower threshold(4, 5). Unless severe and followed by a seizure, coma, or other noticeable impairment at the awakening time, it can go unrecognized and be prolonged in patients with type 1 diabetes, and in worst cases, can lead to ‘dead-in-bed’ syndrome (5). Detection of nocturnal hypoglycemia is critically important; if recurrent and undetected, even mild asymptomatic episodes can lead to further impairment of defenses against future episodes due to hypoglycemia-associated autonomic failure and defective counterregulatory responses to subsequent events (4, 6). In addition to the increased risk for future episodes, the daytime effects after an episode of nocturnal hypoglycemia, such as fatigue, impaired mood and higher calorie intake and weight gain, considerably lower quality of life (5).

Several risk factors have been associated with nocturnal hypoglycemia including demographic and non-demographic factors: age, race, BMI, comorbidities, stress, and diabetic nephropathy; physical exercise – with greater risk associated with evening exercise; tight glycemic control; excessive insulin concentration during the day; previous episodes of nocturnal hypoglycemia; and low bedtime glucose levels (2, 7, 8).

With the recent availability of continuous glucose monitoring (CGM) devices, better diabetes management is possible that includes detection of asymptomatic episodes of nocturnal hypoglycemia that go unrecognized with self-monitoring blood glucose (SMBG) devices, which are not commonly used during sleep hours. In fact, the 2017 American Diabetes Association (ADA) consensus statement on measures beyond glycated hemoglobin emphasizes the role of CGM in diabetes management, especially for nighttime and asymptomatic hypoglycemic events, which SMBG devices typically fail to detect, and provides standardized recommendations for analyzing CGM data (1, 9).

The richness of CGM data has enabled extraction of many useful insights, such as retrospective analyses revealing trending patterns, that can increase the daily decision-making power of diabetes patients. Furthermore, CGM data
combined with artificial intelligence (AI) techniques can provide prediction of impending adverse events, such as hyperglycemia or hypoglycemia, within a time horizon leading to the event. Contreras and Vehi provide a review of (10)1849 articles from 2010-2018 applying AI techniques focused on predicting BG levels. The AI techniques were categorized into learning models that included neural networks and decision trees, information discovery models, such as clustering techniques, and models to extract reasoning from information, such as Bayesian methods. The review also reports a smaller group of studies on detection of adverse effects of diabetes, such as hypoglycemia or hyperglycemia. The majority of the reported studies in this category, however, address real-time detection of adverse effects rather than predicting future events within a prediction horizon.

Very few researchers have developed models to predict nocturnal hypoglycemia using CGM data (11-13). One model, for instance, was based on a Kalman filter method with earlier version of the work including voting algorithm approach (11). Another group of researchers used a support vector regression model originally developed for diurnal hypoglycemia detections with added features of physical exercise and sleep time to predict nocturnal hypoglycemic events (12). These studies were limited by small cohorts, dependency on additional sensors (e.g., motion, sleep), and unrealistically optimal patients’ data entry in controlled environments. In addition, a major limitation of these methods is the short prediction horizon, typically chosen at 30 minutes prior to impending hypoglycemic event. With the short prediction horizon, such models are usually used in the context of CGM-enabled insulin pump devices, which have an automatic corrective mechanism to control and suspend the basal insulin delivery. However, the long prediction horizon, such as the work proposed herein, is applicable to broader CGM users including the non-pump users.

Another important factor that has not been examined in the prediction of nocturnal hypoglycemia is the marked distinction between the early (normally defined by midnight-3 am) and late portion of nighttime sleep (3-6 am). The early stage of sleep is considered in the slow wave sleep (SWS) while late sleep is dominated by rapid eye movement (REM) portion of the sleep cycle. These phases of the sleep cycle dictate different glucose needs from the brain, which are markedly reduced in early sleep compared to late night sleep or awake time (14). It is reported that 60% to 70% of nocturnal hypoglycemic episodes occur during late sleep, between 3 am and 7 am (14). Compared to early nighttime hypoglycemia, the counterregulatory hormone response is significantly weaker during late night hypoglycemia (5). Moreover, due to distinct physiological differences, some of the treatment recommendations, such as bedtime snack, were found to be effective for only early nighttime hypoglycemia, but not for late night events (5).

The most ideal approach for minimizing nocturnal hypoglycemia is, therefore, to enable patients to manage their impending hypoglycemia well before going to sleep. This means extending the prediction horizon for the duration of sleep. This manuscript describes an effort to develop a prediction model from CGM data with an extended prediction horizon. The early performance results along with the challenges of early and late-night hypoglycemia prediction are reported.

Methods

Based on the ADA guideline of international consensus on using CGM device (1), nocturnal hypoglycemia was defined by the glucose level falling below 70 mg/dL and lasting at least 15 minutes. An overall nighttime hypoglycemic event was defined by the episode happening from midnight-6 am; early-night hypoglycemia was defined from midnight-3 am, and the late-night events from 3-6 am.

Over 1 million nights/days of CGM data were voluntarily uploaded by 9,800 individuals with type 1 diabetes using the MiniMed™ 530G system (Medtronic MiniMed Inc., Northridge, CA) Data from a 6 pm to 6 am window were analyzed. MiniMed™ 530G system users had the option of turning on the system’s threshold suspend feature and setting it to a value between 60-90 mg/dL in consultation with their physician. Upon suspension of insulin delivery, an alarm alerts the user of the pump suspension and, if not disabled by the user, the suspension can last up to 2 hours before insulin delivery resumes. All of the users in the present study had the threshold suspend feature activated with different predefined low threshold, which for the majority was set to 60-70 mg/dL.

The prediction was based on a random forest machine learning model composed of 100 trees and built using python scikit-learn library. Each decision tree spits out a prediction score and the final class is defined by the class with the highest ensemble-average probability score. The random forest classifier was selected for its robustness, accuracy, scalability, and ease of maintenance. For the testing purposes, prior to model finalization, a smaller dataset comprised of approximately 1000 users each with an average of 300 nights of uploaded data (total of 300K nights) was also considered. The positive label for the nights in the dataset was assigned if at least one nocturnal hypoglycemic event was detected per night. The total night samples were first sorted from the furthest night to the most recent night in increasing order by the timestamp of the users streaming the data. The first 80% of the dataset was then considered
for training (10-fold cross validation) and the latest 20% of the data was reserved for the holdout test. The model performance was assessed based on the night data in the test set using the area under the curve (AUC) of the receiver operating characteristics (ROC) curve.

The feature vector was composed of three categories of features: SG features, count-based features, and temporal location features. SG features were extracted as statistical properties of the previous sensor glucose time series. Count-based features were simply a count of the number of hypoglycemic events in the past windows. Temporal location features captured the time of day and day of week, which are important because hypoglycemic events have a tendency to recur on a daily or weekly basis. For the same model, three types of performance for nocturnal hypoglycemia prediction were assessed with similar feature vectors and prediction timepoint at midnight, which included 1) overall nighttime with 6-hour prediction horizon (midnight-6 am); 2) early-night with 3-hour prediction horizon (3-6 am); and 3) late-night with 6-hour prediction horizon (midnight-6 am) only looking to predict if the hypoglycemic event happened 3-6 am.

Results

Study Population

The 9,800 users had a mean±SD age of 45.34±16.38 years (51% female and 49% male) and had been using the MiniMed™ 530G device on average for about 100 days and had been on insulin at least 1 year and maximum of 71 years. The CGM device enabled users to log their carbohydrate consumption as well as administer insulin boluses, although these auxiliary inputs were at the users’ discretion and not consistent throughout their uploads. The prevalence of nocturnal hypoglycemia among the users was 18.7% for the overall nighttime period (12-6 am), where 12.7% of the users exhibited early-night and 11.8% exhibited late-night hypoglycemia.

Overall Nighttime Prediction

The overall nighttime prediction covered the prediction horizon of 6 hours, from the midnight to 6 am, for each user. This prediction duration was for any hypoglycemic event that occurred regardless of its occurrence during early or late night. The overall performance of the model based on the total number of nights (collected from different users) in the test dataset was 0.84 as depicted in Figure 1 by the full AUC metric. The scatter plots show the AUC-based model performance for each user in the test dataset as a function of hypoglycemia prevalence in the totaled nights (about 300 nights) for each user. When the number of users was increased 10 fold, the performance of the model remained unchanged (Figure 1b). The performance of the model deviated less from the mean as the prevalence of hypoglycemia increased indicating more stable hypoglycemia detection for users with higher recurrence.

![Figure 1: Model performance for the overall nighttime hypoglycemia prediction with 6-hour prediction horizon for approximately 1000 users (a) and 9800 users (b). Scatter points represent AUC values for each user in the test dataset. Full AUC represents the value calculated over all the data points included in the test set.](image)

Early versus Late-Night Prediction

The counterregulatory hormone response to low BG during the early and late portion of the night makes differs for these two stages of sleep with respect to predictability of hypoglycemic occurrence. For the early-night hypoglycemia
prediction with prediction horizon of 3 hours from midnight, the model yields 0.90 AUC-based performance as calculated by the full AUC metric (Figure 2a). A separate prediction for the late night for the same user population, however, reveals a lower performance of 0.75 by the model (Figure 2b). For both predictions and for the users with greater hypoglycemia prevalence (referred to as skew in the plots), the user-based performance of the model approached the mean value.

![Figure 2: Model performance for early-night model with 3-hour prediction horizon (a) and late-night model with 6-hour prediction horizon (b) for 9800 users. Scatter points represent AUC values for each user in the test dataset. The full AUC represents the value calculated over all the data points included in the test-set.](image)

**Late-Night Patterns**

To understand the more specific patterns associated with the late-night hypoglycemia, the smaller dataset of about 1000 users (approximately 300 thousand nights of data) was assessed more closely. The variable-wise probability density functions of two samples were compared for the same components of the feature vector as described in the Methods section: the sample size of 11% (of all the nights) with history of late-night hypoglycemia (positive labels) and the sample size of 77% with no late-night history of hypoglycemia (negative labels).

The comparison revealed some unique characteristics for user with late-night hypoglycemia which include: lower SG values at midnight, average downward SG trend before midnight, higher recent hypoglycemic event count, and, in general, a non-zero count of late-night hypoglycemia over the past couple of months.

**Trends in False Negatives Predictions of Late-night Hypoglycemia**

Comparing the early-night and late-night predictions, the rate of false positives was similar, but the false negatives were significantly higher in the late-night predictions. For the late-night false negative predictions, the users could be categorized into four distinct classes as described in Table 1. The illustration of an example for each class is shown in Figure 3 for class 1 (Figure 3a), class 2 (Figure 3b), class 3 (Figure 3c), and class 4 (Figure 3d).

Discussion

This manuscript describes one of the first attempts to use CGM data to predict nocturnal hypoglycemia with an extended time horizon on a large cohort (~10,000 individuals) with more than 1 million nights of sample data from a wide demographic population (Insert some of the demographic attributes). The main goal of this study was to assess the feasibility of predicting nocturnal hypoglycemia solely based on CGM sensor glucose readings. The presented model can predict hypoglycemia events throughout the nocturnal sleep interval with the prediction horizon of 6 hours at the midnight timepoint with an AUC of 0.84. One previously reported predictive model using a prediction horizon greater than one hour showed that performance decreased with horizon extension, but was optimized when set on 30 minutes (15). To our knowledge, this is the first study using CGM data with a 6-hour extended prediction horizon and high performance, which might enable patients to better address potential hypoglycemia prior to going to sleep.

The main limitation of models with short prediction horizons that are typically around 30 minutes is that they are normally coupled with an automatic insulin suspension (shut-off). This automatic control was designed to reduce hypoglycemic exposure and to help individuals prone to hypoglycemia and/or with impaired hypoglycemia awareness (14). Although, overall, predictive low glucose suspension has been shown to effectively reduce exposure and frequency to nocturnal hypoglycemia (16-18), it can result in some elevation of glucose levels during the night and in the morning, or increase the time spent in moderate hyperglycemia (17-19).

It is also important to note that the use of threshold suspend is not particularly designed to eliminate the hypoglycemic events since it normally becomes active at the start point of the episode; however, depending on the threshold setting, this feature can be helpful in shortening a hypoglycemic event. As a result, the use of threshold suspend in our subjects did not eliminate the nocturnal hypoglycemic episodes. Similar observation has been reported by the Juvenile Diabetes...
Research Foundation study (6) where frequent and prolonged hypoglycemic episode were noticed despite the activated nighttime CGM profile to adjust overnight basal delivery rate. Thus, the ultimate objective of this research is to benefit large spectrum of CGM users by leveraging the large data set collected from insulin pump users to evaluate the potential of nocturnal hypoglycemia prediction.

**Challenges of Late-Night Hypoglycemia Prediction**

Due to differences in counterregulatory responses to low-glucose levels during the early portion of the sleep cycle versus the late portion (dominated by REM sleep), as well as influences from circadian factors, it is expected that hypoglycemia prediction follows a different pattern in each portion of sleep. In fact, this study showed that, when using the same feature parameters, prediction of early-night hypoglycemia results in significantly a higher performance (AUC = 0.90) compared to late-night prediction (AUC = 0.75). While the false-positive rate was similar for both predictions, late-night prediction suffered from significantly higher false negatives and thus, a greater chance of missing an impending late-night hypoglycemic episode.

This observation indicates that a different or additional set of features that can more specifically relate to late-night sleep characteristics may be required for improved prediction. More specific features, in turn, implies having thorough understanding of the relationship between the late-night portion of sleep and hormonal response to BG regulations. Unfortunately, for insulin-dependent patients, this relationship is not fully understood as the bolus insulin and body’s natural insulin secretion do not follow similar glucose regulation (2). In fact, when it comes to insulin and body counterregulatory responses, contradictory findings have been reported. For example, the Somogyi effect or rebound hyperglycemia, is the phenomenon that causes the BG to rise to the hyperglycemic level in early morning in counterreaction response to a severe drop in late-night BG to hypoglycemic levels. This Somogyi effect could perhaps be recognized in some of subjects in this study classified as #1 and # 3 in Table 1. However, some other researchers have challenged the Somogyi effect and in fact, reasoned a lower rather than higher BG level in the morning due to sleep-induced impaired counterregulatory responses (5). Adding to the complexity of the matter is the fear of encountering a hyperglycemia episode in patients that face an elevated SG reading at bedtime; this result could motivate them to administer bolus insulin or skip the valuable bed time snack. For instance, in our cohort, 30% of the nights SG readings started above 180 at midnight; subsequently 6% of those nights had late-night hypoglycemia. This adds to the challenges of predicting impending hypoglycemia solely based on SG readings if at the prediction timepoint an SG reading is at a hyperglycemic range.

Although several risk factors have been associated with nocturnal hypoglycemia, the predictive power of those risk factors still remains to be fully investigated and trusted (5). Some researchers have found weak link between patients demographics, such as age, sex, years of diabetes, and hypoglycemia (20). While the Somogyi effect seems to be correlated with a higher sum of bolus insulin, Woodward et al. (21) found neither an association of total insulin bolus to nocturnal hypoglycemia, nor any link between type of insulin, and frequency of insulin injection. The only predictive factor reported was bedtime SG level.

Besides patients’ demographic and CGM-based SG trajectory measurements, other studies on nocturnal hypoglycemia have looked to include more auxiliary input data provided by the patients to strengthen the prediction power. These additional data inputs include nutritional intake logs and insulin regimen (type, dose, time). Although valuable inputs, and possible to collect under controlled study conditions, the lack of consistency of log entries introduces a challenge for building a predictive model in free-living situations.

In addition to nutritional intake and insulin regimen, physical exercise and emotional state (such as stress and anxiety) have shown to affect glucose hemostasis. For instance, it has been reported that daily stress can increase the instability of glucose levels and risk of hypoglycemia (22). Physical exercise for insulin-dependent diabetes patients has been among the factors most strongly associated with severe hypoglycemia. Exercise enhances the insulin sensitivity in the muscles which can result in lowering of BG levels up to 8-10 hours after exercise. Thus, if performed during the evening, strenuous activity can pose a great risk for late-night hypoglycemia (23). In fact, Campbell et al. (7) reported that the risk of hypoglycemia following an evening exercise can be alleviated by consuming the snack only for the early stage of sleep but not in the late portion of the night. Due to the strong association of exercise and emotional state of the patients with insulin and glucose metabolism, some studies have used additional sensors to track these stimuli and include them in the feature space of the predictive models (12, 13). Eren-Oruklu et al. (13) showed improved performance of their hypoglycemia predictive model with inclusion of emotion and physical activity compared to their previously developed model without these factors. Although important and beneficial, the inclusion
of these factors and the use of additional devices besides CGM can also introduce a challenge in predicting late-night hypoglycemia in free-living conditions.

Besides exercise and stress, it is important to recognize the impact of the sleep pattern on the body’s physiological hormonal response to BG regulation. According to the report by the Centers for Disease Control and Prevention, about 1 in 3 adults do not get enough sleep and 15% of Americans work the night shift and many more work at night in addition to their day work thus, having irregular circadian rhythm (24). Irregular sleep pattern, short duration of sleep, and poor-quality sleep have been associated with prevalence of diabetes and impaired insulin response, and directly impact the nocturnal counterregulatory response to hypoglycemia (25). Although a predefined window of sleep from midnight to 6 am was considered in this study according to the recommendation by International Consensus on Use of CGM (1), it is important to recognize that not all the subjects sleep during this window and for the full duration.

Future work will focus mostly on the nocturnal hypoglycemia and on developing methods to include more patient input, most importantly emotion, exercise, and sleep pattern. This will also include methods to detect meals consistently since food logs could be inconsistent. Moreover, since some of the false-negative cases revealed some of the late-night glucose profile characteristics, such as Somogyi effect, we anticipate prior detection of these events could also help with the prediction modeling. Some of the long-term effort will also focus on developing personalized models to help patients better manage their diabetes according to their living conditions, such as their unique sleep pattern and BG profile.

**Conclusion**

This manuscript describes a model using CGM data to predict nocturnal hypoglycemia with acceptable performance with an extended prediction horizon. Early night prediction was more accurate than late night prediction. We attribute challenges in late-night hypoglycemia prediction mainly to lack of clinical understanding of some of the residual effects during the day manifesting at this portion of the sleep. We anticipate inclusion of additional BG-altering stimuli, such as emotion, exercise, and sleep patterns, that may improve late-night hypoglycemia predictability. However, inclusion will require additional devices that may not be convenient for patients in free-living conditions. Future work will focus on more data-driven methods to predict patient-specific inputs in order to enrich the model feature vector and improve the predictability.

Abstract
Modeling variance in patient outcomes using medical claims and other forms of aggregated administrative data may ignore significant contributions associated with providers who are not recorded in billing transactions. We examined the association between interdisciplinary provider factors and length of stay (LOS) for 1,099 lumbar spine surgery patients. Interdisciplinary provider “dose” (number of providers/case), “workload” (care of other patients), and “activity” factors were defined and generated. Hierarchical Regression models were used to test the impact of these provider factors controlling for the effect of socio-demographic and clinical factors. Interdisciplinary provider factors explained 12% of additional variance in LOS. EHR-based interdisciplinary care team representations hold promise in contributing to our understanding of health care delivery and quality.

Keywords: interdisciplinary care, nursing documentation, workload, length of stay, electronic health records (EHR)

Introduction
While traditional health care delivery and quality analysis incorporates clinical factors1-4 such as disease type and severity, there is considerable variation in outcome that is not explained leading to studies that incorporate additional social determinants of health, environmental, and genetic attributes. Health care delivery systems and provider characteristics may also be considered as a source of such additional variance4-6. Provider characteristics such as licensure, clinical experience, professional education and training, and knowledge of practice guidelines have led to variations in treatment, outcomes, as well as the cost of care1,7,8. Past research that modeled the shared variance between provider characteristics and patient outcomes has been based on billing data, unit level aggregated data, or survey data9-13. However, billing and aggregated data does not represent many of the providers associated with treating a patient, such as nurses, medical residents and other non-physician professional providers. Thus, such models could either mask or combine the contribution of important members of the care team. Furthermore, assessing the contribution of the individual provider, especially nurses, to clinical outcomes is considered to be challenging due to the lack of valid measures14,15. Compared to billing and other forms of aggregated data, electronic health records (EHRs) provide comprehensive clinical and care process data, time-stamped with contribution of individual providers (non-billing)16-18. However, only limited research has utilized EHR data to measure the contribution of individual providers and investigate the impact of provider characteristics on patient outcomes19.

The length of stay (LOS) is a frequently used patient outcome and a proxy measure of the cost that depends on many clinical and non-clinical factors. A comprehensive systematic review of 107 articles on the use of EHR to develop risk prediction models from 2009-2014 only reported three studies with LOS predictions20. However, none of these models include provider attributes, especially related to nursing or other non-physician professionals. There are many studies that
utilized the aggregated and other forms of provider (mainly nursing) data which showed positive effects of provider characteristics on reducing LOS\textsuperscript{21,22}. Results of research reviewing 17 articles examining the relationships between nurse staffing and LOS showed evidence for reductions in LOS associated with higher ratios of nursing personnel in hospital settings\textsuperscript{22}. Furthermore, the recent studies by Cho et.al. (2017) concludes that the nurse staffing (fewer patients per nurse) was significantly associated with the reducing LOS of surgical patients\textsuperscript{23}. Also, a meta-analysis on nursing workforce characteristics by Kane et.al. (2007) found strong evidence on direct care RN hours leading to shorter LOS\textsuperscript{24}. However, measures used in these studies could not distinguish between providers in direct patient care or those involved in administrative or outpatient activities due to the aggregate nature of the data. Also, the cross-sectional datasets used in these studies do not allow the opportunity to study trends or estimate lagged-timing effects. Understanding these trends or lagged effects could better explain the relationship between nursing and other professional care flow and resulting LOS, that could ultimately lead to optimizing the available provider resources for better patient care\textsuperscript{24}.

Factors effecting the LOS among clinical populations managed by interdisciplinary providers is of a greater interest. Populations undergone spinal procedures are generally associated with intense pain in the postoperative period, especially for the initial few days\textsuperscript{25,26}, and are typically managed by interdisciplinary provider teams. Adequate pain management in this period has been seen to correlate well with improved functional outcome and LOS\textsuperscript{25,27,28}. Lumbar Spine surgery (LSS) is a common spinal procedure done in hospitals, and usually considered a treatment of certain spinal disorders when conservative management of pain and other symptoms fail. The rate of LSS is highest in the United States compared to other countries, and associated with high surgery cost and related post-surgical care\textsuperscript{28,29}. Following surgical procedures like LSS, providers from many disciplines work together to reduce the pain and increase mobility for timely discharge. Nurses contribute with ongoing pain assessment, developing the pain management plan, implementing non-pharmacologic interventions (cold therapy, music therapy), and evaluating responses to such interventions for adjusting the pain management plan\textsuperscript{30,31}. Physicians contribute with ordering analgesics (particularly opioids) and ordering physical therapy interventions depending on the patient recovery. The physical therapist (PT) contributes to patient care by assessments and conducting mobility trainings\textsuperscript{28,29}. Respiratory therapists (RT) may also be involved in the care of patient recovering after LSS\textsuperscript{32}.

The purpose of this preliminary cohort study was to examine the effect of interdisciplinary provider factors on the LOS after LSS. We hypothesized that the number of providers (provider dose) performing patient care activities during the first two days following LSS is associated with LOS. Also, we hypothesized that the provider workload across multiple patients under their care influences LOS. Thus, the specific objectives of this study were to: (i) Examine the variance in LOS explained by the provider workload (as defined by their documented activities for other patients during the first two days) above and beyond the variance explained by the socio-demographic and clinical factors for different provider types, (ii) Examine the impact of provider dose (e.g. the number of distinct providers during the first two days) on LOS controlling for the effect of providers’ level of activity within the encounter and their workload on other patients, (iii) Examine the variance in LOS explained by the interdisciplinary provider factors: workload, level of activity, and dose (during the first two days) above and beyond the variance explained by socio-demographic and clinical factors.
Methods

Data Sources and Study Cohort
Data for this retrospective study were extracted from the University of Kansas Medical Center’s Healthcare Enterprise Repository for Ontological Narration (HERON), an i2b2-based clinical integrated data repository\textsuperscript{33,34} that includes EHR, billing records, and clinical registries. We identified the cohort of interest from the HERON system using the i2b2 query and analysis tool with specific current procedural terminology codes to select patients who had posterior LSS consisting of laminotomy, laminectomy, or fusion (arthrodesis) during the period January 2008 to December 2018. Patients 45 years or older with LOS of three days or more (as defined by billing records reported to the Vizient Clinical Database\textsuperscript{35}) and who have inpatient PT assessment data were included. Medical records were excluded for patients with a history of neoplasm, intraspinal abscess, spinal deformity (i.e., scoliosis and kyphoscoliosis), spine fractures, vertebroplasty, osteomyelitis, and cauda equina syndrome. Based on these criteria, a cohort of 1,099 patients was identified.

Selection of Measures and Covariates
All the variables of interest for the study were selected from the HERON system. Clinical and socio-demographics were selected based on the most commonly used variables to predict LOS flowing inpatient stay in general, but are acknowledged to be limited in scope as the focus of this study was to develop and evaluate novel representations of the interdisciplinary care teams\textsuperscript{36,37,38,39}. Interdisciplinary provider factors were generated from the discrete care activities performed by different provider types: medication administrations (by nurses), flowsheet documentation (by nurses), medication orders (by physicians), procedure orders (by physicians), flowsheet documentation (by physical therapists), and flowsheet documentation (by respiratory therapists).

Provider factors described as Dose, Workload, and Activity were defined as follows:

- **Dose**: the number of distinct providers involved with patient care during the first two days. (e.g. 3 distinct nurses administered medications during the first two days). In the data set we have 6 variables, each representing one provider type related activity.
- **Workload**: represents the activities for and severity of the other patients a patient’s providers cared for during the first two days. Workload factors were created using following three sub-components.
  - **Other patients**: number of other patients cared for by the providers (during the two days these 3 nurses did medication administrations for 7 other patients).
  - **Other patients’ severity**: average severity of other patients (average value of All-Patient Refined Diagnosis Related Group (APR-DRG) severity of 7 other patients is 2, which indicates on average they cared moderately severe patients).
  - **Other patients’ activity**: average number of activity (EHR facts available) for other patients (on average these 3 nurses did 15 medications administrations per other patients they cared during the first two days).

- **Activity**: Number of activities (EHR facts available for medication administration by nurse, flowsheet documentation by physical therapists, etc.) for the given patient/encounter (during the first two days these 3 nurses performed twelve medication administration on the given patient).

Abbreviated but representative Clinical and Socio-demographic factors used to establish a baseline for variance analysis included Medical Severity Diagnosed Related Group (MSDRG), Charlson comorbidity index, Intensive Care Units (ICU) days, Age at Admission, Gender, Race.
Data Management and Statistical Analysis

Prior to conducting inferential statistical analysis, univariate normality of continuous variables was tested, and transformations were performed whenever needed (natural log transformation for LOS). Sixteen outliers were identified using criteria of standardized values falling outside the range of -3 to +3 interval\cite{40,41} and removed prior to the analysis. To decompose the variance attributed to various factors, we fitted a hierarchical regression model with natural log transformed LOS as the dependent variable. Variables representing socio-demographic factors and clinical factor were entered at the first step. We updated the baseline model (at the first step) for each provider type specific activity (e.g. medication administration by a nurse, medication orders by a physician, etc.). At the second step we entered the workload factor (to address objective i), and at the third step we entered the provider activity factor (control variable). At the fourth and final steps we entered the provider dose factor (to address objective ii). The variation attributed with each step of the hierarchical model (all provider types combined) was graphically analyzed using a Venn diagram representation (to address objective iii).

Results

The study sample of 1,099 patients had total of 1,146 encounters following LSS with 583 encounters (50.87%) for men and 563 (49.13%) for women. Majority of the encounters 967 (84.38%) were for white patients, while 103 (8.99%) encounters were for African Americans. The average age of these patients at the time of the encounter is 64.94 (SD=12.76). Almost equal proportions of patients in the sample were categorized with moderate severity (43.80%) or minor severity (43.45%), 10.38% of patients in the sample were categorized as having major severity, and remaining (approximately 2%) as extreme severity. Average LOS following LSS for this sample was 5.38 (SD=4.90). 150 encounters (13.09%) had ICU days with mean ICU days being 2.85 (SD=4.79). The average value of Charlson comorbidity index for LSS patients in this sample was 1.98 (SD=1.48).

Providers Associated with Patient Care

During the first two days following LSS, out of the total 223 physicians involved, 135 physicians ordered medications, while 211 physicians ordered medical procedures. Out of the total 1,387 nurses involved, 1,137 nurses administered medication, and 1,058 nurses have documented in flowsheets. Based on the flowsheet documentation there were 76 physical therapists and 183 respiratory therapists treating LSS patients during the first two days following LSS. Summary statistics in Table 1 shows, during the first two days, on average 5 nurses were involved with LSS patients care, while 1 to 2 physicians were involved with ordering medication or procedures. Also, most of the encounters had two physical therapists and two repository therapists involved. The average number of medication orders by physicians (32.66) slightly exceeded the average number of medication administrations (30.99) by nurses; perhaps scheduled orders for administration after the first two days or at discharge. Nursing flowsheet documentation activity was five to six times greater than physical therapists and with higher variance (coefficient of variance; 0.84) between encounters compared to physical therapy documentation activity (coefficient of variance; 0.61).

LOS Distribution for MSDRGs

Patients in the sample were assigned into 34 different MSDRG categories with the majority (40.83%) assigned into MSDRG 460 (Spinal fusion except for cervical without MCC), and 7.15% without any particular DRG code assigned. We combined the other DRGs into meaningful groups by keeping adjacent MSDRGs together. To visualize we recoded the provider dose (number of providers associated with care) for each encounter as “Low” if the provider dose for that particular
encounter was less than the median for all the encounters, and otherwise as “High”. As shown in Figure 1, the encounters assigned with MSDRG:460 having either low or high provider dosage has approximately equal median LOS, with low dose having relatively more outlying cases for all six provider related care activities. For most of the other DRGs, procedure orders by more physicians were associated with longer LOS. Furthermore, for most DRGs flowsheet documentation activity by less nurses, physical therapists, and respiratory therapists was associated with longer LOS.

Figure 1: Relationship between provider dose and LOS (for MSDRGS)

A-Medication administrations by nurses, B-Flowsheet documentations by nurses, C-Medication orders by physicians, D-Procedure orders by physician, E-Flowsheet documentations by physical therapists, F-Flowsheet documentations by respiratory therapists
Decomposing Variance: Baseline Model

Baseline regression model explained 20.39% of variance in LOS with (R=.45, Adj. R² =19.39, F(14,1113)=20.36, p<.001). Race, Age at visit, ICU days, MSDRG and Charlson Comorbidity were significant predictors of LOS (p<.01, p<.05, p<.001, p<.05 respectively). Compared to White patients African American patients (β = .0098 and p<.01) had higher LOS. Compared to encounters with unassigned MSDG, encounters having other DRGs, groups;453-455 (β = 0.163); 456-459 (β = 0.176); 471-473 (β = 0.180) had higher LOS. Age at visit showed a quadratic relationship (β = .000048) with LOS. As ICU days increased by one unit and Charlson comorbidity increased by one unit LOS (at log scale) was incised by (β = .141), and (β = .018) units respectively.

Decomposing Variance: By Different Provider Type and Related Care Activity

The additional variance in LOS that is attributed to each step (for provider factors, beyond the first step) of the hierarchical regression and unstandardized β value for the provider dose effect is shown in Table 2. Variance portioning at the second step showed significant impact of workload factor on explaining variance in LOS among all three non-physician provider related activities, significant impact for medication orders by physicians (p<.05), while non-significant impact for procedure orders by physicians. With respect to nursing, workload factor with flowsheet documentation had slightly higher impact on LOS than medication administration (2.71%, p<.001 compared to 1.98%, p<.01). Variance portioning at the third step showed significant impact of provider activity factor on explaining the variance in LOS only for physicians and physical therapist. Additional variance in LOS explained by the provider dose factor at the fourth step was significant only for physicians and respiratory therapists. Thus, above and beyond the variance explained by all other factors, physician dose and respiratory therapists dose has an impact on explaining additional variance in LOS. Among the set of final four step models, the highest additional variance in LOS was observed for the model with flowsheet documentations by physical therapists. Positive unstandardized β values for provider dose indicates that, controlling other factors, increasing the provider dose had led to increase the LOS in all provider type and related activities. However, this effect is significant only with both types of orders by physicians and respiratory therapy flowsheet documentation activities.

**Decomposing Variance: For All Provider Types and Related Care Activities**

Following similar hierarchical approach but using the full set of variables (all 6 workload variables, all 6 activity variables, and all 6 dose variables) for all provider type and related activities, we investigated the overall variability in LOS explained by the provider factors above and beyond socio-demographic and clinical factors. As illustrated in Figure 2, we started with the baseline model which explained 20.39% variance in LOS, and addition of workload factors (now workload for medication administration by nurses, workload for flowsheets documentation by nurses, workload for medication order by physician, etc.) explained 6.40% of additional variance (p<.001) in LOS. Adding provider activity factors explained additional 2.27% (p<.001) of variance in LOS. Adding provider dose at the final step explained additional 3.27% (p<.001) of variance in LOS. Final model with socio-demographic and clinical factors, provider workload, provider activity, and provider dose accounted for 32.33% variance in LOS.

![Figure 2: Variance explained by socio-demographic, clinical, and provider factors](image)

**Discussion**

Our study sought to explore new representations of interdisciplinary care team activity and staffing, and then examined the variance in LOS after Lumbar Spine Surgery attributed to these provider factors. One of the important features of this study was that provider factors used in the analysis have rarely been considered in most of the studies predicting LOS. Further, we have considered modeling the effects of interdisciplinary providers, especially including non-physician providers, as they are extensively involved in patient care. Using comprehensive, time-stamped EHR data we created variables to represent providers’ workload on other patients they cared for during the same day, their activity with patients, and the exact number of providers associated with the care for a given time frame (provider dose). Compared to aggregate data, such variables (factors) provide more accurate and direct measures to investigate the effects of provider attributes on LOS. With newly constructed factors and complied EHR data, we were able to quantify interdisciplinary provider activity following LSS at a more detailed level. Post LSS patient care for the study cohort was performed by interdisciplinary care team consisting of but not limited to, nurses, physicians, physical therapists and respiratory therapists. As a major finding, our study confirmed the significant contribution of interdisciplinary provider factors on explaining the variation in LOS.
While a comprehensive clinical analysis of LOS was not the focus of this study, consistent with previous LOS studies, we found significant contributions of age, race, and ICU days, comorbidities, and medical severity to the variance in LOS for patient stays following LSS. Our results showed that workload on other patients was a more significant factor explaining the variance in LOS than individual patient care activity and staffing. The impact of other patients’ workload on LOS was relatively strong for all three non-physician providers compared to physicians, while nurses’ flowsheet documentation workload showing the most significant contribution on explaining the variance in LOS. Our models identified the significant impact of physical therapy activities conducted on a given patient, and the level of physician activities on a given patient on explaining the variance in LOS. Positive unstandardized $\beta$ values for provider dose indicates that, controlling for other factors, increasing the provider dose leads to an increase in LOS for all provider type and related activities. Results showed stronger physician dose effect and repository therapy dose effect on LOS. Previous studies on nursing showed positive effects of nursing staffing on LOS at the aggregate level and our study captured the effect of direct nursing care and was able to confirm the association between of many different nurses providing the care at the initial stages on increasing the LOS. One of the other important features of this study was that we analyzed the overall shared variability by combining the effects of all interdisciplinary provider types and related activities.

Findings of this study can be useful to hospital administrators when making daily work assignments. As higher provider workload driving longer LOS, for example, with nurses’ work assignments, hospital administrators may consider a balance between the severity of patients and number of patients. Also, with results indicating higher provider dose at the initial days of care driving longer LOS, for example, they may consider assigning the same physical therapist, as scheduling allows, for handling the patient care activities during the post-surgery rehabilitation. Overall, hospital administrators can utilize the results found in this study to identify better provider assignment, workload allocation, and scheduling strategies. Finally, while the final model with socio-demographic and clinical factors, and three provider factors accounted only for 32% variance there is ample opportunity for researchers to include a set of comprehensive clinical characteristics as well as define and evaluate additional provider factors to further decompose the variance in LOS.

**Limitation and Future work**

While we leveraged comprehensive EHR activity data to create provider factors, their definitions were prospectively defined by the investigators and represent an initial conception of interdisciplinary care team activity. In this study, we have pre-selected a general and limited set of clinical variables, for future studies we have recognize the need for including variables that have been identified to be driving the variations in length of stay through evidence based practices for LSS patients. As we focus further on robust LOS analysis, identifying rich clinical factors and care practices (medications, procedures, diagnosis, complications, labs, functional measures, alerts, etc.) through high dimensional feature (variable) selection machine learning algorithms may also be appropriate. Moreover, in this study, we have mainly focused on provider activity related factors, but acknowledge the importance of defining clear and consistent provider factors while investigating the effects of provider type, specialty, experience and credentialing on the variance in LOS. Thus, we hope to extend this study by integrating these factors as well as provider work assignment data from other sources such as staffing and assignment systems, human resource
information systems, and other public provider data repositories like National Plan and Provider Enumeration System (NPPES), Nursys, and the National Database of Nursing Quality Indicators.

Conclusion
Our study shows the feasibility of generating richer representations of care team activity from the EHR and its potential value in decomposing the unexplained variance in outcomes (LOS) attributed to the direct patient care actives performed by interdisciplinary providers. The quantity, patterns and timing of direct patient care actives performed by interdisciplinary providers may someday provide actionable indicators of patient outcomes, including LOS. Additional research is needed to determine how these findings could be used to improve health care quality and delivery.

Achievability to Extract Specific Date Information for Cancer Research

Liwei Wang, MD, PhD1, Jason Wampfler¹, Angela Dispenzieri, MD1, Hua Xu, PhD², Ping Yang, MD, PhD³, Hongfang Liu, PhD¹

Abstract

Accurate identification of temporal information such as date is crucial for advancing cancer research which often requires precise date information associated with related cancer events. However, there is a gap for existing natural language processing (NLP) systems to identify dates for specific cancer research studies. Illustrated with two case studies, we investigated the feasibility, evaluated the performances and discussed the challenges of date information extraction for cancer research.

Introduction

Cancer is the second leading cause of mortality in the US and despite extensive research and rapid advancements made in understanding this complex and heterogeneous disease, further innovative research leveraging real-world patient data could spearhead major therapeutic development. Observational studies, classically used to identify risk factors and prognostic indicators, were shown to be effective in estimating treatment effects¹. Observational studies have the advantage of reduced cost, being timely and offering a broad range of observable patterns making them an appealing method for cancer research. However, in order to draw conclusive results, labor- and time-intensive conventional data collection methods are required for observational studies².

Over the last decade, Electronic Health Records (EHR) systems have been increasingly implemented at US hospitals. Huge amounts of longitudinal and detailed patient information, including lab tests, medications, disease status, and treatment outcome, have been accumulated and are available electronically. One of the challenges faced in conducting EHR-based cancer research is to extract information from clinical narratives. Cancer-related events can vary among different cancers. For example, “transplant” and “conditioning” before bone marrow transplant therapy are specific events for multiple myeloma. Traditional chart review has been labor intensive and expensive. With the advancement of cancer informatics research, natural language processing (NLP) techniques have been explored to extract cancer-related events with some success. In cancer research, accurate identification of temporal information associated with cancer-related events is crucial ³. For example, diagnosis dates and treatment start dates of cancers are both important for survival analysis ⁴,⁵, postsurgical death evaluation within 30 days ⁶ or evaluation of post treatment side effect ⁷. Pinpointing diagnosis dates of cancer at various stages are crucial for selecting therapy ⁸,⁹, therefore, it’s very important for personalized cancer therapy ¹⁰. Earlier diagnosis dates were also associated with more favorable outcomes among specific cancer types ¹¹. In addition, initial treatment date is an important factor for effective cancer management ¹² and better health outcomes ¹³.

Existing clinical NLP efforts focus on profiling time line instead of pinpointing exact dates associated with specific events for unstructured data. For example, the Sixth Informatics for Integrating Biology and the Bedside (i2b2) Natural Language Processing Challenge for Clinical Records ¹⁴ was to extract three types (before, after and overlap) of temporal relations between the given events and between events and temporal expressions with a focus on temporal reasoning in clinical narratives. The Clinical TempEval challenges in SemEval from 2015 to 2017 also addressed temporal information extraction and temporal relation tasks. The evaluation was conducted separately for time expression, event and temporal relations. Temporal relations (before, after, overlap, before_overlap), which is most related to the above issue of extracting dates associated with specific cancer events, were evaluated at two-level through 1) the most coarse level, i.e., relating events to the document creation time; 2) narrative container relations, i.e., the event occurred within a certain time frame, which is not specifically associated with a date. ¹⁵⁻¹⁸

Systems produced ¹⁹⁻²² based on the above tasks are capable to extract temporal relations only on document level between events and document creation time or between events and a certain time frame. Gaps exist in identifying date information for specific EHR-based cancer studies: 1) they mostly use documentation dates as anchor dates; 2) they are not capable to extract exact dates associated with specific events across clinical documents of the same patient; and 3) they have not been practically used and evaluated in real clinical context.
There are very few existing studies focusing on date extraction for observational studies. One study attempted to automatically generate an epidemiological line list for real-time monitoring and responses to emerging public health threats, disease onset date was identified with the accuracy of 0.01 to 0.37, outcome date with the accuracy between 0.36 to 0.66 using word embeddings. However, this was a population-level study, without emphasis on exact date extraction for precise research purpose. Ruud et al. used the SAS text mining tool (SAS Text Miner) to extract date, time, physician, and location information of follow-up appointment arrangements from 6,481 free-text dismissal records at Mayo Clinic. The 6,481 free-text dismissal records were manually reviewed by a health services analyst to determine whether the instructions contained follow-up appointment arrangements. Sensitivity of date extraction achieved 0.996 (0.994–0.998) and specificity achieved 0.842 (0.828–0.856). Nevertheless, the study only focused on dismissal records of in-patient encounters.

In this study, we investigated the date extraction task using two case studies: one from malignant solid tumors (lung cancer) and one from malignant liquid tumors (multiple myeloma), this study investigated the feasibility, evaluated the performances and discussed the challenges of date information extraction for EHR-based cancer research, which to our knowledge has not previously been studied.

**Methods**

Figure 1 shows the overall study design for the two case studies, i.e., lung cancer and multiple myeloma. We developed a rule-based information extraction system using the open source clinical NLP pipeline MedTagger as the platform. The system consists of two steps: (1) identifying events: we first identified sentences with events from electronic health records (EHR). Negated events were removed. (2) extracting dates associated with events: we then extracted dates within or around these sentences and linked the dates with extracted events. Evaluation was conducted against the reference standards after normalizing dates with MedTime and heuristic rules. The following sections will elaborate each part in detail.

![Figure 1. Overall study design.](image)

**Date sets**

For lung cancer, an existing lung cancer cohort containing 4,110 patients definitively diagnosed with primary lung cancer from 1997 to 2016 was used for this study. Previously human abstractor manually reviewed charts to extract diagnosis dates for each patient. In this study, clinical narratives from various data sources including pathology reports and clinical notes were retrieved from Mayo Clinic clinical data warehouse (CDW). We randomly selected 499 lung
cancer patients and associated clinical narratives as the training set for deriving language expression patterns. The remaining 3,611 patients were used as the test set to evaluate the NLP system.

For multiple myeloma, we randomly selected 318 patients with a treatment date after year 2000 from an existing multiple myeloma database consisting of 11,656 patients collected over the past 50 years. Human abstractors have manually reviewed charts to extract treatment start dates for each patient. Similar to lung cancer, we retrieved the associated clinical narratives from Mayo Clinic CDW. Among the 318 patients, 185 patients have information on chemotherapy and 133 patients have information on transplant. For chemotherapy, 93 patients were used for development and 92 were used for testing, for bone marrow transplant 70 were used for development and 63 were used for testing. Transplant data elements include transplant type, transplant mobilization and transplant conditioning. However, there were gaps in the data abstraction as for the patients who underwent stem cell transplant, not all patients had their mobilization and conditioning information extracted. In the training set, only 17 out of 70 patients had mobilization fields completed and 26 had conditioning fields completed. In the testing set, the respective numbers were 26 out of 63 and 41 of 63.

**NLP method**

For lung cancer, the event to be extracted was lung cancer diagnosis. We first identify the sentences with mentions of lung cancer diagnosis by developing a custom dictionary of terms that described the histological cell types of lung cancer, examinations of lung, symptoms of lung cancer and positive malignancy of lung tumor. This dictionary was developed using the training data set. For pathology reports, histological cell types of lung cancer and positive malignancy of lung tumor were used to identify lung cancer in the diagnosis section. For clinical notes, the whole dictionary was used associated with the mention of “diagnosis” to identify the sentence with lung cancer diagnosis. After extracting lung cancer diagnosis, we then extracted dates associated with this event from both pathology reports and clinical notes.

To extract dates associated with lung cancer diagnosis in pathology reports. A two-step strategy was developed:

1. If the lung cancer diagnosis was identified in pathology reports without the section of “Path Review of Outside Specimen”, then extract the dates of the pathology reports. Outside specimen refers to the specimen prepared by other institutions instead of Mayo Clinic.
2. If there is a section of “Path Review of Outside Specimen” in the pathology report, and the lung cancer diagnosis was identified from the outside specimen, then extract the date associated with the outside specimen.

To extract dates associated with lung cancer diagnosis in clinical notes. A three-step strategy was developed:

1. If a date was appearing in the same sentence with lung cancer diagnosis, then extract the date.
2. If there is no date appearing in the same sentence with lung cancer diagnosis, but there is a date appearing in the sentences surrounding that sentence with lung cancer diagnosis, then extract the date.
3. If there is no date appearing in the same sentence or surrounding sentences with lung cancer diagnosis, then use the clinical date as the date of lung cancer diagnosis.

For multiple myeloma, events to be extracted included chemotherapy and bone marrow transplant. Bone marrow transplant has three data elements, i.e., conditioning, mobilization and transplant type, each of them has multiple values (Table 1). To identify sentences with mentions of treatments, we also employed the dictionary lookup approach by constructing a dictionary consisting of chemotherapy drugs and transplant data element values. Additional keywords found during the training process were added into the dictionary.

**Table 1.** Values of three transplant data elements.

</tr>
<tr>
<td></td>
<td>5=Cyclophosphamide/TBI</td>
<td></td>
</tr>
</tbody>
</table>
After identifying the values of chemotherapy and transplant data elements using the dictionary, a four-step strategy was developed to extract dates:

1. If a date was appearing in the same sentence with values of chemotherapy or transplant data elements, then extract the date.
2. If there is no date appearing in the same sentence with values of chemotherapy or transplant data elements, but there is a date inference in the sentence such as “currently receiving bortezomib, day +7”, then we use the clinical note date as the anchor date to infer the actual date.
3. If there is no date or date inference appearing in the same sentence with chemotherapy or transplant data elements, but there is a date appearing in the sentences surrounding that sentence, then extract the date. In our study, we first label the anchor sentences with any mentions of values of chemotherapy or transplant data elements. Then one sentence before the anchor sentence and two following sentences after the anchor sentence were extracted.
4. If there is no date appearing in the same sentence or surrounding sentences with values of chemotherapy or transplant data elements, then use the clinical note date as the anchor date of values of chemotherapy or transplant data elements.

After the above steps, the extracted date information can be linked to chemotherapy as conditioning and mobilization are pre-transplant procedures. Therefore, after extracting all dates associated with the values of the three transplant data elements, dates of transplant type were used as the anchor dates to identify dates associated with mobilization and conditioning. Conditioning usually was done two days before transplant, we used a time window of 4 days to identify date of conditioning associated with transplant type. Mobilization may be done as early as more than one month before transplant, we used a time window of 80 days to identify date of mobilization with transplant type.

Date Normalization

Dates extracted from pathology reports are all in the formats like “4/10/12” or “2012-04-10”. In contrast, dates extracted from clinical notes could be expressed in different formats, for example, “6/12/14”, “05-02-2016”, “Jan 7th, 2013”, “June 2015”, “April 17th”, or even in unprecise way such as “the end of March”, “early July”, “late 2012”, etc. Therefore, it is necessary to normalize the extracted dates before evaluating against the reference standards which are in the format of “2013-10-28”. A strategy of two-level date normalization was utilized. For the extracted dates with “yy-mm-dd”, “mm-dd”, “mm” or “yy-mm”, MedTime was used to normalize the dates. For the unprecise time, a set of heuristic rules were developed to map them to exact dates.

MedTime is the open source NLP pipeline for clinical temporal information extraction. It uses clinical note dates as anchor dates and can be used to normalize the extracted dates. Input dates with year, month and day in various formats as mentioned above will be normalized to the format of “YYYY-MM-DD”. If the input date has only information of year and month, it will be normalized to the day of “15”. For example, “June 2015” will be normalized to “2015-06-15”. If the input date has only information of month and day, the clinical note year will be used as the diagnosis year. For example, if “April 17th” appears in the clinical note recorded on “2014-02-14”, it will be normalized to “2014-04-17”.

The heuristic rules were primarily used to normalize obscure time of year, season and month. The following rules were used to normalize obscure time of year. Using such heuristics, a substitute date can be generated for all cancer events, from aggressive cancer types to multiple treatments that could occur over a short period of time, to prevent any missing data in data analysis.

- Exact mention of year was normalized to the middle date of the year, July 1, e.g., 1998 was normalized to July 1 1998.
• Early year: Feb 15 of the year, e.g., Early 2000 was normalized to Feb 15 2000.
• Beginning of year: January 15 of the year, e.g., Beginning of 2002 was normalized to January 15 2002.
• Middle of year: July 1 of the year, e.g., Middle of 2004 was normalized to July 1 of 2004.
• Late year: November 15, e.g., late 2006 was normalized to November 15 2006.
• End of year: December 15, e.g., end of 2008 was normalized to December 15 2008.

Four seasons were defined based on a three-month interval with spring starts from March and ends after May considering the weather in Rochester MN. The following rules were used to normalize obscure time of season.
• Exact mention of seasons was normalized to the middle date of the season, e.g., spring 2012 was normalized to April 15 2012.
• Taking “winter” as an example of obscure mention of seasons:
  a. Early winter: Dec 31, e.g., early winter 2001 was normalized to Dec 31 2001.
  b. End of winter: Feb 15, e.g., end of winter 2003 was normalized to Feb 15 2003.
  c. Late winter: Feb 1, e.g., late winter 2005 was normalized to Feb 1 2005.
  d. Middle of winter: Jan 15, e.g., middle of winter 2007 was normalized to Jan 15 2007.

The following rules were used to normalize obscure time of month.
• Exact mention of months was normalized to the middle date of the month, e.g., January 2011 was normalized to January 15 2011.
• Taking “June” as an example of obscure mention of months:
  a. Early or beginning of June: June 5, e.g., Early June 2012 was normalized to June 5 2012.
  b. Middle of June: June 15, e.g., Middle of June 2013 was normalized to June 15 2013.
  c. Late or end of month: June 25, e.g., Late June 2014 was normalized to June 25 2014.

Evaluation
Evaluation was conducted based on event value and date match within a time window of 6 days or 30 days. For lung cancer, it was counted as a match if extracted lung cancer diagnosis and date match with the reference standard within a time window of 6 days or 30 days. We randomly selected 20 from non-matched patients within 30 days and analyzed the reasons. For multiple myeloma, it was counted as a match if extracted values of chemotherapy, transplant type, transplant mobilization and transplant conditioning match with the reference standard within a time window of 6 days or 30 days. All un-matched cases within 30 days were reviewed for error analysis.

Results
Among the whole lung cancer cohort of 4,110 patients, 4,034 have 14,890 pathology reports, with an average of 3.7 notes per patient. 4,051 patients have 173,070 clinical notes, with an average of 42.7 notes per patient. Table 2 shows the evaluation results of diagnosis date extraction from pathology reports and clinical notes for the 3,611 testing patients. From the results matched within 6 days, diagnosis dates of 1,228 (34.0%) patients came from pathology reports done at Mayo, additional 1,777 (49.2%) came from the pathology reports with outside specimen reviewed at Mayo Clinic, combining clinical notes, 3,206 could be found achieving 88.8%. From the results matched within 30 days, diagnosis dates of 1,627 (45.1%) patients came from pathology reports done at Mayo, additional 1,638 (45.3%) came from the pathology reports with outside specimen reviewed at Mayo Clinic, combining clinical notes, 3,414 could be found achieving 94.5%.

The most common errors are due to outside materials (45%) and human errors (25%) (Table 3). When patients came from another hospital or country, the information of diagnosis date was often not complete in clinical notes and pathology reports. Human error may primarily result from typing process where a very near keyboard number was mistakenly typed in. For example, diagnosis date of “2013-01-22” maybe typed as “2011-01-22”. Dictionary insufficiency accounted for 5%. For those errors from NLP rules, the primary challenge came from the inference for lung cancer diagnosis, accounting for 15%. This mainly came from patients who were referred from other institutions and experience a long journey for lung cancer diagnosis. We only integrated date inference piece into the NLP tool without “year” inference, the case (5%) missing from NLP needed to use “year” inference, i.e., “Since her last evaluation one year ago, she was diagnosed as having a non-small lung cancer”. Date ambiguity happens when two dates appeared in one sentence, such as clinical note date and diagnosis date, it’s hard to be certain which date should be used.

For multiple myeloma, 312 out of 318 patients have 44,976 clinical notes, with an average of 144 notes per patient. Table 4 shows the evaluation results of treatment dates extracted from clinical notes for the testing patients. 60 (65.2%) out of 92 chemotherapy treatment start dates matched with the reference standard within 6 days, and additional 11 (12%) were matched within 30 days. For transplant type, only 1 more case was found when using 30 days match range compared with 6 days match range. For mobilization, 2 more cases were found when using 30 days match range compared with 6 days match range. For conditioning, no more cases were found when using 30 days match range compared with 6 days match range.

Table 5 shows the error analysis for chemotherapy treatment date. Around half of 21 unmatched cases were due to human errors and outside materials (52.4%). In the remaining unmatched cases, the most challenge part came from lacking semantic inference for dates in NLP rules (33.3%). These cases were mostly referral patients who had a history of chemotherapy treatment in other institutions, and the clinical notes at Mayo Clinic only recorded the obscure time. For example, “She initially took thalidomide. She took treatment for about one to two years and then was observed until 2012”; or “He has been on ibrutinib for nearly three years”. When the chemotherapy in the reference standard was “Other” without clear definition of drug names, it is also challenging to extract corresponding chemotherapies. The last error came from the unprecise date mentioned in clinical note where only “year” was recorded. Through our heuristic rules, the year was normalized to “07-01” of the year, but the reference standard used “01-01”.

Table 6 shows the error analysis for dates of transplant data elements. Outside material accounts for 75% for transplant type. Human error accounts for 71.4% for mobilization and 76.5% for conditioning. The “other” value was not clearly defined in dictionary. Thus, it was hard to extract. Since date mentions were very diverse, one was missed in the NLP rules.

Discussion

Temporal extraction systems have not been transportable from one condition (e.g., colon cancer) to another (e.g., brain cancer) as shown in the SemEval challenge. When training and testing on only notes from colon cancer patients, the top system achieved F1s of 0.76 for document time relations in 2016 with an increase of 0.058 compared with 2015, and 0.48 for narrative containers with an increase of 0.22 compared with 2015. When training on notes from colon cancer patients and testing on notes from brain cancer patients, the best F1 achieved 0.50 in linking events to document creation time and above 0.30 F1 for linking events to their narrative containers, with a 20+ point drops in performance. Different patient cohorts and linguistic patterns behind different cancers are the underlying reasons for the results.

In the two case studies used in this research, lung cancer and multiple myeloma, all clinical notes were obtained from Mayo Clinic CDW which recorded not only events happened at recording time, but also recorded historical events with associated dates, if any. But different features of date expressions can be found due to distinct differences of various events in the two different cancers. Most multiple myeloma patients have clear records with treatment start dates. Since almost half of lung cancer patients in the cohort were referred from other institutions, learnt from the
results (Table 2), in the clinical notes the history of lung cancer may be recorded very unclearly with more obscure time used than the multiple myeloma case.

Therefore, extracting dates associated with various cancer events required different event extraction dictionaries, different date extraction strategies as well as different approaches for linking dates with extracted events. Our study demonstrated that it is feasible to extract exact dates associated with specific cancer events for EHR-based cancer research. However, some challenges exist as illustrated in the following.

To extract precise dates associated with cancer events, it’s crucial to assert events first followed by temporal information extraction. However, it’s hard to accurately extract events as the events scatter in different data sources and there are no definite event mentions, as shown in the lung cancer case study. When using different data sources, different NLP strategies were necessary to extract events. Pathology reports record lung cancer diagnosis mainly through specific histologic cell types or assertion of positive malignancy in lung related biopsy sites. While in clinical notes lung cancer diagnosis is often represented by other miscellaneous terms, e.g., from lung examinations and symptoms of lung cancer in addition to specific histologic cell types or assertion of positive malignancy. This needs a large amount of time for developing dictionary during the training process if there was no one available. Second, the diagnosis of lung cancer may be a long journey and lacking definite diagnosis mentions was common. When the initial examinations provided uncertain results, the suspicious results would just remain undecided in one facility until it was ascertained in another facility. During the process, the mention of date and diagnosis are often existing in sentences far away from each other. To capture this complex situation, the date and diagnosis across multiple sentences were extracted using NLP. However, it’s hard to accurately extract diagnosis and date when too many sentences were involved, especially when there was no definite diagnosis mentions and there was a need to infer.

Since a lot of patients have been referred to Mayo Clinic for further treatment from other institutions, recording of exact diagnosis dates are not very clear in some cases. For example, lung cancer diagnosis date may be mentioned as “early winter 2000”. Given the long history of cancer registry databases, inconsistency of date normalization may exist among human abstractors to normalize the obscure time to specific dates. The gap may also exist between the heuristic rules we developed and the rules human abstractors used. In addition, different physicians have different styles for recording notes and there were no unified rules for recording dates. For example, it’s hard to normalize the chemotherapy start time recorded as “05/12”, because it’s hard to determine if “05” was month or year, and if “12” was month or “day”.

Linking dates to the associated events lies in the fact that events may be dependent to each other. As shown in the multiple myeloma case study, both transplant mobilization and conditioning affiliated to transplant type. Extracted mobilization and conditioning dates were linked to transplant type dates using inference rules, which may result in errors. Linking mobilization and conditioning values to associated dates was hard because 1) some patients may have several transplants within short time intervals, 2) different mobilization and conditioning values may appear repeatedly in clinical notes. This poses challenges not only for NLP but also human. In fact, as shown in evaluations we found human made many errors when linking mobilization and conditioning values to associated dates which NLP had successfully avoided.

In addition, events may have multiple related dates and it’s hard to choose the optimal date, as shown in both case studies. For lung cancer, multiple dates associated with definite lung cancer diagnosis existed in pathology reports. For example, one patient may have the same lung cancer diagnosis from different pathology reports on different dates using different specimens. For multiple myeloma, some patients may have as many as more than 20 times of chemotherapies, some of which were within very short time intervals. Thus, NLP techniques can accelerate the data abstraction process but not completely replace human efforts.

Conclusion

It is feasible to extract exact dates associated with specific cancer events for EHR-based cancer research using automatic NLP method to facilitate cancer registry curation. However, data extraction in various cancer registry databases has been ad hoc for specific research purpose. To gear with the demands for research-oriented information collection, developing NLP algorithms needs to consider the differences among various cancers in event extraction.
dictionaries, date extraction strategies as well as approaches for linking dates with extracted events. We plan to extend our investigation to include more cancer patients and more cancer types.

Towards augmenting structured EHR data: a comparison of manual chart review and patient self-report

Nicole G. Weiskopf, PhD, Aaron M. Cohen, MD, MS, Joely Hannan, BS, Thad Jarmon, MBA, David A. Dorr, MD, MS
Department of Medical Informatics and Clinical Epidemiology, OHSU, Portland, OR

Abstract
Structured electronic health record (EHR) data are often used for quality measurement and improvement, clinical research, and other secondary uses. These data, however, are known to suffer from quality problems. There may be value in augmenting structured EHR data to improve data quality, thereby improving the reliability and validity of the conclusions drawn from those data. Focusing on five diagnoses related to cardiovascular care, this paper considers the added value of two alternative data sources: manual chart abstraction and patient self-report. We assess the overall agreement between structured EHR problem list data, abstracted EHR data, and patient self-report; and explore possible causes of disagreement between those sources. Our findings suggest that both chart abstraction and patient self-report contain significantly more diagnoses than the problem list, but that the information they capture is different. Methods for collecting and validating self-reported medical data require further consideration and exploration.

Introduction
Electronic health record (EHR) data serve a number of important roles beyond their primary purposes related to patient care, including clinical research, algorithm development and machine learning, epidemiologic or population-based studies, or in measuring the quality and safety of care. In the age of the Quality Payment Program and other value-based care initiatives, one of the most important uses is to calculate and report clinical quality measures (CQMs). CQMs are written with varying levels of formalization and adherence to standards. At one end of the spectrum, measures included in the Centers for Medicaid and Medicare Services quality reporting program are specified as electronic CQMs (eCQMs). These eCQMs are currently written in the Health Level 7 Health Quality Measure Format and employ Quality Data Model logic; in the future eCQMs will be written in Clinical Quality Language, also maintained by Health Level 7. The clinical concepts required to calculate CQMs are encoded in official value sets using a variety of medical standards and terminologies. The value sets are available at the Value Set Authority Center, which is maintained by the National Library of Medicine. CQMs that are not fully specified range in formality from plain language to carefully specified logic. These CQMs also rely on the availability of certain key clinical concepts, and therefore list specific concept codes for medications, diagnoses, and procedures.

Regardless of whether specific concept codes are provided in measure specifications, the most efficient way to calculate CQMs, electronic or otherwise, is through the reuse of structured EHR data. Structured data may be used in native EHR quality calculation engines, or extracted from the EHR via automated processes, enabling consistent and continuous (or at least regular) calculation. Unfortunately, there are limitations to structured EHR data, including incompleteness, inaccuracy, and non-current data. Chan et al.’s 2010 literature review found that the quality of clinical concepts needed for quality measure calculation was highly variable and often poor. How best to assess, understand, and improve the quality and reliability of structured EHR data remains an open question. One limiting factor is the fact that traditional approaches to data quality assessment often rely on the availability of a gold standard, which is one of the most common methods of EHR data quality assessment as well. The problem with this approach is that it is very rare to have an actual gold standard available, meaning that most such efforts must rely upon comparison against other sources of information that are themselves likely to suffer from limited validity and reliability (e.g., paper medical records or direct observation of clinical encounters).

Rather than assume that one single source of medical information is the gold standard against which other sources can be compared, it may be best to approximate the truth by combining data from multiple sources. Structured data represent only a small portion of the data contained within the EHR, which also includes large quantities of narrative notes and other forms of non-structured data, such as images and scanned files. In fact, it has been shown that structured and unstructured EHR data do not always agree. Another alternative source of medical information is patients themselves. There is substantial literature on comparisons between self-report and the medical record, with highly variable findings that are impacted by clinical condition of interest, demographic factors, or data collection methods. For example, Vigen et al. measured agreement between self-reported diabetes and hypertension diagnoses in breast cancer survivors and clinical data extracted from Kaiser Permanente’s Virtual Data Warehouse, which was constructed from a combination of EHR data, outpatient pharmacy data, and
administrative claims data. They reported high levels of agreement for both diagnoses (diabetes $\kappa = 0.87$; hypertension $\kappa = 0.80$). In contrast, Wagaw et al. looked at the same two diagnoses and compared structured EHR data from two urban health clinics against patient self-report, and found only moderate agreement for both diagnoses (diabetes $\kappa = 0.76$; hypertension $\kappa = 0.69$). In the Wagaw study, the research was limited to data from two clinics, whereas the Kaiser Permanente clinical database contained medical records from multiple locations and sites of service, including pharmacy data. Another reason for the disparity in results are the methods of collecting self-report data. In the Wagaw study, self-reported data were collected using a self-administered questionnaire, while Vigen et al. collected patient self-report via in-person interviews.

While the limitations of EHR data quality and the variable level of agreement between EHR data and patient self-report indicate that there is no single gold standard when it comes to medical information, the discrepancies between these data sources provide an opportunity to bring these sources together to create a more comprehensive, timely, and accurate picture of patients' medical status and histories than what we glean from purely structured data. Therefore, to develop a deeper understanding of the limitations of structured EHR data and explore options for augmenting these data, we compared the presence of five diagnoses related to cardiovascular health across three data sources: structured problem list data, manual chart abstraction data, patient self-report data collected via a survey. Our goal was to characterize and quantify agreement between these data sources and to begin to identify and understand the underlying factors that may lead to disagreement between these sources.

**Methods**

We measured agreement between three data sources on a set of five diagnoses related to cardiovascular health. The three data sources were: 1) the structured problem list queried from the OHSU instance of the Epic relational database; 2) manually abstracted diagnosis information from the complete medical chart available through the OHSU Epic EHR instance; and 3) patient self-report, collected via survey. Per eCQM specifications, encounter diagnoses – not problem list – are used for calculation; however, patient self-report requires a global response similar to the problem list (i.e., at the patient level, not encounter level). The trade-off in the temporality and sensitivity of encounter diagnoses versus the precision (positive predictive value) of the problem list was thought to favor the use of the problem list for the purposes of this comparison. The diagnoses included were diabetes, hypertension, heart failure, myocardial infarction, and stroke. Level of agreement was determined via a combination of descriptive statistics, paired tests of proportion, and Fleiss’ kappa. Error analysis was conducted via manual chart review to uncover causes of disagreement and implications for augmentation of the structured problem list data.

**Subjects, Recruitment, and Institution**

The population of interest was defined as patients between the ages of 18 and 89, with English listed as their preferred language, having had at least one outpatient visit with the Oregon Health & Science University (OHSU) cardiovascular department within the previous calendar year as of 2/12/2018. OHSU is an academic medical center in Portland, Oregon, that includes two hospitals, with a total of 572 beds, and a number of ambulatory care clinics. From this population, a random sample of 4,000 patients was selected as potential participants. Batches of invitations to participate in a brief survey regarding their medical care and history were sent to these patients via email until at least 300 participants initiated the survey. The respondents comprised the study sample for all three data collection arms. Chart review was not performed on those records labeled as “restricted” within the OHSU Epic instance. This study was approved by the OHSU Institutional Review Board (#00017632).

**Data and Concept Extraction**

This study is part of a larger project to examine the impact of data quality on clinical quality measure (CQM) reliability. The CQMs used in this project cover a combination of four general cardiology measures and a set of specialty heart failure measures. These CQMs require a number of clinical concepts in order to calculate denominator inclusion and numerator adherence, including several diagnoses related to cardiovascular health.

*Problem List Data:* Diagnoses were queried from the problem list in Epic via the Integrated Care Coordination Information System, a population management system. Relevant active diagnoses were identified using ICD-10-CM codes from diagnosis value sets downloaded from the Value Set Authority Center maintained by the National Library of Medicine (diabetes mellitus: 2.16.840.1.113883.3.464.1003.103.12.1001, hypertension: 2.16.840.1.113883.3.464.1003.104.12.1011, myocardial infarction: 2.16.840.1.113883.3.526.3.403, stroke: 2.16.840.1.113762.1.4.1047.44, and heart failure: 2.16.840.1.113883.3.526.3.376). Each diagnosis was coded as either present or absent for each participant and had to be present at or before the time the survey was sent out.

*Patient Self-Report Data:* While self-reported medical history is often collected in the medical setting, we were unable to find a validated instrument that addressed the combination of concepts required for this research.
Therefore, a REDCap survey was designed to assess relevant diagnoses, medication usage, tobacco use and therapy, laboratory results, and heart failure status and treatment (the analyses described in this manuscript focus only on the diagnoses).\textsuperscript{11} The survey was designed with input from and review by cardiology providers at OHSU, and sought to balance depth and breadth of information collected with instrument brevity and required health literacy. Diabetes mellitus, myocardial infarction, stroke, and hypertension were assessed with forced binary checkboxes indicating presence or absence of the diagnosis. The diagnosis of heart failure, which the cardiology providers decided was more complex, was described in greater detail and used Likert-like response options: definitely not, maybe not, unsure, maybe yes, and definitely yes. For the purposes of the analyses described in this paper, the responses of maybe yes and definitely yes were considered to be affirmative, and any other response was considered negative.

**Chart Review Data:** Diagnoses were extracted from the OHSU Epic instance by one of three trained chart reviewers. For each of the five diagnoses, an annotation guide was created that included a list of diagnosis names, abbreviations, and terms based on the official value sets described above and review of common medical terminology. The reviewers used these term lists to search for structured and unstructured references to those diagnoses anywhere in the patient chart, which were then reviewed in greater detail. When relevant results were not found via the search tool, the reviewers were instructed to also review other information sources within the chart that could not be searched in an automated fashion; these other sources included PDFs of reports and letters from providers and linked records from partner institutions and providers available from health information exchange. Chart reviewers were told not to make interpretations based upon evidence supporting a diagnosis (e.g., laboratory results or medication orders), but rather to look for explicit diagnoses documented by providers. As with the problem list data, each diagnosis was coded as either present or absent for each participant.

**Analysis**

The overall goal of the analysis was to determine the degree of overlap and difference between the three data sources, as well as to understand the reasons why there was disagreement. Outcomes included similarity of proportions across the sources, agreement between the sources, and error analysis for the discrepancies. To begin, the presence of each of the five diagnoses in each of the three data sources was determined at the participant-level and then assigned to one of the seven possible categories of agreement, as summarized in Figure 1.

**Statistical tests:** For each diagnosis, Cochran’s Q test was used to test whether the proportion of diagnoses present was the same for each data source. For diagnoses where there was determined to be a significant difference in proportion, post-hoc analyses comparing pairs of data sources were conducted using McNemar’s test. Bonferroni corrections were applied to the original alpha of 0.05, resulting in an alpha of 0.01 for the Cochran’s Q tests and 0.003 for the McNemar tests. Agreement between the three sources for each diagnosis was determined using Fleiss’ kappa (\(\kappa\)). Proportional Venn diagrams were created for each diagnosis using the software program eulerAPE.\textsuperscript{12}

**Error analysis:** Error analysis was conducted on a sample of cases where there was disagreement between the data sources. Where present, two cases were selected for review for each agreement category and each diagnosis. For each case, an attempt was made to uncover the source of disagreement for that diagnosis through further review of the chart, value sets, and system processes. The chart-based error analysis was conducted by one of the trained chart reviewers (JH), and was reviewed by the principal investigator (NGW) to ensure consistency of findings. Where a cause of the disagreement could not be determined via chart review, the principal investigator reviewed the relevant queries, diagnosis coding processes, and value sets in an effort to uncover disagreement causes related to the backend systems. Once the disagreement sources were identified, a deductive approach was used to iteratively review and categorize the sources in order to identify a set of key factors resulting in the disagreement.

**Results**

We sent survey invitations to 1,700 eligible patients, 307 (18\%) initiated the survey by clicking yes on the consent page and completed the section of the survey relating to medical history. Of those 307 respondents, 32

![Figure 1. The three data sources (problem list, chart review, and self-report via survey) represented as sets in a Venn diagram. Overlapping segments indicate participants with the same diagnosis found in more than one data source.](image-url)
had restricted charts in our Epic instance, and were therefore not included in our analyses, for a final sample of 275 participants.

Mean participant age was 60.1 years, with a standard deviation of 15.3 years. Participants were uniformly distributed according to sex (51.6% female), and disproportionately white (94.2%) and non-Hispanic (97.1%). Participants had a mean of 4.9 ± 4.0 unique diagnoses on their problem lists and 10.5 ± 6.0 unique medication classes on their medication lists. See Table 1 for details.

Overall, 76% of the participants had at least one of the five diagnoses according to at least one of the three data sources, for a total of 380 distinct diagnoses. There was complete agreement for 182 of these cases (48%). Hypertension was the most commonly-reported diagnosis across all three data sources, and stroke the least common. More specifically, hypertension was reported in at least one of the three data sources for 63% of the participants, heart failure for 28%, diabetes for 20%, myocardial infarction for 16%, and stroke for 12%. The data source with the highest rate of endorsed diagnoses was the patient survey, in 70% of all participants reported at least one of the five diagnoses. Sixty-five percent of the participants had at least one of the diagnoses according to chart review, and 55% according to the structured problem list. The proportion of participants with each diagnosis by data source is summarized in Table 2.

Of the seven possible data source agreement categories, a diagnosis being present in all three sources was the most common category for each diagnosis is shown in Table 3. Of the seven possible data source agreement categories, a diagnosis being present only in the problem list or in the problem list and patient survey were the least common (2% and 1% respectively). Across all diagnoses combined, the most common category of data source agreement was when a diagnosis was present in all three sources (48%), and after that was when a diagnosis was only reported in the patient survey (22%). The complete breakdown of agreement category for each diagnosis is shown in Table 3.

Statistical results

Cochran’s Q tests showed statistically significant differences in proportions of positive cases between the three data sources for each of the five diagnoses after correcting for multiple hypotheses (adjusted p-value of 0.01). Post-hoc pairwise McNemar tests showed significant differences in proportion between the structured problem list and chart review for myocardial infarction, hypertension, and stroke; significant differences in proportion between the structured problem list and patient self-report for myocardial infarction, heart failure, and stroke; and no
significant differences in proportion between chart review and patient self-report (adjusted p-value of 0.003). Significant differences of proportions are indicated by asterisks for Cochran’s Q and lowercase matched letters for McNemar tests in Table 2.

Fleiss’ kappa indicated moderate agreement between the three data sources for myocardial infarction (κ = 0.52) and stroke (κ = 0.49), substantial agreement for hypertension (κ = 0.62) and heart failure (κ = 0.67), and the highest agreement for diabetes (κ = 0.85). Agreement is summarized in Figure 2 using Venn diagrams.\textsuperscript{12}

![Figure 2. Proportional Venn diagrams showing relative rates of diagnoses present in each of the three data sources. $\kappa$ indicates Fleiss’ kappa, CR = chart review, PL = problem list, SR = patient self-report via survey, and $n$ refers to the total number of cases in which the diagnosis was present in any of the three data sources.](image)

Error analysis: categories of factors causing disagreement

In each case of disagreement between the three data sources, the disagreement might be due to false positives in the source(s) in which the diagnosis was present or false negatives in the source(s) in which it was not present. We conducted error analysis on 57 (29\%) of the 198 cases where a diagnosis was present in only one or two of the data sources. Our analysis revealed five categories of factors that could lead to disagreement between the three sources via the presence of false negatives or false positives. These categories included research error introduced by our process, healthcare system factors, documentation factor, patient factors, and diagnosis factors. Problems with self-report were the most difficult to definitively identify and categorize, since, and in most cases these causes of disagreement could only be suspected, not definitely proven because the underlying truth could not be extrapolated from the information available in the chart. These factors are summarized in Table 4 and described in more detail below.

**Healthcare system factors:** We identified two situations related to the healthcare system that led to false negatives in the problem list data and chart review data. First, false negatives sometimes occurred in both the EHR-derived sources when primary care was provided outside of the OHSU system. A subset of these cases included patients receiving highly focused specialty care (e.g., vascular surgery) at OHSU. Both of these factors are related to the fact that healthcare is often delivered across multiple institutions and by multiple providers.

**Documentation factors:** We found two factors related to EHR documentation practices. False negatives and false positives in the problem list sometimes arose when the problem list was not consistently maintained and was therefore out-of-date, either because a resolved problem was not removed or because an active problem was not added (or was added after the measurement period concluded). The second factor in this category was the use of copy and paste, which sometimes led to false positives in the chart review data when an erroneous diagnoses, rather than being eliminated from the chart, were propagated forward in narrative notes over time.

**Patient factors:** Patients who are less engaged with their healthcare or who have lower health literacy might not fully grasp their own health status, leading to false negatives or false positives in self-report. The other patient-related factor, medical complexity, refers to the fact that patients with multiple active diagnoses and medical concerns may have incomplete medical charts (false negatives in the problem list or chart review data), and may also
have difficulty understanding the entirety of their own medical situation, leading to false negatives or false positives in the self-report. As noted above, these factors often could not be identified with certainty, but there were instances where low engagement was mentioned explicitly in the chart, or where medical complexity could be inferred.

**Diagnosis factors:** There were two types of factors identified in this category. First, the acuity of a diagnosis appeared to be associated with the presence of false negatives in the problem list. Acute and historic diagnoses (like a myocardial infarction or stroke experienced prior to the initiation of care at OHSU) were not always added to the problem list. Similarly, diagnoses that were chronic but well-controlled (like hypertension or diabetes controlled via lifestyle changes) were not always present on the problem list. The other factors in this category involved the existence of related diagnoses. First, diagnoses with semantic similarity sometimes led to false negatives or false positives in patient self-report, as when a patient conflated cardiac arrest and myocardial infarction. Second, there were cases when a diagnosis was initially expected, added to the problem list, then ruled out, but not deleted from the problem list or appropriately labeled in the chart as erroneous. For example, a patient might be admitted via the emergency department with a suspected myocardial infarction, only to have this diagnosis ruled out via testing.

**Research error:** This final category includes factors arising from our research process that led to false negatives or false positives in any of the three data sources. ETL errors sometimes led to resolved diagnoses being labeled as active in our problem list data (false positives) or missing certain diagnoses entirely (false negatives). Chart review errors led to false positives and false negatives in the chart review data. Value set problems occurred when a value set included codes and problem names that didn’t necessarily indicate the diagnosis of interest, which might lead to false positives or false negatives in the problem list data or the chart review data (e.g. Dressler’s syndrome is included in the myocardial infarction value set, but may have other causes). Finally, there were some known limitations involving the validity of the survey, especially with language that was either too clinical, leading to false negatives in the self-report data, or too broad, leading to false positives in the self-report data.

**Error analysis: categories of source disagreement**

**Problem list only:** Due almost exclusively to problem list false positives resulting from ETL errors (research error) or failure to maintain the problem list, leading to the inclusion of resolved problems.

**Chart review only:** Due either to false negatives in the problem list and self-report or false positives in the chart review. False negatives in the problem list data resulted from healthcare system factors and diagnosis-related factors, though false negatives in the self-report data were harder to diagnose. We also found some false positives in the chart review data stemming from documentation practices, specifically use of copy and paste, and chart review error (research error).

**Patient survey only:** Due either to false negatives in the two chart-derived data sources, or false positives in the self-report data. This form of disagreement was one of the most difficult to diagnose. Some of these cases were a combination of chart review error leading to false negatives in the chart data and diagnosis-related factors leading to false negatives in the problem list data. Self-report false positives may have occurred because of survey validity.

### Table 4. Error analysis revealed five categories of factors potentially leading to false negatives or false positives in the data sources.

</table>
limitations (research error), diagnosis-related factors like diagnoses with semantic similarity, or patient factors, like low health literacy leading to poor comprehension of the survey. In many cases the cause of disagreement could not be determined based on information available for error analysis in the chart. It is likely that in some of these cases patients were reporting information that was absent from the OHSU chart, likely due to healthcare system factors.

**Problem list and chart review, but not survey:** Due either to false negatives in self-report or false-positives in the two chart-derived data sources. Definitive causes could not be identified for most of these cases. Patient factors like low health literacy or low engagement, or diagnosis-related factors like the presence of well-controlled chronic diagnoses (therefore not the focus of their medical experience) leading to false negatives in survey data were a possible culprit. Alternatively, cases where a false positive was present in the chart review data, stemming from the use of copy and paste (documentation factor) or the presence of rule-out diagnoses (diagnosis-related factor), could have led to the presence of that same diagnosis on the problem list when it should have been deleted during problem list maintenance (documentation factor).

**Problem list and chart review, but not chart review:** This form of disagreement appeared to be largely, though not exclusively, related to temporality and time windowing problems leading to false positives in the problem list data and self-report data. There were cases when no-longer-active diagnoses were mistakenly captured from the problem list through our ETL process (research error) or were not removed from the problem list following resolution (documentation issues). Similarly, temporality was intentionally absent from the survey questions in order to improve readability, but at the expense of survey validity in some cases; diagnoses reported by patients were not always current, effectively leading to false positives in the survey (research error).

**Chart review and survey, but not problem list:** Generally the cases we reviewed in this category were due to false negatives in the problem list, though a combination of false positives in the chart review and self-report data would also be possible. Causes of problem list false negatives included diagnosis-related factors like acute historic events and chronic well-controlled diagnoses not being added to the problem list. There were also cases where a patient did not receive primary care at OHSU or received only very specific specialty care at OHSU (system factors) leading to diagnoses that were found in unstructured notes or other media, but which hadn’t been added to the problem list.

**Discussion**

This study explored the agreement between the structured EHR problem list, manual chart review, and patient self-report for five diagnoses commonly associated with cardiovascular health and treatment, in the service of understanding the potential value-added of the latter two data sources when combined with structured EHR problem list data. Tests of proportion showed significant differences between the three data sources for all five diagnoses, but no differences in proportion between the chart review and patient self-report data. Fleiss’ kappa coupled with proportional Venn diagrams revealed varying degrees of agreement between the data sources, with diabetes mellitus having the highest level of agreement, and stroke the lowest. Error analysis identified several different potential sources of disagreement between the three data sources. These potential causes of disagreement could be grouped into five broad categories: research error, healthcare system factors, documentation factors, diagnosis factors, and patient factors. While potential causes of disagreement could be identified in many cases, the degree of certainty about those causes varied, ranging from high confidence to strong suspicion to conjecture.

**Patterns of agreement between sources**

The diagnoses found in the problem list generally had high overlap with those found in via chart review, with the problem list diagnoses being largely a subset of those found via chart review, as shown in Table 3 and visualized in Figure 2. Exceptions occurred when chart review revealed that a diagnosis present on the problem list was erroneous or out-of-date, or when the ETL process used to collect the problem list data led to research errors. We also found that chart review captured a significantly larger proportion of diagnoses than the problem list for myocardial infarction, hypertension, and stroke. Error analysis showed that these differences in proportion might be due to diagnosis-related factors, including the fact that prior acute events and well-controlled chronic diagnoses were not always added to the problem list, even when they were noted in the unstructured medical history. Second, due to healthcare system factors, diagnoses that were not the focus of care at OHSU were less likely to be entered on the problem list. This aligns with previous work that found that primary care providers are responsible for the majority of problem list documentation.13

Chart review and patient self-report, by contrast, had similar proportions with no significant differences between the two sources for any diagnosis, but limited overlap, as shown in Figure 2 and indicated by Fleiss’ kappa. The results of the tests of proportions may be misleading, as they fail to reveal patient-level differences. Both data sources were equally likely to report a given diagnosis across the entire sample, but not necessarily for the same
patients. In aggregate tasks, such as calculating the denominator count of a CQM, the overall result is likely to be similar regardless of whether chart review or self-report is used. There is a clear and meaningful difference between these two sources, however, for individual patients, whether in the context of quality measurement or — more importantly—patient care. Of the 44 patients with myocardial infarction present in either chart review or self-report, for example, for only 20 is it present in both data sources. Out of all 380 diagnosis cases in our sample, fewer than half are shared amongst all three data sources.

In cases where a patient self-reported a diagnosis that was not present in chart review, it is generally difficult to discern whether the self-report was a false positive or the chart review resulted in a false negative. In other words, without further study it can’t be determined if patients were more likely to endorse diagnoses they did not have, or if they were reporting information that was missing from the OHSU medical records. In the opposite scenario, in which a patient did not report a diagnosis that was present in the chart review, the truth was sometimes easier to discern based on the level of evidence found in the chart,14 though the reasons why a patient would not report a diagnosis that is reported with high certainty in the chart remain difficult to understand or quantify without further research. Possible causes to consider include patient factors like limited patient health literacy and survey validity issues around the differences between lay language and clinical language.

Patterns of agreement across diagnoses

Across all the diagnoses, the highest level of agreement was for diabetes mellitus, which also had no significant differences of proportion for the pairwise tests between sources (though Cochran’s Q did show a difference across all three sources). This finding is possibly because this is a diagnosis associated with a high level of confidence (certain tests can be considered a gold standard in diagnosis) and a high level of actionability, meaning that it’s likely to be documented by providers and likely to be understood by patients. In the cases we reviewed where the three data sources were not in agreement, possible factors resulting in disagreement included the diabetes being very well-controlled (diagnosis factor), management by a non-OHSU provider (healthcare system factor), and research errors around data collection or survey design.

Heart failure and hypertension showed substantial agreement across the three data sources, though with more variability than for diabetes. The accuracy of hypertension diagnoses in EHRs is known to vary,15 perhaps because this is a diagnosis that often does require a certain accumulation of evidence, or because this is a diagnosis that is commonly managed by primary care providers. It is somewhat surprising that agreement was not higher across the data sources for heart failure. Error analysis showed that some of this disagreement can likely be attributed to the fact that heart failure may be conflated with related diagnoses, either in the chart or in patient self-report (e.g., congenital heart defect without heart failure). It may also be that patients with heart failure, owing to demographic differences or medical complexity, differ from other patient populations. In fact, the importance of health literacy in heart failure treatment and self-care has been highlighted in other work.16

Stroke and myocardial infarction showed the lowest agreement across the data sources, with Fleiss’ kappa for both indicating “moderate” agreement. As discussed above, disagreement between chart review and the problem list for these two diagnoses is at least partially due to the fact that prior acute events are not always added to the problem list. The large proportion of cases reported only in the patient survey—38% of potential myocardial infarction cases and 42% of potential stroke cases—suggests either that there is a substantial amount of relevant medical history that does not make it into the OHSU record, that patients are fundamentally misunderstanding their own medical histories, or some combination of the two.

Considering a role for patient self-report

The relationship between problem list data and diagnoses identified through manual chart review, i.e., that the former is largely a subset of the latter, is unsurprising. There is certainly value in developing approaches for encoding diagnoses present in unstructured data to make them more readily actionable. Patient self-report, however, provides information that is often entirely absent from the EHR, in either structured or unstructured data (22% of all diagnoses mentioned in any of the three data sources were found only in patient self-report). By definition, these diagnoses must be either true positives missed by the two EHR-based sources, or false positives, erroneously endorsed by patients or resulting from research error. More work is needed to quantify and characterize which cases are which, but it must be assumed that at least some of them are true positives, and that there is value in incorporating this information into the patient record. Our error analysis revealed that many of the diagnoses found only in the survey were from patients who received the majority of their care outside of OHSU, suggesting that in many cases we are observing fragmentation of medical information across the healthcare system. This is a recognized problem in healthcare,17 resulting in problems not just in quality improvement or research efforts, but at the point of care, when providers must make
clinical decisions without complete information. Transfers of care between providers and institutions are especially complicated from a medical record standpoint, and often the tasks of collecting and documenting complete medical histories from previous care settings is placed on already overburdened providers. Re-entering data that have already been encoded in structured data by other providers or at other institutions is an inefficient use of providers’ time. There are various approaches for overcoming this problem using technological and systems-based approaches, including health information exchange via regional health information organizations and standardized medical terminologies for medical data exchange.\(^{18-21}\)

In the era of the engaged patient, there may also be value in trying to incorporate patient self-report data into the EHR through properly validated and adjudicated means. There is already growing use of patient-reported outcomes in clinical care, quality assessment, and research; patients’ knowledge of their own medical status and history could potentially play a similar role, especially given that patients are already asked (often repeatedly) to provide information regarding their medical history. From a pragmatic standpoint, it is worth noting that although our initial survey development process was lengthy and a formal validation process is still required, once implemented this was an efficient way to collect data and, overall, was far less resource-intensive than the manual chart review process. Eliciting valid and reliable information from patients requires further study and must draw on existing work in psychometrics and patient-reported outcomes, but our findings strongly suggest that there is potential value in patient self-report if we wish to create complete, accurate, and current medical records.

Limitations

There are limitations to the generalizability of this work due to the focus on cardiology, the population definition (patients with cardiology visits in the past year), differences in documentation practices across institutions, and the limited type of clinical concepts included (only diagnoses), and possible response bias. We only invited patients with email addresses present in the EHR to complete the survey, which implies a certain degree of technological literacy and engagement with the healthcare system. Similarly, patients who completed the survey may have differed from those who did not in terms of engagement or literacy. Broader and more systematic work in this area is necessary to draw more generalizable conclusions about the differences between the three data sources. As mentioned in methods section above, we also recognize that there are inherent limitations and assumptions resulting from our decision to rely on problem list diagnoses instead of including encounter diagnoses. The sensitivity of the latter is generally higher, which could improve the sensitivity of secondary use cases relying upon structured data, though potentially at the cost of decreased precision.

Another limitation is that our survey, though informed by clinicians and medical literature, was not formally validated or assessed for reliability. There were also intentional tradeoffs in the survey design to increase accessibility of the survey items and decrease the overall time required to complete the survey, both of which may have led to decreased validity and granularity of information in the responses. As mentioned above, further work in this area should draw heavily on psychometrics approaches to instrument design and validation. The development of validated tools to assess patient medical history would be greatly beneficial.

Lastly, more formal error analysis is required to generate a more generalizable understanding of the factors that lead to differences between patient self-report, structured problem list data, and chart review data. A systematic approach looking at a larger representative sample of patients across multiple institutions would also tell us more about the degree of impact of the different causal factors, allowing prioritization of approaches to ameliorate these causes of disagreement. We intend to address these issues in future work.

Conclusion

Patient self-report and manual chart review both present an opportunity to identify significantly more clinical concepts than are present in structured EHR data. Moreover, the overlap between chart review data and patient self-report data is often limited and varies depending upon the concept of interest. Although the data quality problems associated with EHRs are increasingly well-accepted, manual chart review and abstraction is often considered to be the closest thing to a gold standard we have available, and the impact of data quality problems is not well understood. By comparing chart review data to patient self-report, we have demonstrated not only that chart review is sometimes erroneous, but also that the chart itself may be inaccurate, incomplete, or out-of-date. Further work is needed to determine when and to what extent patient self-report are reliable, as well as how best to collect such data in a valid fashion, but our initial results indicate that these data provide an opportunity for identifying data quality problems in the EHR as well as for potentially ameliorating those data quality problems.

Acknowledgements
Our thanks to Jayne Mitchell and James Mudd for their clinical expertise, to Michael Kahn, Stephen Persell, and Joan Ash for their guidance in methodology and synthesis, to Elizabeth Parker and Nelly Bostan for their patience and perseverance in data collection and chart review, and to the patients who participated in this study. This research was funded under National Library of Medicine K01 LM012738.

Introduction

The Department of Veterans Affairs (VA) Veterans Health Information Exchange (VHIE), formerly known as the Virtual Lifetime Electronic Record (VLER) Health Program, is a Veteran-focused portfolio of programs that gives VA and authorized Community Care Partners secure access to certain parts of a Veteran’s electronic health record for the purpose of care coordination across the health care continuum. VHIE established a technological platform to securely exchange health information between VA and the community, both at an organizational level (VA Exchange) and at the personal provider level (VA Direct Messaging). VHIE connects the Department of Veteran Affairs with care organizations through national networks (e.g., eHealth Exchange). Today, VA is connected to more than 314 eHealth Exchange members and will expand community provider access to Veterans health information by joining the CommonWell Health Alliance and Carequality national networks.

Each day, thousands of documents are sent and received by VA and community providers to coordinate the care of patients. However, VA provider adoption and utilization of the VHIE, specifically the Joint Legacy Viewer (JLV), remains low and far from the critical mass necessary to achieve desired impacts on Veterans care and on health care costs. As of March 2019, JLV usage reports showed only 17.3% of 311,920 VA staff with access to JLV were Active Users logging in to the system.

Provider adoption is one of the four pillars of the VHIE Program¹ and increasing VA provider utilization is key to program success for several reasons:

1. Veterans Health Administration (VHA) Directive 6371, released April 30, 2019, established that VA medical facilities “must implement the Veterans Health Information Exchange (VHIE) Program…which provides the capability of electronic health information exchange (eHIE)…to advance the delivery of Veteran-centered clinical care.” The directive requires implementing VHIE (JLV) technology and educating and training VHA staff on the use of the VA Exchange.

2. The VA MISSION Act of 2018 specifically addresses health data exchange between VA and the private sector and opened the door for a shift to opt-out consent (no signed consent required) for Veteran participation in VHIE. This policy change will drastically increase the amount of Veterans health information available for electronic exchange and will create internal and external expectations that (all) VA providers use the VA Exchange to manage Veterans care.

3. Most enrolled Veterans (80%) have other health insurance (e.g., Medicare, Medicaid, Tricare, private insurance) and are likely to receive care outside of VA. This rate could be higher for rural Veterans as community care may be more accessible than VA care.

4. “Repetition of medical services by providers is one of the major sources of healthcare costs,” and use of HIEs to coordinate patient care can reduce redundant and unnecessary medical tests and lead to significant cost savings⁶⁻⁸.

In 2016, the VA Office of Rural Health (ORH) and VHIE program office began collaborating on a social marketing (communications) project to increase VA provider adoption and utilization of the VHIE. The VHIE Superuser Survey, conducted in 2018, was designed to help gain a deeper understanding of VA employees demonstrating the “model” behavior – accessing and using the VA Exchange at a high rate. The survey investigated VHIE utilization patterns and user perceptions about the VHIE and its use, as well as data of interest to the VHIE program regarding the user experience, including system access, use case(s), data quality, training, and barriers and facilitators to using the VHIE.
The survey also sought to discover psychographic information about “superusers” to better understand them as a consumer of HIE technology.

Survey findings will inform the development of a strategic communications campaign to increase VHIE adoption and utilization by VA providers and staff. In addition, knowledge gained from the VHIE Superusers survey will be used to help prioritize enhancements to the program, reduce and remove barriers to VHIE adoption and utilization, and improve the user experience.

HIE adoption is also an issue facing community health care organizations and barriers are similar to those experienced by VA(9-13). This work serves to add to existing knowledge about the motivators, facilitators, and barriers to HIE adoption; and the use of social marketing in interventions to influence provider behavior change.

Methods

Social marketing uses commercial marketing concepts and techniques to promote voluntary behavior change, and has been employed by international and national public health interventions for decades(14, 15). The social marketing process includes nine process elements completed across three phases: I) Research and Planning, II) Strategy Design, and III) Implementation and Evaluation(16). It is “an invaluable referent from which to design, implement, evaluate, and manage large-scale, broad-based behavior-change focused programs(17).” Though patients (consumers) are generally the intended target, social marketing may also be used to influence behavior change in health care providers(18-20).

The VHIE Superuser Survey was developed as the research vehicle to collect the quantitative and qualitative data necessary to complete the consumer analysis, market analysis, and channel analysis elements of Phase I. Survey questions were designed to elicit information regarding the VHIE user experience as well as to answer six strategic questions posed by the consumer-based health communications (CHC) process. Answers to these questions (below) provide insight into the consumer’s reality and “lead to communications that are relevant, meaningful, and compelling to the audience(21).”

1. Who will the target consumer be and what are they like?
2. What action should the target take as a result of communication?
3. What reward should the message promise the consumer?
4. How can the promise be made credible?
5. What communications openings and vehicles should be used?
6. What image should distinguish the action?(21)

To confirm the selection of the VHIE Superuser as an appropriate model of the desired behavior, questions based on Theory of Planned Behavior constructs were included to assess target audience members’ intention to perform the desired behavior (VHIE utilization in the workflow), their attitude toward the desired behavior, subjective norm, and perceived behavioral control.

VA Research Electronic Data Capture (REDCap), a web-based application for building and managing online surveys, was used to create open-ended, single-select, multi-select, and Likert Scale questions. VHIE and ORH staff, and VHIE Rural Health Community Coordinators tested the survey and provided feedback regarding question clarity and survey completion time. The final VHIE Superuser survey consisted of 32 questions and addressed four domains: Access, Utilization, Data Quality, and User Experience.

VHIE analytics were used to identify VA medical centers/healthcare systems retrieving documents from external sources at high (>14,000 patient record views/facility) and low (<2,000 patient record views/facility) rates. Nine sites were selected for participation in the VHIE Superuser survey; four designated as rural and five as urban.(22) [Comparison of rural and urban is of interest to the ORH as rural Veterans may be more likely to obtain care in the community due to distance/travel time to a VA facility, and ORH supports VHIE Community Coordinators at 56 rural VA Medical Centers.]

As this research was focused on the VHIE “consumer” and identifying current behavior and a model of the desired behavior, a purposive sample was established consisting of 162 VHIE users with the highest number of patient record
views at their site in the previous six months. Email addresses for the target Superusers were confirmed in the VA Outlook Global Address List; five were “undeliverable” reducing the total survey population to 157.

The initial survey email was sent July 17, 2018 and survey reminder emails were sent July 24th, July 31st, and August 7th. To increase the survey completion rate (only 15.3% as of 7/31/18), content and formatting changes were made to the final two email reminders. Emails were personalized with information specific to the recipient, such as their position title and home facility; and persuasive language and visually-appealing graphic elements were added.

Results

The final survey response rate of 52.2% was calculated using a sample size of 82. The sample was comprised of 36 participants from four rural sites (44%) and 46 participants from five urban sites (56%). Among all survey respondents there was wide variation in years worked at VA, with the shortest duration six months and the longest tenure slightly more than 38 years. The mean time employed with VA was 10.6 years. Nurses responded to the survey invitation at the highest rate (39.0%), followed by physicians (26.8%) and pharmacists (13.4%). Respondents who selected the “Other” category (23) included Psychologists (6), Social Workers (4), and Vocational Rehabilitation Counselors/Specialists (4).

It is important to note survey participants responded to questions based on their experience with either one or both VHIE user interfaces: VistAWeb or the Joint Legacy Viewer (JLV). VistAWeb, an intranet web application providing read-only access to individual patient electronic health records (EHR) was implemented in 2010 and served as VA’s first health information exchange (HIE). To modernize the system and meet Federal mandates for interoperability, JLV was deployed to all VA Medical Centers in 2014. JLV, co-developed by VA and the Department of Defense (DoD), connects VA to the private sector through national networks and enables users to view comprehensive electronic health records from all VA, DoD, and community health information exchange partner facilities where a Veteran receives care. An important difference between JLV and VistAWeb is that VistAWeb allows for aggregated data views that combine internal and external data in single data displays (e.g., allergies together, medications together, problems, etc.). VistAWeb, which was scheduled to be decommissioned in September 2017, was still available and in use during the survey period.

Survey Domain #1: VHIE Access

To better understand the “how” and “how often” aspects of VHIE access, and to identify any access issues, questions in this domain concerned the interface used to view Veterans non-VA (community) health information, frequency of access, and perceptions of ease in accessing the VHIE. Respondents were also asked to share open comments about VHIE navigation in general.

Survey participants were asked to select all methods used to access Veterans non-VA health information. More than half of respondents (52.6%) reported using JLV, and slightly more than a third (35.3%) used VistAWeb; 61.4% selected both JLV and VistAWeb. This may indicate that VHIE Superusers were early adopters of VistAWeb and that many have been successfully transitioned to JLV.

Almost three-quarters of Superusers (73.4%) access the VHIE daily, and overall ease of accessing data in the VA Exchange was rated “Neutral” (3.03) on a 5-point Likert Scale. Regarding access, 82% of survey respondents (n=67) provided comments about VHIE navigation and the user interface. Qualitative analysis of text responses revealed three predominate themes: connectivity, functionality, and a preference for VistAWeb over JLV. For both connectivity and functionality, the speed (slowness) of the system was an overarching theme. Almost one quarter of respondents (22.4%) used the word “slow” in regard to connecting and logging into the VA Exchange as well as loading documents (patient records), and “time-consuming” was referenced five times. Inaccessibility to the VHIE because the “system was down” was cited by 11 respondents, and 10 specifically referred to issues with the log in process (two-factor authentication). Almost one-fifth of survey respondents (19.4%) mentioned the transition from VistAWeb to JLV, compared the functionality and user friendliness of the two interfaces, or declared a preference for the system they had already been trained to use and are accustomed to using in their workflow.
**VHIE Access Themes – Sample of Supporting Superuser Quotes**

**Theme #1: Connectivity issues prevent access to the VHIE.**

“Becomes problematic when sites are not available or when the JLV goes down as there is no other alternative to get the info I need.”

“JLV is not quickly accessible to log in and sometimes goes down.”

**Theme #2: Functionality and navigation inhibit utilization of the VHIE (JLV).**

“Too limited – can’t search, often have to open multiple single entries to try to find what you’re looking for. Often need information like a test result that is not retrievable (not the most recent or several years ago).”

“I find JLV somewhat difficult to navigate to [location] information I am seeking.”

**Theme #3: Superusers were comfortable using VistAWeb and prefer it over JLV.**

“When Vista Web was available, the information I was able to access was more useful and decreased the time to find pertinent data that would help the clinical team make treatment decisions…”

“I prefer to use VistAWeb over JLV - some of that may be that I have more experience with VW, but it also allows us to access information not available in JLV.”

**Survey Domain #2: VHIE Utilization**

The second survey domain assessed utilization of the VHIE as influenced by Veteran patient characteristics, community health data types searched for in the VA Exchange, and how community data was used in the work setting. Participants were asked to check all responses that applied to the statement, “I access VLER/VHIE when working with a Veteran who...” Selection of [Veteran] “has self-reported care in the community” prompted a follow-up question regarding the type of community care reported by the Veteran.

Sixty-eight percent of respondents reported using VHIE to look up patient records when working with a new enrollee or patient transferred from the DoD, and 61.8% accessed the VHIE when a Veteran self-reported community care. Interestingly, 36.8% reported a Veteran-initiated request to look up their health record. Almost half of the respondents (48.7%) selected “Other Patient Type” and provided varied text responses. Most commented on clinically-specific situations, but use of the VHIE when a Veteran referenced medication(s) prescribed by a provider outside VA emerged as a theme.

**Figure 1.** Types of community care reported by Veterans to VHIE Superusers (n=76).
As shown in Figure 1, more than half of respondents (52.6%) reported Veterans referencing receiving diagnostic imaging in the community. Specialty care treatment and visiting community Emergency Rooms (ERs) were both reported by 47.4% of respondents, followed by labs in the community (43.4%) and community care for a chronic condition (40.8%). Less than one-third mentioned Veterans acknowledging health care from a community provider through the Veterans Choice Program.

In terms of interest in specific data categories, nine of the 13 listed data types were reported by more than half of survey respondents (=>51.3%) (Figure 2). More than three-quarters of respondents searched for problems/medical history (78.9%) and lab results (77.6%). While viewing all data types has the potential to impact and improve care coordination, more than two-thirds of respondents reported searching for lab results (#2), imaging results (#3), medications (#4), and procedures (#5); which may contribute to cost reduction through eliminating duplication.

**Figure 2.** Data types searched for in VHIE (n=76).

**Figure 3.** VHIE Superuser data use cases (n=76).
Responses to the question regarding utilization of Veteran health information obtained through the VA Exchange are shown in Figure 3. The top five uses, (1) reviewing treatment course for chronic illness, (2) reviewing community hospitalizations/ED notes, (3) preparing for scheduled appointments, (4) coordinating care, and (5) managing medications were reported by more than half of respondents.

Survey Domain #3: VHIE Data Quality

The third survey domain assessed Superusers perceptions of the quality of the health information (i.e., data accuracy and completeness) received from the VA Exchange. The overall mean score for data quality was 3.85 on a 5-point Likert Scale where “1 = Very Poor” and “5 = Very Good.” Close to two-thirds of respondents (63.9%) rated VHIE data quality as either “Very Good” or “Somewhat Good.”

The top three responses selected for the question regarding data quality issues experienced when using VHIE were (1) incomplete data (59.3%), (2) duplicate data in multiple locations (37.3%), and (3) “other” data quality issue” (33.9%). Five survey participants who selected “Other data quality issue” reported that there were “no problems” with data quality, and one respondent added, “other than not every facility can/has signed up to play with us.”

When asked about specific data not currently available that would be helpful in their work, several respondents referred to progress notes - either more or better (from the community). Other responses included a list of patients’ current providers, surgical history, and psychological evaluations. Two items suggested by multiple respondents were current and past appointments (VA and community) and prescriptions written by community providers. It should be noted that this was not a required question, yet 10 respondents voluntarily responded with “not applicable” or “none,” indicating they were able to access the information to perform their work.

Survey Domain #4: VHIE User Experience

The final domain of the VHIE Superuser survey collected information regarding the VHIE user experience and perceptions of benefits and drawbacks. In addition, motivation for VHIE use, facilitators and barriers affecting utilization, and VHIE training received were addressed in this domain.

Sixty-six survey participants shared their perception of the benefit(s) of using the VHIE in their work. Qualitative analysis of the text responses revealed three predominate themes: coordination and continuity of care, access to outside information, and better patient care. Expediting health record sharing (i.e., the process to obtain Veterans health information from other VA and non-VA providers) and eliminating duplication (e.g., tests, treatment) were also strong themes.

VHIE Benefits Themes – Sample of Supporting Superuser Quotes

Theme #1: VHIE use helps provide coordination and continuity of care.

“Accessing digital information in real time is invaluable in providing coordinated, comprehensive care.”

“Helpful tool to increase continuity, efficiency, and thoroughness for patient care.”

Theme #2: VHIE use provides access to helpful health information from other VA and non-VA providers.

“Being able to gather a complete medical picture of the Veteran from both VA and non-VA care to provide the best possible care possible.”

“It allows me to follow the Veterans who receive their primary care outside the VA - to follow labs, follow medication dosing, and see the education that has been provided by non-VA providers.”

Theme #3: VHIE use leads to better patient care.

“Allows me to better evaluate the Veteran’s needs, previous/current care, medical stability...”

“Outside records greatly benefit Veteran care.”

Sixty-five survey participants shared text comments about their perception of the drawbacks of using the VHIE. More than half of respondents (55.4%) cited technical issues as a drawback. Within this theme, slowness of the system was
the greatest drawback (30.8%), followed by inaccessibility due to the system (JLV) being down (9.25%), log in/authentication issues (7.7%) and navigation (7.7%). The second major theme concerned the lack of data available from community partners (18.5%). The third theme, “no drawbacks to VHIE use,” was mentioned by 13.8% of respondents to this question.

**VHIE Drawbacks Themes – Sample of Supporting Superuser Quotes**

**Theme #1: Technical issues are a drawback of VHIE utilization.**

“The process is so slow at times that it is not always possible to utilize in the context of a standard clinic appointment time. Just the process of logging into JLV can be cumbersome…”

“System is frequently down or access is slow, also amount and type of information is limited.”

**Theme #2: Lack of information available from community providers is a drawback of VHIE utilization.**

“Unfortunately, not all community providers are accessible in VHIE.”

“Limited facilities who participate and notes at outside facilities are often sparse.”

**Theme #3: There are no drawbacks to using VHIE in my work.**

“There is no drawback that I can think of.”

“None.”

When Superusers were asked what motivated them to use the VHIE, the overwhelming choice selected by survey participants (84.5%) was “desire to improve care coordination” A formal directive from leadership motivated less than a quarter of respondents. Fifteen respondents chose to report an “other” motivation, which included participation in a JLV test, efficiency, and for claims processing.

User Experience domain questions also intended to discover the perceptions of facilitators and barriers to utilizing the VA Exchange. Survey participants were asked to select all applicable items. Of sixty-seven respondents, more than three-quarters (77.6%) reported that ease of accessing the VHIE in the work setting facilitated its use. Other top facilitators included facility support for VHIE use, and the ability of support staff to access the VHIE.

Through their responses to questions in the VHIE Access domain, Superusers established clear themes regarding barriers and echoed them in the User Experience domain: connectivity, functionality, and a preference for VistAWeb over JLV. Ninety percent of respondents reported “slow connection or system not available” as a barrier, almost two-thirds (63.4%) perceived the “time consuming” aspect of VHIE use as a barrier, and one-third felt VHIE use interfered with the workflow. Text responses for “Other” barriers were similar to already established technology-related themes concerning the log in process, navigation, and functionality.

Eighty-three percent of survey participants indicated they had been “self-trained.” The VHA Office of Health Informatics (OHI) launched a comprehensive communications campaign to alert all VA Computerized Patient Record System (CPRS) users about the transition from VistAWeb to JLV. Although technological limitations prevent definitive attribution, the number above would suggest many users were self-trained using the JLV videos promoted in OHI communications. Other training methods, such as group training or one-on-one training were reported at significantly lower rates: 16.9% and 2.8% respectively. Those respondents who selected “Other VLER/VHIE training” (9.9%) referenced the JLV test email, word-of-mouth, and learning by trial-and-error.

It should be noted rural Superusers (69.4%) reported far more facilitators of VHIE use than their urban counterparts (30.6%). Facility support for VHIE use (83.3%), ability of support staff to access VHIE (82.4%), and effective training (75%) were the top three facilitators. VHIE Community Coordinators at rural sites were considered a facilitator by 71.4% by respondents. Rural Superusers (41.7%) also reported less barriers to VHIE utilization than urban (58.3%).

To further understand why Superusers are utilizing the VHIE at such a high rate, survey participants were asked to respond to a series of statements assessing Theory of Planned Behavior constructs. This theory, often employed by patient-level health behavior change interventions, is used to predict the likelihood of an individual performing a behavior based on attitude, subjective norm, and perceived behavioral control. On a 5-point Likert Scale where “1 =
Strongly Disagree” and “5 = Strongly Agree,” respondents expressed a positive attitude about the VA Exchange and its use, support from their peers for using VHIE, and confidence to successfully use the VHIE. Each statement scored 4 or higher except for the statement regarding peer use of the VHIE (3.47). These results indicate the Superusers are a good “model” of the desired behavior (VHIE adoption and utilization).

![Figure 4](image-url)

**Figure 4.** Theory of Planned Behavior Constructs and VHIE Superuser Behavioral Intent (n=72).

**Discussion**

Whether working in a rural or urban facility, those who currently use the VA Exchange most, the Superusers, share commonalities. They have a positive attitude toward VHIE, despite technical barriers impeding or preventing use. Their shared desire to deliver high quality, coordinated care to Veterans and their ability to access the VHIE throughout the work setting motivate and facilitate VHIE utilization. The Superusers believe there are benefits of incorporating use of the VA Exchange in their workflow and have identified use cases for better and more efficient care delivery. They feel that while data quality is good, gaps still exist and HIE participation by more community providers would help provide salient missing information. As 70% of the survey respondents have been with VA five years or more, they are experienced with and more comfortable using VistAWeb, but through self-directed training can develop the necessary knowledge and skills to successfully transition to JLV.

As key consumers of Veterans health information, Superusers have expressed a clear intent to look outside VA for information to coordinate Veterans care. They routinely view community medical histories, lab and imaging results, medications, and procedures and notes. They have found the value of VHIE use to co-manage care of Veterans with chronic conditions and community hospitalization or emergency department admissions. They gather information to prepare for appointments and often review discharge summaries, immunizations, and allergies.

The VHIE Superuser Survey effectively captured data and psychographic information to create a vivid picture of the model VHIE user and their reality. Survey findings and answers to the six CHC strategic questions and are currently being used to develop a communications campaign promoting the benefits of VHIE use, facility/peer support for VHIE use, and the availability of self-directed training videos to quickly gain the skills necessary to begin accessing and using the VHIE in the clinical setting (social marketing Phase II). The campaign is scheduled to launch at 56 rural VA Medical Centers in late summer 2019. Throughout the campaign JLV training video completion will be monitored; and Active JLV Users, Patient Record Views, and Unique Patients Viewed will be measured. Program evaluation (Phase III) will measure the communications intervention ability to influence behavior change and what, if any, role the self-directed JLV training played in technology adoption and utilization.
Conclusions

While the MISSION ACT of 2018 will expand access to community care for Veterans, and an opt-out policy change will dramatically increase the amount of Veterans health information to be exchanged between VA and community providers, meeting the full intent of the law and VHA Directive 6371, and maintaining Veterans trust in VA, requires a greater number of VA providers actively using the VHIE. As the opt-out consent policy for VHIE goes into effect in October 2019, Veterans will be asking their VA providers if they are viewing electronic community health records as part of standard care.

Results of the VHIE Superusers Survey are consistent with previous study findings indicating those who use the VA Exchange are motivated to do so by a desire to provide high quality, coordinated care for patients, and that technical barriers may prevent users from incorporating VHIE into their workflow and encouraging others to do the same (23). Video training, available for viewing at the user’s convenience, provides an attractive and effective alternative to group training or one-on-one training; especially for individuals who perceive time for skills-building as limited.

Employing the social marketing process to address low HIE utilization may be an effective approach to influencing and changing provider behavior, but requires planning and research to collect the quantitative and qualitative data necessary to understand the target audience and their reality. As the VA transition to a new EHR looms on the horizon (as it does for many community providers), an effective evidence-based communications program facilitating new health IT adoption has application inside and outside VA.

Acknowledgements

The authors would like to thank the VHIE Superusers, VHIE Community Coordinators, and VHIE program office team for their time and assistance with this study. This work was funded by the Department of Veterans Affairs Office of Rural Health and conducted in collaboration with the VA Office of Health Informatics, VHIE Program Office. It received Quality Improvement determination from the VA Maine Research and Development Committee and met compliance with VA National Center for Organizational Development, Organizational Assessment Sub-Committee and VA Office of Research and Development guidelines for surveying VA employees for VA operational and research purposes.

Abstract
Genomic medicine has created an urgent need for scalable genomic education. One promising approach is self-guided learning platforms. Understanding how these platforms are used is critical to guide their effective development and implementation. This study contributes a log-based method to study user engagement with online genomic educational videos among participants in a genomic screening study. We collected baseline demographics, logged participant usage and compared pre- and post-education genomic knowledge. Participants (N=390) who chose website access differed from those who declined access (N=81) and were more likely to be non-Latino, English speaking, younger, and have higher educational attainment. Only 45% who accessed the website viewed at least one video. The average video exposure time was 12 minutes. Longer exposure was not associated with an improvement in the user’s genomic knowledge. Our study and future studies of user analytics should be used to guide the development of effective, scalable genomic education methods.

Introduction
The integration of genomic medicine into research and healthcare has created a need for effective, efficient, and scalable genomic education. Traditionally, genomic education is provided by a healthcare provider, often a genetic counselor, in a one-on-one, face-to-face session. With the growing practice of genomic medicine, this model is not sustainable due to workforce limitations, including lack of access to genetic counselors1, limited expertise among nongenetic providers2,4, and stringent time constraints for all healthcare providers. Additionally, in the research setting, there is growing consensus that researchers have an obligation to return individual genetic research results though they may not have the knowledge or infrastructure to provide the necessary genomic education5. These changes and accompanying challenges raise the need to not only develop alternative genomic education methods, including web-based video methods, but also approaches to measuring the use and effectiveness of these platforms.

Studies have begun to demonstrate the potential effectiveness of alternative genomic education methods. Several studies have shown videos and interactive web-based methods to augment or provide equivalent genomic education to traditional genetic counseling. Web-based tools are also positively endorsed by providers and patients6-12. A study of non-patient users demonstrated improved genetic knowledge after video education on genomic sequencing13. Studies have also demonstrated videos to be effective for non-genetic medical education and associated with improved knowledge, retention of information and patient satisfaction14-16. With the exception of one study that measured the amount of time a participant spent watching the video15, in all of these studies, participants’ usage of the tool was known because they accessed the tool in the clinical setting or because they followed prompts to the end of the web-based education; no more detailed user analytics were collected. There is one study using public YouTube videos on hereditary cancer syndromes that collected frequency of views but had only limited information on a fraction of the people who viewed the video and had no measure of effectiveness or satisfaction17.

While emerging research demonstrates the potential utility of web-based genomic video education, these studies have lacked data on how individual participants interact with these platforms and content, and how this use is or is not associated with a measure of effectiveness (e.g. change in genomic knowledge, participant satisfaction, etc.). A more complete understanding of participants’ use including the minimal user engagement is needed, especially when the education materials are self-guided and administered outside of a clinical setting.

We developed a log-based analysis to measure individual engagement with web-based education videos among the participants enrolled in a study of genomic screening for Ashkenazi Jewish and Latino individuals. We also explored the associations of participant usage of the videos with demographics, change in genomic knowledge and participant perceived benefits of the educational videos. Our study informs how user data can be collected and should be used to guide the development, assessment and use of future genomic education methods in the research and clinical settings.

Methods

We conducted a secondary analysis of IMAGene participants’ study website and video usage. The IMAGene (Individualized Medicine through the Application of Genomics) (www.imagenestudy.org) study is part of the Electronic MEdical Record and Genomics (eMERGE) consortium. eMERGE is currently in Phase III, and in this phase approximately 25,000 people enrolled in parallel consortium studies are receiving results from genomic sequencing. The IMAGene study is an arm of the Columbia eMERGE study which offered genomic screening using targeted gene sequencing/genotyping to adults who self-identified as Ashkenazi Jewish or Latino/a, who could read and speak English or Spanish and had received care at NewYork Presbyterian – Columbia University Medical Center. The restricted IMAGene study sample addressed the larger eMERGE 3 goal of assessing the ability to interpret genomic data from minority populations. The IMAGene cohort is a non-randomized, convenience sampling of individuals who met study eligibility criteria, actively invited through letters and phone calls or passively invited through flyers and community engagement events. Participants were invited to complete the study via a website, on paper through the mail, by phone or in-person. This analysis focuses on those participants who chose to complete the study and genetic education through the website. The study was approved by the Columbia University Medical Center Institutional Review Board.

Following informed consent, all participants completed a baseline questionnaire, which included demographic questions and a 15-question genomic knowledge scale (GKS). The GKS included questions that were adapted from published scales. After completion of the baseline questionnaire, participants who elected genetic education via the website were invited to view the content of the study website including the study videos. Participants accessed the secure study website at their convenience using their email address and an assigned password. The participant self-determined when they had sufficient genetic education and were not required to view or watch any content on the website. They were then prompted to complete the GKS again (post-education GKS). Participants had two attempts to answer 12 or more of 15 questions on the post-education GKS correctly. If they were unable to do this, a genetic counselor contacted them before they were able to proceed with the study and have genomic screening.

We developed educational videos and documents for this study to provide self-guided genomic education through the study website https://www.imagenestudy.com. The videos and website content were developed by a team of geneticists, psychologists, genetic counselors, research assistants and community members over the course of 12 months. The videos were reviewed on three occasions by the development team and iterative improvements were made. The website hosts eight videos (Table 1); videos 2-7 were revised to improve clarity on January 27, 2017. Video 5 was removed after March, 2017 because of a change in the study protocol, and analysis of this video is not included in this study. In this analysis, we present user data from the old and new videos together unless otherwise specified. The video topics included genes, inheritance and genetic mutations, genomic screening for genetic conditions, interpretation of different types of screening results (e.g., personal genomic results and carrier screening) and personal, familial and reproductive implications of screening results. The average video duration for the English language videos was 3.5 minutes. The total time to view all videos was 26 minutes. The videos’ Felsch-Kinkaid reading grade level ranged from 9.0-12.0 and 6.4-10.6 when the genetic terms that were defined in the video were removed. The Spanish language video covered all topics and was almost 10 minutes long. It was viewed by only four participants, and therefore no analysis for this video was completed.
Participants who elected not to have website access received a DVD of the website videos and paper materials that included the same information as that on the website. Since we were unable to measure usage of these offline materials, these participants were not included in our usage analysis. All participants were notified of the option to contact study personnel or the study genetic counselor by phone or email.

The website was accessed by participants on their own devices at their convenience from July, 2016 to August 2018 and unobserved by study personnel. We logged and measured user specific data including website access and duration and type of video viewed and performed a retrospective analysis of the log files of the website with focus on log data for video playing patterns. The atomic unit of the log files is event. Each event corresponds to a type of action. The analysis was performed using Python2.7, and the scripts are available upon request.

We measured the number of participants (i.e., users) who accessed the website, the total number of times they accessed the website, and the length of these accesses. Website exposure is the sum of all the website accesses for each participant. We measured the number of videos users accessed, number of videos users completely viewed, and the total time of video access. Video access is defined by the observation of a “video playing” event. Repetitive accesses to one video counted as one access. The video exposure time is the total length of time for all video accesses including repetitive views. The videos are composed of pages of content which are similar to animated slides in Microsoft PowerPoint, and this internal structure is referred to as a “page” in this analysis. The last page of each video displays study contact information without audio. Video completion was defined as reaching the last page of video. The events recorded in the log files were segmented into sessions to analyze users’ actions on each video. Each event is associated with a page view ID. We created sessions by grouping events based on page view ID prefix, and a session is dedicated to the access of one video from one user.

To enable the evaluation of associations between exposure time and participant characteristics, participants’ video exposure times were divided into three categories: (1) minimal - those who had web access but had less than 120 seconds of video exposure time, (2) moderate - those who had 120 to 600 seconds of video exposure time and (3) maximal - those who had over 600 seconds of video exposure time.

Summary statistics are presented in frequencies, means and ranges. Unadjusted analysis included Chi squared analysis and Fisher exact tests to evaluate categorical variables, and two sample t-tests and ANOVA to evaluate continuous variables. Forward multiple regression models were built to further examine the relationships between video exposure time and change in GKS score. In the simple analysis, demographic and baseline variables associated at an alpha <0.1 with predictor, video exposure time, and the outcome, change in GKS score, were defined as confounders. The final models adjusted for the identified confounders. We completed the analysis for old and new video exposure times separately and combined exposure times. The results did not differ, so we present the combined analysis. Statistical analysis was complete in SAS 9.4. Given the exploratory nature of this analysis, we did not assign a threshold of statistical significance.

Results

A total of 471 participants were enrolled, and 390 elected access to the website. The participants who elected access differed demographically from those who chose not to access the website. Participants who elected website access were more likely to be non-Latino/a, US born, English speaking, younger than 45 with a greater-than-high-school education, and privately insured (Table 2). Only 14 participants without website access proceeded with the study, and therefore it is difficult to assess differences between these two groups for these variables. The participants who had access to the website performed better on the 15 pre-education GKS (no website access: average 9.6 range 0-15, website access: average 11.8, range 2-15; p-value <0.0001). There was no difference in the change in the GKS from baseline to post education between the two groups (no website access: average 5, range 1-5, website access average 1 range -6-11; p-value 0.19).

<sup>a</sup> comparison of participants with and without website access
<sup>b</sup> Non-Latino participants identified as Ashkenazi Jewish
<sup>c</sup> 4 participants who completed the questionnaire electronically and completed study enrollment before the website was live.

Of the 390 participants who had access to the website, 303 (78%) accessed it a total of 1166 times. The average number of website sessions per user was 3.8 with a range of 1 to 32 times. The average total time of website sessions per user was 5.8 minutes with a range of 0-50.5 minutes (Figure 1).
Of the 303 users who access the website, 136 (45%) accessed a video in over 617 website sessions. The average video exposure time per user was 13.5 minutes with a range of 1 second to 34 minutes for old videos and 12.5 minutes with a range of 1 second to 45 minutes for new videos (Figure 2 a,b). The combined (old and new videos) average video exposure time per user was 12 minutes with a range of 1 second to 50 minutes. For the 136 participants who accessed a video (old or new), the average number of videos accessed was 3.8 with a range of 1-7 (Figure 3a,b). The viewing patterns of the individual new videos were assessed. Evaluation of the user viewing patterns showed that the greatest viewer drop-off occurred in the first five seconds. Users who spent more than five seconds on the video typically completed the video to the final page (data not shown).

**Figure 2ab.** Histogram of video access time for the old (a) and new videos (b).

**Figure 3ab.** Histogram of number of videos accessed for the old (a) and new videos (b).
The frequency of users by video exposure time were: (1) minimal (n=269), (2) moderate (n=53), and (3) maximal (n=68). There were a few differences in the demographics by exposure time; participants who were English speaking and completed the study questionnaires online were more likely to have moderate to maximum video exposure time. People who did not complete post-education questionnaire had lower video exposure time (Table 3). Video exposure times were associated with baseline 15 question GKS score (average 11.5 (range 2-15), 11.9 (8-15), 12.6 (6-15), respectively, p-value 0.003).

In the unadjusted analysis there was no difference in the change from baseline to post education in GKS across video exposure groups (Figure 4). After adjusting for the confounders of baseline GKS and insurance status, there remained no association between video exposure time and change in GKS score. In the adjusted analysis, the only predictor of change in GKS score was a lower baseline GKS score (Table 4).

### Table 3. Demographics of participants who had access to the website stratified by video exposure time. N (n is noted next to the variable if data is missing), column percentage. Chi squared and Fisher exact.

Overall, participants rated the educational materials positively with over 85% moderately or strongly agreeing that the website materials helped them understand the different conditions included on the genomic screen, how genomic screening can be helpful to them or their family members and improved their understanding of how genetic variants affect their risk to develop a genetic condition (Figure 5). The overall mean summed score of the website evaluation was 22 with a range of 13-57 on a scale that had a best possible score of 13 and a worst possible score of 84. Participant summed website evaluation score was not associated with video exposure time (data not shown).

**Discussion**

This study is one of the first studies to demonstrate the feasibility and value of conducting detailed participant-specific usage analytics when developing scalable genomic education methods. The collection of log-based participant usage data enabled an exploratory analysis of participants’ characteristics and use patterns, which begins to illustrate the challenges of delivering genomic education through non-traditional, scalable platforms. The majority of participants (83%) expressed interest in learning through the website. Of the 390 participants who requested access, a minority 17% of participants accessed more than 10 minutes of videos. Video usage was not associated with improvement in genetic knowledge as measured by knowledge questions that were part of the study baseline and post-education questionnaires. It is possible that participants accessed other resources through the website besides the videos, for which usage was not directly measured. Additionally,
participants may have already had knowledge of the material included within the videos, and the non-random design of the study allowed participants to self-select which videos to view based upon their perceived baseline knowledge.

The lack of participant usage data for the prior published studies limits our ability to compare our results. As with other studies of alternative educational materials in genomics and other healthcare settings, the majority of the participants who accessed the website endorsed the benefits of the information. Our experience differs from prior studies with regard to a change in participant genomic knowledge and other measurable participant outcomes. These differences are potentially related to a variety of factors though likely a significant factor was the study setting. Our educational tool was used at home and was self-guided, did not have any required content, and the education was not supervised in a clinical or research appointment.

Many of the other studies have administered educational intervention in a healthcare setting or in advance of a clinical appointment. We suspect that their participant usage was higher, because in those settings participants were supervised and given a task to complete and may have felt greater obligation to be compliant as opposed to an unsupervised home setting. However, to be truly scalable, education will need to be delivered in a manner that requires minimal provider supervision and is convenient for the individual. Additionally, our participants who were having genomic screening may have had lower motivation to view the videos compared to participants in other studies who were receiving focused education about a specific indication for which they were referred. Collection of participant usage data across different clinical scenarios will help to better elucidate differences in participant use and influencing factors.

Our experience supports prior concerns that web-based learning is not desirable for all participants and may exacerbate healthcare disparities. Participants who declined access to the website were older, had lower education levels, were more likely to be immigrants, speak Spanish as their primary language and have Medicare or Medicaid than those who chose to access the study website. While it was not measured, they likely had less access to internet devices. These participants as well as participants who requested access to the website but had minimal video usage were much more likely to choose to complete the study questionnaire on paper. In this era of increasing web and electronic based studies, there are individuals who do not have web access and/or are less comfortable learning via a website or video and completing electronic forms. Furthermore, despite efforts to make the website accessible to as many people as possible with translation of content into Spanish, very few people who spoke Spanish as their primary language had meaningful video usage. Other studies have demonstrated effective video health education in minority populations and low literacy populations when the tools have been developed for these specific populations. This suggests one single tool will not meet the needs of all, and it may be necessary to develop multiple tools to address the variable needs of different populations and ensure maximum effectiveness.

The pattern of participant usage provides important insights for future development of self-guided tools. The greatest decline in views occurred in the first five seconds of a video, and participants who watched a video in its entirety were more likely to watch other videos than those who did not. The educational videos developed for this study were visually basic with minimal animation and a voice over. Information was presented in a manner similar to a genetic counseling session; in accessible language and using analogies to explain complex information. This is likely not the most engaging manner in which information could be provided, but our strategy was limited by the research budget. Potentially platforms that immediately engage users with interesting and motivating stories and visually interesting illustrations could capture the viewers’ attention and motivate viewers to continue to watch and increase overall usage.

There are several limitations to our study. Overall, the results of this study are exploratory given the modest sample size. Future, larger, more inclusive studies are needed to confirm our findings. Our study was also restricted to participants who identified themselves as Latino or Ashkenazi Jewish and requested the receipt of genomic screening results; therefore, our findings may reflect unique perspectives of these populations and people who elect to have genomic screening results. Additionally, while the web-platform and video education were available in both English and Spanish languages, only English-speaking participants had meaningful use of the videos. The GKS was an adaptation of other scales and was not validated, and it is possible that there were educational benefits to using the website that were not captured by the GKS. The videos were modified mid-way through the study to reflect changes in the study protocol and make changes to improve the content and presentation; though duplicate analysis of exposure to old or new videos alone did not differ from the analysis of the combined video exposure.

**Conclusion and Practice Implications**

The development of scalable genomic education delivery methods is necessary but is more challenging than anticipated. More user testing with detailed user analytics is needed during the development stage to identify and
adequately address issues of user engagement and retention. Overcoming these hurdles will require collaboration with professionals specialized in the development of interactive websites and video education in order to identify ways to deliver information in an interesting and engaging fashion. Because of the cost associated with robust development, the genomics community needs to collaboratively develop scalable and adaptable tools. Similar to the way genomic sequencing data are shared to advance collective knowledge, existing and emerging health information technologies including effective genomic education methods should be leveraged to enable tailored, layered, and large-scale communication.5

More studies that include detailed user analytics are warranted to continue to explore the effectiveness of novel methods of genomic education in more diverse groups of individuals. Finally, we need to appreciate that even with scalable effective genomic education, there will be individuals for whom traditional models will be preferred and more effective based upon the characteristics of the individual and the clinical context.

Abstract

Cardiotoxicity related to cancer therapies has become a serious issue, diminishing cancer treatment outcomes and quality of life. Early detection of cancer patients at risk for cardiotoxicity before cardiotoxic treatments and providing preventive measures are potential solutions to improve cancer patients’ quality of life. This study focuses on predicting the development of heart failure in cancer patients after cancer diagnoses using historical electronic health record (EHR) data. We examined four machine learning algorithms using 143,199 cancer patients from the University of Florida Health (UF Health) Integrated Data Repository (IDR). We identified a total number of 1,958 qualified cases and matched them to 15,488 controls by gender, age, race, and major cancer type. Two feature encoding strategies were compared to encode variables as machine learning features. The gradient boosting (GB) based model achieved the best AUC score of 0.9077 (with a sensitivity of 0.8520 and a specificity of 0.8138), outperforming other machine learning methods. We also looked into the subgroup of cancer patients with exposure to chemotherapy drugs and observed a lower specificity score (0.7089). The experimental results show that machine learning methods are able to capture clinical factors that are known to be associated with heart failure and that it is feasible to use machine learning methods to identify cancer patients at risk for cancer therapy-related heart failure.

Introduction

Cancer is the second leading cause of death in the US.1 There has been a great amount of effort and resources invested in the development of new cancer therapies. The mortality rates of many cancers are being brought under control with the improvement of cancer treatment.2 However, these anticancer treatments often have various side effects. For example, cardiotoxicity is one of the well-documented adverse events of cancer treatments resulting either from accelerated development of cardiovascular diseases in cancer patients or from the direct effects of the treatment on the structure and function of the heart.3 Traditional chemotherapy such as anthracyclines have been known to cause cardiovascular complications.4,6 Cardiotoxicity related to cancer therapies has become a serious issue that diminishes cancer treatment outcomes. A recent study examined various anticancer therapies and reported a significant correlation between quality of life (QoL) and chemotherapy cycles.7 Early detection and possible prevention of cardiotoxicity in cancer treatments is a potential solution to improve cancer patients’ safety and QoL. Identifying cancer patients with high risk of cardiotoxicity is a critical step towards early detection and possible prevention.

In the last two decades, the introduction of targeted anticancer therapies has revolutionized the treatment of both hematological malignancies such as multiple myeloma, chronic myeloid leukemia and solid malignancies such as breast and renal carcinoma.8,9 Contemporary cancer therapy has led to a 23% reduction in cancer-related mortality rate and rapid increase in cancer survivorship in the last 15 years.10 However, some devastating side effects of these treatments have also resulted in increased morbidity and mortality.11,12 Examples of these targeted cancer therapies include human epidermal growth factor 2 inhibitors, inhibitors of vascular endothelial growth factor pathway and tyrosine kinase inhibitors and proteasome inhibitors. Most recently, immune checkpoint inhibitors have also been associated with cardiotoxicity.13,14 Despite the efficacy of these therapies, their widespread use has paradoxically resulted in the emergence of serious cardiovascular effects/complications such as cardiomyopathy/heart failure, coronary artery disease, myocardial ischemia, hypertension, arrhythmia, thromboembolism, and pericardial disease.15 One of the most relevant clinical implications of these complications is treatment interruption, which is associated with cancer recurrence. Due to the high incidence and negative impact on patient outcomes, new medical subspecialties such as Cardio-Oncology were created to optimize the care or management of patients receiving these cancer therapies. Identifying patients with high risk of cardiotoxicity using historical electronic health records (EHRs) could be potentially used to improve cancer treatment safety and QoL.
Rapid adoption of EHRs has made longitudinal clinical data available to research. There is an increasing interest in using longitudinal EHRs to develop computational algorithms for disease onsite prediction. Researchers have applied standard statistical regression models and machine learning methods to predict the onsite of heart failure among general patient cohorts. For example, Wang et al. developed a heart failure predicting model using random forests (RFs) and examined various prediction windows. Sun et al. proposed a method to combine knowledge and data driven method to identify risk factors of heart failure from EHRs. Wu et al. compared three machine learning models including Boosting, support vector machines (SVMs) and logistic regression (LR) for heart failure prediction. While machine learning-based predictive models showed decent performance, previous studies identified issues such as imbalanced data and the lack of modeling temporal sequence among clinical events. Recently, Choi et al. applied recurrent neural networks (RNNs) for heart failure prediction and compared RNN with a traditional machine learning model – SVMs. Their study reported that deep learning models were able to leverage temporal relations among clinical events to improve performance of heart failure prediction with a short observation window of 12-18 months. Rasmy et al. also examined the generalizability of RNN in predicting heart failure onset risk using a large and heterogeneous EHR data set. Researchers from the cancer community have applied statistical regression models for risk assessment of heart failure after cancer treatments. For example, Ezaz et al. applied regression analysis to assess risk scores of heart failure among breast cancer patients after trastuzumab therapy. Authors used a study cohort consisted of women from 67 to 94 years old from the SEER-Medicare database diagnosed with early-stage breast cancer. Although machine learning has been successfully applied to the general patient cohorts for heart failure prediction, it’s not clear whether it can be applied to cancer patient cohorts to support early detection and possible prevention of cardiotoxicity in cardiotoxic cancer therapies.

This study focused on the prediction of cancer patients developing heart failure after cancer diagnoses. We examined four machine learning algorithms for heart failure prediction among cancer patients from the University of Florida Health (UF Health) Integrated Data Repository (IDR). We compared four widely used machine learning models including LR, RFs, SVMs, and Gradient Boosting (GB) for heart failure prediction among cancer patients. We systematically examined variables including patient demographics (gender, race, age), diagnoses, medications, and procedures as machine learning features. We also compared one-hot encoding and term frequency-inverse document frequency (TF-IDF) encoding for all four machine learning methods. Furthermore, we compared the performance of heart failure prediction on general cancer patients with the performance on cancer patients with exposure to chemotherapy drugs. Our ultimate goal is to develop predictive models for identification of cancer patients with high risk of cardiotoxicity to prevent or minimize the risk of cardiotoxicity in cancer treatments.

Methods

Data set

In this study, we used EHR data from UF Health IDR. Supported by the UF Clinical and Translational Institute (CTSI) and the UF Health, the UF Health IDR is a secure, clinical data warehouse (CDW) that aggregates data from the university’s various clinical and administrative information systems, including the Epic electronic medical record (EMR) system. As of February 2019, the IDR contains data for encounters that occurred after June 2011, with a total of more than 1105 million observational facts pertaining to 1.17 million patients. From UF Health IDR, we collected a total number of 143,199 cancer patients from Jan 1st, 2011 to Dec 31st, 2017. We identified cancer patients using the diagnosis codes (at least one cancer diagnosis code). The extracted EHR data contains patient demographics, diagnoses in both the International Classification of Disease version 9 (ICD-9) and the International Classification of Disease version 10 (ICD-10), medications in RXNORM codes, and procedures in CPT codes. This study was approved by the UF Institutional Review Board.

Definition of cases and controls

Starting from the initial cancer patients, we removed patients diagnosed with only benign type of cancers. Then, we identified the first diagnosis date of cancer as cancer index date, denoted as CAID. Following previous studies from Choi et al. and Rasmy et al., we defined the heart failure onset date (HFOD) as the first encounter date of three consecutive heart failure diagnosis encounters occurred within 12 months.

Cases: Following previous studies on heart failure prediction of general patient cohorts, cases of heart failure were defined as follows: (1) having at least three encounters with qualified heart failure diagnoses defined in Table 1 occurred within 12 months; (2) the CAID must before the HFOD – this rule removed the cancer patients with existing heart failure conditions before cancer diagnosis; (3) at least have one medication record or one procedure record – we want to ensure that the patient received treatments at UF Health.
Controls: Controls were defined as cancer patients without any qualified heart failure codes defined in Table 1.

Data used for prediction: We used all structured EHR data, including patient demographics, diagnoses, medications, and procedures occurred before the HFOD for prediction. Clinical variables occurred at or after HFOD were not used.

Case-control matching: For each case, up to 9 controls were selected according to criteria defined as follows: (1) having the same gender and race as the case; (2) age is within five-year interval of the case; (3) having the same major cancer type; (4) the first encounter date of the control is within a year with the first encounter date of the case; (5) having an encounter occurred either within 30 days before or any time after the HFOD of the case. The encounter date closest to the HFOD is denoted as reference encounter date. For cases that could not be matched to any controls, we removed them from the data set. To facilitate comparison with previous studies, we followed the same case-control matching procedure without replacement. Figure 1 shows an overview of the case-control matching procedure.

Figure 1. An overview of case-control matching procedure

Machine learning algorithms

In this study, we explored four widely used machine learning algorithms including LR, SVMs, RFs, and GB. We applied LR as the baseline method and compared it with SVMs, RFs, and GB. For LR, RFs, and SVMs, we adopted implementations in the scikit-learn library (http://scikit-learn.org). For GB, we used the implementation from the XGBoost package (https://github.com/dmlc/xgboost). For LR, we optimized the optimization method (solver), the regularization parameter $e$, and the tolerance of termination criterion $e$. For SVMs, we used the Radial Basis Function (RBF) kernel and tuned the regularization parameter $e$, and the tolerance of termination criterion $e$. For RFs, we performed the optimization on the parameters including the number of trees (n_estimators), the tree splitting function, the tree max depth (max_depth). For GB, we optimized the learning rate (eta), the maximum depth of a tree (max_depth), and the number of boost trees (n_estimators) and chose the logistic regression for binary classification as the objective function to evaluate the training loss and regularization.

Variable grouping and feature encoding

In this study, we used patient demographics (gender, race, age), diagnoses, medications, and procedures to develop machine learning models for heart failure prediction. As previous studies have identified the sparseness issue of using the diagnoses and medications as features, we grouped the diagnoses codes (ICD-9 or ICD-10) and medication codes (RxNorm concept unique identifier codes or drug names) according to existing disease groupings.

For diagnoses codes, one previous study from Choi et al. grouped the ICD 9 codes using the Clinical Classification Software (CCS) groups (having a total number of 283 groups) and Rasmy et al. grouped ICD 9 codes using PheWAS (Phenome-wide association studies) groups (about 1,800 unique PheWAS groups). Following the study of Rasmy et al., we mapped the ICD-9 and ICD-10 codes to the PheWAS groups. Using the PheWAS code translation table, we mapped a total number of 36,701 unique ICD-9 and ICD-10 codes into a total of 4,973 unique PheWAS groups.

For medication codes in RxNorm concept unique identifiers (RXCUIs), we mapped them to the ingredient-level RXCUIs. For example, Abraxane (with RXCUI 589511) is a brand name for a chemotherapy drug with the ingredient...
Paclitaxel (RXCUI 56946). Thus, we mapped all RXCUI of 589511 to RXCUI 56946 when developing machine learning models. After mapping all medications to their ingredient level RXCUI codes, we mapped a total number of 19,774 clinical-level RXCUI codes to a total of 2,376 ingredient-level RXCUI codes.

To convert the clinical variables into machine-readable features for training, we compared two encoding methods. The first method is one-hot encoding where variables are encoded using binary values of ‘1’ (indicating feature occurred in a sample) or 0 (indicating feature not occurred). The resulted one-hot encoded data is a sparse matrix of 1 and 0. In the one-hot encoding, the frequency of variables is not considered. Variables occurred multiple times were counted only once. In the second encoding method, we further considered the frequency of variables among patients. Inspired by the term frequency-inverse document frequency (TF-IDF) strategy, we treat each patient as a document and each feature as a word in the document. Then, we applied the standard TF-IDF calculation to convert each patient into a TF-IDF weighted vector. For each machine learning algorithm, we trained two models for one-hot encoding and TF-IDF encoding, respectively.

Experiments and evaluation

Using stratified sampling, we split the data into a training set with 13,956 patients (1,566 cases and 12,390 controls) and a test set with 3,490 patients (392 cases and 3,098 controls). We optimized the machine learning models using five-fold cross validation and grid searching. We trained machine learning models using the training set and evaluated the performances using the test set. Following the previous studies, we used the area under the receiver operating characteristic curve (AUC or AUC-ROC) for evaluation. We also conducted statistical tests to compare different methods. The statistical test scores were calculated by sampling 100 times from the test data and each time a number of 1,745 (50% of the test set) samples were randomly selected. We used the t-test to calculate p-values. We also reported the sensitivity and specificity determined using the Youden’s index to facilitate comparison.

After case-control matching, we identified a total number of 1,958 cases and 15,488 controls. Table 2 compares the descriptive statistics between the case and control groups. For demographic information, the case and control groups have a similar distribution as a result of the matching procedure. On average, patients in the case group have more diagnoses, medications, and procedures compared to the control group patients. In both case and control groups, the most common cancer subgroups include cancer of skin, female breast cancer, prostate cancer, and lung cancer.

Table 3 compares the performance of four machine learning models using two different encoding strategies. The last column shows the statistical p-values between two encoding strategies for each method. The baseline LR achieved an AUC of 0.8795 and 0.8762 for one-hot encoding and TF-IDF encoding, respectively. The statistical test (p-value of 0.1072) showed that there is no significant difference between the two encoding strategies for LR. For other machine learning methods, the TF-IDF encoding outperformed the One-hot encoding with significant p-values. The GB model trained with TF-IDF encoding achieved the best AUC of 0.9077 outperforming all other models with statistical p-values of <0.01. The AUC scores of the SVMs-based models are notably lower than other machine learning models (p-values of < 0.001), which is consistent with the experimental results reported by Wu et al.18 in a similar study. The GB model trained with one-hot encoding obtained the best sensitivity of 0.8546 and the SVMs trained with one-hot encoding obtained the best specificity of 0.8657.

Discussion and Conclusion

In this study, we examined four machine learning algorithms for heart failure prediction using cancer patients’ EHR data from UF Health IDR. Starting from a total number of 143,199 cancer patients, we identified 1,958 qualified cases who developed heart failure after diagnoses of cancers, which were matched to 15,488 controls by gender, age, race, and major cancer type. We compared two feature encoding strategies including one-hot encoding and TF-IDF encoding in developing machine learning methods. The GB model with TF-IDF feature encoding achieved the best AUC score of 0.9077, significantly outperforming other machine learning methods. The experimental results show that it is feasible to use machine learning methods to identify cancer patients with risks of cardiotoxicity. Previous studies have applied machine learning methods for heart failure prediction among general patient cohorts without anchoring on any diseases. This study demonstrated the feasibility of using machine learning methods for heart failure prediction among cancer patients. Among the four machine learning models, LR and RFs achieved decent performance. However, the performance of the SVMs model is relatively lower than other machine learning methods. A similar study by Wu et al.18 also reported that SVMs achieved lower performance in general patient cohorts. We also explored two feature encoding strategies including one-hot encoding and TF-IDF encoding. The experimental results (Table 3) showed that the models trained with the TF-IDF encoding method achieved better performance compared to one-hot encoding method for SVMs, RFs, and GB. A possible reason is that the TF-IDF encoding can capture frequency information of variables thus to enhance performance.

We looked into the subgroup of cancer patients with exposure to chemotherapy drugs to further examine the prediction performance. To facilitate subgroup analysis, two UF Health physicians (NW and KM) manually reviewed a total
number of 1,557 ingredient-level medications used by at least 10 patients and identified 104 chemotherapy drugs. The top three drugs are methotrexate (used by 1,486 patients), cyclophosphamide (used by 1,371 patients), and carboplatin (used by 1,275 patients). Using this list of chemotherapy drugs, we identified 458 patients with exposure to chemotherapy drugs from the test set and calculated the sensitivity and specificity. For this subgroup, the best machine learning model (i.e., GB) achieved a sensitivity of 0.8824 and a specificity of 0.6300, respectively. Compared with the scores on the entire test set (a sensitivity of 0.8520 and a specificity of 0.8138), this subgroup has a better sensitivity but a significantly lower specificity. This may indicate that exposure to chemotherapy drugs is a strong but not deterministic risk factor for heart failure detection. As many chemotherapy drugs are known to have cardiotoxic side effects, it’s not surprising to see that chemotherapy drugs are strong risk factors. Yet, the low specificity indicates that it is still challenging for machine learning models to figure out why some cancer patients develop cardiotoxicity after exposure to chemotherapy treatments while others do not.

This study focused on the prediction of cancer patients who developed heart failure after cancer diagnoses. Compared with the results from general patient cohorts, the machine learning models achieved a better AUC score in our cancer patient cohort constructed from the UF Health IDR. We compared the statistics between our cancer patient cohort with general patient cohorts used in previous studies. The cancer patient cohort used in this study has more rich medication and clinical procedure information. For example, the average numbers of medications and clinical procedures in a general patient cohort constructed by Rasmy et al. from the Cerner Healthfacts® dataset 1 are remarkably lower (27.26 in cases and 1.4 in controls) than our cancer patient cohort (87.7 in cases and 20.4 in controls). This may be one of the reasons that the machine learning methods achieved a better AUC on our cancer patient cohort.

We also calculated the feature importance using the best machine learning model (i.e., GB with TF-IDF encoding method). The results show that diagnosis of essential hypertension, atrial fibrillation, shortness of breath, tobacco use disorder, and hyperlipidemia are the top risk factors for heart failure prediction. These factors are clinically known risk factors for heart failure, indicating that the machine learning models are able to capture important clinical factors for heart failure prediction. Our ultimate goal is to develop predictive models to identify cancer patients with high risks of cardiotoxicity to prevent or minimize the risk of cardiotoxicity in cancer treatments. This study demonstrated the feasibility of machine learning methods for the prediction of cancer patients developing heart failure after cancer diagnoses. Even though machine learning methods can identify important clinical factors, the mechanism of cancer therapy-induced cardiotoxicity is largely unknown. The low specificity score on the subgroup of cancer patients with exposure to chemotherapy drugs shows that it’s still challenging for machine learning models to identify cancer patients with high-risk of cardiotoxicity after chemotherapy. This study is a preliminary step to assess machine learning models for heart failure prediction among cancer patients. To further improve the performance for cancer patients with exposure to chemotherapy drugs, we plan to explore advanced machine learning models such as deep learning and non-clinical factors such as patient genomics data.

This study has limitations. Similar to other EHR-based studies, our study may suffer from incomplete information, varying length of observation, and coding bias. We carefully designed the cancer patients who later developed into heart failure, yet, some of the cases may not necessarily come from cancer treatments. We expect more carefully designed studies to further evaluate our findings.

Lagged Correlations among Physiological Variables as Indicators of Consciousness in Stroke Patients

Tahsin T. Yavuz¹, Jan Claassen, MD, PhD, FNCS², Samantha Kleinberg, PhD¹
¹Stevens Institute of Technology, Hoboken, NJ; ²Columbia University, New York, NY

Abstract

Consciousness is a highly significant indicator of an ICU patient’s condition but there is still no method to automatically measure it. Instead, time consuming and subjective assessments are used. However, many brain and physiologic variables are measured continuously in neurological ICU, and could be used as indicators for consciousness. Since many biological variables are highly correlated to maintain homeostasis, we examine whether changes in time lags between correlated variables may relate to changes in consciousness. We introduce new methods to identify changes in the time lag of correlations, which better handle noisy multimodal physiological data and fluctuating lags. On neurological ICU data from subarachnoid hemorrhage patients, we find that correlations among variables related to brain physiology or respiration have significantly longer lags in patients with decreased levels of consciousness than in patients with higher levels of consciousness. This suggests that physiological data could potentially be used to automatically assess consciousness.

Introduction

Patients in intensive care units (ICUs) are extremely challenging to treat given the complex, critical, and changing nature of their conditions. Each patient’s state fluctuates over time, due to recovery or worsening, and as a result of interventions. However it can be difficult to gain insight into this state, and to identify factors that can be intervened upon to improve outcomes. That is, clinicians need to understand not only what is happening but why it is happening. One of the most fundamental factors influencing treatment decisions and predictions of prognosis in an ICU is a patient’s state of consciousness. Despite the critical nature of this information, there is not yet a way to measure consciousness automatically. Instead, clinicians administer labor-intensive tests such as the Glasgow Coma Scale (GCS), often only once a day. These subjective daily assessments make it difficult to determine causes and effects of consciousness, which may also fluctuate between assessments. Instead, if consciousness could be measured automatically and continuously, this would have both clinical impact (better understanding of prognosis, earlier identification of changes in consciousness, and reduced burden on clinicians) and research implications (more frequent assessments would enable analysis of causes and effects of consciousness).

While consciousness is still poorly understood, ICUs now routinely collect large amounts of data that can provide insight into a patient’s state. Multimodality monitoring including EEG, cardiovascular parameters, and brain physiology is now being increasingly used to guide clinical care in ICU, and for research predicting ICU outcomes. Despite the success of machine learning in analyzing ICU data, there has not yet been an effort to use routinely collected ICU data to gain insight into consciousness. We focus in particular on automated detection of factors related to consciousness in stroke patients in the neurological intensive care unit (NICU), due to the severity of illness and potential for improving care with a better understanding of consciousness. While data in the NICU is high frequency (often at a resolution of 5 seconds), there are many challenges in using this data to automatically detect consciousness, including the need to combine multiple sensing modalities and identify sometimes subtle signals within noisy data. First, different variables are measured for different patients, necessitating methods that do not require all possible variables to be present. Similarly, we expect different levels of consciousness to manifest indirectly across features in multiple variables. Since consciousness is assessed infrequently (generally once a day), there are few training labels, which poses a challenge for most classification methods. On the other hand, these labels also make it difficult to treat the problem as one of changepoint detection (determining when the system’s parameters or structure change), since we do not know precisely when a change occurred (e.g. if consciousness is high on Monday morning, and low on Tuesday morning we do not know when the change happened in between).

Instead, we propose that multimodality monitoring (MMM) can be used to gain insight into consciousness, by examining lagged correlations between the measured variables. We hypothesize that since many biological variables are
correlated, when consciousness is interrupted, these correlations may be too. Thus, rather than use raw MMM data directly, we propose that the time lag of correlations is a highly informative feature. While prior methods exist to identify lagged correlations, we introduce the first method to identify when the lag between correlated variables changes, and to do so in multimodality data while being robust to noise. We build on cross-correlation, which is widely used to find the lags (delays) in time series, introducing a new approach that can identify when lags change over time. We further contribute a kernel that is better suited to multimodality physiological data (allowing identification of more subtle relationships), and an optimization procedure to identify lags across an entire time series (e.g., patient’s ICU stay) while being robust to noise and outlying values. Experimentally, we show that this method can accurately recover true changing lags on simulated data, while existing work that does not account for changes has significantly lower accuracy. Finally, we apply the approach to a set of NICU data from 61 patients with subarachnoid hemorrhage (SAH), identifying biologically plausible relationships. In particular, we find that brain and cardiovascular variables are correlated with shorter delays in patients with high versus low levels of consciousness.

The primary contributions of our work are:

1. We motivate the use of lagged correlations for gaining insight into biomedical data.
2. We introduce nonstationary normalized cross-correlation ($N^2C^2$), a new method for automatically identifying lagged correlations whose timing may change over time. This highly general approach may be applicable to many types of biomedical time series, as well as time series more generally.
3. We apply $N^2C^2$ to NICU data and demonstrate novel differences in lags that appear to depend on state of consciousness.

Our approach provides a first step toward both better use of high-frequency ICU data to gain insight into previously invisible patient states, as well as a better and more objective understanding of consciousness in the ICU.

Related Work

Consciousness is a fundamental and yet unsolved problem in biology.5, 6 Most studies of consciousness focus on EEG and fMRI data,7 but this does not allow continuous measurement in the ICU. In the ICU, consciousness is generally assessed with qualitative instruments such as the Glasgow Coma Scale (GCS)8 and Alert, Voice, Pain, Unresponsive (AVPU) scale.9 Recent studies have shown that consciousness rests on the brain’s ability to sustain rich brain dynamics10 and metastability in brain dynamics can be used to understand altered levels of consciousness.11 There have been some efforts using bedside EEG to predict changes in consciousness in stroke patients,1 and using network dynamics to distinguish comatose from healthy patients using EEG.12 Other efforts have used EEG data to identify differences in sleep patterns between patients with different states of consciousness.13 However, we are not aware of work using this data to detect the current state of consciousness in real-time.

On the other hand, machine learning analysis of ICU data has focused on predicting readmission14 or ICU outcomes3 and classifying physiological features to identify disorders.15 Yet, physiological data has been shown to provide insight into brain activity, such as in a recent study that identified correlations between physiological signals (including respiration, CO₂ levels in blood, heart rate) and fMRI-monitored brain connectivity.16 Other works showed that delayed cerebral ischemia after SAH could be predicted from physiological time series data.17 Thus, it is possible that physiological data could provide a window into not only clinical outcomes, but also brain function and potentially consciousness. We hypothesize that time lags between variables may be an important signal. For example, lags in resting state fMRI and EEG provided insight into neuronal processes,18 and lags are widely studied among physiological data more generally, including in analysis of electrodermal activity.19 One of the most common methods for examining such lagged relationships is cross-correlation, which has been applied to local field potentials to gain insight into brain regions.20 Cross-correlation is a measure of similarity between two time series. For two time series with identical values, where one is a shifted version of the other, correlation will be highest, with a value of 1. To identify the lag with the maximal correlation for a pair of variables, essentially one time series is iteratively shifted with the correlation being repeatedly computed. Cross-correlation has been used for time delay estimation.21, 22 such
as for finding the phase shift between acoustic signals, but this aims to find the shift between two measurements of the same process, whereas our variables capture different processes that may causally influence one another.

While there are many extensions to cross-correlation, including faster to compute and normalized versions, it still poses problems for biological time series. First, it is assumed that the lag is the same for the entire time series, which is unlikely to be true for a patient whose physiology and state is changing—particularly in the ICU. Second, even during times of relative stability, there are smaller fluctuations due to both physiology as well as the noise and error inherent in biomedical data. By assuming a single lag, these approaches may be susceptible to the effects of outlying values. While some works have applied cross-correlation to nonstationary time series, they have done so by first removing the trends in the data to make it stationary, whereas we propose that the trends are highly informative in ICU and other physiological data where we aim to uncover the causes of changes in state. Most fundamentally, there is currently no method that can identify when and how the lags between variables change over time. We propose that this is a critical signal for assessing consciousness, and methods for finding changes in lagged correlations may have many applications to the other types of health data described above.

Method

As a first step toward automated assessment of consciousness, we focus on identifying how time lags between correlated variables change as a function of consciousness. To do this using physiological data routinely collected in ICU, we introduce a new method, \( N^2C^2 \) (nonstationary normalized cross-correlation), based on normalized cross-correlation (NCC), that identifies when and how the lags between variables changes over time. Unlike the state of the art, which assumes the lag between two time series remains constant, this allows us to identify both gradual shifts in time lag (e.g., slow change from 1 to 5 second lag) as well as sudden transitions (e.g., such as after an intervention). Further, this indirectly provides detection of changepoints, but with more context (i.e., what is changing) and more flexibly (i.e., not requiring a change to be in the mean of a variable’s value), than the state of the art without the need for specifying a model as in many prior works. Thus our output may be that from hour 0 to hour 10 heart rate (HR) and respiration rate (RR) are synchronized with a lag of 0, while from hour 10 to 12, RR lags HR by 1 minute. By testing how the lags differ across patients in different states of consciousness, we can learn characteristics of these states, which could be used for detecting an individual’s current level of consciousness and further when it changes (e.g., when the lag between certain variables grows). Figure 1 shows an overview of the procedure.

We build upon NCC, which is more interpretable than cross-correlation and can handle variables with varying ranges. This is particularly important for MMM data, where variables differ substantially in range, standard deviation, and frequency. NCC is defined as:

\[
NCC(x, y, l) = \frac{\sum_{t \in T} (x[t] - \bar{x})(y[t + l] - \bar{y})}{\sqrt{\sum_{t \in T} (x[t] - \bar{x})^2} \sqrt{\sum_{t} (y[t + l] - \bar{y})^2}}
\]

where \( x \) and \( y \) are time series with the same measurement frequency, \( T \) is the time series, and \( l \) the lag being tested. \( NCC(x, y, l) \) is then the correlation between \( x \) and \( y \) where \( y \) is shifted \( l \) time steps. While NCC can tell us how related two time series are and with what lag, it has the fundamental limitation that the time lag is constant across time.

\( N^2C^2: \) finding changing lags over time

We now introduce nonstationary normalized cross-correlation (\( N^2C^2 \)), which identifies changes in lagged correlations for a set of time series data \( D \). In the case of physiological data, the lags may differ between patients, or within a patient over time (e.g., due to an intervention or change in status). Lags further can fluctuate over time both due to the underlying biology as well as our noisy measurements of it. Thus some seeming changes may be due to relationships that have a time window (e.g., variation within 1-5 min). If we simply accepted the most significant lag at each timepoint, we could then find frequent oscillation between 1 and 5 minutes, even though there is no actual change. To address this we make two key assumptions:

Assumption 1 Lags between physiological variables in ICU tend to zero.
Figure 1: This figure shows an overview of the proposed method. First, we set the length of time window, \( W \). Then, sliding this time window across the series we search over each lag \( l \) in the set of possible lags between \( A \) and \( B \). To identify which lags are significant, we use a permutation test. To ensure lags change smoothly and are not sensitive to outlying values, we determine the lags for the entire time series at once, using the 3D surface shown. Finally, we output a sequence of lags for variables \( A \) and \( B \). In this example, the lags increase non-monotonically across time, with \( B \) having an increasingly delayed response to \( A \)'s value.

Assumption 2 True lags have higher NCC and at a short timescale, lags are stable.

Assumption 1 says that if all else is equal, we believe that shorter lags are more biologically plausible in our application areas. For other applications the reverse may be true, such as when there is a known delay in information transmission. Assumption 2 says that if we find a lag, say, of 3 seconds between HR in a patient’s data at time 0, a lag of 0 at time 1, and lag of 3 seconds for times 2-10, despite assumption 1, the lag at time 1 is unlikely to be zero because we believe lags are locally stable. By stable we mean that having smaller or no changes in lags is more probable than large changes. In practice we may find multiple lags with similar significance levels (perhaps lag 0 was only slightly more significant than 3 at that time), and this is used to ensure smooth transitions at short timescales. While this ensures some smoothness in lags, by examining lags as forming a continuous surface we are still able to identify when there is a change in the trend, such as if lags shift from an average of 0 to an average of 3 over time.

Step 1: Finding potential lags In general, we focus on finding relationships between all pairs of variables \( x, y \) in either direction (with \( x \) lagging \( y \) or vice versa), though this set could be constrained for example when it is known that the correlation must be in one direction or the other. For instance, if we want to find the speed of the sound in a certain material then knowledge of the microphones’ positions can be used to inform the direction of each lag (as it should be from the microphone closest to the source to the others). Note that treating each direction separately (finding the most likely lag from \( x \) to \( y \) and vice versa) enables us to find the lags for each stage of a feedback loop. We assume the data \( D \) is a \( v \times T \) matrix, where \( D(x, i) \) is the value of variable \( x \) at time \( i \). We are able to calculate correlation when some portion of the data are missing, however we also apply methods that have been developed for imputing missing values in ICU and biomedical data to reduce the degree of missingness. More formally, we aim to identify lags that change over time, so we first partition the time series into a set of overlapping windows of size \( w \), with the step size being the measurement frequency (i.e. the window advances by one unit at each step). The parameter \( w \) should be chosen to be small enough that lags are likely to remain stable within this period (so \( w \) should be smaller in data that changes rapidly rather than in systems that are more stable), while being large enough that there are enough measurements to accurately calculate the NCC. While the choice of \( w \) is important, it mainly should be chosen to reflect the scale at which changes are happening, and is not sensitive to small differences. For the ICU data in this paper, we select a \( w \) of 300 minutes (5 hours), since we use data at a resolution of 1 minute. Since there can be many local fluctuations, with a shorter window it becomes more challenging to identify the overall patterns in this noisy data.

Within each window, we iterate over the set of potential lags \( l \in [0, l_{\text{max}}] \), calculating \( NCC(x, y, l) \) using only the data in the window (as again the lag may change over time). That is, for each pair of variables \( x \) and \( y \) in \( D \) for each
window \( w \), we iterate over the lags to form the set of scores:

\[
N^2C^2(x, y, t, w)[t] = \sum_{i \in [t-w, t+w]} (x[i] - \bar{x})(y[i + \ell] - \bar{y}) \sqrt{\sum_{i \in [t-w, t+w]} (x[i] - \bar{x})^2 \sum_{i \in [t-w, t+w]} (y[i + \ell] - \bar{y})^2}.
\]

(2)

The output is for the window centered at time \( t \), a vector of size \( l_{max} \) with correlation scores for each lag. By repeating this for each time \( t \in T \), we have a set of vectors covering the entire time series. Unlike NCC, this uses a subset of the data (rather than the whole time series) at each step, and rather than identify the maximum correlation, outputs the score for all lags.

**Step 2: Assessing significance of lags** As we have stressed, one of the challenges posed by biomedical data is that lags between variables may fluctuate without there being a significant change in the relationship between variables, such as due to noise, measurement error, or relationships with time windows rather than single lags among other reasons. Thus we cannot simply select the lag with the highest correlation at each \( t \), as this may lead to undesirable properties across the time series, namely a violation of our assumption of local stability of lags. To address this, we first identify which correlations are statistically significant, then from that set optimize for a set of smoothly changing lags across the entire time series.

First, not all tested variables will be correlated, so we must determine which pairs (and at which lags) to accept. Since it can be challenging to determine a null hypothesis, we use a permutation test to find the null and then determine which correlations are significant compared to that. The permutation test shuffles the times associated with one variable’s data within the tested window and then recomputes the correlation. The idea is that by breaking the temporal sequence of the data, we can then learn the distribution of scores for time series that are uncorrelated. This is repeated \( S \) times to obtain a distribution of correlation scores for uncorrelated data. In this work we use an \( S \) of 200. Using this, we can determine if, compared to this null distribution, our observed results are statistically significant. The result of this step is a subset of the lags from the first step (those determined to be significant), though there may still be multiple significant lags at each time for each variable pair.

To find the single most likely lag for each pair \( x, y \) at each time \( t \in T \) we apply a kernel to give higher weight to shorter lags (as in our assumptions), and then identify lags using the entire sequence of scores. First, we apply a stretched tricube kernel to \( N^2C^2(x, y, t) \). We use only the positive side of the kernel (\( 0 \leq u \leq 0.5 \)) in:

\[
K(u) = \frac{70}{81}(1 - |u|^3)^3.
\]

(3)

As a result, we have a kernel that encodes a preference for lags closer to zero while still allowing the possibility of longer lags. Figure 2 shows the tricube kernel and our stretched version. As shown, our kernel has the same preference for shorter lags, but decreases more slowly as the lag increases, allowing for identification of longer lags. In this setting, negative lags are captured by testing both \( N^2C^2(x, y, t) \) and \( N^2C^2(y, x, t) \), which further allows identification of feedback relationships.

The kernel encodes assumption 1 (shorter lags are more plausible), but still leaves us with a number of lags at each timepoint. To select between these, we now formulate this as an optimization problem using assumption 2. After applying the kernel, we concatenate each \( N^2C^2(x, y, t) \) vector. This leads to a matrix of size \( T \times l_{max} \), with \( l_{max} \) being the maximum tested lag. Each entry of the matrix is the associated \( N^2C^2 \) score. We can visualize the result as a 3D surface, as shown in figure 1. Intuitively, to select the sequence of lags \([0,T]\) we aim to find the optimal path through the surface. The optimal path is one that maximizes significance while minimizing distance (to avoid large jumps). This optimization problem (max significance, min distance, with a preference for smaller lags as in assumption 2) is akin to voting, and can be solved using the Borda count, applied to sliding windows. Borda count gives a higher ranking to higher correlations and voting among the adjacent lags leads to a stable transition, which fulfills assumption 2. Note that the count is applied to a sliding window (here of length 10, which is sufficiently large to ensure smoothness, while being small enough to allow for changes in lags), which allows for transitions and changes in lags whereas applying it to the entire time series would force consensus. After using Borda count, we have a single series of length \( T \), with the lags between variable \( x \) and \( y \). Note that the series of lags can be discontinuous, since two
variables may not be significantly correlated across the time series. In both physiological data and nonstationary time series (e.g. stock price data), causal relationships may emerge or change across the time series, so two variables that are correlated in one state (regime) may be unrelated in another. Discontinuities may also exist due to missing data.

**Experiments**

We now apply our approach, \( N^2C^2 \), to ICU data from SAH patients to gain insight into consciousness. Before application to the real ICU data, we first evaluate the method on simulated data to demonstrate that it can correctly find changing lags and can do so with higher accuracy than methods that do not account for changing lags.

**Simulated datasets**

Before applying our approach to NICU data, where ground truth is unknown, we first evaluate it on simulated cases. This allows rigorous evaluation in cases where ground truth is known. We aimed to create simulated data that has the relevant properties of our real ICU dataset. While our work aims solely to discover variations in correlation, the structure of our simulation uses causal models to generate observations. We have a set of \( N \) continuous variables, each of which can trigger changes in other variables over a range of lags even when there are no changes (e.g. fluctuation in [1,5] minutes for the entire time series). Other relevant parameters include the probability of activation (i.e. how often does \( y \) change after \( x \) changes) and strength of relationship (i.e. how much does \( x \) change after \( y \) changes). At each timepoint the lag is randomly selected within the actual range, which can also vary over time. Activation probabilities varied from 0 to 1, such as when a relationship is inactive during one time range and true in another.

In this experiment we used \( N = 20 \), generated random connections (allowing feedback loops), set delays as random 10-time unit windows chosen from [1,50] (e.g. [1,10]), chose activation probabilities from Gaussian distribution (\( \mu = 0.8, \sigma = 0.5 \)), set the strength from Gaussian distribution (\( \mu = 0.5, \sigma = 0.5 \)), and used a significance threshold of 0.1 (for consistency with the NICU data). The time lags change 2 to 4 times per relationship across each time series.

We generated 1000 time series with these settings, and evaluate recall (also called true positive rate), which is the fraction of correlations recovered with their true lags (the detected lag is within the actual range for a given time \( t \)). That is, for \( x \) and \( y \) where there is a true correlation between them across time series \( T \), the recall is a summation over each \( t \in T \) with a value of 1 if the identified lag is true, and a 0 if the identified lag is false. Note that this is evaluated for each time in each sequence, creating many opportunities for potentially missed or incorrect lags. Due to the complexity of the structures, and difficulty of evaluating accuracy when there are many complex indirect relationships, we are primarily interested in recall of true relationships. We compare our approach to \( NCC \), which is applied to the entire time series (rather than windows), and uses the same pre- and post-processing otherwise. This comparison allows evaluation of the impact of identifying changing lags rather than a global lag.

Overall, recall for our approach, \( N^2C^2 \), was 78.2%. In contrast, recall for \( NCC \) was 23.4%. Thus we are able to correctly recover the majority of lags at most timepoints for correlated variables, and identify the correlation between

all correlated variables. However in some cases we identify the correlation with an incorrect time lag. In contrast, NCC finds either the average lag (yet if lags are 10 or 20, the mean lag of 15 will never actually occur) or the most dominant lag (i.e. if one lag is true for 2/3 of the time, that would be identified). Thus we can see it is critical to capture changes in lags. Note that when there are many related causes it can be harder to recover the true timing when examining only correlations. Further, in the generating causal model it is possible to create unfaithful datasets (e.g. with cancelling out), in which case the correlations are impossible to identify, and relationships can be very weak. However, we created these challenging datasets to ensure the approach would be viable in challenging real-world data.

Investigating consciousness in NICU data

We ultimately aim to develop methods to continuously and automatically measure consciousness. Toward this end, we focus on better understanding stroke, using data from subarachnoid hemorrhage (SAH) patients in the NICU at Columbia University Medical Center. We aim to learn whether NCC can identify a signal that can be used to differentiate patients based on their state of consciousness. For each patient we have a set of continuously recorded physiological measurements including respiratory and cardiovascular measures (e.g. respiratory rate, heart rate) and brain-related indicators (e.g. brain oxygenation, brain swelling, blood flow in the brain). However not all variables were measured for all patients and monitors may be started at different times. Values that were missing for 30 minutes or less were imputed using the Fk-NN approach introduced by Rahman et al. and which had high accuracy on this dataset. While variables are measured at varying frequencies, up to every 5 seconds, we use minute-averaged data, as in prior work on discovering causal relationships in this dataset. For all patients, consciousness was assessed by physicians daily during morning rounds between 8 AM and 11 AM. Due to the variation in ICU stay duration, the data contains 302 measurements of consciousness in 61 patients, with a maximum of 18 measurements and minimum of 1 measurement per patient. Consciousness was mapped to a scale from 0 to 5 (introduced in our prior work). In this work we use measurements of 0 (impaired consciousness) and 4 and 5 (intact consciousness, grouped together due to the small number of individuals with 5). We focus on these values due to the challenge of identifying transitions that may occur in between measurements.

As a result, we have 55 assessments of low levels of consciousness (no response) and 88 measurements of high levels (following commands). For each assessment, we examined lagged correlations among all variables in the prior 10 hours, using a sliding window of 5 hours. We tested for lags between all pairs of variables in both directions, unless more than 20% of data in the time window (across both variables) was missing. For significance testing, after the permutation test described in methods (using a one-tailed t-test with p < 0.1 to determine significance) we used the Mann-Whitney U test to determine which lags are significant. We use a threshold of p < 0.1 due to the high variation in data and small sample size.

Table 1 highlights the significant differences across impaired and intact consciousness for brain-related variables. As shown, across all pairs of variables there was a significantly longer delay when patients had lower levels of con-

Conclusion

A patient’s level of consciousness is a critical piece of information for clinicians determining prognosis and treatment in the ICU. While fully automated detection of consciousness remains a challenging task, we have taken strides toward this end, showing how high frequency ICU data can potentially be used to continuously detect such states. We introduce nonstationary normalized cross-correlation (N$_2$C$_2$) to detect changes in lags between correlated variables. This approach is highly general, and can be used to detect correlations that change over time in many types of time series (e.g. body-worn sensor data, financial time series). We applied our approach to a set of NICU data, and demonstrate how lags between physiological variables differ significantly in SAH patients with high and low levels of consciousness. Overall, variables had significantly lower lags when consciousness was high compared to when it was low. Future work is needed to investigate the exact mechanism behind the differences in lags and whether this feature can be used to continuously detect changes in consciousness. Abstract

As health IT has become overloaded with patient information, provider burnout and stress has accelerated. Studies have shown that EHR usage leads to heightened cognitive workload for nurses, and increases in cognitive workload can result in stronger feelings of exhaustion and burnout. We conducted a time motion study in an oncology division to examine the relationships between nurses’ perceived workload, stress measured by blood pulse wave (BPw), and their time spent on nursing activities, and to identify stress associated with EHR use. We had a total of 33 observations from 7 nurses. We found that EHR-related stress is associated with nurses’ perceived physical demand and frustration. We also found that nurses’ perceived workload is a strong predictor of nurses’ stress as well as how they spent time with their patients. They also experienced higher perceived mental demand, physical demand, and temporal demand when they were assigned to more patients, regardless of patient acuity. Our study presents a unique data triangulation approach from continuous stress monitoring, perceived workload, and a time motion study.

Introduction

Numerous health information technologies (ITs) have been implemented in hospitals, and influence patient care, nursing activities, and turnover time and volume.1 There is a growing body of literature describing nurses’ work using observational studies.2-10 Several variables have been identified to affect nurses’ activities. For example, patient care time and quality is significantly correlated to nurse staffing and patient acuity.11-14 Patient acuity helps nurse managers determine levels of patient care, staffing, nurse-patient assignment, and the cost of care.15 In addition, the differences in the working pattern among nurses have also been noted.16 Nurses’ perceived workload is significantly correlated to the amount of work that could have been delegated but was not, nurse-patient ratio, and the amount of documentation.17 However, although evidence has shown the impact of these variables, only one study has controlled for these potential confounders to assess nurses’ time allocation on nursing activities.18

In addition, as health IT has become overloaded with patient information, provider burnout and stress has accelerated.19,20 While the amount of literature investigating physician burnout from EHR usage is robust, limited research has explored EHR burnout among nurses. However, studies have shown that EHR usage leads to heightened cognitive workload for nurses, and increases in cognitive workload can result in stronger feelings of exhaustion and burnout.21,22 Similarly, Gregory and colleagues found that nurses’ and physicians’ perception of having insufficient time to complete tasks related to alerts in the EHR was a significant predictor of cognitive weariness, a subscale of burnout in the disseminated questionnaire.23 One study conducted a survey with advanced practice registered nurses exploring the association between EHR related stress and burnout.24 Moreover, more than half of the respondents reported that the EHR added frustration to their day, and insufficient time for documentation in the EHR was commonly reported as well. After adjusting for demographics and practice characteristics, researchers found that EHR frustration and insufficient documentation time were both significant predictors of burnout among nurses. In another survey, 61% of nursing personnel reported feeling heightened frustration when using their respective EHR systems.25 While the
existing evidence discussed suggests that EHR usage leads to burnout among nurses, further investigation must be done in order to properly characterize the association in order to facilitate solutions.

We conducted a time motion study to observe and record nursing activities during their working day shifts between 7am to 7pm. In a prior study, we reported our design and approaches to collect and visualize nursing workflow in three activity dimensions: communication, hands-on tasks and location.\textsuperscript{26,27} Communication represents whom nurses are interacting with; hands-on tasks represent tasks nurses are physically performing (i.e. preparing medication); and location represents where nursing activities take place. We explored these three activity dimensions across the continuum of time to understand multitasking and task switching in nursing practice.\textsuperscript{26,27} We also controlled the distribution of observation time by splitting the 12-hour nursing day shift into three time blocks: 7am-11am, 11am-3pm, and 3pm-7pm. Our novel approach explores the three activity dimensions, across the continuum of time, to understand the phenomena of multitasking in nursing practice.\textsuperscript{26,29-31} The study found that nurses multitasked (having communication and hands-on tasks simultaneously) 39.48\% of all times. The study design and methods also demonstrated a practical and reliable approach to conducting and analyzing time motion studies.\textsuperscript{26,27}

In this paper, we present a new time motion study in an oncology division with the same study design as the previous study,\textsuperscript{26,27} but included additional variables to investigate factors affecting nursing practice, such as staffing, patient acuity, nurses’ perceived workload, and their physiological response to stress, blood pulse wave (BPw). BPw is described as the pulse wave that travels through the circulatory system when the heart contracts and blood is ejected.\textsuperscript{32} BPw is related to cardiac demands,\textsuperscript{32} which represents an elevated or aroused physiological state and is correlated with potential psychological or emotional stressors.\textsuperscript{33} There are few studies about BPw and its relation to stress, but literature regarding pulse wave velocity (PWV) is flourishing. The definition of PWV is comparable to that of BPw, as it is the velocity of the arterial pulse that propagates through the circulatory system.\textsuperscript{33} PWV is used clinically as a measure of arterial stiffness, and is determined by measuring the time it takes a pulse wave to travel a given distance among the blood vessel.\textsuperscript{34,35} A number of studies have discovered associations between mental stress and both PWV and arterial stiffness due to the contribution of stress to increased blood pressure and risk for hypertension.\textsuperscript{36-40} Specifically, acute mental stress has been found to lead to significantly sustained increases in PWV,\textsuperscript{36,37,39} and individuals suffering from chronic stress are more likely to have greater, prolonged PWV values.\textsuperscript{40} The evidence suggests the similarity of BPw and PWV, and that BPw or PWV, can serve as an adequate measure of psychological stress. In this study, we used a commercial device capable of continuously measuring BPw.

The purposes of the study were to examine the relationships between nurses’ perceived workload, stress measured by BPw, and their time spent on nursing activities. We were especially interested in identify stress associated with EHR use. To our knowledge, we were the first study integrating data sources from nurses’ perceived workload, BPw, and a time motion study.

**Methods**

**Setting and Sample**

The time motion study was conducted in an oncology division at a mid-west academic medical center. We recruited registered nurses who worked in the observed unit. We observed nurses in the general patient care and adjacent areas such as the nursing station, hallway, medication/supply room, and patient rooms. In this unit, nurse-patient ratios ranged from 1:3 to 1:4.

**Observed nursing activities**

We observed nursing activities, such as hand-off (shift reporting), direct patient care (patient assessment, medication administration, procedures), indirect patient care (medication preparation, obtaining medication), interprofessional communication, and EHR review and charting. Due to patient safety and the difficulty of observing nurses in patient isolation rooms, we did not document nurses’ hands-on tasks and communication in these rooms. The observable nursing activities list was refined iteratively with the division’s clinical leadership and research team, and finalized during the training and trial observations. In total, we defined 16 types of communication, 35 hands-on tasks, and 23 locations. A list of example activities with definitions and start-end times can be found in our prior publication.\textsuperscript{26}

We used TimeCaT,\textsuperscript{41} a validated electronic time capture tool developed to support data collection for time motion studies, optimized for touch enabled tablet computers and iPads. Observers document nursing activities in TimeCaT when they shadow nurses.\textsuperscript{41} In TimeCaT, we were also able to visualize workflow and explore the location where nursing activities occurred. The data collected in TimeCaT allowed us to portray nurses’ work: with whom the nurse was speaking (communication), while doing what (hands-on task), and at what location.\textsuperscript{26}
Observers & Inter-observer reliability assessment (IORA)

Our observers were three undergraduate senior nursing students. Observers were required to attend training sessions and trial observations for at least 12 hours. We established the inter-observer reliability via the IORA feature provided in TimeCaT.\textsuperscript{41} The IORA in TimeCaT considers four types of agreements: 1) proportion-kappa (P-K): evaluates the naming agreement on virtually created one-second activity, based on the Kappa statistic. P-K provides a global assessment of the agreement over time; 2) naming-kappa (N-K): a systematic pairing approach based on time-overlap, and provides a Kappa statistic representing the agreement on activity naming; 3) duration-concordance correlation coefficient (D-CCC): agreement on the duration of an activity.\textsuperscript{26} We ensured that the IORA results indicated consistent agreement between our observers before the data collection (Table 1).

Data Collection

No identifiable information or health records were collected. A typical 12-hour nursing day shift was split into three time blocks: 7am-11am, 11am-3pm, and 3pm-7pm. The 4-hour observation time block minimized the chance of unbalanced data if a 12-hour day shift happened to have a heavy or light workload, and also prevented observer fatigue. Each 4-hour observation was a one-on-one observation: one observer shadowed one nurse. Observers maintained a certain distance from the observed nurse during the observation, and were not allowed to interact with the observed nurse in order to collect data reflecting true time duration and context. After approval from the local Institutional Review Board, observers obtained informed consent from the observed nurse as well as permission from patients to observe their care.

Stress: We measured BPw as the indication of the nurse’s stress level.\textsuperscript{32} We used a wearable device on the upper arm of the nurse to continuously measure BPw. The device has been used for monitoring chronic stress and assessment of patients’ mental stress. During the time motion study observations, we provided the wearable BPw measure, developed by Biovotion, to the observed nurse. The wearable device at the upper arm measures biometric signals continuously with timestamps, including BPw. Biovotion has been used for monitoring chronic stress\textsuperscript{45} and assessment of patients’ mental stress.\textsuperscript{44} For each 4-hour observation, the continuous stress (BPw) data were collected and integrated with the time motion study data.

Perceived workload: At the end of each observation, we asked the observed nurse to fill out the NASA task-load index (TLX), which is widely used to assess perceived workload. The NASA-TLX consists of 6 questions:\textsuperscript{44} 1) Mental Demand: How much mental and perceptual activity was required?; 2) Physical Demand: How much physical activity was required?; 3) Temporal Demand: How much time pressure did you feel due to the pace at which the tasks or task elements occurred?; 4) Performance: How successful were you in performing the task?; 5) Effort: How hard did you have to work (mentally and physically) to accomplish your level of performance?; and 6) Frustration: How irritated, stressed, and annoyed versus content, relaxed, and complacent did you feel during the task? Nurses rated their perceived workload from 0 (very low) to 100 (very high).

Staffing: We collected staffing data for each observation including nurse-patient ratio, patient type (primary, non-primary, or in isolation), number of consecutive days worked, number of discharges by the observed nurse, and patient acuity. We assessed patient acuity based on an adapted AcuityPlus, which is a patient classification methodology developed by the QuadraMed Corporation.\textsuperscript{45} It has been used to determine the acuity and the type of care needed for each patient, such as communication and cognitive support, safety management, activities of daily living, etc. AcuityPlus has been validated by several studies.\textsuperscript{46,47} Based off of the acuity and care, each patient then was assigned a numerical acuity score. The acuity score ranged from 15 (lowest acuity) to 43 (highest acuity).

Nurses’ demographics: We also collected nurses’ age, education, gender, and years of working experience.
Data Analysis

We performed descriptive analysis to summarize nurses’ time spent and stress on nursing activities in communication, hands-on tasks, and locations. We used one-way ANOVA with post hoc analysis and Bonferroni correction to examine group differences, and paired t-test to compare two variables as repeated measures in every observation. We performed the linear mixed effects model to examine factors affecting outcome variables and account for correlation of repeated observations from the same nurse. All statistical analyses were two-sided at significance level 0.05 and conducted in SAS 9.4 and IBM SPSS 25.0.

Results

We completed a total of 33 observations (132 hours) with 7 registered nurses from May 2018 to February 2019. We also conducted a post-hoc analysis and found that our sample size has an 80% power to detect an effect size of 0.6 with linear mixed effects model at significance level 0.05. This was calculated based on a two-sided Wald test of regression coefficients in linear mixed effects model adjusting for design effect and correlation of repeated measures from the same nurse. From the seven nurses, six nurses had three to six observations; one nurse had one observation; 4.41 observations on average. Among the 33 observations, nine were on Monday, 1 on Tuesday, 6 on Wednesday, 5 on Thursday, 9 on Friday, 0 on Saturday, and 3 on Sunday; 11 were 7am-11am, 10 were 11am-3pm, and 12 were 3pm-7pm. Participating nurses have a mean age of 30, with 3.64 years of working experience on average. One male nurse participated, and all nurses have a bachelor’s degree. Table 2 summarizes the demographics, staffing, and nurses’ perceived workload, stress by BPw, and time spent in patient rooms per 4-hour observation.

Before compositing patients’ acuity scores for a single observation (nurse patient ratios ranged from 1:3 to 1:4), we examined whether nurses’ time spent in the patient room was being influenced by patient acuity or patient types: primary patient (P), non-primary patient (NP), and in isolation (ISO). One-way ANOVA showed that there were no differences of nurses’ time spent in a patient room among the three patient types (p=0.8635). Patient acuity was also not a significant predictor for time spent in a patient room (p=0.0847). However, there were differences of the mean patient acuity scores among the three patient types (P: NP: ISO, mean(SD) = 18(1.27): 19.35(1.48): 20.22(2.10), p<0.0001). The patient acuity scores for ISO and NP are significantly higher than P. We used the average acuity score and number of patients as the patient load in an observation. We also computed weighted acuity scores to adjust for the average acuity score in an observation. We weighted patient acuity scores with weights as following: weight_P=18/(18+19.35+20.22); weight_np=19.35 / (18+19.35+20.22); weight_iso=20.22/(18+19.35+20.22). As a result, the single patient acuity score for each observation can be calculated as weighted acuity = weighted acuity total/number of patients. During the analyses, we did not find average acuity or weighted acuity as a significant factor to stress or time spent.

We examined nurses’ time spent on nursing activities (Table 3) and found that nurses spent the most time communicating with patients (28.07 mins) and other nurses (24.41 mins), followed by phone calls (6.45 mins), and communication with family (6.15 mins). For hands-on tasks, nurses’ spent most time on EHR (45.54 mins), and the time is significantly higher than the second highest hands-on task: direct medication time (15.17 mins) (p=0.000). Nurses spent the most time in patient rooms (84.18 mins) and at the nursing station (80.44 mins).
Factors associated with nurses’ average stress

We performed linear mixed effect models to examine factors associated with nurses’ average stress in a 4-hour observation. When considering the simplest linear mixed effect models with each individual fixed effect, only perceived physical demand, temporal demand, effort, and frustration shows statistically significant (Table 4). We also did not find any difference in stress across time blocks (7am-11am, 11am-3pm, and 3pm-7pm) (p=0.759).

Nurses’ EHR stress and perceived workload

When examining nurses stress while using EHR (EHR charting and review) and their perceived workload, we found that nurses with higher perceived physical demand and frustration were associated with higher stress (p<0.05) (Table 6). But again, none of the nurses’ demographics or staffing showed statistical significance.

**Nurses’ EHR stress and EHR use time**

When examining nurses’ EHR stress and the time spent on EHR, we did not find nurses’ EHR stress associated with longer use of EHR (p=0.846) (Table 7). None of nurses’ demographics or staffing showed significant different either. We also did not find longer EHR use with more nurse-patient ratio (p=0.733).

</table>

Dependent variable: average time in own patient room; Fixed effects: age, years of experience, number of discharges, number of patients, and weighted acuity.

**Stress with own patients vs. other patients**

We also examined nurses’ stress in patient rooms, both paired t-test and Wilcoxon signed ranks test showed that nurses have similar stress in own patients room and in other patients room (own patients room stress: other patients’ rooms stress respective, Mean(SD) = 2.40(0.12): 2.56(0.73), p=0.180).

**Nurses time spent in own patients room and patient acuity**

Besides nurses’ stress, we were interested in whether nurses’ time spent in own patients room being influenced by patient acuity. The result from the linear mixed model, after accounting for nurses’ demographics and staffing, was similar to what we found with one-way ANOVA. We did not find patient acuity associated with nurses’ time spent in own patient’s room (p=0.895), nor any nurses’ demographics and staffing variables (p>0.3).

**Nurses time spent in own patients room and perceived workload**

We also examined whether nurses time spent in patient rooms was associated with their perceived workload. The results showed that nurses’ time spent in own patient rooms had a positive relationship with perceived physical demand, temporal depend, and effort. In other words, when nurses expressed increases in perceived physical demand, temporal demand, and effort, they have likely spent more time in their patient rooms (Table 9).
Several studies have investigated the association between nurses’ workload and the quality of care they provide. One study found that higher workloads, higher acuity assignments, and poorly organized work environments were all key predictors of omitted or significantly delayed patient care. Similarly, another study found that larger patient to nurse ratios contributed to increased missed care. Beyond patient volume and acuity, researchers also found that nurses’ subjective or perceived quality of care and patient safety were strongly related to the number of missed care events. In addition, nurses’ perceived workload contributed to their ability to provide quality care. Using the NASA-TLX and nurse-reported missed essential care reports, researchers determined that even though staffing ratios and patient acuity were strongly associated with missed nursing care, their effects were greatly reduced when taking into account the nurses’ perceived workload. Our findings are consistent with these studies that nurses’ demographics, staffing, and patient acuity were not statistically associated with nurses’ stress. Instead, their perceived workload plays an important role in their time allocation and vice versa. Thus, nursing workload coupled with how that workload is experienced.

### Discussion

**EHR stress associated with nurses’ frustration**

Provider burnout and stress has accelerated due to being overloaded with patient information. Studies have shown that EHR usage leads to heightened cognitive workload for nurses, and increases in cognitive workload can result in stronger feelings of exhaustion and burnout. Similarly, a study found that nurses’ and physicians’ perception of having insufficient time to complete tasks related to alerts in the EHR was a significant predictor of cognitive weariness, a subscale of burnout in the disseminated questionnaire. Additionally a survey of advanced practice registered nurses explored the association between EHR related stress and burnout. More than half of the respondents reported that the EHR added frustration to their day, and insufficient time for documentation in the EHR was commonly reported as well. After adjusting for demographics and practice characteristics, researchers found that EHR frustration and insufficient documentation time were both significant predictors of burnout among nurses. In another survey, 61% of nursing personnel reported feeling heightened frustration when using their respective EHR systems.

In our study, we collected continuous stress data and perceived workload, and coupled with the time motion study, enriched our ability to examine nurses’ EHR stress and validate nurses’ perceived frustration. Our results showed that nurses spent 45.54 minutes per 4-hour time block using the EHR, and this EHR use time was much more than any other communication or hands-on activities. We also found that nurses’ perceived physical demand and frustration were significantly associated with EHR stress. Previous studies reported frustration of using EHR due to insufficient documentation time. It seems ironic that nurses have spent the most time on EHR among all activities, are frustrated, but need more time on EHR. Although we did not detect association between nurses’ stress and longer use of EHR, the insignificant results may be due to that we do not have sufficient power to detect small effects (type II error). We also noticed that the continuous stress monitoring is better at detecting high stress in safety-related events, such as when being the second check witness and in the isolation room. More studies are needed to investigate the use of continuous stress monitoring to detect EHR-related stress. A better EHR design is also required to decrease EHR documentation time and cognitive load in using EHR.

**Nurses’ perceived workload**

Several studies have investigated the association between nurses’ workload and the quality of care they provide. One study found that higher workloads, higher acuity assignments, and poorly organized work environments were all key predictors of omitted or significantly delayed patient care. Similarly, another study found that larger patient to nurse ratios contributed to increased missed care. Beyond patient volume and acuity, researchers also found that nurses’ subjective or perceived quality of care and patient safety were strongly related to the number of missed care events. In addition, nurses’ perceived workload contributed to their ability to provide quality care. Using the NASA-TLX and nurse-reported missed essential care reports, researchers determined that even though staffing ratios and patient acuity were strongly associated with missed nursing care, their effects were greatly reduced when taking into account the nurses’ perceived workload. Our findings are consistent with these studies that nurses’ demographics, staffing, and patient acuity were not statistically associated with nurses’ stress. Instead, their perceived workload plays an important role in their time allocation and vice versa. Thus, nursing workload coupled with how that workload is experienced.

Dependent variable: nurses’ time spent in own patient rooms; Fixed effects: single perceived workload, age, years of experience, number of discharges, number of patients, and weighted acuity.

**Nurses’ patient load and perceived workload**

We also noticed that nurses with more patients expressed a higher perceived mental demand (p=0.044), physical demand (p=0.041), and temporal demand (p=0.010). In addition, higher perceived frustration is associated with higher patient acuity (p=0.014). All models have accounted for nurses’ demographics and staffing.
may directly affect patient care quality and delivery. This could also be problematic due to the fact that nurses frequently experience interruptions, which was found to be associated with an increased perceived workload.51

Nurses’ time spent on direct patient care and EHR- is there a balance?

Although not statistically significant, we found a trend that nurses’ increased EHR use was associated with less time in own patient room. Also, it seems rational that nurses would spend more time with patients with higher acuity, but we did not find any significant differences in nurses’ time spent based on patient types and acuity. After adjusting for repeated measures, we still did not find any differences due to patient acuity, nurses’ demographics, or staffing variables. Previous research has found that patient care time and quality are significantly correlated to nurse staffing and patient acuity.11-14 However, the complexity and variety of what nurses’ actually do may have impeded nurses’ functions and responsibilities in patient care. Nurses expressed lack of time being with their patients and frustration on insufficient resources needed.32,53 While top-of-license practice is recommended and needed for quality patient care, it remains critical, but unknown, regarding the best strategies to support the health IT world that nurses currently and will continue to face.

Study Limitations

The study had several limitations, 1) one unit in one hospital within one academic health system; 2) The small sample size (n=33); 3) Potential insufficient power to detect small effects (type II error); 4) Utilizing only one commercial device for BPw. Although some studies have utilized the wearable device to assess patients’ stress, we did not test the reliability of the device prior to the study. However, the wearable stress monitoring device did detect sensible stress outcomes. For example, nurses had the highest stress when being the second check witness and in the isolation room; Other limitations include 5) Lack of documented activities in the isolation room, as observers were not allowed access to the isolation room for safety reason; 6) Participation bias as the study required nurses’ participation and consent 7) Observation bias due to human capacity to accurately record every action.54 We may have missed some activities in rapidly changing activities, but we minimized the inconsistency between observers through rigorous training, JORA, and clearly defined definitions of each activity; 8) We detected association between variables, but cannot conclude the causal relationship. Additional qualitative research or a larger sample size would be needed to validate the findings.

Conclusion

We conducted a time motion study to examine the relationship between nurses’ stress and perceived workload, and their association with particular nursing activities. Our study presents a unique data triangulation approach from continuous stress monitoring, perceived workload, and a time motion study, and could be replicable to other healthcare organizations or disciplines. The approach enriched our ability to detect EHR-related stress and was validated by nurses’ perceived physical demand and frustration. Our findings also showed that nurses’ perceived workload is a strong predictor of nurses’ stress as well as how they spent time with their patients. They also experienced higher perceived mental demand, physical demand, and temporal demand when they are assigned to more patients, regardless of patient acuity. Future studies should investigate the use of continuous stress monitor to identify potential support needed, as well as internal stress reduction techniques that could help with reducing perceived stress for nurses.

Acknowledgement

The project was supported by the Healthcare Innovation Lab at BJC HealthCare/Washington University School of Medicine. We especially appreciate the support from the study site, nurse managers, and nurses who participated in the study.

Patient Messaging Content Associated with Initiating Hormonal Therapy after a Breast Cancer Diagnosis

Zhijun Yin, PhD, Jeremy L. Warner, MD, MS, Qingxia Chen, PhD,
Bradley A. Malin, PhD
Vanderbilt University, Nashville, TN

Abstract

Hormonal therapy is an effective, but challenging, long-term treatment for patients with hormone-receptor-positive breast cancer. Raising the rate of patients who initiate therapy may be possible by characterizing the factors that influence a patient’s decision. We hypothesized that online patient portal messages convey such factors. To investigate this hypothesis, we focused on breast cancer patients who were prescribed hormonal therapy at Vanderbilt University Medical Center and sent messages through the portal between diagnosis and therapy initiation. We first conducted a topic modeling analysis to generate the main themes of portal messages. We subsequently applied survival analysis to learn the association between the factors conveyed in messages, in term of semantic word groups, and the time elapsed from diagnosis to therapy initiation. We found that consulting with healthcare providers increased the probability of therapy initiation, while mentions of symptoms or negative emotions exhibited a reduced probability.

Introduction

Approximately 12% of U.S. women will develop breast cancer over their lifetime. It is the second most diagnosed cancer (after skin) and has the second highest cancer death rate (after lung) for U.S. women. It is estimated that there will be 268,600 new breast cancer cases in 2019 in the U.S. and over 41,000 women will die from the disease. Hormone-receptor-positive breast cancer makes up 80% of diagnosed cases. In hormone-receptor-positive breast cancer, the cancer cells grow and spread with the assistance of hormones (e.g., estrogen) in the blood. Hormonal therapy, which works by preventing estrogen from stimulating breast cancer cell growth, is an adjuvant (post-surgical) treatment for patients with this type of breast cancer. Evidence suggests that taking hormonal therapy medications, such as tamoxifen, can reduce cancer mortality by one third. As such, it is often recommended that patients take hormonal therapy medications for at least five years.

Adhering to hormonal therapy is not easy for a breast cancer patient. It is reported that nearly 50% of breast cancer patients prescribed hormonal therapy dropped off a regimen before completing a five-year treatment course. There are many factors that may contribute to medication discontinuation behavior. For example, side effects (e.g., depression) can lead to medication discontinuation. As a result, various studies have focused on learning the factors behind why breast cancer patients choose to stop taking a hormonal therapy medication. These studies can be roughly categorized into three classes based on the data that they investigate: 1) interview or survey, 2) structured electronic medical records (EMRs), and 3) user generated content (UGC) in online environments. The first two classes hold merit, but have notable limitations. Generally, studies based on interviews are often time consuming and not scalable to large study cohorts, while survey-based studies are often confined to the pre-defined questionnaires. Studies based on structured EMRs are, on the other hand, limited in that they lack description of treatment experience (e.g., patient’s feelings and emotions). By contrast, UGC has been shown to be an effective resource to learn about a patient’s health related behaviors. For example, studies have shown that the messages that patients send to healthcare providers in a patient portal were indicative of the likelihood of discontinuing hormonal therapy medication.

However, few studies have focused on what factors affect the time at which a breast cancer patient initiates hormonal therapy, relative to their diagnosis. This information is important because it can provide insights into why a patient delays making a decision to start the therapy. While several studies investigated patient decision making, most relied on interviews or qualitative methods. For example, Beryl et al. conducted a longitudinal series of interviews to identify the decision-making process of hormonal therapy. They found that most patients starting a therapy is not a single decision, but rather is a series of decisions. More generally, Marla et al. pointed out that shared decision making needs to center on the person rather than the medical encounter, suggesting the importance of listening to the patient. Thus, in this study, we focused on the secure messages sent by patients to their healthcare providers, one particular type of UGC, in an online patient portal. There are several clinical factors that are likely to affect the decision to start hormonal therapy; e.g., undergoing additional surgery or an unplanned stay in the hospital. We hypothesized that the messages patients convey through online portals contain factors associated with the time from breast cancer diagnosis to hormonal therapy initiation. To investigate this hypothesis, we focused on the EMRs and portal.
communications sent by breast cancer patients prescribed hormonal therapy at Vanderbilt University Medical Center (VUMC). Particularly, we studied patients who sent messages after their diagnosis date, but before taking a hormonal therapy medication. We applied topic modeling to infer the main themes that were discussed in these messages and performed a survival analysis to study the extent to which the themes were associated with the time that breast cancer patients started their treatment.

Methods

Data
This study used de-identified data from the VUMC EMR system and was approved by the Vanderbilt University Institutional Review Board. In this setting, all patient identities were replaced with persistent pseudonyms by a third-party honest broker and all dates within a patient’s records were consistently shifted by a random number of days that were uniformly sampled from the (-365, -1) range. We focused on the patients who were diagnosed with stage I to III breast cancer and were prescribed any of the following hormonal therapy medications: anastrozole, exemestane, letrozole (aromatase inhibitors; AIs), or raloxifene, tamoxifen (selective estrogen receptor modulators; SERMs). We restricted the cohort to those who sent messages between their diagnosis date and the first documentation of a hormonal therapy medication.

Topic Modeling and Word Clustering
Natural language clinical text has high dimensionality, but is also quite sparse. Thus, we to better summarize the content for inference purposes we reduced the dimensionality. There are two general types of methods to realize this goal, both of which we adopted for this project, as they serve different purposes: 1) topic modeling to identify the main messaging themes, 2) word clustering, based on a lower dimensional representation of words (e.g., word embedding terms of word2vec), to create message content predictors for inference.

Topic modeling is a statistical approach for discovering latent topics in a collection of documents or messages. For example, Latent Dirichlet Allocation (LDA) is a generative statistical model that assumes each document can be represented by a small number of topics, where each word in the document can then be generated by one of these topics. The inferred topics can be interpreted by their most relevant terms. Topic modeling is notable because it allows terms to be used in multiple topics and it has often been observed that it groups terms that are similar in their global context. In this study, we applied LDA, as implemented in Mallet Java package (version 2.0.8), to identify the main themes that were communicated in patient portal messages. Since LDA is an unsupervised technique, we adopted the coherence score to determine the optimal number of topics. The coherence score essentially measures the extent to which two high probability terms in a topic appear together in either external documents (e.g., in Wikipedia) or the modeling documents. We selected the number of topics with the highest average coherence score across the proposed topics. This was accomplished by learning LDA models for 2 to 26 topics (with a step size of 1) over all of the messages. To mitigate word sparsity and ensure interpretability, we replaced each term with its lemma form and retained only nouns, verbs, adjectives and adverbs. We also generated bi-gram terms using the genism python package (version 3.6.0) to capture more meaningful phrases. We report on two aspects of this process in our experiments. First, we consider the most salient terms. Saliency of a term is a weighted term frequency that is introduced for better characterizing term importance in describing message topics. The weight is defined as the sum of the Kullback-Leibler divergence between each marginal topic distribution and its conditional distribution on the given term. Second, we consider the topic distribution and sample relevant terms for each topic. The topic distribution is calculated after combining all of the messages into a single document. We display the most terms with the highest distribution in each topic.

Additionally, we applied word clustering to generate semantic word groups for inference purpose. Word clustering relies on a measure to calculate the similarity between two terms. For example, word2vec is a low dimensional representation technique that can be applied to measure semantic word similarity. It represents a group of shallow, two-layer neural networks that are trained to reconstruct linguistic contexts of words. The premise of word2vec is to apply each term to predict their adjacent neighbors, which represents the word similarity in a local context. If a standard clustering algorithm (e.g., k-means or hierarchical clustering) is applied, a term can only belong to a semantic word group. In this study, we observed that topics inferred from topic modeling techniques, in spite of good interpretability in summarizing the main themes, are poor in inference tasks. This might be due to the fact that the number of inferred topics is very small, which induces substantial information loss. However, increasing the number of topics would increase the possibility of conceptual overlap between topics, which reduces topic interpretability. Directly applying terms expressed in the messages as predictors is a simple method to avoid information loss.
noted earlier, the high dimensionality and sparsity of natural language may not be beneficial for inference. For example, the number of unique terms can be larger than the number of messages. Furthermore, the correlations between terms will require additional regularization in the model, which makes inference more challenging.

In this respect, word clustering can reduce the correlation between term predictors and reduce the dimensionality, which leads to less information loss than topic modeling. To do so, we first trained a word2vec model based on all of the messages sent by breast cancer patients. We then ran an agglomerative hierarchical clustering algorithm with complete linkage, implemented in the scikit-learn python package (version 0.18.1) with 25 to 1000 groups (with a step size of 25). We applied the elbow rule to the standard deviation of the group size, such that we selected the number of groups at the angle where the marginal gain begins to diminish. This was done because, heuristically, a larger group is more likely to contain multiple meanings while a small group is more likely to have little contribution to dimensionality reduction.

Survival Analysis

To perform survival analysis, we investigate how the message content, measured by semantic word groups, is associated with the time from the diagnosis date until a breast cancer patient initiated a hormonal therapy medication.

Statistical Model. We applied a Cox proportional hazards regression model for the survival analysis. The Cox model is applied to investigate the effectiveness of independent predictors with respect to the time when an event of interest occurs. There are two benefits in applying a Cox model in this study. First, the Cox model is semi-parametric and does not assume any particular survival distribution. Second, the Cox model can make use of right-censored patients by incorporating both time (in terms of when an event happened or the latest time without event) and medication use status (e.g., patients who started taking hormonal therapy medications or did not by the end of follow-up) into the model. If the records showed that patients started taking hormonal therapy, then the event occurred. By contrast, if patients did not take any hormonal therapy medication by the end of data observation window, then right censoring occurred. The risk for an independent predictor is represented by the hazard ratio (HR) in the form of the expected exponential of its estimated coefficient in the Cox model. If the HR is bigger (smaller) than 1, then the variable is associated with an increased (decreased) risk of taking a prescribed medication. We used the implementation of the Cox model from the lifelines python package (version 0.9.4) to conduct the survival analysis.

Variables. We defined an observation window of one and a half years from the diagnosis date. The dependent variable was binary, where 1 indicated that a breast cancer patient started taking the medication and 0 indicated that the patient is right censored. The time between the diagnosis date and the start of medication use (or the end of the observation window) was measured in 6-month blocks. The message content variables were constructed as follows: 1) for each patient, we aggregated all the messages sent between the diagnosis date and either the start of medication use or the end of the observation window. As such, we represented each patient as a document of messages; 2) we replaced the words in each message document with their corresponding semantic word group numbers; and 3) we calculated the term frequency – inverse document frequency (TF-IDF) values for each semantic word group in each document, which we subsequently applied as the values of semantic word group variables.

Figure 1. A summary of the patient messages in this study, shown as a histogram of the number of (a) messages sent per patient and (b) terms expressed per message.

Additionally, we introduced four independent variables: 1) the age at diagnosis, 2) race as documented in the EMR, 3) cancer stage at diagnosis, and 4) the number of Current Procedural Terminology (CPT) codes. We dichotomized
the race into Caucasian and non-Caucasian categories. We encoded advanced cancer stage (stage III) with 1 and early cancer stages (stage I and II) with 0. We included the number of CPT codes because, intuitively, the more procedures a patient is affiliated with, the greater the likelihood that they may delay the start of a hormonal therapy regimen. We report the statistically significant features at the 0.05 significance level.

We also applied the Kaplan–Meier (KM) estimator to estimate how the probability of starting hormonal therapy changes over time. In clinical studies, this estimator is often relied upon to measure the proportion of patients who live for a certain amount of time after treatment. We use the implementation of KM in the *lifeline* python package (version 0.9.4) to calculate and visualize the proportion of breast cancer patients who begin hormonal therapy along the treatment timeline.

**Results**

**Cohort Summary**

The study cohort consists of 336 breast cancer patients prescribed hormonal therapy medications between the years 2005 to 2017, which consisted of 30% of all the breast cancer patients with early stages. The average patient age is 54.8 (with a range of [22, 88]). Based on race in the EMR, 90.1% of the cohort is Caucasian (303). With respect to the disease, 89.3% of the cohort were diagnosed with early stage breast cancer (300). The patients generated a total of 3,329 messages. Figure 1(a) depicts the frequency distribution of the number of messages generated per patient. It can be seen that most patients posted a limited number of messages. For example, 71.7% of the patients sent less than 10 messages during this period. By contrast, only 11.7% of the patients sent at least 20 messages. Figure 1(b) summarizes the frequency distribution of the distinct terms per message. It can be seen that most of the messages contained only a small number of terms. For example, 58.9% of the messages contained no more than 50 terms. By contrast, only 12.0% of messages contained at least 100 terms.

**Top Salient Terms**

![Top Salient Terms](image)

*Figure 2.* The 30 most salient terms in the patient portal messages. The terms are ordered in a descending rank according to their saliency.

Figure 2 demonstrates the 30 most salient terms (from top to bottom) in the portal messages. In most cases, the more frequent the word, the higher the saliency; however, there are some exceptions. For example, the terms *time, week, work, question, start* and *leave* have relatively higher frequency but lower saliency, suggesting saliency might be more effective in describing the importance of a term. Figure 2 further illustrates that *surgery, appointment* and *chemo* are among the most salient words, while other terms such as *back pain, result,* and *prescription* have relatively lower saliency.
Message Topics

Table 1. The most relevant terms for each of the six inferred topics. The topic distribution is shown in the rightmost column. The terms are ordered based on their probabilities in each topic in a descending manner.

<td>16.18%</td>
</tr>
</tbody>
</table>

Table 1 shows the six topics that were learned from the messages. Here, we take a moment to provide some intuition into the topics. First, the most distributed (or mentioned) topic (#1) is about symptoms (17.46%). Second, the next most distributed topic (#2) is about chemotherapy (16.87%). Third, the next most distributed topic (#3) is about surgery. Fourth, the next most distributed topic (#4) is about laboratory tests. Finally, and the last two topics (#5, 16.33% and #6, 16.18%) are about prescriptions and communications, respectively. Note that the topic distribution is calculated after combining all messages into a single document.

Model Fitting

Our approach finally generated 150 semantic word groups, which served as message content predictors in the survival analysis. Our Cox model presented a concordance of 0.872, suggesting a good fit. With respect to the four control variables, it was found that the advanced cancer stage indicated a reduced probability of patients initiating hormonal therapy (HR = 0.851, P = 0.001). This suggests that patients with early stage cancer are more likely to begin hormonal therapy. It was also found that the number of CPT codes correlated with a decreased probability of starting hormonal therapy (HR = 0.983, P < 0.001). Neither the age at diagnosis nor the race were found to be statistically significant.

![Figure 3](image_url)

**Figure 3.** The KM curve for the probability that patients did not initiate hormonal therapy. The intersection of the dashed lines indicates that 50% of patients began hormonal therapy 3 months after diagnosis.
Figure 3 shows the KM curve for the probability of not starting hormonal therapy as a function of time. The horizontal dashed line indicates where the probability is 0.5. The dashed lines illustrate that 50% of the patients initiated hormonal therapy at 3.24 months (0.54 × 6-month unit). It can further be seen that approximately 80% of breast cancer patients began hormonal therapy within one and a half years of the diagnosis.

**Semantic Word Groups**

The semantic word groups that are positively associated with hormonal therapy initiation. The terms are ordered based on their similarity with the center of the group in a descending manner.

Table 2 shows the semantic word groups that are positively associated with the start of hormonal therapy. Based on this result, there appear to be four types:
- Mentions of semantic word groups related to cognitive processes (#12, HR = 1.964, P < 0.001), suggestion-related nouns (#24, HR = 1.408, P < 0.001), and communication or consulting related verbs (#39, HR = 1.405 P = 0.001).

- Mentions of semantic word groups related to schedules (#131, HR = 1.764, P < 0.001; #99, HR = 1.370, P = 0.001; #37, HR = 1.379 P = 0.005), locations (#100, HR = 1.391, P = 0.002; #140, HR = 1.224, P = 0.040), and paperwork (#120, HR = 1.336, P = 0.008).

- Mentions of semantic word groups related to symptoms (#40, HR = 1.928, P < 0.001), vital and test related words (#106, HR = 1.457, P < 0.001), medication dosage (#32, HR = 1.326, P = 0.009), discontinuation of certain medications (#27, HR = 1.297, P = 0.016), medications for chemotherapy and radiation (#138, HR = 1.238, P = 0.026), and verbs related to manage health conditions (#36, HR = 1.215, P = 0.001).

- Other semantic word groups, such as time related words (#59, HR = 1.599, P < 0.001; #3, HR = 1.243, P = 0.026), and adjectives (#21, HR = 1.306, P = 0.010).

**Table 3.** The semantic word groups that are negatively associated with hormonal therapy initiation. The terms are ordered based on their similarity with the center of the group in a descending order.

Table 3 shows the semantic word groups that are negatively associated with the start of hormonal therapy. Based on this result, there appear to be three types:

- Mentions of symptoms (#65, HR = 0.596, P < 0.001; #82, HR = 0.631, P < 0.001; #29, HR = 0.721, P = 0.003; #149, HR=0.645, P=0.001), different physician roles (#20, HR = 0.769, P = 0.012), reconstruction and other surgery (#123, HR=0.730, P=0.002), body components (#130, HR = 0.797, P = 0.042), negative emotions (#52, HR=0.811, P=0.033), x-ray related examinations (#17, HR = 0.696, P = 0.001).
- Mentions of fitness service (#33, HR = 0.647, P = 0.001), distances and hours (#10, HR=0.668, P<0.001; #81, HR=0.748, P=0.007) have decreased probability of taking hormonal therapy.
- Mentions of communication related terms (#126, HR = 0.737, P = 0.002; #41, HR = 0.796, P = 0.024).

Discussion and Conclusion

Primary Findings

This study investigated the messages sent by patients through the VUMC patient portal after their breast cancer diagnosis and before the start of hormonal therapy. We characterized how certain factors mentioned by the patients correlated with when they initiated a regimen of hormonal therapy medications. There were several notable findings. First, our exploratory analysis showed most patients sent only a limited number of messages. This is a similar observation to those made about individuals who published posts in online health communities. Second, our topic analysis suggested that patients were primarily communicating about their symptoms, chemotherapy, surgery, laboratory tests and prescriptions. This has face validity because surgery and chemotherapy are two of the most common interventions that take place before hormonal therapy is prescribed. These two interventions often generate side effects that require additional medications to manage. Third, our survival analysis suggested that breast cancer patients with advanced cancer stages and a larger number of procedures (as documented by CPT codes) were associated with a decreased probability of hormonal therapy initiation. This confirms our expectation that CPT codes should be control variables in the survival analysis. The KM curve indicated that most breast cancer patients who initiated hormonal therapy did so within 6 months after their diagnosis.

There are several notable findings from a comparison of the semantic word groups that increased and decreased the probability of hormonal therapy medication initiation. It should be recognized that it is the factors that are mentioned in the messages (e.g., the act of taking surgery), instead of the mentions themselves, that are material to this investigation. First, we observed that patients who mentioned consulting-related words and chemotherapy were more likely to initiate hormonal therapy. This suggests that obtaining suggestions from healthcare providers may help realize a smooth transition from diagnosis to taking hormonal therapy. By contrast, patients who mentioned symptoms and surgeries were less likely to start hormonal therapy, suggesting that complex health conditions or significant procedures (e.g., surgery) may delay the start of taking hormonal therapy. In particular, women who must undergo repeated breast conserving surgeries due to positive margins, as well as those who develop post-surgical complications (e.g., infection), may be less likely to initiate hormonal therapy; this phenomenon has been studied in the context of adjuvant radiotherapy. It should be noted that, while symptoms-related semantic groups were found to be both positively and negatively associated with the start of hormonal therapy, they are referring the different symptoms (e.g., #40 against #29). Second, it was observed that patients who mentioned negative emotions (e.g., depression and anxiety) were less likely to initiate the therapy. By contrast, patients who mentioned afford related verbs (#36) or acceptable related adjectives (#21) were more likely to start therapy. This emphasizes the importance of complex health conditions in affecting the start of therapy. Finally, we found that patients who mentioned scheduling related terms are more likely to start therapy. This suggested that actively managing appointments with healthcare providers is beneficial to start therapy.

Limitations and Future Work

Despite these findings, we wish to highlight several limitations, which serve as the basis of future research. First, our findings were generated from a cohort that were predominantly Caucasian and diagnosed with early stage breast...
cancer at a single medical center, which may limit their generality. Second, we are unable to discern whether hormonal therapy was prescribed in the adjuvant or neo-adjuvant (pre-surgical) setting. Neoadjuvant hormonal therapy was intensively studied in the early 2000’s but then fell out of favor; recently it has been used more often in the context of “window of opportunity” trials. This is an important distinction, since the initiation rate of neoadjuvant hormonal therapy is expected to be close to 100% because it is a prerequisite to the surgery. Third, the cohort consisted of the patients who were prescribed hormonal therapy medication; however, it would be useful to compare this population with patients who had the same disease but did not undergo hormonal therapy. Such a comparison could provide greater insight into a patient’s decision-making process with respect to this treatment. Fourth, while our study demonstrated the effectiveness of applying word clustering to group single terms, it is limited in that there were still several groups that were difficult to interpret their meanings. It will be interesting to investigate the extent to which including human judgment in clustering process can help improve the interpretability of word groups. Further, we identified the start of the hormonal therapy based on the medication entry date recorded in EMR system. It will be very interesting to investigate the intended start of the therapy. Future work can also consider incorporate insurance status, income and healthcare provider characteristics into the model, as well as investigate the influence that patient have on their first hormonal therapy prescription. Finally, another useful future direction is investigating the extent to which hormonal therapy initiation is associated with hormonal therapy medication discontinuation.

Abstract
As a step toward learning to automatically insert new concepts into a large biomedical ontology, we are studying the easier problem of automatically verifying that an IS-A link should exist between a new child concept and an existing parent concept. We are using a Convolutional Neural Network, a powerful machine learning method. However, results depend on the quality of the training data. We use SNOMED CT (July 2017) for training and the subsequent release for testing. The main problem is to find a good set of negative training data. We experiment with two approaches, based on uncle-nephew (not connected) pairs of concepts. We contrast using the complete Clinical Finding hierarchy of SNOMED CT with using the powerful Area Taxonomy ontology summarization mechanism to constrain the training data. The results for the task of verifying IS-A links are improved by 8.6% when going from the complete hierarchy to the Area Taxonomy.

Introduction
Biomedical terminologies are structured and organized knowledge systems. They play a major role in enabling precise communication and in support of healthcare applications, e.g., Electronic Healthcare Record (EHR) systems [1-3]. A terminology, which typically consists of up to hundreds of thousands of concepts interconnected by many more relationships, can be viewed as a complex network with concepts as nodes and relationships as links. The hierarchical IS-A relationships between concepts are the backbone of the terminology. An IS-A relationship, from concept A to concept B, represents that concept A is a specialization of concept B. For example, within SNOMED CT [4], the concept Corneal infection IS-A Eye infection, because corneal infection is a specialization of eye infection. Due to the size and complexity of biomedical terminologies, their enrichment, i.e., adding new concepts at the proper positions in the concept hierarchy, is difficult and labor-intensive. Any semi-automatic framework that can predict/verify the place of a new concept in the terminology hierarchy is highly desirable.

In a previous study [5], we trained a Convolutional Neural Network (CNN) model to learn the likely locations of new IS-A links from the whole SNOMED CT hierarchy. We trained the model with data from the SNOMED CT 2017 July release and tested its ability to verify IS-A relationships of new concepts added to the SNOMED CT 2018 January release. This approach was based on document embeddings for each concept in the SNOMED CT. This preliminary study achieved an average F1 score of 0.70. In this paper, we suggest an improvement by using better training data.

One of the challenges when training machine learning (ML) models, and especially Deep Learning (DL) models, is dealing with imbalanced training data of different levels of quality. The training data is considered as high quality if it is balanced across the testing categories and is correlated to the test cases with good coverage. For example, to train a Convolutional Neural Network model for image classification, the data used for training has to be balanced across the image categories. It should be general enough to cover the possible test cases and task-oriented enough so that it does not deviate too far from the test data in various aspects, such as format, resolution, and brightness. High quality, task-oriented training data typically improves the results of ML techniques.

While training the CNN model with the whole SNOMED CT seemed to be a straightforward solution in our previous work, the modeling differences among the 19 hierarchies of SNOMED CT propagate inevitably to the CNN model. This may impair the performance of the trained CNN model in distinguishing IS-A links in different hierarchies. The features that the CNN model incorporates from the Clinical Finding hierarchy are rarely useful for distinguishing IS-A links in other hierarchies, e.g., Specimen, that are covering a different subject, because different hierarchies are modeled following different modeling principles and are often modeled by different curators.

Secondly, the training data provided by SNOMED CT is naturally unbalanced, as there are orders of magnitude fewer concept pairs connected by IS-A links than pairs of concepts not connected by IS-A links. This issue was handled by random downsampling from the set of concept pairs not connected by IS-A links. When selecting such pairs, we followed the idea of choosing negative training data that is closely related to the positive training data to
define an improved decision boundary. In particular, if B is a new concept with an IS-A relationship to a concept A, written as (B, A), then we select as the negative sample a pair of concepts B and C, such that C is a sibling of A and there is no IS-A relationship from B to C. This pair of concepts defines an uncle-nephew relationship relative to the pair (B, A).

In a long-range research program, our team has developed a taxonomy-based framework to support the summarization and visualization of biomedical ontologies [6-8]. An Area Taxonomy is a summarization network composed of area “nodes,” each representing a set of similar concepts. Training a model with uncle-nephew concept pairs from the same area implies that the CNN model will tend to incorporate more fine-grained features, learned from closer concept pairs, than general features when training with uncle-nephew pairs. This training data enables the CNN model to learn subtle differences between IS-A and non-IS-A pairs of concepts. Area taxonomy can also be utilized for quality assurance tasks, such as verifying missing IS-As, for a terminology [9].

Previous work on applying machine learning techniques to terminology enrichment is quite diverse. An effective weakly supervised ontology enrichment algorithm has been reported by Pembeci et al. [10] that uses concept similarity scores computed via Word2vec models to discover other related concepts. Jayawardana et al. used Word vector embeddings to derive candidate vectors and then trained an SVM model to calculate representative vectors for concepts [11]. OmicsCNN [12] is a dedicated DL framework to generate feature distances on “omics data” through a novel layer called OmicsConv to prepare omics data for clinical applications and scientific discovery.

In this work, we use the Clinical Finding hierarchy of 109,366 concepts of SNOMED CT as our test-bed. We utilize Doc2Vec [13] as our embedding encoder to generate concept-level vectors. We prepared two sets of training data, one using random SNOMED CT hierarchy data and another one with data obtained from our Area Taxonomy, and we trained two Convolutional Neural Network models respectively. We compared their performance on predicting the hierarchical IS-A relationships within the Clinical finding hierarchy of SNOMED CT. To validate our approach, we tested the two models with the 1,027 new concepts that were added to the Clinical finding hierarchy between the SNOMED CT July 2017 release and the January 2018 release.

Background

Convolutional Neural Network

Deep Learning [14] has been successfully applied to many tasks, such as computer vision [15] and speech recognition [16]. Convolutional Neural Networks (CNNs) have been extensively studied and used for various applications including image recognition, semantic parsing, search query retrieval, sentence modeling, classification, prediction, etc. CNNs utilize layers of convolving filters that are applied to local features [17], to serve as input for trainable classifiers for prediction tasks. This paper focuses on using a CNN as the model to solve a problem that is essential to ontology maintenance, namely how to verify the parent(s) for a newly added concept B. This is equivalent to verifying whether there is an IS-A link from a new concept B to an existing concept A.

Doc2vec

As most of the ML algorithms require input in numeric format, numeric representations of variable-length text, ranging from sentences to documents is a challenging task. Doc2vec (Paragraph Vectors) [13], an extension of Word2vec (word embedding) [18], projects variable-length documents or paragraphs to fixed-length vectors. It is an unsupervised framework that learns continuous distributed vector representations from unlabeled text data of a document, while preserving the inter-relationships within the text in the numeric format. In such vector representations, similar pieces of text are close to each other in Euclidean or cosine distance in lower dimensional vector spaces. The original Paragraph Vector paper [13] recommended combining the Distributed Memory version of Paragraph Vector (PV-DM) with the Distributed Bag of Words (PV-DBOW) representation to obtain consistency, which is done in this study.

Areas and Area Taxonomy

In previous work, we defined an area is a group of concepts all of which have identical sets of lateral relationship types. Lateral relationships are all binary relationships in SNOMED CT except for IS-A relationships. An Area Taxonomy is a network that consists of nodes representing areas and child-of links connecting areas. Area taxonomies have applications in quality assurance of terminologies [19]. Figure 1 illustrates the derivation of an Area Taxonomy. Figure 1(a) shows an excerpt of 16 concepts, drawn as labeled ovals, from SNOMED CT’s Clinical Finding hierarchy. Concepts of each area are grouped together in a dashed rectangle, labeled by the common set of relationships types. The arrows denote IS-A links. Lateral relationships are inherited along the IS-A
links between concepts. For example, *Infected corneal abrasion* and *Infective uveitis* (and three other concepts) are grouped together (in a green rectangle), because they all have the same lateral relationships: Associated morphology, Finding site, and Pathological process. Figure 1(b) shows the Area Taxonomy for 1(a). All colored rectangles represent nodes, which are connected by hierarchical child-of links that are derived from the corresponding IS-A relationships in SNOMED CT. Ochs et al. developed software [20] to automatically derive Area Taxonomies.

**Figure 1.** Derivation of Area Taxonomy. (a) Excerpt of 16 concepts from SNOMED CT’s Clinical Finding hierarchy. (b) Area Taxonomy for the excerpt in (a).

Areas with the same number of lateral relationship types have the same color and are shown at the same level. For example, the areas *{Causative agent, Finding site, Pathological process}* and *{Associated morphology, Finding site, Pathological process}* appear in the second level in green. *Eye infection* and its descendants in the grey rectangle are now represented by the area *{Finding site, Pathological process}*.

**Figure 2:** Serializing the hierarchical structure of one concept into one document.
Methods

We used the SNOMED CT July 2017 release as training set and the subsequent January 2018 release as testbed. The data preprocessing follows the same workflow as in our previous study [5] to generate documents and train embedding vectors, but is limited to the Clinical Finding hierarchy of SNOMED CT. We will illustrate the document generation process below, as it is crucial for understanding the next step.

i. Create one “document” per focus concept (see Figure 2). We use a concept’s corresponding SNOMED CT ID as the unique ID for a document. The hierarchical information related to this focus concept is used as the content of this document. Specifically, we chose this concept’s parents (targets of IS-A links from this concept), and its children (sources of IS-A links to this concept). Unlike our previous study, a concept’s sibling(s) are neglected in this study without showing accuracy loss. By constructing a document this way, a concept becomes the focus topic of this document and its closely related concepts “describe” the meaning of it in the ontology hierarchy.

ii. To maintain the existing hierarchical relationships of the focus concept to some degree, we arrange these concepts as follows: A concept’s parent(s) are placed at the beginning of the text, followed by the concept itself, and then by the child(ren) of this concept. Thus, the order of the whole document text is: Parent(s) — Focus concept — Child(ren) (Figure 2). Tabs are used as separators between concept groups. For example, Infectious thyroiditis has two parents, Thyroid infection and Thyroiditis, and two children, Acute suppurative thyroiditis and Viral thyroiditis. Thus, the content of the document for the concept Infectious thyroiditis is defined as “ID Thyroid infection, Thyroiditis \ Infectious thyroiditis \ Acute suppurative thyroiditis, Viral thyroiditis” where \ is the ASCII tab character, and ID stands for the ID of the focus concept.

Figure 3: Data flow during vectorization phase. N = 109,366 is the total number of concepts in the Clinical Finding hierarchy of the SNOMED CT July 2017 release.

After constructing a document for each concept, we passed the list of all documents to the Gensim implementation of Doc2Vec to generate two embeddings (displayed as black arrows in Figure 3). Gensim automatically generates
the document-level vectors while maintaining the semantic topics of the documents. We performed experiments with both the Distributed Memory version (PV-DM) and the Distributed Bag of Words (PV-DBOW) version of Paragraph Vector [13]. The PV-DM model and the PV-DBOW model function as two “vector dictionaries.” For each concept, we can retrieve its corresponding two vectors (denoted as Vector_{pv-dm} and Vector_{pv-dbow} in Figure 3) by sending its corresponding document ID to the two models, respectively. This is indicated by two blue arrows emanating from the green SNOMED CT repository. The vector dimension was set to 128. The use of those two embeddings is new and was not done in the previous study [5].

The same CNN model architecture was employed as in the previous study [5]. It was tailored to accommodate two vectors with a dimension of 128. The modification of stacking two vectors in depth for each concept as input does not require changing the previous CNN model, because the convolutional operations work across the depth dimension, such as, for example, when processing RGB channel data for color image input [14].

Distinguishing between IS-A and Non-IS-A Training Data

To train a CNN model that can verify an IS-A link between a pair of concepts, we need to train the model with both IS-A connected concept pairs and concept pairs with no IS-A connection. The IS-A connected concept pairs are explicitly defined in the terminology hierarchy. The judicious selection of non-IS-A concept pairs is critical for the accuracy of the model. In our previous study [5], we limited the non-IS-A pairs to only uncle-nephew pairs. Figure 4(a) illustrates this. Consider an IS-A relationship from a concept A to a concept B. A sibling C of B is an uncle of A. Thus the pair of A and C is called an uncle-nephew pair. The concept D has an IS-A relationship to concept Q and is not an uncle of A. The concept C is hierarchically related to B as its sibling. Thus, C has a higher probability of being mistaken as A's parent than D, which is not hierarchically related to B. In other words, the non-IS-A pair of A and C is more similar than the pair of unconnected concepts A and D to the IS-A pair (A, B). It is more useful to learn to distinguish between an IS-A pair and (one of) its uncle-nephew non-IS-A pairs than between an IS-A pair and an arbitrary non-IS-A pair, which might be “far away" from the IS-A pair.

![Figure 4](image-url) Illustrating two potential training data patterns

Utilizing the Area Taxonomy, the uncle-nephew pairs can be further divided into two types: uncle and nephew concepts are from the same area or uncle and nephew concepts are from different areas. In Figure 4(b), both C and D are A’s uncles, because they are siblings of B. However, C is in the same (red) area as A, while D resides in another (green) area. The uncle-nephew pair of A and C is more similar to the IS-A pair (A, B) than the uncle-nephew pair of A and D, since concepts from the same area share the same set of relationships types, and are more similar to each other. Our hypothesis is that the CNN model will become more accurate by training it with uncle-nephew pairs from the same area, because it can learn to distinguish between IS-A pairs and closely related non-IS-A pairs. As a result, the derived CNN model should be better at verifying whether a concept pair should be connected by an IS-A link or not, achieving better accuracy.

We demonstrate the above observation with a concrete example (Figure 5) from the Clinical Finding hierarchy. Let the nephew concept be Conjunctival diphtheria (in yellow). Its uncle concepts are Viral conjunctivitis, Parasitic conjunctivitis, and Tumorlet. Conjunctivitis (called also pinkeye) is an infection of the conjunctiva, the transparent tissue that covers the white part of the eye. These 3 concepts are the siblings of the concept Bacterial conjunctivitis, which is the parent of Conjunctival diphtheria. As Figure 5 shows, the uncle concept Viral conjunctivitis (in green) is in the same area {Associated morphology, Causative agent, Finding site, Pathological process} as Conjunctival diphtheria, while the other two uncle concepts Parasitic conjunctivitis and Tumorlet (in red) are in different areas.
Causative agent, Finding site, Pathological process] and [Associated morphology, Finding site, Pathological process], respectively, than Conjunctival diphtheria. Conjunctival diphtheria is structurally more similar to Viral conjunctivitis as both of them have the same four lateral relationships, while it is structurally different from Parasitic conjunctivitis and Tumorlet, which have only three lateral relationships.

Indeed, Viral conjunctivitis is closer to Bacterial conjunctivitis, the parent of Conjunctival diphtheria, than to Parasitic conjunctivitis and Tumorlet. Thus, we formulate the following hypothesis.

**Hypothesis:** Using uncle-nephew pairs as training data for non-IS-A pairs, with both taken from the same area, will improve the CNN model’s classification accuracy for non-IS-A and IS-A test cases, compared to training with pairs where uncle and nephew are randomly chosen from the Clinical Finding hierarchy.

**Testing the Hypothesis**

To evaluate our model’s performance on real, previously unseen data, we used new concepts from the SNOMED CT 2018 January release. A pre-trained Doc2Vec model returned a pre-determined vector for an existing concept or inferred a vector for a new concept from the new concept’s name. However, if all the word(s) in a new concept’s name are not in the trained vocabulary (i.e., they were never seen before when training the model), the inferred vector for this concept would be a random vector. To avoid this situation, we limited testing the CNN model to new concepts with multiple parents existing in the July 2017 release. It is true this limitation restricts our model’s applicability to about one-third of the concepts in SNOMED CT. For new concepts with only one existing parent, we suggest that it is better to use them for training the model afterward, rather than testing against them without having the model learned any knowledge about them. The detailed procedures for preparing test data for both IS-A concept pairs and non-IS-A concept pairs are as follows (Figure 6).

We used new concepts added in the SNOMED CT January 2018 release and their parents. To get the inferred vector for a new concept N, we randomly selected one of its parents – say Parent 1 in Figure 6(a). Then Parent 1’s name is concatenated with N’s name as the “query” to the Doc2Vec model. The vector inferred by the Doc2Vec model is then paired with one of the remaining parents’ vectors, say the vector for Parent 2 to form a vector pair (N, Parent 2). This vector pair, as one test case, is sent to the pre-trained CNN model for IS-A link verification. Similarly, we paired the inferred vector for N with vectors for Parent 3 and Parent 4, respectively to create two test cases, namely, whether the CNN model can verify the IS-A links for the pairs (N, Parent 3) and (N, Parent 4).

As the Doc2Vec model is pre-trained, i.e., it is not updated during the inference process, the inferred vectors are independent of each other. Therefore, we can create other sets of test cases by generating all the possible pairs between N and its parents. For example, as shown in Figure 6(b), we concatenated the names of N and Parent 2 to...
get the inferred vector for N, and then paired the inferred vector with vectors for Parent 1, Parent 3, and Parent 4 as three test cases.

Figure 6. (a) Three IS-A test cases if pairing up the new concept N with its first parent. (b) Repetition of (a), but now we are pairing up N with Parent 2.

Following this setup, out of 2,005 new concepts added to the Clinical Finding hierarchy of the January 2018 release, we selected 1,027 concepts to generate a total of 7,494 IS-A concept pairs for testing the CNN model’s accuracy when verifying IS-A links for the new SNOMED CT release. Out of the 1027 concepts, 797 concepts are leaf nodes.

For non-IS-A test pairs, we first collected the existing parents of all the new concepts that were used for IS-A testing to form a “Parent set.” Then for each new concept, we paired it with all the concepts from the “Parent set” except its own parents, generating non-IS-A test pairs (Figure 7). By doing this, the non-IS-A test data is not limited to only uncle-nephew pairs, but allows general combinations of new concepts with other existing parent concepts. The CNN model’s performance on such concept pairs reveals its generalizability to the broader population of non-IS-A test data. We randomly selected 7,494 non-IS-A concept pairs to match the number of IS-A concept pairs.

The process to convert from a test pair into a vector pair is demonstrated in Figure 7. After the test pairs for both positive and negative samples were selected, we query the PV-DM and PV-DBOW models to get the corresponding concept vectors. For each concept pair, we obtained four vectors (two vectors for each concept). To get the corresponding vector pair, we concatenated the two vectors generated by the same model into one vector. Then the two long vectors were sent into the pre-trained CNN model in a random order to compute a class label (0 or 1) as the prediction result. For an IS-A test concept pair, label 1 is correct if there is an IS-A link between these two concepts in the new SNOMED CT release. For a non-IS-A concept pair, label 0 is correct if there is no IS-A link between these two concepts in the new SNOMED CT release. We repeated the training and testing ten times with randomly chosen 90:10 splits between training and validation data to obtain a consistent evaluation of the efficacy of our methodology.
Besides examining the quality of the training data, we also scrutinized the quality of the concept vectors from the Doc2Vec embedding. We experimented with the “iterations/epochs” parameters of the PV-DM and PV-DBOW models. This is a parameter to control how many times to iterate over the training corpus. The typical iteration counts suggested in the original “Paragraph Vectors” paper [13] are 10-20 for tens-of-thousands to millions of documents. Thus, we experimented with 10, 20, and 50 iterations for comparison.

**Results**

We first report the prediction results of our CNN model with the 7,494 IS-A connected concept pairs. Table 1 summarizes the performance comparison between using original (= “unsummarized”) training data from the whole Clinical Finding hierarchy (shown as “hierarchy”) versus training data from the same area only (shown as “area”). The Precision, Recall, and F1 scores for ten tests are presented in Table 1. The model trained using the Area Taxonomy data is superior to the model trained using hierarchy data in both best F1 score (0.78 vs. 0.73) and average F1 score (0.75 vs. 0.69). The standard deviations of the ten F1 scores for both trained models are the same (0.018).

Next, we evaluated our model’s performance on non-IS-A concept pairs. The Precision, Recall, and F1 scores for ten tests are presented in Table 2. Table 2 summarizes the performance comparison for non-IS-A concept pairs between using data from the whole hierarchy (shown as “hierarchy”) versus using training data from the same area (shown as “area”). The model trained with Area Taxonomy data achieved the same F1 value as the model trained with the whole hierarchy (0.78). The standard deviation of the ten F1 scores for the “hierarchy” model is 0.005, and it is 0.008 for the “area” model.

The training time for the 10, 20, and 50 iterations was 485, 947, and 2035 seconds, respectively, with the same hardware configuration. The CNN models trained on top of these three vector spaces achieved an average F1 score of approximately 0.745 for IS-A testing, for each of the 10, 20, and 50 iterations. For non-IS-A testing, the average F1 scores for the 10, 20, and 50 iterations were 0.784, 0.775, and 0.753, respectively.

Discussion

In this study, we set out to evaluate the hypothesis whether using terminology summarization, in the form of the Area Taxonomy summarization network, can help in obtaining high-quality training data. For this, we used only uncle-nephew pairs from the same area as the non-IS-A training data. The hypothesis was proven only partially correct. Sharpening the distinction between IS-A pairs and non-IS-A uncle-nephew pairs by selecting non-IS-A pairs from the same area improved the F1 score for identifying IS-A pairs by 8.6% on average from 0.69 to 0.75, while for non-IS-A pairs there was no improvement. Perhaps focusing the non-IS-A training on uncle-nephew pairs close to IS-A pairs, helps improve identifying IS-A pairs, but not the broad non-IS-A pair population tested. We note that the non-IS-A testing was set up by pairing each focus concept with the parents of all other focus concepts. That is, those are not uncle-nephew pairs. Such broad testing data is a fair representation of the large number of non-IS-A pairs. However, the non-IS-A training performed in our study, by its nature, did not improve identifying these non-IS-A pairs.

The average F1 score for non-IS-A pairs is 0.78, which is slightly higher than for IS-A pairs (0.75). The standard deviation is lower for the non-IS-A pairs. Interestingly, for IS-A pairs the recall is higher than the precision while it is the opposite for non-IS-A pairs. Even though the average F1 score (0.78) for non-IS-A did not improve with summarization, it is still higher than the F1 score (0.75) for IS-A identification. The corresponding best F1 scores are even closer (0.80 vs. 0.78). For the hierarchy approach the IS-A identification is weaker (average F1 =0.69) than identifying non-IS-A (average F1=0.78). Hence the area summarization approach improved the “weakest point” (identifying IS-A pairs) of the overall performance of the hierarchy approach by obtaining an average F1 of 0.75. As a result, the average F1 scores of both the IS-A and the non-IS-A testing are close (0.75 vs. 0.78) for the area summarization approach. Experimenting with 10, 20, and 50 iterations, the results indicated that while more iterations took more time they actually diminished the F1 values. Hence, there is no point of running more than 10 iterations since the test performance is not improving.
Conclusion

The complexity of terminological data poses a challenge to training machine learning models that can achieve high accuracy on classifying hierarchical relationships between new concepts and their parents. To overcome this challenge, we explored the use of data obtained from the Area Taxonomy, a terminology summarization network, to prepare high-quality training data that can better distinguish between IS-A and non-IS-A concept pairs. With SNOMED CT’s Clinical Finding hierarchy as a testbed, the CNN model trained with the summarized data achieved an average F1 score of 0.75 for identifying IS-A pairs, which is about 8.6% better than for the model trained without summarization.

Abstract

Auditing National Cancer Institute (NCI) thesaurus is essential to ensure that it provides accurate terminology for cancer-related clinical care as well as translational and basic research. We leverage a structural-lexical approach to identify missing hierarchical IS-A relations in NCI thesaurus based on non-lattice subgraphs and derived lexical attributes of concepts. For each concept in a non-lattice subgraph, we use two ways to derive the concept’s lexical attributes: (1) inheriting lexical attributes from its ancestors within the subgraph; and (2) inheriting lexical attributes from all its ancestors. For a pair of concepts not having a hierarchical relation, if the lexical attributes of one concept is a subset of that of the other, we suggest there is a potential missing IS-A relation between the two concepts. Our approach identified 547 non-lattice subgraphs in the 19.01d release of NCI thesaurus which revealed a total of 1,022 unique potential missing IS-A relations. A random sample of 100 relations was evaluated by a domain expert. Among these relations, 90 can be obtained by the way of inheriting lexical attributes from ancestors within non-lattice subgraph, among which 76 were confirmed as valid (a precision of 84.44%); and 82 can be obtained by the way of inheriting all ancestors, among which 73 were confirmed as valid (a precision of 89.02%). The results show that our structural-lexical approach based on non-lattice subgraphs is effective for auditing NCI thesaurus.

1 Introduction

The National Cancer Institute thesaurus (NCIt) is a biomedical terminology produced by NCI Enterprise Vocabulary Services containing more than 140,000 concepts\textsuperscript{1}. Auditing biomedical terminologies such as NCIt is essential to ensure that it produces an accurate representation of the knowledge of the domain it models. This is especially important because the quality issues in terminologies would cause the applications that use these terminologies to be erroneous as well\textsuperscript{2}. As the terminologies are continuously being expanded, their complexity also increases, making the introduction of errors almost unavoidable. Therefore, Terminology Quality Assurance (TQA) has become an important part of the terminological management lifecycle of all modern biomedical terminologies. However, manually reviewing a terminology to perform TQA is impractical due to the increasing size and complexity of modern terminologies. Therefore, automated or semiautomated approaches are needed to perform TQA efficiently and effectively.

In this paper, we introduce a structural-lexical approach based on non-lattice subgraph (NLS) to identify missing hierarchical relations in NCIt. Recently a number of studies have shown that analyzing lexical features in concept labels in NLSs is a promising way to identify different kinds of defects in biomedical terminologies\textsuperscript{3–5}. In this work, we further work on this idea to come up with a set of lexical attributes for each concept in an NLS. We leverage these lexical attributes to suggest potential missing hierarchical relations in the NLS. A domain expert reviewed a randomly selected sample from the potential missing relations derived to examine the effectiveness of our approach.

2 Background

2.1 NCI Thesaurus (NCIt)

NCI Thesaurus is a biomedical terminology which covers vocabulary for cancer-related clinical care, translational and basic research, and public information and administrative activities\textsuperscript{1}. It was originally created to facilitate interoperability and data sharing by various components of NCI by incorporating terms used by different components and mapping them to unique concepts\textsuperscript{6}. Each concept includes a unique code, a preferred term, abbreviations, synonyms, and definitions\textsuperscript{7}. The content of NCIt is organized in a description logic environment with more than 400,000 relations

\*Corresponding author. Email: licong.cui@uth.tmc.edu
between concepts. NCIt is updated monthly with around 700 new concepts and many additional changes in each new release. It is released in many formats including Ontylog XML, OWL, and flat files. It is also available in both defined and inferred versions. We used the inferred version of the 19.01d release of NCIt in OWL format in this work.

2.2 Terminology Quality Assurance

Various methods have been investigated to facilitate quality improvement of biomedical terminologies like NCIt\(^8\). A type of high-level summary graphs, called abstraction networks, have been widely used to find inconsistencies in many biomedical terminologies\(^9-12\). Min et al.\(^13\) have applied such an approach to the Biological Process hierarchy of NCIt which has led to the identification of different types of errors such as missing roles, missing concepts, incorrect hierarchical relations etc. Mougin et al.\(^14\) have utilized the relations in UMLS semantic network to audit hierarchical and associative relations in NCIt. He et al.\(^15,16\) have employed topological patterns that exists between NCIt and a reference terminology to import new concepts to NCIt. In previous work\(^17,18\), we introduced a lexical-based inference approach to detect missing and incorrect relations in the Gene Ontology. Zheng et al.\(^19\) have proposed a deep learning-based approach to predict concept names for new concepts that are added to SNOMED CT. Cui et al. investigated different ways of analyzing lexical features of concepts in NLSs to uncover missing hierarchical relations in SNOMED CT\(^3,5\) and in NCIt\(^4\).

2.3 Non-Lattice Subgraphs (NLSs)

Being a lattice is considered a desirable property for a well-formed terminology\(^20\). A terminology is a lattice if any pair of concepts has a unique maximal common descendant and a unique minimal common ancestor. Here, a common descendant \(C\) is known as a maximal common descendant of a concept-pair \((A, B)\), if \(A\) and \(B\) have no other common descendant \(D\) such that \(C\) is a descendant of \(D\); and similarly, a common ancestor \(R\) is known as a minimal common ancestor of a concept-pair \((P, Q)\), if \(P\) and \(Q\) have no other common ancestor \(S\) such that \(R\) is an ancestor of \(S\). If a concept pair has more than a single maximal common descendant (or a single minimal common ancestor), it is known as a non-lattice pair\(^20,21\), which may reveal quality issues in terminologies.

It is not economical to separately examine multiple non-lattice pairs which share the same maximal common descendants. To address this, non-lattice subgraphs (NLSs) have been introduced\(^3\). An NLS can be acquired by a non-lattice pair \((c_1, c_2)\) as follows. Firstly, maximal common descendants of the non-lattice pair, \(mcd(c_1, c_2)\), named as the lower bounds, is computed. Then, the minimal common ancestors of the lower bounds, \(mca(mcd(c_1, c_2))\), named as the upper bounds, is computed. Finally, all the concepts as well as relations between (and including) lower and upper bounds is aggregated to generate the NLS. The size of an NLS is the number of concepts it contains. For example, in Figure 1, the non-lattice pair \{1, 2\} (alternatively \{1, 3\} or \{2, 3\}) yields \{6, 7\} as its maximal common descendants. Reversely computing minimal common ancestors of \{6, 7\} yields \{1, 2, 3\}. Then, the concepts \{4, 5\} as well as relations between \{1, 2, 3\} and \{6, 7\} are aggregated to form the given NLS.

\[
mca(mcd(1,2))
\]

\[
mcd(1, 2)
\]

\[
mcd(1, 2)
\]

**Figure 1:** An example of an NLS. Nodes of the graph are concepts. The edges indicate hierarchical IS-A relations where the arrowheads point to the parent concept.

NLSs have been utilized to effectively identify defects in biomedical terminologies. Cui et al.\(^3\) have proposed four lexical patterns found in NLSs which suggest missing hierarchical relations and missing concepts in SNOMED CT. In a previous work\(^4\), we introduced two new lexical patterns applying that approach to NCIt. Cui et al.\(^5\) originally introduced an approach combining NLSs and enriched lexical attributes of concepts to identify missing and incorrect
hierarchical relations in SNOMED CT. We also introduced a method to identify similar NLSs in the Gene Ontology to reduce the effort needed by domain experts in reviewing them.

3 Methods

We first extract all the NLSs in the 19.01d release of NCIt. Then we construct the lexical attributes of concepts in NLSs by two ways: (1) inheriting lexical attributes from ancestors within NLSs; and (2) inheriting lexical attributes from all the ancestors. Based on the lexical attributes, we identify potential missing hierarchical relations between concepts. A random sample of missing relations is evaluated by a domain expert to verify their correctness.

3.1 Constructing Lexical attributes of Concepts

Two lexical sources are leveraged to construct the set of lexical attributes for each concept in an NLS. Firstly we consider lexical attributes of the concept itself. The second source relies on the lexical attributes of the concept’s ancestors. The second source is obtained in two ways.

1. Inheriting lexical attributes from ancestors within the NLS: In this way, we consider concept’s ancestors that reside within the NLS to enrich the lexical attributes of a particular concept in the NLS. Note that we consider all the direct and indirect ancestors of a concept. Therefore, we compute the transitive closure of the hierarchical relation within the NLS to obtain indirect (transitive) ancestors.

2. Inheriting lexical attributes from all the ancestors: In this way, we consider all the concept’s ancestors in the terminology without limiting to the NLS. To obtain indirect (transitive) ancestors, we compute the transitive closure of the hierarchical relation in the entire terminology.

We compare these two ways later in the paper in Section 4. Using these two sources we construct a set of lexical attributes $L_c$ for each concept $c$ in an NLS as follows.

- Load $L_c$ with the set of words contained in the preferred name of $c$.
- For each ancestor $a$ of $c$, add the set of words contained in the preferred name of $a$ to $L_c$. Note that $a$ could be an ancestor within the NLS or an ancestor external to the NLS depending on which way is used as discussed above.

![Diagram]

**Figure 2:** An NLS of size 4 and its remediation. The suggested remediation here is a missing hierarchical relation: “C21663: Fibroadenoma of the Mouse Mammary Gland” IS-A “C21665: Adenoma of the Mouse Mammary Gland”. This can be obtained by both ways: inheriting lexical attributes from ancestors within the NLS and from all the ancestors.

We demonstrate the construction process using the NLS shown in Figure 2, considering ancestors within the NLS. For each concept $c$ in the NLS, we construct a set of attributes $L_{w_c}$ as follows. We initialize $L_{w_c}$ with the lexical attributes obtained from $c$’s preferred name:

- $L_{w_1} = \{\text{mouse, adenoma}\}$
- $L_{w_2} = \{\text{benign, neoplasms, of, the, mouse, mammary, gland}\}$
- $L_{w_3} = \{\text{adenoma, of, the, mouse, mammary, gland}\}$
- $L_{w_4} = \{\text{fibroadenoma, of, the, mouse, mammary, gland}\}$
If we enrich the above sets with the lexical attributes of the ancestors within the NLS, then the resulting attribute sets for each concept \( c (L_{w_i}) \) are as follows (newly added attributes are underlined):

\[
\begin{align*}
L_{w_1} &= \{ \text{mouse, adenoma} \} \\
L_{w_2} &= \{ \text{benign, neoplasms, of, the, mouse, mammary, gland} \} \\
L_{w_3} &= \{ \text{adenoma, of, the, mouse, mammary, gland, benign, neoplasms} \} \\
L_{w_4} &= \{ \text{fibroadenoma, of, the, mouse, mammary, gland, adenoma, benign, neoplasms} \}
\end{align*}
\]

If we use the lexical attributes of all the ancestors in the terminology, then the resulting attribute sets for each concept \( c (L_{a_i}) \) are as follows:

\[
\begin{align*}
L_{a_1} &= \{ \text{mouse, adenoma, murine, organism, benign, epithelial, diagnosis, neoplasm, experimental, neoplasms, cell} \} \\
L_{a_2} &= \{ \text{benign, neoplasms, of, the, mouse, mammary, gland, integumentary, organism, diagnosis, experimental, murine, disorder, system, neoplasm} \} \\
L_{a_3} &= \{ \text{adenoma, of, the, mouse, mammary, gland, integumentary, organism, diagnosis, epithelial, experimental, cell, murine, disorder, system, benign, neoplasm, neoplasms} \} \\
L_{a_4} &= \{ \text{fibroadenoma, of, the, mouse, mammary, gland, integumentary, organism, diagnosis, epithelial, experimental, cell, murine, disorder, system, adenoma, benign, neoplasm, neoplasms} \}
\end{align*}
\]

### 3.2 Detecting Missing Relations

For a pair of concepts \( c_1 \) and \( c_2 \) in an NLS that are not connected by a hierarchical relation, if \( c_2 \)'s lexical attributes \( L_{c_2} \) is a proper subset of the \( c_1 \)'s lexical attributes \( L_{c_1} \), then we suggest \( c_1 \) IS-A \( c_2 \) (i.e. \( c_1 \) is the more specific concept).

After obtaining all such potential missing relations in an NLS, we remove redundant relations that can be inferred by others. For example, if we suggest \( a \) IS-A \( b \) and \( a \) IS-A \( c \) for a particular NLS where \( b \) IS-A \( c \) already exists in the NLS, then we consider \( a \) IS-A \( c \) as redundant, since it can be inferred transitively through \( a \) IS-A \( b \) and \( b \) IS-A \( c \). Therefore, we remove \( a \) IS-A \( c \) from the list of suggestions.

For instance, considering ancestors within NLS, for concepts 3 and 4 in Figure 2, \( L_{w_1} = \{ \text{adenoma, of, the, mouse, mammary, gland, benign, neoplasms} \} \) is a proper subset of \( L_{w_4} = \{ \text{fibroadenoma, of, the, mouse, mammary, gland, adenoma, benign, neoplasms} \} \). Also, considering all the ancestors, \( L_{a_3} = \{ \text{adenoma, of, the, mouse, mammary, gland, integumentary, organism, diagnosis, epithelial, experimental, cell, murine, disorder, system, benign, neoplasm, neoplasms} \} \) is a proper subset of \( L_{a_4} = \{ \text{fibroadenoma, of, the, mouse, mammary, gland, integumentary, organism, diagnosis, epithelial, experimental, cell, murine, disorder, system, adenoma, benign, neoplasm, neoplasms} \} \).

Hence, we suggest concept 4 should be more specific than 3, i.e. Fibroadenoma of the Mouse Mammary Gland IS-A Adenoma of the Mouse Mammary Gland. As discussed above, this can be obtained by both considering ancestors within the NLS and all the ancestors.

Figure 3 contains a size-7 NLS with a potential missing hierarchical relation: “C4887: Metastatic Malignant Neoplasm in the Trachea” IS-A “C4571: Malignant Respiratory Tract Neoplasm” which can be obtained only by considering ancestors within the NLS for constructing lexical attributes.

Figure 4 contains a size-11 NLS with a potential missing hierarchical relation: “C5270: Cerebellar Papillary Meningioma” IS-A “C3569: Malignant Cerebellar Neoplasm” which can be only obtained by considering all the ancestors for constructing lexical attributes. This is because inheriting lexical attributes from ancestors within the NLS yields \( L_{w_11} = \{ \text{malignant, cerebellar, neoplasm, infratentorial, brain, intracranial, central, nervous, system} \} \) which is not a proper subset of \( L_{w_10} = \{ \text{cerebellar, papillary, meningioma, grade, iii, malignant, neoplasm} \} \). However, when all the ancestors are considered, \( L_{a_{11}} = \{ \text{malignant, cerebellar, neoplasm, disorder, central, system, nervous, infratentorial, intracranial, brain} \} \) is a subset of \( L_{a_{10}} = \{ \text{cerebellar, papillary, meningioma, infratentorial, intracranial, brain, cell, malignant, disorder, system, central, meningeal, nervous, grade, iii, neoplasm, meningothe} \} \).
Figure 3: An NLS of size 6 and its remediation. The suggested remediation here is a missing hierarchical relation: “C4887: Metastatic Malignant Neoplasm in the Trachea” IS-A “C4571: Malignant Respiratory Tract Neoplasm”. This can only be obtained by considering the ancestors within the NLS for enriching lexical attributes.

Figure 4: An NLS of size 11 and its remediation. The suggested remediation here is a missing hierarchical relation: “C5270: Cerebellar Papillary Meningioma” IS-A “C3569: Malignant Cerebellar Neoplasm”. This can only be obtained by considering all ancestors for enriching lexical attributes.

3.3 Filtering

We perform three kinds of filtering to avoid generate erroneous suggestions of potential missing IS-A relations: stop word filtering, antonym filtering, and position filtering.

Stop word filtering. Consider the concepts “C4013: Malignant Head and Neck Neoplasm” and “C3260: Neck Neoplasm”. These two satisfy all the requirements to be candidates for a suggestion of a missing hierarchical relations in the form of “C4013: Malignant Head and Neck Neoplasm” IS-A “C3260: Neck Neoplasm”. However, upon close
observation, it can be seen that this suggestion is wrong since it gives the idea of *Head Neoplasm* is a subtype of *Neck Neoplasm*. Existence of such stop words in concepts make them more prone to generate erroneous missing hierarchical relation suggestions. Therefore, If a concept contains such stop words, we do not make any suggestions. Moreover, we also do not consider such concepts to enrich lexical attributes of other concepts. That is, if a concept with stop words exists as an ancestor of another concept, we do not enrich the lexical attributes of the latter with the former. The stop words used to perform this filtering are: “and”, “and/or”, “or”, “no”, “not”, “without”, “due to”, “secondary to”, “except”, “by”, “after”, “able”, “removal”, “replacement”, “NOS”, where “NOS” represents “Not Otherwise Specified”.

**Antonym filtering.** If the constructed enriched lexical attributes of a particular concept contains an antonym pair, such concepts are more prone to erroneous suggestions as well. For example, consider the concepts “C60996: Malignant Epithelial Small Polygonal Cell” with attributes {small, cytoplasm, with, large, abundant, polygonal, epithelial, neoplastic, cell, malignant} and “C36822: Malignant Epithelial Large Cell” with attributes {large, epithelial, neoplastic, cell, malignant}. Even though attributes of C60996 is a proper subset of C36822, suggesting a hierarchical relation between these two is obviously not accurate since C60996 is discussing small cells and C36822 is discussing large cells (note that “small” and “large” is an antonym pair). Therefore, after obtaining the set of attributes, we check the set to ensure that it does not contain an antonym pair. The antonym pairs are obtained from WordNet.

**Position filtering.** For concepts with short names, they may appear as a part of other concepts’ names in various positions (e.g., beginning, middle, or end). For concepts whose names are not appearing at the end of other concepts’ names, it is likely to suggest incorrect missing IS-A relations. For instance, concept “Fentanyl” appears at the beginning of concept “Fentanyl Citrate Pectin-Based Nasal Spray”, and the subset inclusion may wrongly suggest “Fentanyl Citrate Pectin-Based Nasal Spray” IS-A “C494:Fentanyl”. Therefore, we filter out such cases by assigning a constraint such that the shorter concept should always appear at the end of the longer concept.

### 3.4 Evaluation

To evaluate the performance of our approach in accurately identifying missing hierarchical relations, we randomly selected a sample of missing hierarchical relations from the overall results for evaluation. These samples were provided to a domain expert (author MAB). Existing erroneous hierarchical relations in NCIt may help derive incorrect suggestions for missing hierarchical relations. Therefore, for the potential missing relations identified as incorrect by the domain expert, in a second round of evaluation, we provided the domain expert with existing hierarchical relations that were used to derive the incorrect ones. If the domain expert disagrees with the existing relation as well, then we marked it as an incorrect existing hierarchical relation. For instance, the NLS in Figure 5 denotes such a scenario.

**Figure 5:** An NLS of size 8 and its remediation. The suggested remediation here is an incorrect hierarchical relation: “C3779: Giant Cell Carcinoma” should not be a subtype of “C3780: Large Cell Carcinoma”. The existence of this relation derives the incorrect suggestion of “C4452: Lung Giant Cell Carcinoma” IS-A “C4450: Lung Large Cell Carcinoma”.

“Ancient” filtering. If a concept contains such stop words, we do not make any suggestions. Moreover, we also do not consider such concepts to enrich lexical attributes of other concepts. That is, if a concept with stop words exists as an ancestor of another concept, we do not enrich the lexical attributes of the latter with the former. The stop words used to perform this filtering are: “and”, “and/or”, “or”, “no”, “not”, “without”, “due to”, “secondary to”, “except”, “by”, “after”, “able”, “removal”, “replacement”, “NOS”, where “NOS” represents “Not Otherwise Specified”.

**Antonym filtering.** If the constructed enriched lexical attributes of a particular concept contains an antonym pair, such concepts are more prone to erroneous suggestions as well. For example, consider the concepts “C60996: Malignant Epithelial Small Polygonal Cell” with attributes {small, cytoplasm, with, large, abundant, polygonal, epithelial, neoplastic, cell, malignant} and “C36822: Malignant Epithelial Large Cell” with attributes {large, epithelial, neoplastic, cell, malignant}. Even though attributes of C60996 is a proper subset of C36822, suggesting a hierarchical relation between these two is obviously not accurate since C60996 is discussing small cells and C36822 is discussing large cells (note that “small” and “large” is an antonym pair). Therefore, after obtaining the set of attributes, we check the set to ensure that it does not contain an antonym pair. The antonym pairs are obtained from WordNet.

**Position filtering.** For concepts with short names, they may appear as a part of other concepts’ names in various positions (e.g., beginning, middle, or end). For concepts whose names are not appearing at the end of other concepts’ names, it is likely to suggest incorrect missing IS-A relations. For instance, concept “Fentanyl” appears at the beginning of concept “Fentanyl Citrate Pectin-Based Nasal Spray”, and the subset inclusion may wrongly suggest “Fentanyl Citrate Pectin-Based Nasal Spray” IS-A “C494:Fentanyl”. Therefore, we filter out such cases by assigning a constraint such that the shorter concept should always appear at the end of the longer concept.

### 3.4 Evaluation

To evaluate the performance of our approach in accurately identifying missing hierarchical relations, we randomly selected a sample of missing hierarchical relations from the overall results for evaluation. These samples were provided to a domain expert (author MAB). Existing erroneous hierarchical relations in NCIt may help derive incorrect suggestions for missing hierarchical relations. Therefore, for the potential missing relations identified as incorrect by the domain expert, in a second round of evaluation, we provided the domain expert with existing hierarchical relations that were used to derive the incorrect ones. If the domain expert disagrees with the existing relation as well, then we marked it as an incorrect existing hierarchical relation. For instance, the NLS in Figure 5 denotes such a scenario. “C3779: Giant Cell Carcinoma” should not be a subtype of “C3780: Large Cell Carcinoma”. The existence of this relation derives the incorrect suggestion of “C4452: Lung Giant Cell Carcinoma” IS-A “C4450: Lung Large Cell Carcinoma”.

![Figure 5](image-url)
4 Results

4.1 Summary Results

A total of 9,512 NLSs were extracted from the 19.01d version of NCIt with sizes ranging from 4 to 644. Out of these, our approach identified 547 NLSs with potential missing hierarchical relations. These NLSs contained a total of 1,022 potential missing hierarchical relations (note that an NLS may contain more than one missing hierarchical relation). It can be seen from Table 1 that 441 out of 547 NLSs can be identified by the way of inheriting lexical attributes from ancestors within NLS and suggests 925 potential missing IS-A relations; and 422 out of 547 can be identified by the way of inheriting lexical attributes from all the ancestors and suggests 847 potential missing IS-A relations. The two ways identified 750 potential missing IS-A relations in common.

4.2 Evaluation

The evaluation sample contained 100 potential missing relations observed in 83 NLSs identified by our approach. The domain expert concluded 85 (85%) of missing hierarchical relations are valid. Table 2 shows 15 examples of valid missing hierarchical relations in the form of subconcept and superconcept, for instance, “C7155: Primary Central Chondrosarcoma” IS-A “C3737: Mesenchymal Chondrosarcoma”. For the 15 invalid ones, the domain expert further inspected the existing hierarchical relations that were used to derive the invalid ones and verified that 8 of them were actually incorrect. Table 3 lists five examples of incorrect existing relations. For example, “C66775: Borderline Ovarian Mucinous Adenofibroma” should not be a subtype of “C4934: Benign Female Reproductive System Neoplasm”, since the word “borderline” indicates that it is on the borderline between benign and malignant, and may exhibit malignant behavior.

We summarize the evaluation result in Table 4 according to the two ways of inheriting lexical attributes. Among 100 NLSs, 90 were identified by the way of inheriting lexical attributes from ancestors within NLS suggesting 76 correct missing IS-A relations (a precision of 84.44%); and 82 were identified by the way of inheriting lexical attributes from all the ancestors suggesting 73 correct missing IS-A relations (a precision of 89.02%).

5 Discussion

This paper presents a structural-lexical approach to audit NCIt based on enriched lexical attributes of concepts in NLSs. The results indicate that most missing IS-A relations can be commonly obtained by considering ancestors within the NLSs and all the ancestors to enrich the lexical attributes. The former way identified more potential missing IS-A relations than the latter did, while the latter achieved a better precision than the former did.

5.1 Analysis of Failure Cases

The primary focus of this work was to identify missing hierarchical relations in NCIt. Upon observation of the false positives, it could be noted that a majority of them (53%) occur due to the existing erroneous hierarchical relations in NCIt. For example, in Figure 5, Giant Cell Carcinoma is categorized as a subtype of Large Cell Carcinoma. However, under the current (2015) WHO classification, Giant Cell Carcinomas are classified as a separate category of tumor. Therefore, Giant Cell Carcinoma should not be a subtype of Large Cell Carcinoma. Likewise in a separate case, our approach inaccurately identified “C39951: Testicular Fibroma” IS-A “C4092: Benign Epithelial Neoplasm” as a missing relation. However, it could be seen that this was obtained due to the erroneous existing relation “C39951: Testicular Fibroma” IS-A “C3709: Epithelial Neoplasm”, since a Testicular Fibroma does not arise from Testicular
Table 2: Fifteen examples of valid missing hierarchical relations obtained by our approach.

Epithelium, but from the Stroma.

Next we give an example of the false positive cases which are not due to the existing erroneous hierarchical relations in NCIt. Our method suggests “C115093: Recurrent Oropharyngeal Undifferentiated Carcinoma” as a subtype of “C9268: Recurrent Malignant Nasopharyngeal Neoplasm” since it inherits lexical attribute “malignant”
from an ancestor “C150531: Recurrent Malignant Pharyngeal Neoplasm” and inherits lexical attribute “nasopharyngeal” from another ancestor “C4107: Nasopharyngeal Type Undifferentiated Carcinoma”. However, “C4107: Nasopharyngeal Type Undifferentiated Carcinoma” indicates that it looks like nasopharyngeal carcinoma under the microscope, but is not a nasopharyngeal carcinoma. Oropharyngeal carcinoma and nasopharyngeal carcinoma behave differently biologically, with nasopharyngeal carcinoma having a worse prognosis, and they are caused by different types of virus (HPV in oropharyngeal carcinoma, and EBV in nasopharyngeal carcinoma). Therefore, our suggestion is incorrect since our approach is incapable of capturing the subtle difference between “nasopharyngeal” and “nasopharyngeal type”.

5.2 Comparison with Previous Work

In our previous work\(^4\), we used six lexical patterns in NLSs to identify missing hierarchical relations in NCIt. One of the patterns was “Containment”, where we suggested hierarchical relations if the set of words of a concept is a subset of another. The “Containment” pattern was restricted to lower and upper bounds of the NLS while this work we have no such restriction. Also, we only considered the lexical attributes of the preferred term, while in this work we also enrich it with the lexical attributes of the ancestor terms. Furthermore, we perform three filtering steps to avoid obtaining incorrect suggestions.

The structural-lexical approach based on enriched lexical attributes was first introduced by Cui et al.\(^5\) to audit SNOMED CT. While our approach is similar to theirs, we perform a number of additional steps to improve performance and coverage. We do not skip considering an entire NLS if it contains stop words or antonym pairs as was done previously\(^5\). Rather, we perform a much fine-grained filtering by considering stop words and antonym pairs at the concept level, not the NLS level. Additionally, we also address an issue mentioned in Cui et al.’s work regarding incorrect suggestions when the set of words of a concept is a subset of another concept’s set of words. More importantly, in this work we introduce another way to enrich the lexical attributes of a concept: by considering all its ancestors (not only the ancestors within the NLS). This way was actually found to have a higher precision. Moreover, we do not put any restriction on the sizes of NLSs for evaluation in this work, while the evaluation was limited to small (size 4, 5, and 6) NLSs in the previous work.

5.3 Limitations and Future Work

While achieving a higher precision in suggesting missing hierarchical relations, our approach only covers a small portion of NLSs in NCIt (547 out of 9,512). New lexical patterns need to be identified to suggest remediations for the remaining unsolved NLSs. In this work, we enriched the lexical attributes of a concept by its ancestor lexical attributes. We expect to investigate into other methods that can be used for enriching, such as synonyms, definitions and other attribute relations. Another limitation of this work is that only one domain expert was involved in the evaluation. We plan to perform future evaluations by multiple domain experts to increase the robustness of the evaluation. In addition, although some of the failure suggestions of missing IS-A relations further revealed incorrect existing relations, it depended on the domain expert’s manual review. It would be desirable to develop automated methods to detect incorrect existing relations.

6 Conclusion

In this paper, we applied a structural-lexical auditing approach based on enriched lexical attributes of concepts in non-lattice subgraphs to suggest potential missing hierarchical relations in the National Cancer Institute thesaurus. This approach achieved a precision of 84.44% by inheriting lexical attributes from ancestors with NLSs, and a precision of 89.02% by inheriting lexical attributes from all the ancestors in the entire terminology, indicating the effectiveness of our approach. This approach could be generally applied to any biomedical terminology for quality assurance purposes.

Predicting Adverse Drug-Drug Interactions with Neural Embedding of Semantic Predications

Abstract
The identification of drug-drug interactions (DDIs) is important for patient safety; yet, compared to other pharmacovigilance work, a limited amount of research has been conducted in this space. Recent work has successfully applied a method of deriving distributed representations from structured biomedical knowledge, known as Embedding of Semantic Predications (ESP), to the problem of predicting individual drug side effects. In the current paper we extend this work by applying ESP to the problem of predicting polypharmacy side effects for particular drug combinations, building on a recent reconceptualization of this problem as a network of drug nodes connected by side effect edges. We evaluate ESP embeddings derived from the resulting graph on a side-effect prediction task against a previously reported graph convolutional neural network approach, using the same data and evaluation methods. We demonstrate that ESP models perform better, while being faster to train, more re-usable, and significantly simpler.

Introduction
Drug-drug interactions (DDIs) are an important challenge to patient safety. Patients are commonly prescribed multiple drugs at a time, a phenomenon known as polypharmacy. The incidence of polypharmacy has been increasing1, and is generally very high in some patient groups, such as the elderly – the CDC reported that between 2011 and 2014, 66.8% of those 65 years and older take three or more prescription medications2. While multiple drugs can enhance each other’s efficacy and may be given in combination intentionally, many drug combinations can have unintended and harmful physiological consequences1. For example, if two medications affect the same biological pathway, they might compete for a substrate and the effect of one or both might be decreased or altered, side effects might be exacerbated, or new side effects might result from the drug interaction.

Identifying and accounting for polypharmacy effects is difficult1,3. While new drugs are tested for side effects during clinical trials, it is not feasible to investigate every possible combination of the new drug with all drugs currently on the market, let alone all investigational agents. As clinical trials do not exhaustively capture even the side effects of individual drugs, pharmacovigilance systems have been put in place for post-market surveillance to monitor for, and support regulatory action against, harmful drug effects. One such system is the Food and Drug Administration’s Adverse Event Reporting System (FAERS)4. Physicians, pharmacists, and others submit Adverse Drug Event (ADE) reports, which can then be analyzed for patterns of reporting, including identification of putative polypharmacy effects5. It is challenging to analyze these reports manually, so a range of data mining methods have been developed to detect drug/ADE associations6. Of importance for the current work, Tatonetti et al. developed a comprehensive database of DDI side effects, called TWOSIDES, using a data mining approach leveraging adverse event reports7.

Because of the combinatorial explosion of possible drug pairings to investigate, the development of computational methods to predict new polypharmacy side effects is a key task in pharmacovigilance. Several approaches to predicting drug-drug interactions have been described. Some approaches harness the idea that similar drugs will take part in similar drug interactions7. For this purpose, modeling of chemical and structural similarities has been explored7,8. Other approaches employ unstructured text, such as the Medline biomedical literature corpus, to extract interaction information with text mining techniques9. A third group of approaches to the DDI prediction problem uses binary classification techniques in order to classify a given drug pair as interacting or not interacting. A promising way to do this is to consider DDI prediction a link prediction problem, where drugs are nodes and side effects are the links between them6,10. However, predicting not only the presence of adverse effects of DDIs, but also the nature of such side effects, has not been extensively explored. For a detailed account of previously reported DDI prediction methods, the interested reader is referred to a recent comprehensive review by Vilar, Friedman and Hripcsak11.

The current work is inspired by Zitnik et al.’s graph convolutional network approach called Decagon11. Decagon makes use of the conceptualization of drug interactions as a graph, where drugs are nodes and side effects are edges, with different side effects being represented by edges of different types. Identifying polypharmacy side effects then becomes a multi-relational link prediction task. Graph embeddings are learned for drugs (nodes) as well as side effects.
(edges), and then used to predict which types of links are likely to exist between pairs of drugs. It is important to note that not only the presence of an interaction is predicted, but also the nature of this interaction, a distinguishing feature from other approaches such as Fokoue et al.’s link prediction model\(^\text{10}\). In fact, Decagon is reportedly the first approach to modeling different polypharmacy side effect types\(^\text{11}\). Decagon is trained on data from TWOSIDES, as well as various information sources for drug target and protein-protein interaction data, and achieves high performance as measured by area under the receiver operating curve (AUROC) and area under the precision-recall curve (AUPR) for the task of predicting side-effects given a drug pair. On this task, Decagon outperforms several baseline multi-relational link prediction approaches by at least 0.1 in mean AUROC across ADEs; RESCAL\(^\text{12}\), a multi-relational tensor factorization approach involving the decomposition of a matrix encoding drug-drug relationships into components representing drugs and side effects, achieves a mean AUROC of 0.693; and DeepWalk\(^\text{13}\), a procedure which produces neural embeddings based on a biased random walk through the node neighborhood within the network and then uses these embeddings as a basis for logistic regression, achieves a mean AUROC of 0.761. Additionally, Decagon is used to predict novel DDIs, a number of which were supported by the literature. However, this approach also has limitations. First, node embeddings are learned with a graph convolutional network\(^\text{14}\) approach in which d-dimensional node embedding vectors are linked by d-dimensional edge matrices. The computational demands of training such graph convolutional networks is high, limiting applicability to larger datasets – a problem that will not be eliminated by increasing compute power, as data set size increases at a similar rate\(^\text{15}\). Second, while the process produces vector embeddings for drugs (nodes), side-effect (edge) embeddings are represented by matrices and are thus challenging to re-use as they exist in a space of different dimensionality to the resulting drug vector space. Third, a simpler model might have advantages over Decagon because of its parsimony: if a smaller number of parameters is sufficient to model the underlying data, models with fewer parameters may avoid overfitting, and generalize better.

In the current work we propose an alternative approach to DDI prediction which builds upon Zitnik et al.’s graph conceptualization of the DDI prediction problem, but uses Embedding of Semantic Predications (ESP)\(^\text{16}\), which can address each of these challenges, for representation learning. ESP is a method for generating vector embeddings for biomedical concepts, such as drugs and side effects, from concept-relationship-concept triples called predications, using a neural network. ESP makes use of vector symbolic architectures, in which the composition (binding) and addition (superposition) operators are used to create transient embeddings for composite concepts (such as INHIBITS cytochrome p-450) from their component vectors. During training, embeddings are updated such that vectors for concepts occurring in predications with similar predicate-argument pairs become more similar (closer in vector space) to each other. Conversely, vectors for dissimilar concepts approach orthogonality in the vector space. The high dimensionality of vectors in ESP (e.g. 10,000 bits in binary vector implementations) makes it unlikely for vectors to be similar to each other by chance alone\(^\text{17}\) – an n-dimensional vector space contains \(2^n\) nearly orthogonal vectors\(^\text{18}\). Vectors are randomly initialized before the encoding process begins. For each positive triple in the training set, updates are made to the weight vectors representing the subject (S(s)), predicate (P(p)), and object (C(o)) as follows:

\[
S(s) + = P(P) \odot C(o) \times \alpha \times (1 - NNHD(S(s), P(P) \odot C(o)))
\]

\[
C(o) + = S(s) \odot P(P) \times \alpha \times (1 - NNHD(S(s) \odot P(P), C(o)))
\]

\[
P(P) + = S(s) \odot C(o) \times \alpha \times (1 - NNHD(S(s) \odot C(o), P(P))
\]

Note that, while ESP learns only one embedding for relationships (the \textit{predicate vector} P), two embeddings are learned for each concept: the \textit{semantic vector} (S) and the \textit{context vector} (C). \(\odot\) is the binding operator, \(\odot\) is the release operator (inverse of binding), and + is the superposition operator. The implementation of these operators depends on the vector symbolic architecture approach used. Here we use the Binary Spatter Code\(^\text{16,17}\), in which binding is the elementwise XOR. Because XOR is its own inverse, the release and binding operators are equivalent in this implementation. The superposition operator, which allows multiple vectors to be “added” together, retains the elementwise most common element (1 or 0) across the superposed vectors, with ties broken at random. The update steps are also modulated by a linearly decreasing learning rate (\(\alpha\)) and the similarity between the desired and current vectors, measured as the non-negative normalized Hamming Distance (NNHD)\(^\text{16}\). Analogous update steps are completed for negative samples, which are created by substituting random objects for the objects in positive triples (using -NNHD rather than 1-NNHD). The optimization objective, which is achieved through stochastic gradient descent, is the cross-entropy function defined as follows:

\[
\sum_{(s,P,o) \in D} \log \left( \text{NNHD}(S(s), P(P) \odot C(o)) \right) + \sum_{(s,P,\neg o) \in D^r} \log \left( 1 - \text{NNHD}(S(s), P(P) \odot C(\neg o)) \right)
\]
where \((s, P, ¬o)\) is a training triple and \((s, P, o)\) is a training triple with corrupted object (a negative example). In words, the optimization objective is to create representations of concepts that minimize the distance between subjects and representations of their corresponding predicate-object pairs, while maximizing the distance between subjects and representations of predicate-object pairs that they do not correspond to. An illustration of the ESP architecture used to learn the embeddings is shown in Figure 1.

**Figure 1.** Illustration of the ESP architecture used to generate 5-dimensional embeddings for a 10-concept vocabulary. Adapted from Cohen et al. 

This network trains matrices of weights consisting of the vector embeddings for each drug, activated separately during training using one-hot vector representations. For example, when encoding warfarin-BLEEDING-aspirin, the input and output vectors are one-hot vectors, with a 1 in the warfarin position and a 1 in the aspirin position, respectively. When multiplying the vector by the weight matrix, all columns are set to 0, except the ones pertaining to these particular drugs. Consequently, only the weight matrix components for the concepts and predicate of a triple are involved in the update step that encodes it. This update proceeds toward the optimization objective shown above. The weight matrices are updated so as to move \(S(\text{warfarin})\) closer to \(P(\text{bleeding}) \otimes C(\text{aspirin})\); \(C(\text{aspirin})\) closer to \(S(\text{warfarin}) \hat{} P(\text{bleeding})\); and \(P(\text{bleeding})\) closer to \(S(\text{warfarin}) \otimes C(\text{aspirin})\). We refer the interested reader to Cohen et al. for a detailed exposition of the algorithm and evaluations across a range of pairwise entity-level tasks.

Because similar representations will be learned for similar concepts, we can query the resulting vector space for concepts related to (similar to) a given concept (or concept composition). In our approach, we generate representations for drugs and side effects based on drug/side-effect/drug triples, resulting in input weights which serve as semantic vectors and output weights which serve as context vectors for drugs, and predicate vectors for side effects. In the generated vector space, the bound product of the semantic and context vectors for two drugs should then be similar to the predicate vectors of the polypharmacy side effects that might be observed when the two drugs are taken in combination. A query of interest might thus be: “What polypharmacy side effects might be expected when taking warfarin and aspirin together?” The response is the predicate vector most similar to the bound product of \(S(\text{warfarin})\) and \(C(\text{aspirin})\) over all possible side effects, minimizing \(\text{NNHD}(P(\text{side effect}), S(\text{warfarin}) \otimes C(\text{aspirin}))\).

ESP has previously been used successfully in predicting side effects for individual drugs. Most recently, Mower et al. utilized concept-relationship-concept triples from SemMedDB, a knowledge base extracted from the MEDLINE corpus of medical literature using SemRep, to construct an ESP model which provided input to a supervised machine learning model trained to predict which side effects might be seen for which drugs, achieving strong results with an area under the receiver operating curve (AUROC) of 0.96 and 0.95 across two different test sets. The success of ESP...
for predicting individual drug side effects raises the question of whether the approach might be used to predict DDIs as well. In this paper, we explore the hypothesis that ESP has utility for the polypharmacy side effect prediction task.

**Methods**

When selecting data for pharmacovigilance research, balancing level of curation with representation of emergent signals (such as those that might be found in ADE reports) is challenging\(^1\). As a result, prior evaluations of pharmacovigilance approaches have used a range of diverging data sets for training and evaluation. Because of the large variety of available data and their particular biases and limitations, it can be difficult to directly compare the performance of pharmacovigilance models\(^1\). To minimize this problem, we elected to use the same dataset used for evaluation of a recently published approach to identifying specific drug-drug adverse effects, to facilitate direct comparison of our results. Commendably, Zitnik et al. published both the data sets used in their approach and their code. As a result, we were able to use the same data as well as the same train/test splits, as produced by the publicly available code. The data were downloaded from Stanford’s SNAP website\(^2\) and the code was downloaded from Marinka Zitnik’s GitHub page\(^3\). We performed the additional preprocessing steps described by Zitnik et al., taking care to follow their methods as closely as possible. This included discarding any triples for side effects that occurred in fewer than 500 drug interaction triples, reducing the total number of side effects in the dataset from 1317 to 963.

After modifying the Decagon code to output the testing set as well as the data subset used for training, we allowed Decagon to complete several epochs of training. However, in our own execution of the protocol, we were not able to run Decagon for up to 100 epochs as described by Zitnik et al. (with documented early stopping) within a reasonable time frame, possibly due to differences between our groups’ computational resources. With a single NVIDIA Tesla p40 GPU we observed training times of roughly 36 hours per epoch, with a one-time up-front setup and initialization time of about 6 hours. Consequently, we obtained predictions over the testing set after allowing Decagon to train for 12 epochs only. We present both these results and the previously-published Decagon results showing best-documented performance, enabling fair comparison within constraints of our timeframe and computational resources.

The downloaded data set consists of 9,643,506 triples, of which 7,323,790 are drug-drug interaction triples, 2,289,960 are protein-protein interaction pairs, and 29,756 are drug target pairs (linking drugs to proteins). While the downloaded data set also contained individual drug side effects, these data are not used in the published code and were consequently left out for the purposes of the current research as well. The training data consist of 80% of the total data, with the remaining 20% being equally divided between the validation and test sets. In Decagon, the validation set is used to determine the early stopping point by computing the cross-entropy validation loss over the validation triples after each epoch; training is stopped early if validation loss does not improve for 2 consecutive epochs. Testing is performed exclusively over the testing set triples. It is of note that in the original Decagon work, the authors doubled the size of the dataset in the downloadable data files by also including all training triples in their inverted form, treating the “reverse” side effect edge types as separate edge types, resulting in a total of 963*2=1926 side effects (drug-drug edge types). Later, for purposes of analysis, we examine AUCs per side effect, only considering the original 963 side effects.

From these data, we created subject-predicate-object triples (predications) as input for ESP training (Table 1).

An ESP model was trained using the open-source Semantic Vectors package\(^{15,24,25}\) pre-release version 5.9 with vector dimensionality of 16,000 bits. Unlike previous releases, this version allows predicate vectors to be trained (in addition to semantic and context vectors). This capability is essential for our approach to DDI prediction, as we generate trained embeddings for side effects (represented as predicates), as well as drugs.

We converted the testing data set to a list of similarity comparisons to be made. For each triple in the test set, we bind the semantic vector for the first drug with the context vector for the second drug and compare the similarity of the resulting compositional vector with the predicate vector for the side effect:

\[
NNHD(P(\text{side effect}), S(\text{drug 1}) \otimes C(\text{drug 2}))
\]
The result is a similarity score between 0 and 1. Identical vectors score 1 and orthogonal vectors 0. It is important to note here that the publicly available Decagon data sets, like most drug-drug interaction data sets, only contain positive examples, i.e. data points with a ground truth label of 1. ESP originates from methods that learn representations of words from free text, where the same problem exists; ESP therefore automatically performs negative sampling in the training process to account for this. However, during testing of ESP, we must test using generated negative examples. The published Decagon code generates negative examples by choosing 2 random drugs and connecting them with a random side effect, making sure that the resulting triple (edge) is not observed in the original, positive data. Additionally, for each side effect, we generate the same number of negative examples as we have positive examples. The negative testing examples produced by the Decagon code were used for evaluating the ESP model.

Evaluation was performed with Anaconda® version 4.6.8 and Python version 3.6.8 using the scikit-learn package version 0.19.1. As in the original Decagon protocol, AUROC and AUPRC were calculated on a per side effect basis. Precision at $k$ was also calculated, with $k=50$, and all three metrics were averaged across all side-effects.

While 16,000-bit vectors have been shown to perform well on a range of prior ESP evaluations, training time and model parsimony might be improved by using lower dimensional vectors. In order to determine the minimal space requirements of a model with acceptable accuracy, we analyzed several lower embedding dimensionalities. Due to the distributed nature of the vector representations (information is spread as a pattern across the entire vector), it is possible to test the loss in accuracy for smaller dimensional vectors without re-training, but rather by truncating the trained vectors. We thus truncated the trained 16,000-dimensional representations to 8000, 4032, 2048, 1024, 512, 256, 128, and 64 bits and computed performance metrics for each of the resulting vector spaces.

Querying the vector space for familiar concepts presents an opportunity to qualitatively evaluate whether the learned representations are meaningful. Using the Semantic Vectors open source software, the vector space was queried using various drugs, side effects, and compositional concepts to assess whether the space is intuitively interpretable.

Finally, we investigated the proximity of related side effects to each other using a visualization of the side effect vectors, created using Uniform Manifold Approximation and Projection (umap-learn package14,27, version 0.3.7), which projects multi-dimensional representations into two dimensions. Individual side effects were colored according to their class as listed in the downloaded Decagon datasets. Many side effects did not belong to any category, and some categories had few or no side effects in them. Of the remaining categories, we visualized the 6 most frequently occurring side effect classes.

Code and data for all preprocessing, training, and evaluation steps are available on Github28,29.

**Results**

The performance metrics for ESP and Decagon, averaged over 963 side effects, are shown in Table 2. The mean AUROC for the 8-epoch ESP model was 0.903 (range 0.841-0.977); the mean AUPRC was 0.875 (range 0.779-0.976); and the mean AP@50 was 0.865 (range 0.550-1.0). These results exceed both the published Decagon results (in Table 2) and those of our locally-trained Decagon model after 8 epochs: mean AUROC of 0.855 (range 0.259-0.949); a mean AUPRC of 0.793 (range 0.366-0.934); and a mean AP@50 of 0.638 (range 0.066-0.950).

Table 2. Performance metrics for ESP and Decagon.

Our 4-epoch ESP model took roughly 3.5 hours to train with 16,000 dimensions (bits), including setup time and time spent making predictions over the test set. Each epoch took an average of 50 min. 4 epochs of training Decagon were completed in 6 days and 4 hours including setup and test set prediction, with an average of 36 hours per epoch.

The mean area under the receiver operating characteristic curve over 963 side effects for different vector dimensionalities, created by truncating the 16,000-dimensional vectors, are shown in Figure 2.
Example queries of the trained vector space are shown in Table 3. The search returns the vectors that most similar to the query term, along with a similarity score.

Discussion

ESP outperforms Decagon (both best published performance and our locally-trained model) when predicting polypharmacy side effects by all measures. Furthermore, ESP achieves this performance while training a factor of 43.2 times faster per epoch than Decagon, and for 8 epochs only. The best performing Decagon models were run up to 100 epochs (the number of epochs prior to early stopping was unfortunately not documented). We restricted our locally-trained model to a maximum of 8 epochs on account of resource constraints, which explains the modest difference in performance from previously published results. Additionally, we note that ESP produces re-usable embeddings of the same dimensionality drugs and side effects, which can be used to answer various questions using vector symbolic architecture operations. Using this approach, as well as projection visualization using UMAP, we were able to interpret the embeddings produced by the model.
The high performance that ESP was able to achieve is notable. Considering that Decagon substantially outperformed several baseline approaches, the improved performance of ESP over Decagon puts this model among the top in class. The multimodal network representation and modeling of multiple side effects simultaneously, which allows sharing of model parameters across side effects, is an advantage of Decagon over some alternative polypharmacy side effect prediction models that is shared by ESP, and may be in part responsible for improved performance as the model can learn to generalize across similar concepts (such as ‘kidney failure’ and ‘acute kidney failure’, shown in Table 1).

While training time may not be the most significant factor in determining which models are superior when abundant computational resources are available, a faster model is preferable if degradation of accuracy is not a tradeoff that has to be made. Less extensive hardware requirements enable academic researchers with relatively modest computational resources to reproduce and build upon extant research, thus enabling scientific progress through improved equity. But even for those research groups with high-end computing clusters and multiple GPUs at their disposal, it should be considered that training complex neural network models can incur significant energy costs, with carbon footprints equivalent to as much as five times that of an average car, including manufacture\(^{30}\). In comparison, ESP can be trained on commodity laptops or servers. Financial and environmental costs aside, one may argue that resource intensive computations will become progressively easier as processing power increases in accordance with Moore’s law (at least for some time\(^{11}\)); however, this is a difficult case to make in informatics, where much work is based on data sources that increase in size at an incredible pace themselves\(^{14}\). As we harness biomedical literature, electronic health record data, social media sources, and adverse event reports, we also observe their sustained and sometimes explosive (e.g. EHR and patient reported data) growth. Currently, DDI prediction models should be retrained whenever new adverse event report data become available (e.g. weekly or monthly). With the advent of large volumes of patient-level data, DDI prediction models have the potential to be personalized to individual patients’ demographics, health status, and genetic makeup, requiring scores of different models to be trained and re-trained, further increasing training costs. ESP conforms to previously formulated recommendations to prioritize development of efficient models\(^{30}\) and can help promote research equity by allowing the use of commodity hardware.

The ability to learn representations that correlate with human judgment of similarity between concepts is an advantage of ESP\(^{16}\). In this work, we were able to demonstrate that embeddings learned for related side effects, such as kidney failure and acute kidney failure, are similar (Table 3). However, other types of organ failure are also retrieved by this search. A possible explanation is that patients with multi-organ failure appear in FAERS, and so different sorts of organ failure may become associated with one another. If these organ failures are attached to reports containing the same drug pairs (e.g. drugs used in sepsis), a statistical model will find associations between these drugs and every sort of organ failure. The similarity-based search for side effects using the bound product S(aspirin)⊗C(warfarin) yielded, among others, alveolitis, parotitis, and hemarthrosis. Development of lung disease has previously been reported to be associated with aspirin treatment\(^{32}\); additionally, warfarin has been characterized as a drug causing salivary gland swelling and pain\(^{31}\). Aspirin’s and warfarin’s possible roles, respectively, in exacerbating these adverse events has yet to be established. We also found similarity of S(aspirin)⊗C(warfarin) with hemorrhosis, a bleeding disorder, which is reasonable, considering that warfarin and aspirin are both anticoagulants. We note that similarity search results may refer to indications rather than side effects. Even though Tatonetti et al.\(^{5}\) applied corrections for confounding when creating the TWOSIDES set, with the goal that indications would not appear as side effects, it appears that this effect may not have been entirely eliminated, resulting in our model learning from indication-related statistical patterns remaining in this dataset.

Not all side effect representations for a given side effect category clustered together well in our projection visualization. For example, side effects in the reproductive system, cognitive disorder, and hematopoietic system effect classes are well separated from each other, but nervous system side effects are found throughout the vector space. We suspect that one contributing factor for this is the limited number of types of data in the training set. The only information that ESP has an opportunity to encode into the concept embeddings are polypharmacy side effects and drug target information. As discussed above, side effects appear to cluster because they are actually indications common to particular drug combinations – an additional complicating factor. This was also discussed by Zitnik et al., who reported that many side effects tend to co-occur in this particular data set\(^{11}\). As a result, co-location of embeddings in space is not as interpretable as it might be for richer data sets, with more concept and relation types, which might contribute to more meaningful similarities between the various side effects being learned. Previous applications of ESP have involved rich data sets with multiple relationship types and a number of different types of concepts, which resulted in more readily interpretable similarities.

The parsimony of the ESP model is a desirable feature. While Decagon utilizes approximately 87 million trainable parameters, which are each 32-bit floating point numbers – a total of approximately 2.8 billion bits of training
parameters – using 16,000-dimensional vectors, ESP performs better with only about 36 million single bit parameters, which is over 77 times fewer bits of representational capacity. In fact, even with 1,024 dimensions, ESP approximates Decagon performance, and this dimensionality corresponds to only 2 million trainable bits of representational power – over three orders of magnitude less than Decagon. At 64 bits per embedding – a mere 144,000 bits of trainable parameters – ESP achieves performance that is still higher than the baseline approaches documented by Zitnik et al. This suggests that the vast representational capacity of a trained Decagon model is unnecessary for the task of predicting DDIs that appear in TWOSIDES. More stringent evaluations may be required to reveal any advantages in performance that its larger capacity and more computationally demanding training procedure may confer.

This work has several limitations. Firstly, it is important to note that the data used for training may poorly approximate ground truth. TWOSIDES is a database of information mined from text sources. While a small number of novel drug interactions reported in TWOSIDES have been corroborated through investigation of relevant patient records as well as laboratory experiments, the database contains many unvalidated associations, including some unintuitive side effects that may not withstand curation, such as ‘Mumps’ or ‘Fracture’. These side effects do give us an idea of what the drug interactions may be; for instance, if mumps is increasingly observed in patients taking a certain combination of drugs, it may be plausible to infer the polypharmacy side effect to be a weakening of the immune system. Similarly, if fractures have increased prevalence in the patient population taking particular drugs in combination, we may consider the idea that the interaction of the drugs causes decreased bone density. Yet, using a curated reference set of drug interaction data is preferable over using data obtained through data mining. As discussed above, making models directly comparable is a challenge, which is why we chose to use the same datasets as a comparable previous approach.

Another limitation of this approach is that directionality of relationships between concepts is not encoded. DDIs may be considered symmetric relationships between drugs, as drug A interacting with drug B would also mean that drug B interacts with drug A. Here, we reverse and append all DDI triples in the dataset during preprocessing, creating a separate side effect type representing the “reverse relationship”, as Zitnik et al. did. In other words, for each edge (with a side effect specific edge type) pointing from drug A to drug B, we also add an edge from drug B to drug A, which has a separate, new edge type. While the additional triples (edges) benefit the training of drug embeddings, the predicate embeddings to which they contribute (redundant side effect representations) are not used when making predictions. Conversely, the inverse relationship, despite being known to be true, is not encoded in the retained side effect embedding. Similarly, drug target triples are reversed and appended to the dataset with a new edge type. In the drug target case, this matches the directionality of the relationship: if drug A targets protein B, we cannot also say that protein B targets drug A. Directionality would be obscured if we reversed and appended the drug target triples with the same edge type. Finally, protein-protein interaction (PPI) triples, which are inherently symmetric, are treated differently. Decagon quadruples all PPI triples, first by reversing the order and then by creating an alternative relationship, such that the nodes for protein A and protein B are connected by a total of 4 edges: 2 “interacts_with” edges, one pointing from A to B and one from B to A, and 2 “reverse_interacts_with” edges, one pointing from A to B and one pointing from B to A. While ESP can encode directionality directly, we did not explore this here and instead chose to follow the same input data preprocessing protocol as Zitnik et al. in order to facilitate direct comparability.

In this research, we have followed the training and evaluation protocol reported by an earlier study as closely as possible for the purpose of comparative evaluation, leveraging both written descriptions of the protocol and publicly available data and software. However, during this process, we found some details in the reported protocol ambiguous, and found apparent inconsistencies between the approach described in the paper and the code it refers to. For instance, the number of side effects and proteins reported by Zitnik et al. does not exactly match the number we found in the data ourselves (963 side effects with 500 or more drug pairs, compared to the reported 964; 19081 unique drug targets compared to the reported 19085). Also, neither cross validation nor early stopping are implemented in the publicly released code, though both methods were reported in the paper. The 10% of data reserved as validation set consequently went completely unused in the published code. As a result of the computational demands of training Decagon, a test of statistical significance, which would require Decagon and ESP to each be trained repeatedly, was not performed. Additionally, we found that all data were split into training and test sets, including protein-protein interaction and drug-target data, even though we are not concerned with making predictions for these data subsets. This equates to discarding a portion of the protein-protein and drug-target data without good reason, other than allowing a simple 80/10/10 split across all types of triples. While these discrepancies were reconciled by our group to our best effort, subtle differences in our evaluation pipelines may not have been totally eliminated.

This project has established a foundation for future work. Having demonstrated the accuracy of ESP as compared to previously reported models while keeping the input data constant, we plan on applying the technique to datasets that are (at least partially) curated rather than statistically derived, e.g. the interaction designations in FAERS reports or
the reference set published by Ayvaz et al.\textsuperscript{35}. While accuracy measures such as AUROC and AUPRC may not be affected by this change, the resulting model would presumably have more validity when applied to real data.

Incorporating additional knowledge may also present an opportunity to improve this modeling approach. ESP is a method for encoding a knowledge graph; thus, we can generate embeddings for any number of concepts and relationships based on their connections to each other. Many sources of knowledge regarding drugs and their interactions may be relevant. For example, drug classifications, molecular structure information, and additional information about drug target molecules may allow us to train more comprehensive embeddings which could even be applied to new drugs prior to the appearance of any adverse drug event reports. On the patient level, ESP models for predicting DDIs may help make strides in precision medicine, e.g. by incorporating patients’ individual genetic profiles in the model. Training patient specific models would be made feasible in part due to ESP’s efficiency in both training time and model complexity, each being only about 1-2% of what previously reported models require.

Conclusion

Many individuals are at risk of experiencing adverse events caused by drug-drug interactions. Because DDIs are poorly characterized before drugs are released to market, efficient and accurate analysis of post-market surveillance data is critical to patient safety. ESP, a representation learning method with demonstrated utility in the pharmacovigilance space, provides an alternative approach to DDI prediction. In this work, we have shown that application of ESP to adverse drug event data can yield accurate predictions of polypharmacy side effects, with performance exceeding that of the best reported machine learning models on this task. Being considerably more lightweight in terms of required compute power and model complexity than previously published approaches, ESP can be expected to scale up without imposing undue financial and ethical burdens on researchers, particularly as the volume of data, number of models to train, and frequency of re-training increase. Additionally, we have demonstrated that ESP produces meaningful representations of biomedical concepts that can enable biomedical discovery in novel ways, providing insights that pave the way for further development of ESP models for pharmacovigilance and other applications.

Comparison of Prediction Model Performance Updating Protocols: 
Using a Data-Driven Testing Procedure to Guide Updating

Abstract

In evolving clinical environments, the accuracy of prediction models deteriorates over time. Guidance on the design of model updating policies is limited, and there is limited exploration of the impact of different policies on future model performance and across different model types. We implemented a new data-driven updating strategy based on a nonparametric testing procedure and compared this strategy to two baseline approaches in which models are never updated or fully refit annually. The test-based strategy generally recommended intermittent recalibration and delivered more highly calibrated predictions than either of the baseline strategies. The test-based strategy highlighted differences in the updating requirements between logistic regression, L1-regularized logistic regression, random forest, and neural network models, both in terms of the extent and timing of updates. These findings underscore the potential improvements in using a data-driven maintenance approach over “one-size fits all” to sustain more stable and accurate model performance over time.

Introduction

Clinical environments are continuously evolving through changes in patient case mix, outcome prevalence, and clinical practice shift. These changes can cause the performance characteristics of clinical prediction models to deteriorate over time. As prediction models are increasingly incorporated into electronic health records to support decision-making by providers and patients, model updating strategies to sustain performance are becoming critical components of model implementations. Despite literature documenting performance drift and the availability of multiple updating methods, guidance on the design of model maintenance plans is limited and provides little insight into how differences between learning algorithms may impact updating requirements.

While a lack of model updating can harm the performance and utility of predictions, common model maintenance strategies, such as regularly scheduled model refitting, may be inefficient or even detrimental. The assumption that a new model is necessary neglects information gleaned from previous modeling efforts and can lead to overfit models that lack generalizability, especially when updating datasets are smaller than development cohorts. Such pre-defined updating plans also fail to account for variations in the response of different modeling methods to changes in clinical environments, which may impact the extent and form of shifts in model accuracy. Alternatively, a range of recalibration methods are available that may correct deteriorations in performance by incorporating information in recent observations while retaining information in existing models and reducing the risk of overfitting. Recalibration may thus be more appropriate than refitting for models in clinical use when equivalent or improved performance can be achieved by the former.

Recently proposed methods seek to provide data-driven guidance on when to retain the current model, apply recalibration of varying degrees of complexity, or refit a model. We described a nonparametric testing procedure to select between competing updating methods while minimizing overfitting and taking the updating sample size into consideration. As a baseline, the testing methods under consideration are retention of the existing model, intercept correction, linear logistic recalibration, flexible logistic recalibration, and model refitting. The testing procedure is designed to recommend the simplest updating method that does not compromise accuracy that may be achievable through more complex adjustments. In contrast with other tests, our procedure is customizable and widely applicable to models for categorical outcomes regardless of the underlying learning algorithm.

In this study, we explore whether the long-term performance of clinical prediction models is improved through a data-driven approach to model maintenance. We compare three updating strategies—retention of the original model, predefined model refitting, and application of recommendations of the nonparametric testing procedure. These updating strategies are applied to a model for 30-day mortality after hospital admission in a national population of veterans for which calibration drift, and variability in drift by modeling methods, has been documented across multiple years. We
assess differences in discrimination and calibration over time under each updating strategy, as well as whether and how the learning algorithm underlying the model impacts updating requirements and accuracy.

**Methods**

We developed models for 30-day mortality after hospital admission among patients admitted to Department of Veterans Affairs (VA) facilities nationwide using logistic regression (LR), L1-regularized logistic regression (L1), random forests (RF), and neural networks (NN). Model predictors and cohort eligibility criteria have been detailed in previous work. Each model was developed using a common set of predictors and admissions occurring in 2006. Data from 2007-2013 were collected for both updating and validation. Previous work indicated the LR and L1 were most subject to calibration drift in this population while the NN model did not experience significant calibration drift. Updating was undertaken for all models on an annual basis at the end of 2007 through 2012, with updates based on admissions in the prior 12 months and applied to admissions in the following 12 months. Admissions occurring in 2013 served as validation data for updates at the end of 2012.

We implemented three competing strategies to update the LR, L1, RF, and NN models over time in yearly increments. As a baseline, we retained the original models developed on 2006 admissions and applied these models to all subsequent admissions through 2013. The second updating strategy called for annually refitting each model using all admissions that accrued over the prior 12 months. Hyperparameters for the L1, RF, and NN models were tuned annually using 5-fold cross-validation. Admissions in each year were assigned predicted probabilities based on the prior year’s models. The third updating strategy selected the updating approach for each model based on a nonparametric testing procedure that we have developed for this purpose. A simplified illustration of the testing procedure is presented in Figure 1. The procedure selects between the retention of the current model, intercept correction, linear logistic recalibration, flexible logistic recalibration, or model refitting. Users may specify additional updating approaches for consideration as desired. A two-stage bootstrapping framework accounts for both overfitting and sample size, while avoiding assumptions about the structure of the model’s learning algorithm. In the first bootstrapping stage, updated predictions on the out-of-sample observations are stored to construct a population of pooled holdout predictions. These observations are leveraged by the second bootstrapping stage to characterize the performance of each updating approach. Paired differences in a user-specified performance metric, in this case the Brier score, between the best performance updating approach and simpler approaches are evaluated in the decision stage, with the procedure recommending the simplest update exhibiting no statistically significant difference in accuracy. We specified a Type I error rate of 0.05 for these comparisons.

**Figure 1.** Simplified illustration of the nonparametric testing procedure used to select updating methods under the data-driven annual updating strategy. Hexagons indicate processes; canisters indicate datasets.

Updating sequences were retained over multiple years as needed, allowing updates to build on any prior adjustments to the model. For example, a model based initially on Year 0 admissions was applied to Year 1 admissions. At the end of Year 1, the testing procedure recommended either continued use of the existing model, adjustment of the existing model through recalibration, or replacement of the model with a newly refit model. This updated version of the model was used to generate predictions for Year 2. Following Year 2, the testing procedure considered whether any additional updates to the model as adjusted after Year 1 were warranted, not whether to adjust the original Year 0 model. If additional updating was recommended by the test, those changes were applied in addition to the existing Year 1
adjustments. At any point, if the test recommended refitting the model, then all previous models and sequences of adjustments were replaced by a new model moving forward.

We conducted analyses to assess the influence of each updating strategies on the long-term performance of the LR, L1, RF, and NN models, as well as to compare the updating requirements of the different models. Models were assessed for both discrimination (area under the receiver operating curve, AUC) and calibration (calibration curves, observed to expected outcome ratio, Cox intercept and slope, and estimated calibration index)\textsuperscript{15-17}. We evaluated overall performance of the four models under each updating strategy across the entire validation and updating period (2007-2013). We further measured performance over time under each strategy on a monthly basis. In order to identify any differences in updating requirements, we recorded the recommendations of our nonparametric testing procedure for each of the four modeling methods.

This study was approved by the Institutional Review Board and the Research and Development committee of the Tennessee Valley Healthcare System VA.

Results

This study included data on 1,893,284 admissions to VA facilities nationwide. The initial 2006 models were developed on 235,548 admissions. The validation and updating set, consisting of admissions from 2007 through 2013, included 1,657,736 admissions with a mean of 236,819 per year. Fewer admissions were captured in 2013 because December admissions lacked sufficient follow-up time to ascertain the outcome. The overall 30-day mortality rate was 4.9%. This outcome rate was stable over time, with annual mortality varying between 4.7% and 5.0%.

Table 1: Annual updating recommendations for each modeling approach

Test-based recommendations for annual updates of the four models are noted in Table 1. The nonparametric testing procedure recommended model refitting each year for the NN model. The testing procedure recommended flexible logistic recalibration after the first year for the LR and L1 models, as well as linear logistic recalibration for the RF model. For the L1 model, the recalibration adjustments incorporated after the first year were maintained until the 5th year after model development, at which point an additional intercept correction was recommended. The RF model was also updated again after the 3rd year. Continued periodic updating across the study period was recommended for the LR model, with the testing procedure recommending some degree of recalibration every other year.

Performance of the four models under each updating strategy over the entire validation and updating period (2007-2013) is reported in Table 2 and calibration curves are presented in Figure 2. In most cases, discrimination was unchanged by updating, the exception being the NN model for which refitting (and the test-based strategy) increased the AUC from 0.77 to 0.80. Annually refitting the models improved calibration across the study period compared to
the original models (p<0.05). However, for all models, predictions based on test recommendations exhibited improved calibration compared to predictions based on either the original model without updating or the annually refit models (p<0.05)—the only exception being the NN model for the test-based strategy reduced to refitting. Differences in calibration across updating strategies were highlighted by the calibration curves and most apparent when focusing on the lower risk portion of the curves where over 95% of observations occur. For the LR model, the calibration curves under the test-based updating strategy captured more of the ideal 45° calibration line than either the annual refit or original models. For the RF model, none of the updating strategies resulted in calibration across a large range of probabilities and the calibration curves of all three strategies follow similar patterns; however, both the refitting and test-based updating strategies moved the calibration curve closer to the ideal 45° calibration line for the risk range where most observations fell. In the densely populated risk range, although the magnitude of miscalibration of the L1 model was similar between the refitting and test-based updating strategies, the refitting approach erred toward underprediction while the test-based strategy erred toward overprediction.

Figure 3 displays monthly calibration of all four models under each updating strategy using the estimated calibration index (ECI). This stringent measure of calibration decreases toward 0 as calibration improves17,18. Without updating, calibration of the LR, L1, and RF models decayed over time. Both refitting and test-based updates improved calibration compared to the original model over the course of the 7 years following initial model development. The RF model was an exception to this pattern. In some time periods, such as 2009-2010, refitting the RF model each year did not improve performance compared to the original model without updating. Although calibration of the NN model was stable over time compared to the other models, annually refitting the NN model improved calibration and reduced month-to-month variability in performance. With the exception of the NN model, monthly ECIs under the test-based updating strategy were generally lower and less variable compared to ECIs under the refitting strategy. For those points at which the nonparametric testing procedure recommended updating, ECIs over the prior 12 months (i.e., performance among those admissions serving as the update set) did not reveal clear patterns that differentiated these timeframes from those for which the testing procedure did not recommend updating. Nevertheless, calibration improved immediately after these updates.
Figure 2. Overall calibration by modeling approach and annual updating strategy. Left panels display calibration curves across the range of predictions produced by each model; right panels zoom in on calibration curves for predicted probabilities below 30%, which includes over 95% of all observations.
Figure 3. Calibration over time by modeling approach and updating strategy (smaller values are better). Dotted vertical lines highlight points at which the testing procedure recommended recalibration.

Discussion

We evaluated the impact of three competing updating strategies on performance of models for 30-day mortality after hospital admission over 7 years following initial model development. In addition to common strategies of retaining the original model or routinely refitting the model, we included a new data-driven strategy based on a nonparametric testing procedure for selecting among competing updating methods. This testing procedure is applicable regardless of the learning algorithm underlying the model, allowing our study to compare updating requirements of parallel LR, L1, RF, and NN models.

Updating requirements varied across modeling methods, both in terms of the timing and extent of updates. One year after model development, the nonparametric testing procedure recommended updating of all four models. These initial adjustments lead to immediate improvements in calibration in the months following update. Subsequent updating recommendations were varied and less frequent. The adjusted LR model was further recalibrated every other year with additional intercept corrections. The initial recalibration of the L1 model was retained until the intercept was further adjusted for the final two years of the study. The most significant and frequent updating was recommended for the NN model, which exhibited the least calibration drift over time. The testing procedure recommended refitting each year due to quite small improvements in the Brier score (~0.0001) compared to other updating approaches. As the Brier score takes into consideration both discrimination and calibration, the improvement in both dimensions of performance that resulted from refitting the NN model may have driven this recommendation. Refitting of the other models impacted calibration but did not significantly improve discrimination.

Some form of updating was warranted for all models. Retaining the original model over the course of the study period resulted in inferior calibration compared to routine refitting and test-based updating. Calibration measures of the original NN model did not exhibit significant trends indicative of calibration drift over the course of the study. Nevertheless, refitting this model each year, either as planned or as recommended by the testing procedure, still improved overall calibration, reduced month-to-month variability in calibration, and improved discrimination. Test-based updating of the other models improved upon the simple refitting strategy. Refitting corrected performance drift in the LR and L1 models; however, test-based updating recommendations resulted in lower ECIs (i.e., better calibration) and less month-to-month variability in performance compared to refitting. Refitting the RF model
improved overall calibration compared to the original model, but still resulted in variable calibration over shorter periods and did not correct performance drift over time. On the other hand, the test-based strategy avoided performance drift of the RF model and periods of instability observed under the refitting strategy (e.g., 2012) despite no additional updates being recommended.

In some cases, differences in calibration metrics between updating strategies were small and may not be clinically meaningful in practice. Whether these improvements are clinically meaningful in addition to being statistically significant is an important consideration and an open question for model comparison and impact assessment work. Although small in magnitude, the improvements in calibration under the test-based strategy compared to the refitting strategy highlight how recalibration may be sufficient, or even superior, to the standard practice of undertaking more substantial change by refitting. In addition, impact from recalibration is most likely to occur when patients are scored near user-defined cut-points that are clinically relevant, and assessment of clinically meaningful risk category reclassification anchors around what proportion of patients are near the cut-points (and change classification after calibration degredation).

These findings underscore a need for data-driven maintenance plans for clinical prediction models. A “one-size fits all” updating strategy will not suffice for all models. We cannot assume a new model built on recent data will be more generalizable to and perform better in the next cohort of patients than an existing model, even when large datasets, such as those in this study, are used for updating. Although calibration improved over the entire study period by regularly refitting the RF model, the model built on 2008 admissions did not improve upon, and may have actually performed worse, than the original RF model when applied in 2009. Similarly, we should not assume refitting is superior to simpler updating through recalibration. The intermittent recalibrations recommended by the testing procedure lead to better performance across the study period than routine refitting, both overall and on a month-to-month basis. Tailoring updating methods through data-driven updating strategies may therefore extend the accuracy and subsequent utility of prediction models beyond what might be achieved through simpler maintenance plans. We note, however, that these results may be sensitive to the volume of data available for updating, and further investigation regarding the impact of sample size is warranted.

Our results also highlight differences in the frequency with which models require updating. Despite being applied to the same data and therefore exposed to the same shifts in patient case mix and clinical environments, the LR, L1, RF, and NN models required updating at different time points. With the exception of the NN model, updating on an annual basis was not indicated and annual refits did not provide additional benefits over less frequent updates. Thus, we may experience inefficiencies under model maintenance plans requiring updates on pre-planned schedule. On the other hand, prescheduled updating plans may also neglect to update models in a timely manner, allowing periods of performance drift to go unnoticed and uncorrected. The cost of interim periods of reduced model accuracy may be difficult to assess as the prediction errors may impact patient outcomes, user confidence, and clinical efficiency. As health systems seek to implement clinical prediction more broadly and begin managing many prediction models, additional data-driven methods to determine when models require attention may be necessary and would complement maintenance strategies implementing test-based updating methods.

There are several limitations of the analyses presented here. We evaluated the three updating strategies in one clinical use case and population. Exploring how these updating strategies perform on models subject to different patterns of shifts in the clinical environment would provide more generalizable understanding. In this study, we limited the nonparametric testing procedure to consider five updating methods – retention of the existing model, intercept correction, linear logistic recalibration, flexible logistic recalibration, and model refitting. These updating methods are common and applicable across models; however, additional updating methods, some of which may be specific to certain learning algorithms, could easily be incorporated into the testing procedure. The availability of additional updating methods may impact when and how the test-based strategy adjusted the models over time. Further, we did not explore the impact of sample size. The volume of data available for constructing updates could have important impacts on both the model refitting and test-based updating strategies. For small samples, overfitting becomes more of a concern for the refitting strategy, while overly conservative updates may be a concern for the test-based strategy. We also acknowledge that the test-based updating strategy may be computationally intensive. Leveraging advances in computational resources and refining the number of bootstrap iterations considered in the first bootstrapping stage may reduce any computational burden. Tailoring the number of bootstrap iterations may also allow users to match statistical significance to clinically relevant magnitudes of change. Finally, all three of the updating strategies considered here may be inappropriate in the presence of significant changes in clinical practice or record systems that may render existing prediction models invalid. Any updating strategy must be flexible, both in terms of timing and approach, in response to such situations.

1008
Conclusion

We illustrated the use of a new data-driven updating strategy for clinical prediction models based on a variety of underlying modeling methods and compared this strategy to two baseline approaches in which models are either never updated or regularly refit on recent observations. The test-based updating strategy conservatively adjusted most models by recommending intermittent recalibration rather than repeated model refitting. Despite making limited adjustments to the models, the test-based updating strategy lead to more highly calibrated predictions than either of the baseline strategies. The test-based approach also highlighted differences in the updating requirements of common biostatistical and machine learning models, both in terms of the extent and timing of updates. These results have important implications for the implementation of clinical prediction models and the design of model maintenance plans. As the volume, complexity, and variability of prediction models implemented in health systems grows, data-driven updating policies could support model developers and managers as they endeavor to provide more stable and accurate model performance. In this way, data-driven updating strategies, such as the test-based approach presented here, will become key components of automated surveillance procedures that promote the long-term performance and utility of prediction models underlying a variety of informatics applications for decision support and population management.

Mining Drugs and Indications for Suicide-Related Adverse Events

Tiffany Ding and Elizabeth S. Chen, PhD
Center for Biomedical Informatics, Brown University, Providence, RI

Abstract

There has been a significant increase in suicide rates in the United States (U.S.) over the past two decades. Studies have highlighted the need for further exploration of suicide risk factors, particularly combinations of factors. In this study, a pharmacovigilance analysis was conducted to better understand drugs and indications as risk factors for suicide using data from the U.S. Food and Drug Administration (FDA) Adverse Event Reporting System (FAERS) and Adverse Event Open Learning through Universal Standardization (AEOLUS), a standardized version of FAERS. Association rule mining techniques were applied to 85,071 cases involving suicide-related adverse reactions and demographic subsets of these cases. Preliminary results reveal combinations of drugs and indications that may increase the likelihood of suicide, with certain combinations potentially affecting some demographic groups more than others. Further work is needed to validate the initial findings, explore subpopulations, and determine the broader implications for suicide prevention.

Introduction

Suicide is the 10th leading cause of death nationally.1 With suicide rates increasing nearly 30% from 1999 to 2016, there is a growing need for a comprehensive approach to suicide prevention.2 A key component of this approach is identifying risk factors to better understand and prevent suicidal thoughts and behaviors.3 One realm in which there is still much to be learned is which combinations of drugs or indications lead to an adverse drug reaction (ADR) of suicide and how these combinations may differ across various demographic groups.

With incidence rates of serious ADRs reaching 6.5%, ADRs have been identified as an important area of study.4 The FDA Adverse Event Reporting System (FAERS), a database containing post-marketing reactions for drugs in the United States, has facilitated the study of ADRs.5,6 There is much that can be discovered by mining this database for correlations between specific drugs and suicide-related outcomes. Previous studies using FAERS to investigate drugs and suicide have looked at the relationship between isotretinoin usage and depression and suicide, finasteride usage and suicidal behaviors, and suicidal ideation and suicidal behavior as ADRs for antidepressant drugs.7,9

One challenge in using FAERS is the existence of duplicate cases and misspellings, which makes it necessary to perform extensive data cleaning.10 In 2015, Banda et al. addressed this issue by creating a publicly available version of FAERS that removes duplicate reports, maps events to standardized concept identifiers (drug names to RxNorm concepts and outcomes to SNOMED-CT concepts), and precomputes summary statistics.11 This database, called the Adverse Event Open Learning through Universal Standardization (AEOLUS), was created using FAERS data from January 2004 to June 2015. A limitation of AEOLUS is that it does not preserve the demographic data present in FAERS, so it is necessary to use FAERS as a supplementary resource to retrieve patients’ demographic information.

Through basic analysis of adverse event databases, individual drugs that lead to a specific reaction can be discovered. To discover combinations of drugs that lead to a specific reaction, data mining techniques such as association rule mining (ARM), which generates association rules between items in a database, can be applied.12 An efficient method to find association rules in a database is via the Apriori algorithm.13 Applying ARM to adverse event reporting data can help uncover hidden drug-drug interactions that have serious effects on patients. Previous studies show that applying ARM to FAERS or other spontaneous reporting systems is a promising avenue for knowledge discovery.14 Yildirim applied ARM to FAERS to discover rules associating demographic information with adverse events for cases involving ciprofloxacin.15 Harpaz et al. performed ARM on FAERS data from 2008 to find multi-item associations between drugs and ADRs.16 Guo et al. used ARM to investigate the ADRs of two specific drugs, gadoversetamide and rofecoxib.17

The objective of this study is to apply ARM to cases in FAERS that have a suicide-related ADR in order to determine what combinations of drugs and indications are associated with suicide-related ADRs. Identifying these common combinations could provide guidance for further investigations of the effect of such combinations on suicide risk. Additionally, this preliminary study investigates how these association rules differ between male and female patients as well as across patients in different age groups, which can potentially contribute to informing personalized risk assessment.
Methods

Figure 1 depicts an overview of the study approach, which is based on the Knowledge Discovery in Databases process. The four major steps involved are: (1) Data selection to identify cases with a suicide-related reaction, (2) Data processing and subsetting to split the dataset into distinct demographic groups to allow for more detailed analyses, (3) Data mining using ARM, and (4) Interpretation and evaluation of results using visualization methods and comparison to relevant scientific literature. Data extraction, analysis, and visualization were conducted using the Julia general purpose programming language, MySQL database management system, and Tableau.

**Data selection**

The publicly available AEOLUS database, a standardized form of FAERS, was used as the primary data source. AEOLUS removes duplicate cases and applies standardized vocabulary to map FAERS labels to RxNorm Concept Unique Identifiers (for drugs) and SNOMED-CT identifiers (for indications). Additionally, AEOLUS precomputes some basic statistics such as the proportional reporting ratio (PRR). PRR is calculated as $\text{PRR} = \frac{a}{a+b} / \frac{c}{c+d}$, where $a$ is the number of cases with the suspected drug and suspected ADR, $b$ is the number of reports with the suspected drug and without the suspected ADR, $c$ is the number of reports without the suspected drug and with the suspected ADR, and $d$ is the number of reports without the suspected drug and without the suspected ADR.

The version of AEOLUS used for this study was created using FAERS data from January 2004 to June 2015. The format of the FAERS data collected from January 2004 to August 27, 2012 differs slightly from the format for data collected from September 2012 onwards in that the earlier data identify cases using isr, while the more recent data identify cases using primaryid. Consequently, the AEOLUS database keeps track of both isr and primaryid.

The AEOLUS concept table was queried for all concepts with names that match “%suicid%”. This query returned the following concepts: “depression suicidal,” “completed suicide,” “suicidal behavior,” “suicidal ideation,” “suicide attempt,” and “suicide of relative.” The first five concepts were identified as suicide-related ADRs and were chosen to be used to extract relevant cases for this study. “Suicide of relative” was left out because it is not an adverse reaction experienced by patients themselves.

The identifiers (primaryid for cases prior to August 2012; isr for cases after August 2012) of cases with reactions of “depression suicidal,” “completed suicide,” “suicidal behavior,” “suicidal ideation,” “suicide attempt,” and “suicide of relative” were extracted. These identifiers were used to obtain: (1) the list of drugs and (2) the list of indications for patients who experienced one or more of these reactions. The AEOLUS tables used to extract these data were standard_case_drug and standard_case_indication, respectively. The resulting dataset is referred to as the “full dataset.” Basic statistics regarding the drugs involved in these cases were extracted from the AEOLUS table standard_drug_outcome_statistics, which contains precomputed PRRs and frequencies for each drug-reaction combination.
Data processing and subsetting

The full dataset was segmented according to two demographic factors: (1) sex and (2) age. The purpose of data subsetting was to amplify signal detection of factors that increase suicide risk for specific population groups. AEOLUS does not contain demographic data, but by joining the AEOLUS and FAERS databases using primaryid and isr, demographic data were retrieved for the cases used in this study. Separate lists of drugs and indications were generated for female and male patients who had one of the previously mentioned suicide-related ADRs. Cases without a gender code were excluded. Similar lists were generated for patients in the following age groups: <15, 15-24, 25-34, 35-44, 45-54, 55-64, and >64. The selection of age groups follows the practices of the Centers for Disease Control and Prevention, with the exception that all age ranges less than 15 years old have been combined into one age group because children < 15 years old all tend to exhibit low rates of suicide. Cases with no age field and cases with ages measured in units other than years were excluded.

Data mining

A Julia package (ARules.jl) was used to perform ARM via the Apriori algorithm for the ten datasets (full dataset and nine subsets). The support threshold was set at 0.005 and the confidence threshold was set at 0.01. Support was calculated using the equation \( \text{supp}(X \rightarrow Y) = \frac{P(X \cup Y)}{n} \), confidence using the equation \( \text{conf}(X \rightarrow Y) = \frac{P(X | Y)}{P(X)} = \frac{\text{supp}(X \cup Y)}{\text{supp}(X)} \), and lift using the equation \( \text{lift}(X \rightarrow Y) = \frac{\text{supp}(X \cup Y)}{\text{supp}(X)\text{supp}(Y)} \). The maximum rule length was set to six to allow for the discovery of more complex rules should they exist.

Interpretation and evaluation

Tableau Desktop 2018.2 was used to visualize and organize the top drugs, top indications, and association rules discovered in this study. Association rules were grouped by RhS (right-hand side) to make it easier to see differences between the association rules for each demographic group.

PubMed and Side Effect Resource (SIDER), a centralized database of known ADRs that appear in drug labels, were used as resources to validate findings involving ADRs for individual drugs, SIDER 4.1, which was released in October 2015, was the version used in this study. PubMed was also used to validate findings involving indications or combinations of drugs.

Results

The characteristics of patients who had one or more suicide-related ADRs are described in Table 1. In total, AEOLUS contains 85,071 cases that involve a suicide-related ADR, with the most common suicide-related ADRs being completed suicide, suicidal ideation, and suicide attempt. Note that some cases are associated with more than one suicide-related ADR, so the percentages for each ADR add up to more than 100%.

Table 2 shows the top drugs associated with cases involving suicide-related ADRs. The left-hand side of the table shows the top ten drugs ranked by PRR using a cutoff of count ≥ 3 to highlight stronger signals, while the right-hand side of the table shows the top ten drugs ranked by case count. The “S” superscript following a drug name denotes that the drug has a suicide-related side effect (suicide, suicidal ideation, suicide attempt, completed suicide, or suicidal behavior) in the SIDER database. The “P” superscript denotes that the drug does not have a documented suicide-related side effect in the SIDER database, but there exists at least one PubMed article linking the drug to a suicide-related reaction.

found in SIDER; P, # found in PubMed (where # is the reference to the PubMed article)

Of the 85,071 cases with suicide-related ADRs, 44,782 cases (52.64%) have one or more known indications. 15,617 cases (18.36%) were tagged with only “product used for unknown indication” or “drug use for unknown indication,” while the remaining cases had no indication information. Figure 2 depicts the indications that appear most frequently in the 44,782 cases with known indications. The ten most frequent indications are depicted in their own circles, with the remaining indications grouped together in the circle marked “other.”

*Acetaminophen/Hydrocodone Oral Tablet
Of the 85,071 cases with suicide-related ADRs, 84,330 (99.13%) contained drug data. Table 3 displays the association rules for these cases. Rules should be interpreted as Lhs (left-hand side) → Rhs (right-hand side). For example, the first row of Table 3 should be read as {Ibuprofen} → Acetaminophen, meaning that among patients who had suicide-related ADRs, those who were taking ibuprofen were likely to be also taking acetaminophen. The left-hand side of the rule can contain more than one element, but the top drug association rules that were discovered all have left-hand sides that are one-element sets. In Tables 3-9, only rules with conf ≥ 0.18 and lift ≥ 2 are displayed. The results are grouped by Rhs and ranked from greatest to least lift value within each Rhs. Support and confidence tend to exaggerate the importance of rules involving items that appear frequently in the database even if the relationship between items is weak, but lift attempts to correct for frequency and is thus chosen as the primary measure of rule interestingness in this study.29

The association rules for indications in the 44,782 cases with known indications with conf ≥ 0.18 and lift ≥ 2 are as follows: {depression | smoking cessation therapy} → anxiety (conf = 0.458, lift = 6.083), {sleep disorder} → anxiety (conf = 0.279, lift = 3.707), {insomnia} → anxiety (conf = 0.242, lift = 3.209), {anxiety | smoking cessation therapy} → depression (conf = 0.597, lift = 2.698), {anxiety} → depression (conf = 0.490, lift = 2.212). Unlike in Table 3, some of these rules contain left-hand sides that involve more than one element. For example, the first rule implies that among patients who experienced a suicide-related ADR, those who have indications of both depression and smoking cessation therapy are also likely to have an indication of anxiety.

Tables 4 and 5 show the differences between drug association rules for the 39,095 suicide-related ADR cases that involve female patients and contain drug data vs. the 30,035 cases involving male patients. Tables 6 and 7 show indication association rules for the 21,533 suicide-related ADR cases that involve female patients and contain indications data vs. the 17,721 cases involving male patients.

Association rules for drugs were found to differ across age groups. Table 8 displays association rules for the 8,317 cases that have drug data and involve a patient between 15 and 24 years old. Table 9 displays the association rules for the 14,153 cases that have drug data and involve a patient between 45 and 54 years old. These two age groups are particularly worthy of investigation because suicide is a significant cause of death in both of these age groups. In 2016, suicide was the second leading cause of death among 15-24 year old Americans (436 cases) and the fourth leading cause of death among 45-55 year old Americans (8,437 cases).

The only association rule with conf ≥ 0.18 and lift ≥ 2 that resulted from mining the 4,463 cases that have indications data and involve a patient between 15 and 24 years old is \{insomnia\} → anxiety (conf = 0.280, lift = 4.287). Table 10 displays association rules for the 7,138 cases that have indications data and involve a patient between 45 and 54 years old. Many significant association rules were discovered in this age group, so in order to highlight the most interesting rules, only rules with conf ≥ 0.25 and lift ≥ 4 are displayed.

Discussion

In this preliminary study, FAERS cases involving suicide-related ADRs were used to generate basic statistics and association rules. ARM was performed on all cases with suicide-related ADRs, cases with male patients, cases with female patients, and cases split into seven different age groups.

Table 3 contains the association rules discovered by performing ARM on all cases with suicide-related ADRs. These rules are good starting points for future studies intending to investigate combinations of drugs that may lead to suicide. One example is the rule {Valproate} → quetiapine (conf = 0.26, lift = 3.36). Valproate and quetiapine have been found to increase the rate of self-harm and suicide events when taken individually, but there is yet to be a study of how suicide rates are affected by taking these two drugs concurrently.30

Tables 4 and 5 illustrate how data segmentation allows for the discovery of rules that are hidden when analyzing all patients as one group. For example, one association rule that is seen in the male population is {Amlodipine} → lisinopril (conf = 0.20, lift = 6.06). Amlodipine and lisinopril are often used in combination to treat hypertension, but the preliminary findings of this study suggest that other drugs could be considered when treating hypertension in male patients in order to mitigate the risk of suicide-related ADRs.31
Additionally, this study highlights sex differences when it comes to indications in cases involving suicide-related ADRs. Tables 6 and 7 show that “pain” appears frequently among the top association rules for indications for female patients (present in six out of 18 rules), but “pain” does not appear at all in the top association rules for indications for male patients. This is potentially due to greater pain sensitivity in females, but these findings nonetheless suggest that females experiencing pain concurrently with other indications present in the association rules in Table 6 could have an elevated risk of suicide-related ADRs.32

Drug association rules also differ across age groups. Table 8 shows that the top rules for drugs in cases involving 15 to 24-year-old patients are very similar to the top rules mined using all patients (Table 3), but Table 9 reveals association rules present in 45 to 54-year-old patients that were not significant in the general population. Examples of such rules include {zolpidem} → alprazolam (conf = 0.20, lift = 2.03), {temazepam} → diazepam (conf = 0.23, lift = 3.83), and {albuterol} → varenicline (conf = 0.40, lift = 3.63). Table 10 reveals groups of indications that may increase the likelihood of suicide-related ADRs for patients that are 45 to 55 years old. This study highlights that certain drugs and indications may have differing effects on the suicide risk of patients in different age groups.

One limitation of this study is that it is difficult to determine cause and effect relationships. In the FAERS and AEOLUS databases, it is difficult to determine whether a drug that is associated with a suicide-related ADR is a drug leading to suicidal behaviors or a drug purposefully taken to perform suicide. For example, acetaminophen appears in several association rules discovered in this study. However, since acetaminophen, more commonly known by its brand name Tylenol, is one of the most commonly abused drugs, it is possible that taking acetaminophen is a manifestation of suicidal behaviors rather than the cause.33 This suggests that some of the drugs that appear in the association rules mined in this study are drugs used in suicide attempts rather than drugs leading to suicide-related behavior. Future studies investigating suicide could supplement data from spontaneous reporting systems like FAERS with longitudinal data from electronic health records and claims data, which would provide better evidence for cause and effect relationships.

Another challenge of this study was determining appropriate minimum support and confidence levels for (1) running the Apriori algorithm and (2) determining which rules outputted by the Apriori algorithm are worthy of further investigation. In this study, metrics such as PRR, support, confidence, and lift were used for ranking individual drugs and associations. Additional metrics such as chi-square could be calculated and compared to assess performance. Since support and confidence tend to overlook rare rules and are thus imperfect measures of rule interestingness, implementing the Apriori algorithm using a different interestingness metric as a threshold is worthy of future exploration.34 Sindhu and Kannan have used the Apriori algorithm modified to utilize PRR instead of the traditional confidence as a threshold to mine FAERS.35 Ibrahim et al. have used a hybrid Apriori algorithm that uses PRR and chi-square as interestingness thresholds to mine FAERS.36 Applying these algorithms to data from different demographic segments, as was done in this study, would be a good next step.

Other next steps include studying how drugs and indications differ among various suicide-related ADRs and conducting formal evaluations. Early findings suggest that certain drugs are more likely to lead to some suicide-related ADRs than other suicide-related ADRs. For example, varenicline is associated with 4,069 cases of suicidal ideation in AEOLUS but only 681 cases of completed suicide, whereas acetaminophen is associated with only 876 cases of suicidal ideation but 4,025 cases of completed suicide. Formal evaluations will involve validating the results with clinical experts and established medical knowledge resources as well as determining if there is a statistically significant difference among demographic groups. For example, quantitative evaluations could involve comparisons of rules to characterize similarities as well as differences (e.g., using F-score or Matthews correlation coefficient). Additionally, in order to determine which combinations of drugs and indications contribute uniquely to suicide-related ADRs, a control group could be used (e.g., by removing association rules that appear in populations without suicide-related ADRs from those generated in this study). Potential applications of these findings for supporting clinical decisions and precision medicine will also be further explored (e.g., using longitudinal electronic health data to examine suicide risk for patients who are prescribed a given combination of drugs).37

Conclusion

There is a need to better understand risk factors for suicide. Using data from a spontaneous reporting system and data mining techniques, this study characterized combinations of drugs and indications associated with suicide-related ADRs. These initial findings can serve as a resource for informing investigations of potential drug-drug interactions or comorbidities for suicide risk. Further work is needed to validate the initial findings, explore subpopulations, and determine the broader implications for suicide prevention.

Abstract

This study offers a description of factors that predict the adoption of mobile health technologies (mHealth) and their application for health self-management in emerging adults. Primary data collection occurred at three diverse post-secondary educational institutions (N= 1,329). The analysis used a logistic regression to identify predictors of mHealth adoption. Descriptive analyses are presented on health self-management applications and perceived ease of use and effectiveness. Use of mHealth was high in respondents (58.5%). Factors associated with increased likelihood of mHealth adoption included being female, overweight or obese, having a chronic condition, eating the recommended amount of daily fruit, and engaging in regular moderate exercise. Low household income was associated with being less likely to use mHealth. The most common self-management application for mHealth was for tracking physical activity. Findings related to ease of use and effectiveness ratings by applications may provide insight into designing more effective mHealth tools in this population.

Introduction

The development of digital technologies is spurring the expansion of mHealth, broadly defined as “health care and public health practices supported by mobile devices”¹. mHealth can be thought of as a subcategory of telehealth and includes health apps or mobile phone capabilities that enable immediate access to biometric data, health information, patient education, adherence reminders, or progress on a lifestyle modification goal.² The prevalence of consumer mHealth apps has grown dramatically. In 2017 there were over 318,000 health apps available for download, doubling the number available in 2015.³ This growth is due, in part, to the increasing prevalence of smart phones and watches. As of 2018, the vast majority of individuals in the United States have a cell phone (95%) and smartphone ownership grew dramatically from 35% in 2011 to 77% in 2018.⁴

There is evidence of promising potential for mHealth to improve health behaviors and help individuals self-manage chronic conditions. A systematic review of such interventions based primarily on randomized controlled trials found that mHealth intervention participants were more successful in changing a variety of health behaviors and behavior-related outcomes, including physical activity, smoking cessation, consuming a healthy diet, weight loss, medication adherence, improved blood pressure control, and better glycemic control.¹ Despite the potential benefits of mHealth, there are also significant barriers to widespread dissemination. Recent evidence suggests that as many as 45% of participants in a survey study reported that they downloaded health apps they no longer use.⁵ Furthermore, a 2017 study that explored sustained use for activity trackers found that, on average, participants used trackers for only 129 days.⁶ A separate study estimated that as many as one third of activity trackers were discontinued within 6 months of use.⁷ Successful adoption of mHealth will require a better understanding of the preferences of users and an emphasis on design to encourage sustained and effective use.⁸
With the increasing ubiquity of mHealth and health information technology, it is important to understand its use and impact on health, particularly for younger generations. Emerging adulthood is a distinct development period that occurs between 18 years and 25-30 years marked by an increase in autonomy of decision making and identity formation. Emerging adulthood is often associated with the height of health and well-being; however, recent trends indicate that the rate at which younger adults in the United States are being diagnosed with chronic medical and mental health conditions has grown dramatically. As a result, the periods of young and emerging adulthood provide opportunities for emphasizing primary prevention efforts to improve long term health outcomes. Enduring patterns of health behaviors and lifestyle choices are established during emerging adulthood, providing evidence that this period is uniquely relevant to health promotion and disease prevention efforts.

mHealth technologies, whether consumer chosen or health provider directed, will likely play an increasingly important role in health care. To this end, health care improvement efforts have focused on implementing approaches to care that leverage mHealth to support health self-management. Health self-management consists of the broad set of skills, knowledge, and abilities to manage one’s health and health care decision making across the spectrum from health enhancement or prevention to disease management. As a cost-effective strategy to improve health self-management, understanding predictors of mHealth technology use and factors associated with their effectiveness is becoming increasingly important. To this end, the technology acceptance model sheds light on how users accept and use a technology like mHealth. In addition to important contextual factors, perceived ease of use and effectiveness of a technology influences how and whether the user will adopt a specific technology.

Several distinct characteristics have been noted among users of mHealth. Users are younger, wealthier and work full time. The increased use of health apps was associated with the prevalence of chronic conditions, including obesity. Fitness and nutrition have been identified as the most commonly reported categories of health apps used. Of respondents that use a fitness or nutrition app, most use them at least daily. These findings across the literature were based on samples of adults and did not include a sub-group analysis on younger emerging adults.

The goal of this study was to define factors associated with mHealth use, to describe the intended health self-management applications, and determine their ease of use and effectiveness among emerging adults attending three different institutions of post-secondary education in the southeastern United States. The three primary research questions in this study were: 1) What contextual factors, behaviors, and characteristics of emerging adults are predictive of the likelihood of using mHealth? 2) For emerging adults that use mHealth, what health self-management activities are they used for? 3) What is the perceived ease of use and effectiveness of the mHealth for each health self-management activity?

There are notable gaps in the literature surrounding mHealth use in emerging adulthood. To address them, this study is the first to examine predictors of mHealth utilization among emerging adulthood including describing health self-management applications of mHealth and evaluating perceived effectiveness and ease of use across mHealth self-management applications. The findings will help inform the design and implementation of mHealth enabled prevention efforts in this critical population.

Materials and Methods

Study design and subjects

This data was collected from three different institutions of post-secondary education in a medium sized city located in the southeastern United States. The post-secondary educational institutions surveyed include a historically black college (HBCU), a R1 private university, and a technical community college. All three institutions collaborated on a community engaged and participatory research initiative to inform and improve population health management efforts. Each institution provided the research team with school e-mail addresses from either a random sample of their student body or the entire student body. Students received three e-mail prompts over two weeks from the research team to participate in the study and complete the survey through the Qualtrics web platform. After the survey was completed, students could enter a lottery to win a gift card to a popular online retailer. The study team had a response rate of 18%, which is typical of online surveys sent to students. Inclusion criteria required the respondents be currently enrolled at one of the participating institutions and have an active institutionally affiliated e-mail address. Respondents over the age of 30 or under the age of 18 were excluded from the analysis to focus on the emerging adulthood period of development. This study was approved by the Duke University Institutional Review Board.
Data collection

The survey captured a breadth of information from respondents including demographics, health behaviors, social determinants of health, and information on consumer/commercial oriented mHealth use. mHealth use was collected by asking respondents, “In the past year, how many health-related smartphone apps and/or wearable devices (example: dieting application, FitBit, Apple Watch, sleep tracking) have you used related to your health?”. Respondents provided information on age, gender, race, self-reported family income, and the degree they were pursuing. Data on daily fruit and vegetable in-take and moderate and vigorous exercise were collected using adapted items from the International Physical Activity Questionnaire. Health status was measured using a validated 1-item measure of self-reported health, Body Mass Index (BMI), a validated screening tool for clinical depression, and a self-reported item that asked respondents to indicate any current chronic condition diagnoses. Finally, primary care utilization was measured by asking respondents the frequency of getting routine outpatient care (“How long has it been since you last visited a healthcare provider for a routine checkup or yearly physical?”).

Respondents who indicated they used one or more apps/devices were asked to report what mHealth was used for by selecting a self-management category. Response options for self-management activities included: (1) to track how much activity/exercise I get (e.g. walking, running, cycling); (2) to help me watch what I eat (e.g. food intake, nutritional values); (3) to show or teach me exercises or workouts; (4) to track a health measure (e.g. heart rate, calories burned, blood pressure); (5) to help me manage a specific condition or behavior (e.g. diabetes, smoking cessation); (6) sleep tracking; (7) reproductive health (e.g. ovulation tracking, family planning, pregnancy progression); (8) stress/anxiety management, mindfulness, guided meditation. Respondents were asked additional questions about their experience using mHealth for each selected self-management activity. Of specific interest was self-reported ratings of ease of use and usefulness/effectiveness which have been shown to be predictive of intention to use, self-reported usage, and attitude toward technology use across a broad array of technologies.

Statistical analysis

A logit model was used to estimate the effect of included variables on the probability of using mHealth. The results are estimates of the average marginal effect of each variable on the likelihood of self-reported mHealth adoption. This approach was chosen given that the outcome (mHealth use) is binary and the strength of this dataset is the richness of covariates and diversity of the respondents. The primary hypothesis was higher BMIs would be associated with an increased likelihood of using mHealth as existing literature suggests that this association is present in the adult population.

The analysis also explored what self-management applications were supported by the use of mHealth. The descriptive analysis of the subgroup of emerging adults that reported using mHealth technology illustrates how these technologies were being used to manage health and promote specific health behaviors. Given existing literature examining how mHealth is used, the secondary hypothesis is that the two most common uses for mHealth technologies would be to improve nutrition and physical fitness.

Finally, descriptive statistics were calculated of perceived effectiveness and ease of use of mHealth technologies for each self-management activity to predict intention to use and sustained use. Ease of use and effectiveness ratings were analyzed to provide insights into the categories of mHealth enabled self-management activities that were the most likely to have an impact on long-term lifestyle modification.

Statistical analyses were performed by using Stata statistical software (version 15.1, StataCorp LLC, College Station, TX, USA).

Results

1,329 students were included in the analysis. A strength of this dataset is the diversity of respondents. 21.2% were African American, 40.5% White, 16.9% Asian, and 10.9% Hispanic (Table 1). Across the three post-secondary education institutions, 70.1% of the sample was female. The proportion of students that were overweight or obese was highest at the historically black college. The private university had the highest mean age and self-reported household income. mHealth use was prevalent and the difference in mHealth use was not statistically significant between the three institutions: private college (60.6%), technical community college (55.6%), and historically black college (56.4%).

A logit model was used to predict the likelihood of mHealth adoption based on the variables included in the model (Table 2). These results indicated that being overweight or obese is associated with a 10.5 percentage point increase in the predicted probability of using mHealth technology controlling for the other covariates included in the model. This finding offered support for the hypothesis that being overweight would be associated with a higher likelihood of using mHealth technologies.

Being female was associated with an over 14 percentage point increase in the predicted probability of using mHealth controlling for other variables in the model. Respondents from households under $20,000 were less likely to use mHealth when compared to respondents from households with incomes between $50,000-$99,999. Other income levels were not associated with a higher or lower probability of using mHealth. The endorsement of healthy behaviors also predicted mHealth use. Respondents that reported engaging in the recommended amount of moderate physical exercise according to the American Heart Association were more likely to use mHealth. In addition, eating the
The recommended daily intake of fruits is associated with a 6.2 percentage point increase in the likelihood of using mHealth.

Finally, there were associations between using mHealth across multiple measures of health status. Having a chronic illness was associated with using mHealth as was self-reported health of ‘Very Good’, or ‘Excellent’ which was associated with an 11 percentage point increase in the predicted probability of using mHealth. There was some preliminary evidence that suggests having screened positive for clinical depression is associated with a 6.6 percentage point decrease in the likelihood that a respondent used mHealth; however, this result was significant at a 90% confidence level. The other variables included in the model (vegetable consumption, relationship status, age, race, recommended vigorous exercise, annual primary care visit, or degree type) did not affect the likelihood of mHealth technology adoption.

Respondents that reported using mHealth were asked follow up survey questions to capture how mHealth technologies were used and their perceived ease of use and effectiveness for each health self-management application (Tables 3 and 4).

Physical activity and nutrition tracking were common self-management applications, lending support for the hypothesis that exercise and nutrition would be common uses of mHealth. However, despite the prevalence of mHealth technologies to assist with nutrition tracking, respondents indicated that the effectiveness for this function was lower than other self-management functions with 40.2% indicating nutrition tracking apps were extremely or very effective and only 28.1% reporting that they were extremely easy to use. Respondents, however, found mHealth was especially
useful for managing reproductive health with over 74.8% of respondents reporting that it was extremely or very effective and over 66.5% reporting that it was extremely easy to use. Respondents were less likely to find mHealth useful for managing stress or anxiety with only 35.2% reporting that mHealth was extremely or very effective. However, mHealth for managing stress or anxiety had relatively high ratings for ease of use with 83% of respondents indicating moderately or extremely easy to use.

The overall relationship of the ease of use and effectiveness ratings based on self-management is shown in Figure 1. mHealth self-management applications with higher effectiveness ratings also tended to have higher ease of use ratings. Ease of use and effectiveness ratings for each self-management category had a statistically significant positive correlation ranging from 0.29 to 0.47 with the exception of ‘Manage a Condition or Behavior’, likely due to the small sample size. For example, applications like reproductive health and health measure tracking had high levels of effectiveness and also had high levels of ease of use when compared to other applications. Similarly, nutrition tracking had lower levels of both effectiveness and ease of use. However, effectiveness tended to be rated much lower than ease of use. This was especially true for managing stress and anxiety, which had low levels of effectiveness but high levels of ease of use.

Discussion

Facilitating effective mHealth utilization within emerging adulthood is increasingly being recognized as an opportunity to promote health self-management and improve health outcomes later in life. As health care delivery models assume more responsibility for managing the health of defined populations and communities, novel ways that leverage available mHealth technologies to promote health self-management is a key consideration. This study confirms previous literature that indicates that younger adults are more likely to use mHealth technologies and provides insights into the determinants that predict mHealth adoption and the health self-management activities that these technologies support.

mHealth use was much higher in this sample of emerging adults (58.5%) than among a nationally representative sample of respondents found in relevant recent studies with mHealth usage rates of 22.8% in 2017 and 11.7% in 2012. The dramatic difference could be attributed to the focus on a younger population and the continuation of a general trend towards greater mHealth use. While mHealth use was ubiquitous among respondents, these findings suggest that a key barrier to mHealth adoption in emerging adulthood is related to socio-economic status. Participants from low income families (<$20,000) had a 13.3 percentage point lower likelihood of mHealth adoption when

Figure 1. mHealth effectiveness and ease of use ratings of self-management activity ordered by effectiveness
compared to middle income families ($50,000-$99,999). Previous research suggests that the burden of cost associated with mHealth and lower technology literacy levels are potential explanations for this finding.\textsuperscript{32}

Being overweight or obese and having any chronic illness is associated with higher likelihood of mHealth adoption. This could be a result of these individuals seeking technologies to manage their condition. This is consistent with a previous finding that mHealth users were more likely to be obese.\textsuperscript{5} These results also reveal that being in excellent or very good self-reported health was associated with an increased likelihood of mHealth adoption. This is notable given that self-reported health is predictive of health care expenditures and mortality.\textsuperscript{24}

Female emerging adult respondents were more likely to adopt mHealth technologies, a finding that has been replicated in older populations.\textsuperscript{19,20} A novel finding of this analysis suggests that being at risk of depression was associated with a lower likelihood of using mHealth, however, this result was only significant at a 90% confidence level, thus further research is required to confirm this relationship. Finally, this research provides evidence that there is a relationship between mHealth adoption and the endorsement of recommended beneficial health behaviors. Engaging in the recommended amount of moderate exercise and fruit intake were both associated with a higher likelihood of using mHealth. This is an area of particular promise and further research is required to evaluate the causal direction of this association and to explore the potential implications for designing more effective mHealth interventions.

This research is the first to describe the health self-management activities that mHealth technologies are used for and provide user feedback on perceived effectiveness and ease of use based on the technology acceptance model. Perceived effectiveness and ease of use are predictive of intention to use health related technologies, a key consideration given that user acceptance is important to enable health informatics adoption in health service delivery.\textsuperscript{5,18} Effectiveness and ease of use have been shown to be influenced by individual and community contextual factors such as gender, culture, social determinants, and demographic characteristics.\textsuperscript{17} It will be important to also understand how these determinants are associated with continued use, and more importantly, positive health outcomes. Overall, effectiveness ratings tended to be strikingly lower than ease of use ratings across all self-management activities. This illustrates the challenge of designing mHealth to be effective for behavior change, it requires more than the technology being accessible and user-friendly. It is important to note that the most commonly used self-management activities were not the activities that respondents indicated to be the highest levels of effectiveness and ease of use. Nutrition tracking, for example, was the second most prevalent self-management activity but had lower effectiveness and ease of use ratings when compared to other self-management applications. Conversely, reproductive health self-management had lower rates of mHealth adoption but had the highest effectiveness and ease of use ratings. A possible explanation for this phenomenon is that respondents found that passive mHealth technologies that tracked activity or a health measure to be both effective and easy to use when compared to a self-management activity like stress management and nutrition tracking which requires greater user engagement.

Future directions for this work could create a more specific “user profile” and risk stratification to target mHealth interventions to users that are receptive to this medium of clinical or public health interventions. To do so, special consideration will be paid to the design of mHealth enabled self-management interventions to maximize effectiveness and the user experience. As opportunities to implement mHealth enabled prevention efforts that target emerging adults are explored, researchers and practitioners alike must continue to evaluate opportunities to personalize mHealth interventions and delivery models to realize the full potential health benefits.

Limitations:

This work has several notable limitations. First, given the relatively modest, but not unexpected response rate, there should be caution when generalizing these results to all emerging adults in post-secondary institutions. As with many observational cross-sectional survey study designs, a self-selection bias could make the study sample systematically different from the population of interest. The respondents were all located in the same southeastern city which limits external validity to other geographic regions. The lack of longitudinal data limits the ability to determine the extent of sustained use of mHealth technologies and whether they fulfilled their intended outcome – a key consideration for mHealth to modify health behaviors.

Conclusion

This study provides important insights into mHealth use and their perceived ease of use and effectiveness by self-management application in emerging adulthood in diverse post-secondary institutions of learning. mHealth use is high among respondents when compared to the general population.\textsuperscript{5,20} Higher likelihood of mHealth adoption was
associated with being overweight or obese, female, engaging in moderate exercise, eating the recommended amount of daily fruit, having a chronic condition, and higher levels of self-reported health. In contrast, low household income and screening positive for depression risk (90% confidence level) was associated with a decreased likelihood of mHealth adoption. Tracking exercise and nutrition were the most common applications of mHealth. Ease of use and effectiveness were the highest for mHealth self-management applications associated with reproductive health and health measure tracking and the lowest for managing stress and anxiety. A trend that emerged in the data is that passive self-management functions received higher ease of use and effectiveness ratings. Ease of use and effectiveness ratings were largely correlated with ease of use being consistently rated higher than effectiveness across self-management activities. This finding suggests that an mHealth technology that is easy to use is necessary but not necessarily sufficient to have an impact on health behaviors. Next steps for this work should focus on opportunities to design mHealth interventions that are tailored to the preferences and needs of emerging adults to support health self-management during this critical developmental period.

Perceived Usefulness and Acceptance of Communication Support System in Laparoscopic Surgery

Yuanyuan Feng, MS, Jatin Chhikara, MS, Jordan Ramsey, BS, Helena M. Mentis, MS PHD
University of Maryland Baltimore County, Baltimore, MD, USA

ABSTRACT

In laparoscopic surgery, senior surgeons spend great efforts to convey knowledge to their trainees. Any misinterpretation of the instructions may lead to inevitable errors that have a great impact on patient safety. To support efficient knowledge sharing, we design a communication support system, Virtual Pointer, to convey trainers’ gestures directly onto the laparoscopic video for trainees to see. We implement the design in an international surgical conference and evaluate the perceived usefulness and acceptance of the system among senior surgeons and surgical trainees. The results showed that the system facilitated the trainees to complete the task, increased their knowledge, and reduced the trainers’ guiding efforts. The study indicates that conveying the gestures directly onto video has the potential to support the intraoperative communication. Barriers in the acceptance of the system highlight the design of novel interaction mechanisms to unobtrusively integrate this technique into the surgical workflow.

INTRODUCTION

The operating room (OR) is the key place for residents to acquire surgical expertise. However, over half of surgical adverse events are attributable to the OR-based surgical training[1, 2]. The main cause for these errors is the communication failure in the high-stakes environment with multiple demands between residents and senior surgeons[3]. Residents, on one hand, need to efficiently follow the instructions given by their trainers. On the other hand, they master surgical skills through in-situ learning, which requires them to make their own decisions and get corrected and confirmed from the trainers[3]. Fulfilling these demands rely on the ability of expert surgeons in conveying the knowledge, that is in response to their trainees’ knowledge background, experience levels, and comprehensive abilities.

Previous research has shown that actions, such as pointing or instrument movements, have essential communicative functions that facilitate the conveying and understanding of knowledge[4, 5]. Expert surgeons often use actions to clarify the referred anatomical structure[6], manage the trajectory of the operation[7, 8], and demonstrate the technical skills[9]. These actions are sometimes transformed into explicit instructions when necessary in open surgery. For instance, an expert surgeon may draw on the skin to indicate the path of the incision and to mark the major landmarks of the anatomy[7]. The drawing specifies where the residents should attend and ensures that they are on the same page throughout the operation.

However, in laparoscopic surgery, where the direct view of the operative field limits the ability to directly gesture on the anatomical structures, expert surgeons take great effort in appropriating the view to guide their trainees to see the target structure, make meaning of it, and using it for their actions[3, 9, 10]. Expert surgeons often guide trainees’ hands to maneuver the laparoscopic camera, accompanied by a series of verbal explanations and gestures over the monitor to reveal the subtle changes in the structure to translate what they are seeing into the abstract anatomy in the textbook[3, 9]. The surgical instruments are used to point at the target or draw imaginary lines to elucidate the structures embedded in the tissues. Trainees, on the other hand, need to parse, envision and make sense of their trainers’ actions to perceive the locations and directions. This often engenders a series of checking, clarifying, aligning of the information that is already presented[10]. In this process, any misinterpretations of these actions may lead to inevitable technical and judgment errors that have a great impact on patient safety[11].

To overcome these problems, we hypothesized that conveying the gestures directly onto the video is beneficial. Previous research has shown that communication becomes more effective when annotation and gesturing tools are provided for the shared view of the workspace[12, 13]. For instance, Fussell et al. found that the pointing and representational gestures added on a shared view of a robot assembly task effectively facilitated task communication and reduced performance time[12]. Tang et al. projected the hands over the shared view and found that the gestures allowed the collaborators to be more engaged in communication and the tasks[13]. These studies focused on the communication in completing a task. The communication in OR-based surgical training, yet, entails not only instructions necessary in operating, but also the in-situ knowledge for the trainees to become competent in surgery[3, 9]. It is unknown whether the gesturing tool supports conveying expertise in surgical training.
We designed a Virtual Pointer system, which enables a trainer to point or draw a freehand sketch, i.e., telestrating, over a laparoscopic video for a trainee to see during the operation\textsuperscript{14}. We implement the design in an international surgical conference and evaluate the perceived usefulness and acceptance of the system among expert surgeons and residents. The perceived usefulness is defined as “the degree to which a person believes that using a particular system would enhance his or her job performance.”\textsuperscript{15} In our evaluation, we mainly focus on knowledge sharing in surgical training. The job performance here refers to trainees’ learning performance, i.e. the knowledge they gained, the skills and abilities they developed, and the effort they expended in training, as well as the trainers’ ability in conveying the knowledge. User acceptance is the degree to which a person is willing to use the system in their work practice\textsuperscript{15}. In our study, the user acceptance refers to the trainers’ willingness to use the system in conveying knowledge, as well as the trainees’ willingness to gain knowledge through the annotation or reference on the video provided by the trainers using the Virtual Pointer. The evaluation presents the surgeons and surgical trainees’ perspectives on how they are going to use a Virtual Pointer-like communication support system, what benefits they will gain from using the system, as well as the concerns and barriers in implementing the system in the surgical environment. Based on the findings, we discuss the implications for designing an intraoperative communication support system.

**METHODS**

**Overview of the Virtual Pointer system**

The Virtual Pointer system was designed aiming to facilitate the conveyance of expert knowledge by enabling trainers to point or draw on the laparoscopic video for the trainees to see during an operation. The program works by using a combination of audio key words and hand movements to trigger different functionality. The Microsoft Kinect is used as the gesture and voice control sensor.

![Virtual Pointer Interface](image)

**Figure 1.** The interface of the Virtual Pointer program\textsuperscript{14}. (1: the selected mode; 2: the audio commands; 3: the user’s movement feedback; 4: the laparoscopic view.)

Figure 1 shows the interface of the system. The collection of the verbal commands is shown in the upper left corner. The current mode is presented in the center above the laparoscopic view. The lower left corner shows the user’s skeleton to provide timely feedback of the user’s movement. To awaken the Kinect, the first command is verbally saying “Kinect ready”. When this is said the Kinect starts detecting other verbal cues and gestures. There are two verbal cues the Kinect is looking for, either “Kinect draw” or “Kinect point”, to switch between the drawing mode and the pointing mode. In the pointing mode, the user moves the hand to control a small green circle, which acts as a pointer. In the drawing mode, the user closes their hand to draw over the video. The position of the pointer and the drawing responds to the position of the user’s hand. To clear the screen of all annotations, there is the verbal command “Kinect clear”. When the program is finished being used, the voice command “Kinect close” can be used at any time to set the program to sleep and stop the Kinect from detecting.

**Study Procedure**

Virtual Pointer is a novel instructional system for surgery training. To minimize the learning curve, we first demonstrated how the system works and gave a brief introduction of the study. The surgeons or surgical trainees who consented to participate in the study completed a preliminary questionnaire on demographics and surgical experience.
Based on their experience level (attending surgeon, surgical fellows, and residents) the participants were assigned into two groups – the trainer group (attending surgeons) and the trainee group (surgical fellows and residents).

The trainers were asked to use the Virtual Pointer to guide the researcher to perform a simulated laparoscopic task. The researcher gained the fundamental knowledge of the task from the general surgery textbook and case videos. The trainees were asked to perform the task with the guidance from the researcher using the Virtual Pointer. A general guidance transcript was developed to include the features of pointing and drawing – the pointing was for the anatomical identification, and the drawing was for the indication of where to cut. The in-situ guidance was based on the general guidance transcript and adapted based on the needs of the trainees.

Afterward, the participants completed an evaluation questionnaire on their experience, outcomes expectations, attitudes and intentions of using the system. Due to the different demands in using the technology between the trainers and trainees, we administered two sets of questionnaires – one for the trainers on conveying the knowledge, and one for the trainees on acquiring the knowledge. The questionnaire was adapted from previous research on perceived usefulness and acceptance of educational technologies16,17,18, including 21-item 7-point Likert scale and open-ended questions. The study was approved by the University of Maryland, Baltimore County institutional review board. Verbal consent was obtained from all participants before their participation.

The Simulated Task

The simulated task in the experiment was to separate the cystic duct and cystic artery on a paper model. It is an important step in achieving the “critical view of safety” in the laparoscopic cholecystectomy procedure. This task requires the trainees not only to correctly identify the cystic duct and cystic artery that are embedded in the peritoneum, but also envision the imaginary line of safety over the two structures to avoid dissecting into the common bile duct. Thus, this task involves the effort of both referring to task objects or locations and managing the process of dissection.

Study Settings and Participants

The Virtual Pointer system was connected to a Fundamentals of Laparoscopic Surgery (FLS) Box Trainer System (Limbs & Things, Bristol, UK). The Microsoft Kinect sensor (Microsoft, Washington, USA) was oriented towards the trainer. The trainee stood in front of the FLS Box with the dominant hand controlling the scissors and the other hand manipulating the Maryland dissector. The Virtual Pointer provided an overlay of the reference and annotation from the trainer to the laparoscopic video for the trainee to see. As the transfer of the video created a 2-second lag, we presented the telestration on a secondary display (Figure 2).

Figure 2. Study settings in 2017 Society of American Gastrointestinal Endoscopic Surgeons (SAGES) Annual Meeting. (1: FLS Box Trainer System; 2: Laptop running the Virtual Pointer; 3: Microsoft Kinect sensor; 4: Primary display for the laparoscopic view; 5: Secondary display for the telestration; 6: Virtual Pointer Introduction.)

Recruitment

Attendees of the Telestration-Guided Laparoscopic Visual Skills Practice Station at the Learning Center during the 2017 Society of American Gastrointestinal Endoscopic Surgeons (SAGES) Annual Meeting in Houston, Texas, were
invited for participation. A total of 18 trainers (10) and trainees (8) participated in the study, including four female surgeons and 14 males. Experience levels ranged from novice medical students to senior surgeons with more than 20 years in practice. Among the 18 post-task questionnaires collected, 3 (1 trainer and 2 trainees) were identified to contain inconsistent answers for the same assertion asking in different directions and were removed from the analysis.

Data Analysis

We conducted non-parametric tests for the analysis of the questionnaire responses. For each question, we conducted the one-sample Wilcoxon signed-rank test comparing the sample median with the neutral rate. We used the Mann Whitney U test to compare the responses of the shared questions between the trainers and trainees. Spearmen’s correlations were calculated between questions. The median response of each question was reported, along with the p-values. The analysis was conducted in R version 3.2.2 (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

Perceived Support in Conveying Knowledge

Overall, 75% of the trainers were satisfied with the support of Virtual Pointer in conveying the knowledge during the task, but their ratings were insignificant (M = 5.5, p = 0.137) (Figure 3). 87.5% trainers agreed that the Virtual Pointer saved their efforts spent on teaching (M = 5.0, p = 0.037). However, only around a half of the trainers were satisfied with the amount of time in conveying knowledge via Virtual Pointer (M = 6.0, p = 0.101). And, 55.6% trainers thought the technology may increase their desire to teach (M = 5.0, p = 0.354). In the open-ended questions, the trainers questioned about the efficiency and reliability of the system. Trainer #5, who was not satisfied with the support of the Virtual Pointer, commented, “it requires I do not use the instrument while telestrating”.

Perceived Support in Acquiring Knowledge

Overall, both the trainers and trainees perceived the Virtual Pointer’s benefit in increasing trainees’ knowledge (Trainer: M = 5.0, p = 0.058; Trainee: M = 5.5, p = 0.041) (Figure 4). The most commonly perceived aspect of learning that the Virtual Pointer could improve was the procedure knowledge, with the ratings of both the trainers (M = 6.0, p = 0.031) and the trainees (M =5.5, p = 0.038) significantly greater than neutral. Although the trainers significantly agreed that the system could increase trainees’ knowledge in anatomy (M = 5.0, p = 0.026), the trainees found the limited support in their anatomical knowledge building (M = 5.0, p = 0.066). The system’s effect on laparoscopic skills was the least perceived by only 33.3% trainers and 66.7% trainees, with all the ratings prone to neutral. In addition to accumulating knowledge, the Virtual Pointer was perceived to have a positive effect on enabling trainees to apply the possessed knowledge into practices, by 77.8% trainers (M = 5.0, p = 0.046) and 83.3% trainees (M = 6.0, p = 0.039).

75.0% of the trainers found that the use of the Virtual Pointer may minimize the efforts that trainees spent on learning (M = 5.5, p = 0.036). 66.7% of the trainees agreed with the trainers that the technology reduced their learning efforts. Yet, their agreements were not significant (M = 5.0, p = 0.276). The reduced learning efforts may be due to the effect of the pointing or drawing on clarifying the target structure, as agreed by 83.3% trainees (M = 6.0, p = 0.041). Trainee #3 commented, “it was ease of use and clear”. Besides, 66.7% of the trainees indicated that the system encouraged them to learn more about the procedure (M = 6.0, p = 0.059).
Perceived Moderate Support in Task Performance

We asked the trainers and trainees to evaluate the effect of Virtual Pointer on their task performance, in terms of the easiness, time, effort and distraction (Figure 5). Overall, 66.7% of the trainers and trainees were satisfied with the support of Virtual Pointer in completing the task, however, their ratings were insignificant (Trainer: Median $= 5.0$, $p = 0.167$; Trainee: Median $= 5.5$, $p = 0.066$). 66.7% of the trainees thought that the Virtual Pointer made the task easier and reduced the amount of time to completion ($M = 5.5$, $p = 0.066$). However, the Virtual Pointer was perceived not effective in reducing the performance efforts ($M = 5.0$, $p = 0.144$). Trainee #6, who strongly agreed that it minimized the effort on performing the task, contributed this effect to the trainers, justifying that “it saves time for attendings to explain things to medical students and observers”. Interestingly, one-third of the trainees reported distractions and one-third of the trainees reported no distractions resulted from the Virtual Pointer ($M = 4.0$, $p = 0.705$). These distractions were caused by the trainees’ concern about the accuracy of the information provided in the pointing or drawing, as justified by Trainee #5 that “it is difficult to draw accurate lines and unreliable to follow voice commands and manual gestures”. Besides, as suggested by Trainee #3, the trainees had to switch their attention between the telestrated screen and the field of surgical view.

User Experience of the Virtual Pointer

Figure 4. Virtual Pointer in supporting acquiring knowledge. (AK: acquiring knowledge; The numbers in the circles show the medians of the ratings.)

Figure 5. Virtual Pointer in supporting task performance (TP: task performance; The numbers in the circle show the medians of the ratings.)
User experience is an important factor in user acceptance of technology and implementation of it in the workflow. Thus, we ask the trainers a couple of questions regarding the ease of use. As shown in Figure 6, more than half of the trainers had problems in using the system. Among them, 55.6% of the trainers thought that they would need the support of a technical person to be able to use the system. A main issue of the system, as identified by Trainer #1, was on the sensitivity in capturing the trainers’ hand movements, which interrupting their control of the system. Thus, the trainers relied on the immediate feedback from the system, as commented by Trainer #1, to verify the commands they gave to the system.

**Figure 6.** User experience of the virtual pointer in the surgical training. (UE: user experience; The numbers in the circle show the medians of the ratings.)

### Positive Attitude on the Virtual Pointer for Training

All trainers (M = 6.0, p = 0.007) and 66.7% trainees (M = 6.0, p = 0.063) agreed that using the Virtual Pointer in training was a good idea (Figure 7). 66.7% trainers (M = 6.0, p = 0.026) and trainees (M = 5.5, p = 0.059) agreed that Virtual Pointer was beneficial to trainees’ learning outcomes. Of all participants, only two trainers felt that using the system in training was unpleasant.

**Figure 7.** Attitude towards using the Virtual Pointer in surgical training. (A: attitude; The number in the circles show the medians of the ratings.)

### Intention to Use the Virtual Pointer

Although the trainers held a significantly positive attitude on the Virtual Pointer, they were conservative on using the Virtual Pointer in the lab (M = 5.0, p = 0.107), or the operating rooms (M = 5.0, p = 0.230). On the contrary, the trainees, who were moderately positive on the Virtual Pointer, would like to use the system in the lab training (M = 5.5, p = 0.026), but not in the operating rooms (M = 4.5, p = 0.257). Moreover, for using the system in varying difficulty levels, the approximate balance between ‘agree’ and ‘disagree’ indicates that case difficulty is not a decisive point for trainers and trainees to use the Virtual Pointer.

### Factors Associated with the Acceptance of Virtual Pointer

The Spearman’s correlation between the questions allows us to investigate the factors associated with the acceptance of the Virtual Pointer in surgical training. Mann Whitney U tests were conducted to assess any significant difference for any common questions shared between the trainers and trainees. No significant difference was found. Thus, we combined these two groups for the responses of the common questions in the correlation analysis. Besides, due to the
observed irrelevance of case difficulty for the use of Virtual Pointer, we excluded questions on the case difficulty (IE4, 5) and focused on the factors associated with the use in the lab and operating rooms (IE1, 2).

As shown in Table 1, the use of Virtual Pointer in the simulation lab (IE1) was significantly correlated with the support for task completion (TP1), acquired knowledge (AK1 – 5), and positive attitude on learning outcomes (A3). The use of the Virtual Pointer in the operating rooms was significantly correlated with the support for task completion (TP1), learning efforts (AK6) and acquired knowledge (AK1 – 3, 5). It is noteworthy that learning effort is significantly correlated with the use of the system in the operating rooms, while it is insignificantly correlated with the simulation lab. Task completion is more closely associated with the use of the system in the operating rooms, compared to the lab. On the contrary, acquired knowledge has a smaller effect on the use of the system in the operating rooms, compared to its high correlation with the use in the lab. Moreover, task completion (TP1) and learning efforts (AK6) were significantly correlated with the acquired knowledge, indicating that they may be the primary determinants of the usefulness of the system, as well as the acceptance of the system.

The Spearman’s correlations between unique questions for either the trainers or the trainees were further analyzed. Table 2 shows the correlations between trainer questions. Easy to use was significantly correlated with the use of Virtual Pointer in the lab and in the operating rooms. The satisfactory on the support of the system for conveying knowledge is significantly correlated with the use of Virtual Pointer in the operating rooms, while insignificantly
correlated with the use in the lab. The increase of desire to teach is significantly correlated with the use in the lab, but insignificantly correlated with the use in the operating rooms.

DISCUSSION

In this study, we evaluated the perceived usefulness and acceptance of the Virtual Pointer system, which was designed to support efficient knowledge sharing in surgical training, among senior surgeons and surgical trainees. The study suggests that conveying the gestures directly onto the laparoscopic video has the potential to support intraoperative communication and increase the efficiency of the performance. The participants liked the idea of directly pointing and drawing on the video. The Virtual Pointer was perceived to support the trainees efficiently identify the target referred by the trainers on the monitor, enhancing the trainees’ anatomical knowledge and their understanding of the procedure, minimizing the learning efforts, and facilitating the application of the knowledge into practice. The trainers found it easy to convey the knowledge with the system and could foresee the learning benefits their trainees would have in laparoscopic surgery with the improved mentoring strategy.

To date, extensive effort has been contributed in designing systems to support knowledge sharing in the healthcare environment, such as hand-off tools, information retrieving systems, and augmentative information display20-22. However, there have been limited studies examining the opinions and attitudes of users of such systems, or novel concepts in HIT23, even though user perceptions and preferences are essential in the success of system adoption21. Previous research tended to use the technology acceptance model (TAM) examining the users’ perceived usefulness16, 18. Our study suggests that although perceived usefulness from the users was an important factor, the root determinant is based on the perceptions of both the direct users and the stakeholders who would be affected by the system. For instance, in our study, the trainees are not the direct users of the system. Yet, their knowledge acquisition process is the main concern in the surgical training and in the trainers’ consideration of using the system in the lab or the OR. Besides, we found that the user experience of the system affects how the system is perceived to be used, when it would
be used, and the system efficacy. Responses in our open questions suggest that for a system to be implemented in the surgical environment, the main concern is on the accuracy of the information the system provides and the interruption it may cause into the surgeons’ workflow.

Different users even from similar professional backgrounds use the systems in different ways\textsuperscript{24}. In this study, we captured perceptual nuances of how the system would be used, what it would achieve, and where it could be used. This information could be used not only to validate technology objectives, but also to identify the target cases and environments for deployment, and to envision hindrances for implementation.

The different associated factors between the use in the lab and the use in the operating rooms reflect different system requirements in these two training environments. In the lab training, where trainees can gain proficiency in a safe environment, the system should support the initial learning, where a vast of factual knowledge is recalled and built up, motor skills are developed, and strategies are encouraged to be developed and tested out. In the operating rooms, where patient safety is emphasized, the system should target at improving the quality of performance, making the anatomical variants salient to minimize trainees’ effort in learning to see the field.

It is interesting to find that the trainees intended to use the system in the lab only, although the operating rooms are the key place for the trainees to gain expert vision on the anatomical structure and the decision making to proceed. Our correlation analysis between questions reveals several factors that hinder the acceptance of the system. The user experience is directly related to the success of the system adoption. However, the trainee indicated the concerns that the system may distract them from their task. The distraction may be due to that the illustration was shown on a secondary display, so that the trainees needed to frequently switch their attention between the laparoscopic video, which they were working on, and the Virtual Pointer screen, which they gained information from. This barrier highlights that the lag should be solved and the pointing and telestrating should be integrated into the trainees’ monitor. Besides, the trainers had problems in using the system. The trainers would need the support of a technical person to be able to use the system. They found the gestural and voice control was not very reliable. This barrier could be solved by providing a training session, where the system could be tested out by the users and further configured to recognize the gesture and speech of the individual surgeon. In addition, the system may interrupt the operation as the system required the trainer to pause the procedure and put down the instruments, waving in the air to draw any annotation. To address this issue, new interaction mechanisms that do not depend on arm movements can be designed to control the system. Furthermore, the system lacks precision. The trainees must spend extra effort to identify inaccurate annotations on the monitor, discuss them with the trainer, and make judgments on how to proceed. This suggests the algorithm to be improved to accurately relate the hand position to the pointer.

In this study, we evaluated the system in the Society of American Gastrointestinal Endoscopic Surgeons (SAGES) Annual Meeting, where most attendees are American surgeons. The strength of this setting is that it provided us a diverse pool of American surgeons from different hospitals. However, we acknowledge that surgical training varies among different countries. For example, residents may enter the OR at different levels or they may be trained using different tools. These factors may influence the efficacy of the system in surgical training. Besides, although, we have a rich collection of the trainers, who are the targeted user of the system, we have a limited sample size of the trainees. However, we identified the trend of perceived usefulness in the trainees’ responses and the trend was verified by the trainers’ perceived usefulness.

CONCLUSION

To facilitate the efficient conveyance of expert knowledge in laparoscopic training, we hypothesized to convey the gestures onto the video and designed the Virtual Pointer system that enables trainers to point or draw freehand sketches over a video for a trainee to see. In this study, we evaluated the perceived usefulness and acceptance of the system in surgical training. Our study indicates that conveying the gestures directly onto video is an effective and useful approach for the communication between surgeons. Barriers in the acceptance of the system highlight the design of novel interaction mechanisms to unobtrusively integrate this technique into the surgical workflow.

Acknowledgements

The authors gratefully acknowledge SAGES for equipment support. This work was partially supported by NSF Grants IIS #1422671 and #1552837. The authors thank Hannah McGowan for editing the manuscript, and the SAGES conference committee for the support of surgical instruments, training equipment, and the space.

Abstract

We examined the current state of digital health tracking and information sharing with health professionals among patients with chronic conditions using data from the National Cancer Institute’s 2018 Health Information National Trends Survey (HINTS). Descriptive statistics were used to examine the characteristics of health tracking and information sharing. Chi-squared tests were used to compare across groups, and multivariate logistic regression models were used to control for covariates. Between 17.4-37.6% of respondents reported sharing information with a health professional through either e-mail, monitoring device, text message, or online medical record message. There were sociodemographic differences across health tracking and information sharing modalities, and patients with chronic conditions disproportionately lacked Internet access, a basic cell phone, smartphone, or tablet compared to those without chronic conditions (p<0.05). This suggests there are sociodemographic and technology-based disparities for health tracking and information sharing for patients with chronic conditions.

Introduction

There is growing use of mobile health (mHealth) technologies, including smartphones, apps, wearable devices, and remote monitoring devices, to capture health-related data. Given the near ubiquity of mobile phones, with 95% of U.S. adults owning a mobile phone and 77% owning a smartphone in 20181, digital approaches are a promising way for patients to monitor their health due to their portability and convenience. The ability for patients to access, track, and share health information also provides opportunities for caregivers and care teams to longitudinally monitor behaviors and for interacting with the health system. Sharing health information with the care team facilitates patient-centered care through increased awareness, improved communication, and the ability to capture and transmit patient-generated data to incorporate into clinical care2. Further, the secondary use of patient-generated health data (PGHD) has been valuable in accelerating clinical, public health, and research insights3-5.

There are a number of national initiatives that have set a high priority for promoting data access and sharing for patients. The Centers for Medicare & Medicaid Services Meaningful Use Program (recently renamed the Promoting Interoperability Program) requires eligible professionals and health systems to provide increasing amounts of data access to patients, such as the ability to view, download, or transmit health information to a third party, and to use secure electronic messaging to communicate with health professionals (Stage 1 and 2)6. In 2019, patients must have access to their health information using a third-party app of choice through an Application Programming Interface (API)7. In February 2019, the Office of the National Coordinator for Health Information Technology also proposed a new rule to support individuals in the secure access, exchange, and use of their health information electronically8 to facilitate healthcare system adoption of APIs. This proposed rule discourages information blocking by healthcare systems, payers, and vendors as detailed in the 21st Century Cures Act8. Progress has also been accelerated by the release of an API built on the Fast Healthcare Interoperability Resources (FHIR) standard by the Health Level Seven (HL7) International Argonaut Project9, which allows interoperability between electronic health records and apps, such as Apple HealthKit10. Additionally, the Centers for Medicare & Medicaid Services proposed policy changes to the MyHealthEData11 and Blue Button 2.012 initiatives to improve access, data exchange, and care coordination for beneficiaries through APIs and trusted exchange networks13. Furthermore, research programs, such as the National Institutes of Health All of Us Research Program, which seeks to create a national research resource to study how individual differences in biology, environment, and lifestyle factors influence health, relies on individuals to share information about their health using APIs and other methods14.

Being able to leverage patient health data for clinical care relies on a patient’s access, ability, and willingness to collect and share digital data with health systems15. Several sociodemographic characteristics influence access and use of technologies, such as educational attainment, age, race/ethnicity, health status, and Internet access16. Understanding

1041
the characteristics that could influence digital health tracking and information sharing may allow health professionals to better understand who is likely to share PGHD and identify those who could benefit the most from sharing data. While not all patients will equally benefit from sharing PGHD (e.g., healthy individuals or those with a well-managed condition), data sharing may be particularly important for patients with chronic conditions as digital technologies can facilitate communication, real-time monitoring, or tailored coaching from the care team\(^2\). Patients with one or more chronic conditions may also have a greater need for health tracking and sharing health information with healthcare professionals\(^{17-20}\). While there is evidence that health tracking and data sharing may vary across sociodemographic factors, the latest HINTS survey data from 2018 allows the opportunity to extend prior research by expanding on how different communication modalities are associated with sociodemographic characteristics and chronic conditions\(^{20,21}\). Thus, the objectives of this study were to: 1) describe the current state of health tracking and health information sharing across sociodemographic variables and the number of chronic conditions, and 2) examine the relationship of various modalities through which one can share health information with health professionals among patients with chronic conditions in a nationally representative sample.

**Methods**

Data were from the National Cancer Institute’s 2018 Health Information National Trends Survey (HINTS) 5 Cycle 2, administered January to May 2018\(^{22}\). HINTS is a survey administered to a nationally representative sample of U.S. adults to measure how individuals access and utilize health information\(^{22}\). Survey questions related to health tracking were selected from the larger survey data set including: 1) “Has your tablet or smartphone helped you track progress on a health-related goal such as quitting smoking, losing weight, or increasing physical activity?”; 2) “Other than a tablet or smartphone, have you used an electronic device to monitor or track your health within the last 12 months? Examples include Fitbit, blood glucose meters, and blood pressure monitors”; 3) “In the past 12 months, have you used your online medical record to securely message health care professional within the last 12 months?”. Question 1-3, responses included “Yes” or “No.” For question 4, responses included “0”, “1 to 2 times”, “3 to 5 times”, “6 to 9 times”, or “10 or more times”\(^{22}\). Survey questions related to health information sharing included the following: 1) “In the past 12 months, have you used a computer, smartphone, or other electronic means to e-mail or [use] the Internet to communicate with a doctor or a doctor’s office?”; 2) “Have you shared health information from either an electronic monitoring device or smartphone with a health professional within the last 12 months?”; 3) “Have you sent a text message to or received a text message from a doctor or other health care professional within the last 12 months?”; 4) “In the past 12 months, have you used your online medical record to securely message health care provider and staff (for example, e-mail)”? Response options for these health information sharing questions were: “Yes”, “No”, “Don’t Know”, or “Not applicable.” “Don’t Know” and “Not applicable” responses were categorized as “No”\(^{22}\). For chronic conditions, respondents were asked whether a healthcare professional had ever diagnosed them with the following: diabetes or high blood sugar; high blood pressure or hypertension; a heart condition such as a heart attack, angina, or congestive heart failure; chronic lung condition, asthma, emphysema, or chronic bronchitis; arthritis or rheumatism; depression or anxiety disorder; or cancer.

All analyses were conducted using survey weighting and jackknife variance estimations provided by HINTS to be nationally representative of the U.S. adult population\(^{22}\). All analyses were conducted using SAS (version 9.4, Cary, NC, U.S.). A variable was created for the number of conditions (0 conditions, 1-2 conditions, or 3+ conditions). Descriptive statistics were used to show the characteristics of health tracking and health information sharing. Chi-squared tests were used to compare across groups of patients with 0, 1-2, and 3 or more chronic conditions. To examine the relationship among patients with chronic condition(s) and various information sharing modalities, four multivariable logistic regression models were used to control for relevant covariates with each model estimating the information sharing modality (e-mail, text message, secure online medical record message, and electronic monitoring device). The multivariate models to estimate information sharing via e-mail, text message, and online medical record message only included respondents who had Internet access, at least a basic cell phone, or had ever been offered access to the medical record by a health care provider or health insurer respectively. In the model to estimate information sharing through an electronic monitoring device or smartphone, all respondents were included because there was no survey question that specifically asked about ownership of an electronic monitoring device or smartphone. All models were adjusted for the following covariates: gender, age, race/ethnicity, region, education, household income, occupation, marital status, time since most recent check-up visit, caregiver status, health insurance status, and chronic conditions.
Results

The final analytic sample was comprised of 2,439 respondents after excluding 1,065 respondents who had incomplete sociodemographic data. To compare differences between included and excluded cases, we conducted a bias analysis which showed that excluded respondents may have been less diverse than the general population and were more likely to be older and female (p<0.05). The sample had 48.33% females and a mean age of 53.02 years with a SD of 19.01 years (see Table 1). Respondents were primarily Caucasian, less than 65 years old, resided in an urban location, completed some college or attained a college degree or more, had a household income over $75,000 per year, visited a doctor for a routine check-up within the past year, and had one or more chronic conditions. The majority of respondents (61.09%) accessed the Internet through multiple networks (e.g., Wi-Fi, cellular, etc.), but 12.25% reported that they did not have access to the Internet. Over half of participants (56.42%) had multiple electronic devices (e.g., smartphone, tablet, etc.). There were 3.60% of respondents that reported that they did not have any electronic devices and 7.36% had only a basic cell phone. Age, race/ethnicity, education, income, occupation, time since most recent check-up visit, being a caregiver, having health insurance, Internet access, and electronic device use were associated with the number of chronic conditions (p<0.05).

Health Tracking and Health Information Sharing Characteristics. Health tracking and health information sharing proportions varied across respondents with 0, 1-2, and 3 or more chronic conditions (see Table 2). For health tracking, 43.16% of respondents used a smartphone or tablet to track progress on a health-related goal such as losing weight, quitting smoking, or increasing physical activity. Approximately 11% reported not having a smartphone or tablet. Other than a smartphone or tablet, 36.74% of respondents used an electronic device, such as a blood pressure monitor, blood glucose meter, or Fitbit, to track their health within the past 12 months. In terms of accessing online medical records (OMR) at least once in the past 12 months, 31.67% of respondents indicated that they had done so, however only 17.35% downloaded it to a computer or mobile device. Using an electronic device, smartphone, or tablet to track health and accessing or downloading the OMR onto a computer or mobile device were associated with the number of chronic conditions (p<0.05).

For health information sharing, the most common modality for sharing was e-mail or via the Internet with 37.61% using e-mail or the Internet to communicate with a health professional within the past 12 months. 30.73% of respondents sent/received a text message to/from a health professional, but 3.60% did not have a basic cell phone. There were 17.63% of respondents who shared health information from an electronic monitoring device or smartphone with a health professional. While 17.35% sent a secure message to a health professional through their OMR, nearly half of participants (46.62%) did not have access to their OMR. E-mailing, secure messaging through the OMR, and sharing information from an electronic monitoring device were all associated with the number of chronic conditions (p<0.05).

Health Information Sharing Across Modalities. Sociodemographic characteristics of respondents varied across modalities of health information sharing through e-mail, text message, OMR message, or an electronic monitoring device/smartphone (see Table 3). Across all modalities, individuals with one or more chronic conditions had at least 1.50 or greater odds of sharing health information with a health professional compared to those without chronic conditions (p<0.05). Notably, respondents with three or more chronic conditions had 3.61 higher odds of sharing...
health information with an electronic device or smartphone with a health professional compared to those without chronic conditions (p<0.01).

Among respondents with Internet access, those who were male, 65 years and older, or had their most recent check-up three or more years ago had lower odds of e-mailing a health professional. Those who had at least a college degree, household income >$75,000, or had more than one chronic condition had higher odds of e-mailing a health professional. For text messaging with a health professional, those who were male, disabled, or without health insurance had lower odds of texting, while those who had more than one chronic condition had higher odds of texting. In terms of using an OMR for messaging, those who had one or more chronic condition had greater odds of doing so than those without chronic conditions. For sharing information using electronic devices or smartphones, those who were 50-64 years old or those who had their most recent check-up greater than a year ago had lower odds of sharing. Those who were African American, made $50,000 or more, or had more than one chronic condition also had higher odds of sharing information.

Table 3. Odds ratios (SE) of health information sharing across modalities during the past year.

</table>
Advancements in digital technologies offer unique opportunities for patients to remotely monitor their health and to share these data to inform clinical decision-making. Data sharing could also be accelerated by mitigating infrastructure and technical barriers such as access to broadband Internet and providing technical support to patients to assist them with accessing and using technologies that facilitate tracking and data sharing. Efforts could include tailored patient training materials for various communication modalities, such as e-mail, personal health record, or text messaging since a patient’s preference and proficiency for using these may vary based upon sociodemographic attributes such as age, health literacy, or technology usage. Trustworthiness and privacy may also limit patients’ willingness to share
data with health professionals, so transparent policies that are described in patient-friendly language could help improve patients’ understanding and comfort with data sharing.

Additionally, reimbursement and organizational policies could address barriers to access and information sharing. While much progress has been made to facilitate data sharing, continued efforts focusing on reimbursement, interoperability, and addressing health professionals’ concerns about information sharing will help to advance information sharing. Centers for Medicare & Medicaid Services has made progress in reimbursing health care professionals for communicating and monitoring patients from home with the introduction of three new CPT codes in the 2019 Physician Fee Schedule and Quality Payment Program\textsuperscript{28}. These new codes allow for reimbursement for 20 minutes or more of communication with the patient or caregiver per month, remote monitoring of physiological parameters (e.g., weight, blood pressure, pulse oximetry) with daily recordings or programmed alerts, and patient education and set-up of the devices\textsuperscript{28}. This new reimbursement landscape provides opportunities for enhanced patient-health professional communication, but it is vital to address health professional concerns such as effective use and monitoring of these new data streams\textsuperscript{29-31}. For example, providing meaningful visualizations and summarizations of the data as well as incentives to incorporate PGHD into routine clinical workflows could help with the use of these data in clinical care\textsuperscript{31}. Since reimbursement is tied to patient experience through Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) scores\textsuperscript{32}, there is also an increasing focus on improving patient satisfaction. Providing access to health tracking and information sharing modalities based on individual’s health or technology needs could improve the patient experience through enhancing communication and care management. In the current healthcare landscape, it is still challenging to operationalize the collection and exchange of digital data across healthcare systems for clinical care, quality, and research. The Office of the National Coordinator for Health Information Technology released a 2019 Interoperability Standards Advisory that updated standards for health data to encourage data exchange among patients and health professionals\textsuperscript{33}. However, as the U.S. healthcare system continues to shift towards value-based care, greater efforts to increase patient engagement with tracking and data sharing are necessary, and these should align with quality and payer measures.

**Limitations.** The HINTS survey is a cross-sectional survey, which does not allow for examining causal relationships between variables. The survey is self-reported and lacks variables that may be highly correlated with health tracking and information sharing, such as health literacy, patient activation or engagement, or sociocultural factors. The survey does not assess all the potential modalities of health tracking and communication such as non-electronic mediums (i.e., paper-pencil tracking) which could also be useful in managing conditions. Despite these limitations, this study contributes to health tracking and communication research by expanding upon how various communication modalities are associated with sociodemographic characteristics and chronic conditions in a nationally representative sample of U.S. adults.

**Conclusions**

Patient access to technologies that enable tracking and sharing of health information is important to facilitate personalized and collaborative care, particularly for patients with chronic conditions. Sociodemographic differences exist across health tracking behaviors and information sharing modalities. Access to the Internet, electronic devices, or smartphones is limited among patients with chronic conditions. Additionally, access to online medical records is still limited to all patients overall. As consumer health technologies become more sophisticated, additional research is needed to determine whether these further widen health disparities, particularly for patients with chronic conditions. Future research should also examine longitudinal trends in tracking health and information sharing as the context and needs of patients evolves over time, as well as their impact on health outcomes.

Leveraging Contextual Information in Extracting Long Distance Relations from Clinical Notes

Hong Guan, MS and Murthy Devarakonda, PhD

Biomedical Informatics, College of Health Solutions
Arizona State University, Tempe, AZ

Abstract
Relation extraction from biomedical text is important for clinical decision support applications. In post-marketing pharmacovigilance, for example, Adverse Drug Events (ADE) relate medical problems to the drugs that caused them and were the focus of two recent shared challenges. While good results were reported, there was a room for improvement. Here, we studied two new improved methods for relation extraction: (1) State-of-the-art deep learning contextual representation model called BERT, Bidirectional Encoder Representations from Transformers; (2) Selection of negative training samples based on the “near-miss” hypothesis (the Edge sampling). We used the datasets from MADE and N2C2 Task-2 for performance evaluation. BERT and Edge together improved performance of ADE and Reason (indication) relations extraction by 6.4-6.7 absolute percentage (and error rate reduction of 24%-28%). ADE and Reason relations contained longer text between the entities, which BERT and Edge were able to leverage to achieve the performance improvement. While the performance improvement for medication attribute relations was smaller in absolute percentages, error rate reduction was still considerable.

Background and Significance
Relation extraction is an important problem in biomedical NLP because it helps to identify critical elements of patient care, such as the medications causing adverse drug events, reasons for treatments, and bases for diagnosis, outcomes, and treatment changes, from clinical text. Even in the general domain NLP, relation extraction is an active and ongoing research area. We studied two new strategies for exploiting contextual information to improve relation extraction performance.

One strategy was to use the state-of-the-art neural network model called BERT, Bidirectional Encoder Representations from Transformers, which was shown to achieve significant performance improvement in general domain NLP tasks over task-specific neural architectures that used word2vec, GloVe, or ELMo word embeddings as features. BERT achieves performance improvement in two ways. First, by using multiple layers of bidirectional Transformer encoder blocks which are based on the self-attention model and second by using a learning model that predicts randomly masked tokens in a sequence, called Masked Learning Model (MLM) which is based on the Cloze procedure in Journalism. The self-attention model was shown to better leverage context compared to the neural networks that use LSTMs (Long Short-Term Memory neural networks) and CNNs (Convolutional Neural Networks). Furthermore, BERT pre-trained model only required fine-tuning with task-specific training data and a simple feed forward layer with softmax to predict relation labels.

The second strategy was to use the “near-miss” hypothesis in selecting negative training samples. Typically, negative samples far exceed positive samples in a training set, and the standard approach is to down sample using random selection. But, the strategies used in active learning suggest potential benefits of using near miss samples. A near miss is a negative sample that differs from the learned concept in only a small number of significant points. In psychology of game playing and in AI learning and reasoning, it was observed that the near misses have a significant effect on the outcome. Here, we propose the Edge sampling, which selects negative samples such that relation entities in it are at the “edge” of (or close to) the corresponding positive sample entities in the text. Thus, an Edge negative sample shares a significant text with the corresponding positive sample and yet differs from it by some text (i.e. follows the near-miss hypothesis).

Two recent biomedical NLP challenges focused on Adverse Drug Event (ADE) relation extraction from clinical notes, Medication and Adverse Drug Events from Electronic Health Records 1.0 (MADE) and National NLP Clinical Challenges Task 2 (N2C2). Two obfuscated examples from MADE are shown in Figure 1. While the top performing systems achieved high accuracy (mid to high 0.9 F measures) in extracting medication attribute relations, such as drug-dosage, drug-route, and drug-strength, they substantially under performed on all important ADE and Reason relations.
(indication) relations (mid to high 0.7 F measures). The ADE and Reason relations typically occur over long distances (e.g. up to 501 words apart in MADE) (see Figure 1) and hence there is a challenge and an opportunity to leverage contextual information in these long-distance relations. Here we, therefore, studied the impact of BERT and the Edge sampling on extracting long distance relations using the two datasets.

Example 1:

Example 2:

Mr. [** Name **] comes back for followup examination to pay for peripheral neuropathy. He is approximately 4 weeks status post last cycle of chemotherapy with bendamustine, bortezomib. Early on with this chemotherapy, he had some nausea and vomiting, but has recovered from the same. His other issue of concern at this time and has been some tingling and numbness of his feet and loss of sensation in the tip of his fingers. This probably is related to bortezomib.

Color keys for entities: drug, strength, duration, and ADE
Color keys for relations (indicated by arrows): drug to duration, drug to strength, ADE to drug positive relation, and ADE to Drug negative relation

Figure 1. Relations in the ADE challenges. Example 1 shows medication attribute relations, and Examples 2 shows a positive ADE to drug relation and a negative ADE to drug relation.

Our results showed that BERT alone achieved substantial improvement over the top performing systems for the ADE/Reason relations and the Edge sampling provided additional improvement over BERT with random sampling. Further analysis showed distinct differences in the relation distances between ADE/Reason and medication attributes relations. Thus, this study established new state of the art performance for such long-distance relations in clinical NLP.

Methods

Datasets

The MADE dataset contained 1092 de-identified clinical notes of 21 cancer patients. Each note was annotated with medication information (i.e. drug name, dosage, route, frequency, and duration), ADEs, indications (reasons), other signs and symptoms (SSLIFS), and relations among those entities. The data was split into a training set of 900 notes and a test set of 180 notes.

The N2C2 dataset consisted of 505 discharge summaries from the MIMIC-II clinical care database. Each note was annotated with drug names, dosages, durations, and other entities, and relations of drugs with adverse drug events and other entities. The dataset was split into a training set of 303 notes and a test set of 202 notes.

Detailed characteristics of the two datasets are shown in Tables 1 and 2, which include the number of positive relations and potential negative relations in the training and test sets broken down by relation types. The ratios of potential negative relations to positive relations are also shown in the tables. It can be seen that the ratios are high in the training data of both sets, i.e. substantially more potential negative relations than the positive relations, and the ratios are even
higher in the MADE training dataset. Specifically, the ratio is 13.3 for the ADE-Drug relation, 12.0 for Reason-Drug, and 9.7 overall in the MADE training dataset. These high ratios indicate an opportunity to strategically select negative samples to optimize training.

**BERT (Bidirectional Encoder Representations from Transformers)**

BERT is a new exciting development in neural network models research, demonstrating significantly improved state-of-the-art performance on various general domain NLP tasks, including sentence classification which is relevant to us here. BERT is a pre-trained model that produces sequence (e.g., sentence) and word level representations, which can be fine-tuned for task-specific outcomes such as relation classification and concept extraction. Only a simple feed-forward network with a softmax layer is needed to process the BERT output for task-specific objectives.

In the last few years, word2vec has become the de facto standard for producing feature representations of words in biomedical NLP, which are then processed by task-specific neural architectures such as RNNs, LSTMs, CNNs, and heavily-engineered combinations thereof. On occasion, GloVe or ELMo were used instead to generate word representations, but still required complicated task-specific neural network engineering. BERT approach is to do away with the task-specific architectures and provide a broadly applicable pre-trained model which only need to be fine-tuned for the task, using task-specific training data. Other such approaches were also proposed, for example, OpenAI Generative Pre-trained Transformer (GPT), but BERT was shown to outperform them with a multi-layer bidirectional architecture.

As shown in Figure 2a, BERT uses layers of neural network components known as Transformer encoders, shown as $Tm$ in the figure, to generate representations of input sequences in the output. Each BERT layer processes its input sequence in the forward and backward directions simultaneously, using a novel pre-training objective known as the masked learning model (explained later). The BERT Transformer encoder contains two sublayers (see Figure 2b), the first sublayer is a multi-head self-attention mechanism that allows modeling of the context for each word position and the second is a feed-forward network that provides non-linear activation. The encoder architecture also included a residual connection around each sublayer which was shown to simplify optimization and a sublayer of normalization which reduced computational requirements. Fundamentally, the attention function provides a mapping of a query and a key-value pair to an output. Intuitively and as applied here, an attention layer produces output (say, a word representation) that is based on any arbitrary word positions (of the input sequence) by comparing each
sequence member with each other sequence member (self-attention) and producing a series of probability distributions to assign importance. Multi-headed attention can simultaneously optimize for different input combinations.

As mentioned earlier, in pre-training, BERT uses a novel pre-training objective known as the masked learning model (MLM), where some random words in the input are masked, and the pre-training objective is to predict the original word based on the context. In other approaches, typically next word prediction was used, which limited a multi-layered model to process the input either in the forward direction only or process in the forward and backward directions separately and then aggregate the representations – both these approaches fail to leverage the forward and backward contexts at the same time. The use of MLM was a key invention that enabled simultaneous bidirectional input processing in a multi-layer model, without allowing words-to-be-predicted appearing in the input of an upper layer.

The BERT model we used here came pre-trained with BookCorpus and English Wikipedia (general domain corpus). Corpus words were tokenized using the WordPiece dictionary of 30,000 words and as needed words were split into pieces using # (two hash marks). Word piece representations using biomedical corpus were not readily available at the time of our study, however, recently a BERT model was pre-trained on a biomedical corpus and it was shown to improve entity extraction. In the future, we plan to study performance of this BERT model, that was pre-trained on biomedical corpus, in relation extraction.

We employed BERT in its base configuration of 12 layers (~24 sublayers), 768 hidden size, 12 self-attention heads. In our configuration, BERT produced representations for each word (token) in the input as well as a single sequence representation (shown as CLS). This sequence classification representation from the top layer of BERT (see Figure 2a) was used as the input to a feed-forward layer containing one hidden layer. A softmax layer provided the final relation classification label for the pair of entities in the input sequence.

In our method, as shown in Figure 2c, the input to BERT was a sequence of words that started with the first entity of a relation and ended with the second entity of the relation. As previous studies demonstrated, this is a convenient choice since sentence segmentation of clinical notes text is error prone due to embedded lists and tables which are not well handled by the standard NLP code such as NLTK. We were also constrained by our BERT model input limit which was 512 word-pieces. Entity spans were further marked using the entity tags.

In the training (fine-tuning) stage, the input sequences included all positive samples in the gold standard and an equal number of negative samples, that were either randomly down sampled from all possible negative samples or Edge sampled as described in the next section. Only the sequences that were less than or equal to a heuristically determined (in the validation stage) maximum sequence length were used in training.

The Edge Sampling

In the MADE training dataset, there were 13.3 times as many potential negative samples as the positive samples for the ADE relation. In the N2C2 training dataset the ratio was 4.2. Ideally, the negative and positive samples should be equal for optimum model training. The new sampling method we propose here, called the Edge sampling, tries to select negative samples that share the largest common text (and hence context) with the corresponding positive samples, i.e. near-miss samples.

The Edge sampling works as follows. For each entity of a gold standard relation, the immediately preceding and following entities of the same type as the gold standard entity are identified (if they exist) in the text. From these four neighboring entities and from the original two entities from the gold standard, valid relations are formed by having one (and exactly one) of the gold standard entities as a part of the relations. Valid means the relation meets its entity type requirements and the entities occur in a sequence of words in the document. If entities in a gold standard relation are of different types (as in the case of relations in MADE and N2C2), at most four such new relations can be formed. This is illustrated in Figure 3. Note that, depending on the location and entities in a clinical note, we may find four or less, including zero, such new relations. If any of these relations were already in the gold standard or were picked already as a negative sample, they were removed from the list. Among the remaining relations, the Edge sampling randomly picks one.

If an Edge sample cannot be found for a positive sample, a random negative sample (that was not already picked) was selected from the rest of possible negative samples. Negative example selection takes place only in the training phase. During the evaluation and validation phases, all potential relations were assessed by the model and outcome measured.

Due to practical limitations, our model enforces a maximum sequence length, which is heuristically determined during the validation phase. In training, positive samples longer than the max length or ignored, and similarly in the Edge
Entity types of a relation type R are: $T_1$ and $T_2$

| Entity instances of type $T_1$ in the text (p and f indicate immediately preceding and following i) | $T_{1p}^i$, $T_{1i}^f$ |
| Entity instances of type $T_2$ in the text (p and f indicate immediately preceding and following i) | $T_{2p}^i$, $T_{2i}^f$ |
| Gold standard positive relation of type $R$, $R_i$ | $[T_{i1}, T_{2i}]$ |
| For $R_i$, Edge relation sequences are: $R_1$, $R_2$, $R_3$, $R_4$ | $[T_{11}, T_{21}], [T_{11}, T_{2f}], [T_{1p}, T_{2i}], [T_{1f}, T_{2i}]$ |

Figure 3. The Edge sampling illustrated.

We fine-tuned our BERT-based neural network model separately for MADE and N2C2, each with and without the Edge sampling. We therefore trained (fine-tuned) the model four different times and tested each one. We mostly adopted the default settings of BERT hyperparameters – i.e., training batch size of 16, 10 epochs, and a learning rate of $2e-5$. However, we experimentally determined the optimum sequence length using validation sets - 20% of clinical documents from the N2C2 training set and 10% of clinical documents from the MADE training set. The fine-tuned models were tested on the full MADE and N2C2 test datasets.

For each of the four experiments, we calculated standard Recall, Precision, and F measures individually for all relations as well as for all the relations combined. We compared our results with the published results of the systems that performed best in the task of relation extraction given gold entity labels from the two challenges: the University of Utah system$^{23}$ for MADE (denoted as the MADE_Best), and the UTHealth developed system$^{24,25}$ for N2C2 (denoted as the N2C2_Best). Since the published results did not aggregate performance for the ADE and Reason relations, we obtained their weighted average, weighted by the number of relations evaluated in the test phase, from individual relation results. We used two metrics for comparison: (1) Absolute F measure difference; and (2) Error rate reduction in the F measure achieved by model Y compared to model X, which is calculated as:

$$\text{error rate reduction} = \frac{F_Y - F_X}{1 - F_X}$$

where $F_Y$ and $F_X$ are the F measures of models Y and X respectively. While the absolute F measure difference shows the net improvement in the measure, the error rate reduction is a sound relative measure that shows reduction in the remaining performance gap of the previous model. It is usually expressed as a percentage. Recent studies in the general domain NLP have adapted this metric for effective comparison.$^{1,2}$

We suspected that for certain relation types, such as the medication attributes, the distance between the entities may be short and in which case the potential to leverage contextual information is rather limited. The two datasets might also be different in terms of the distances between entities, since N2C2 contains discharge summaries whereas MADE contains clinical notes. In order to quantify such differences, we studied the sequence length distributions of positive samples, Edge samples, and all negative samples for each dataset and plotted their cumulative distribution frequency.

### Results

Table 3 shows performance evaluation on the MADE dataset. Precision, recall, and F measures were shown for BERT (using random negative instances sampling) and BERT with the Edge sampling (shown as BERT+Edge) for each relation type, for the aggregate of ADE and Reason relations, and for all relations together. The table also shows...
absolute F measure differences between MADE_Best and BERT, BERT and BERT+Edge, and between MADE_Best and BERT+Edge. Percentage error rate reduction was shown between MADE_Best and BERT+Edge.

In terms of absolute F measure, BERT achieves 1.1% improvement overall compared to MADE_Best, but 4.1% improvement for the ADE and Reason relations. Edge improved the overall F measure by additional 1.6% compared to MADE_Best and by additional 1.9% for the ADE and Reason relations. BERT improved the Reason relation extraction F measure significantly (by 6.6%), while Edge improved the ADE relation F measure significantly (by 3.3%). Performance improvement from BERT+Edge over MADE_Best is substantial: absolute F measure improved by 2.7% overall and by 6.4% for ADE and Reason. Notice that the error rate was reduced by 22.7% overall and 23.6% for ADE and Reason. The error rate reduction was substantial for most relations.

</table>

Table 4 shows performance evaluation on the N2C2 dataset in the same way as in Table 3. The general trend of the results is similar to that of the MADE results but notably the absolute F measure improvement for the aggregate of all relations is somewhat smaller. BERT achieves a modest 0.7% F measure improvement overall and Edge managed to add additional 0.4% F measure to a total of 1.1% improvement. On the other hand, BERT improved the F measure of the Reason relation significantly, by 6.8%. The highest Edge F measure improvement was for the ADE relation, adding an additional 1.3% to BERT. While the F measure improvement from BERT+Edge over MADE_Best for all relations combined is relatively small, 1.1%, but the error rate reduction was a substantial 18.3% indicating that the
improvement in relative terms is still significant. The F measure improvement for the aggregate of ADE and Reason relations is 6.7%, and the corresponding error rate reduction was 28.3%, both of them indicate significant improvement. As in the case of MADE results, the error rate reduction was substantial for most relations. Precision and recall details were publicly unavailable for the N2C2_Best at the time of writing this paper.

**Statistical significance test:** Previous studies have used the McNamara test (and is generally accepted as a good test) for determining the statistical significance of F measure improvement of an NLP task. The test requires the contingency (confusion) table from the performance study. Using the data in our study, we determined that the F measure improvement with the Edge sampling was statistically significant at p<0.001 for the MADE dataset for all relations combined and for ADE+Reason relations. For the N2C2 dataset, the improvement was also significant at p<0.001 for all relations combined but was only significant at p<0.03 for ADE+Reason relations. We could not determine statistical significance of performance improvements relative to the MADE_Best and N2C2_Best models because the contingency tables for them are not publicly available at the time of this article.

Another important observation from Tables 3 and 4 is that the Edge sampling consistently improved precision, while often losing ground on recall. Edge improved precision for the overall and ADE+Reason by 4.1% and 5.7% for the MADE dataset, and by 1.2% and 2.3% for the N2C2 dataset respectively. Recall reduced by small percentages across the broad. These results indicate an important characteristic of our Edge sampling approach. We also note that both BERT and BERT+Edge consistently improved recall over MADE_Best.

The sequence length distributions of the positive, all negative, and Edge-sampled relations in the training datasets of MADE and N2C2 are shown in Figures 4 and 5 respectively. We showed the distributions for the ADE and Reason relations and for all the rest of relations. We showed detailed statistics of the distributions in Table 4. Two important observations can be made from the Figure and the Table.

First, the ADE and Reason relation lengths are significantly different from the lengths of the rest of the relations, especially those of the potential negative samples. In the MADE dataset, the median length of the ADE and Reason negative relations is 155 words, which is 4.3 times the median length of the rest of the relations (see Table 5). In N2C2, the ratio is more modest 1.7 times but it is still significant.

Second, the negative sample relation lengths in MADE are significantly longer than in N2C2 for the ADE and Reason relations. The median length of the relations in MADE is 3.04 times the median length of N2C2 negative relations, i.e. 155 versus 51. The median lengths of the rest of the relations are similar in both datasets.
While some differences exist between the two datasets, the ADE and Reason relations are consistently longer than the rest, and therefore, these sequences are likely to contain more context, which can be leveraged by BERT and the Edge sampling. The Figure and the Table also show that the Edge sampling, reduces the negative sample lengths. For example, the median lengths for ADE/Reason are 55 and 32 for the two datasets, which are substantially smaller than the median lengths of all negative samples (i.e. 155 and 51).

Discussion

The methods we used here, BERT and the Edge sampling, better leverage contextual information to improve relation extraction compared to the top performing systems from the shared challenges, MADE and N2C2. BERT makes better use of context in two ways:

1. Multiple layers of Transformer encoders based on the Attention model, rather than the RNN, LSTM, CNN, or combination models thereof, was shown to better leverage context;

2. Using the Masked Learning Model that randomly masks a word in a sequence for conditioning word representations to simultaneously analyze the input bidirectionally, rather than predicting merely an association of words (as in word2vec), or the next words (as in OpenAI GPT), or even a concatenation of representations predicting next and preceding words (as in ELMo).

In addition, BERT only required fine-tuning of a pre-trained model rather than complex task-specific neural networks that use word representations as features thus achieving transfer learning from a large text corpus. For these reasons, BERT in our study performed better than the top performing systems from the challenges. It is interesting to note that the MADE_Best employed a carefully feature-engineered Random Forest and N2C2_Best used complex composition of neural networks consisting of LSTMs and CNNs, and BERT improved upon both approaches.

Selection of negative samples in model training is known to be a challenge, especially when relation entities are multiple sentences apart which gives rise to a very large number of potential negative samples. Most previous studies simply down sampled the larger population, but one study considered a feature-engineered Alternating Decision Tree machine learning model for selecting candidate samples, both for training and testing. The Edge sampling, by preferring negative training samples that share significant context with positive samples, provides a simpler and in combination with BERT higher accuracy compared to the previous candidate selection approach on the MADE dataset.

In can be observed from the results that the performance improvement achievable from contextual information depends on the length of context between relation entities. Quantitatively, the relation distance differences between ADE/Reason and medication attribute relations can be seen in Figures 4 and 5, and in Table 5. Qualitatively, as can be seen from the examples in Figure 1, medication attributes tend to appear in short segments and often have a simple and easy to recognize patterns. These simple patterns can be easily recognized more easily and indeed, the previous studies have achieved very high F measures, often above 0.95, by recognizing such patterns. Whereas, the entities of ADE and Reason appear anywhere and in complex discourse in a clinical document. These typically longer relations offer an opportunity for the sophisticated neural architecture of BERT to create better representations, and hence increase F measure accuracy substantially. It should however be noted that the error rate reduction is significant across most relations with BERT plus Edge.

The Figures 4 and 5, and the Table 5 also show that the Edge sampling, not only takes advantage of the contextual information (by definition) but also reduce the negative sample lengths and make their lengths similar to the positive samples. As we noted earlier, the Edge sampling disproportionately improves precision over recall, which we plan to study further to understand the reasons for it and how it can be leveraged further.

Conclusion

This study makes the following important contributions:

1. We showed that the BERT model, which leverages bidirectional contextual information with multi-layer Transformers, requiring only fine-tuning can provide excellent performance in biomedical relation extraction without complicated, task-specific neural network designs containing RNNs, LSTMs, and CNNs.

2. We showed that the “near-miss” based the Edge sampling of negative instances, rather than random selection, can improve training and therefore model performance especially when there is a large population of potential negative samples to choose from and when relation sequences are long enough to form “near-misses” from positive samples.
3. Both BERT and Edge use contextual information in long distance relations to achieve significant performance improvement. The performance improvement, compared to the previous methods, was substantial for such relations (i.e. ADE and Reason relation): 6.4% absolute F measure improvement (23.6% error reduction) for the MADE dataset and 6.7% absolute F measure improvement (28.3% error reduction) for the N2C2 dataset.

Abstract

Noninvasive vagal nerve stimulation (n-VNS) devices have the potential for widespread applicability in improving the well-being of patients with stress-related psychiatric disorders. n-VNS devices are known to affect physiological signals, and, recently, they have been employed in various protocols involving both acute and longitudinal applications. However, questions regarding response time, “dosage,” or optimal treatment paradigms remain open. Prior work evaluated noninvasively obtained biomarkers that quantify the stimulation efficacy based on the changes in autonomic tone in a randomized double-blind study. In this work, we extend the state-of-the-art by investigating the onset of action for n-VNS in these same physiological biomarkers through a three-day clinical trial, including 233 administrations on 24 human participants, with and without immediately preceding acute traumatic stress. Determining n-VNS latency serves as a substantial step toward optimizing stimulation delivery with higher temporal resolution for personalized neuromodulation.

Introduction

The vagus nerve is a major component of the autonomic nervous system, consisting of afferent (sensory) and efferent (motor) connections to regulate autonomic tone and maintain homeostasis¹. Electrical stimulation of the vagus nerve is hypothesized as a “bottom-up” therapy that acts on the vagal afferents through the nucleus tractus solitarius (NTS), which projects to the brain areas that regulate mood and emotion, such as the amygdala, hippocampus and prefrontal cortex¹,³ (see Figure 1 for the representation of a simplified mechanism of action). Through the modulation of vagal afferents, efferent connections carry information to regulatory organs that modulate autonomic state, such as the heart. Surgical implants for vagal nerve stimulation (VNS) appear effective in the treatment of several psychiatric and cardiovascular disorders, such as epilepsy, depression, migraines, and heart failure⁴–¹². Though high variability in treatment response has been observed with open-loop approaches, various closed-loop algorithms have been proposed for implantable VNS devices using measures related to the heart rate¹³–¹⁸ or neural response¹⁹. Indeed, compared to their open-loop counterparts, the closed-loop implementations of these algorithms on VNS implants in the market have proven effective in improving clinical outcomes²⁰. However, widespread adoption is limited due to the potential for adverse events during implantation and the normal cost and practical challenges associated with implantable devices²¹,²².

Noninvasive VNS (n-VNS) devices provide advantages in terms of usability and low-cost, with proven effects on central brain regions²³–²⁶, cytokines, and patient physiology²⁷–²⁹. Therefore, n-VNS devices have the potential to address many shortcomings of their implantable counterparts, potentially improving patient adherence and broadening use³⁰. Their operation, however, is currently limited to open-loop applications prescribed by the medical professional. Translating implantable closed-loop technologies to the noninvasive neuromodulation realm is not straightforward; the physiological measurements should also be obtained noninvasively, leveraging wearable sensing modalities. Moreover, the effects of n-VNS on human physiology would likely differ from the transient responses to implantable

*Authors equally contributed to this work.
Figure 1. Simplified representation of n-VNS mechanism of action. The understanding of n-VNS kinetics on noninvasively obtained physiological parameters may enable optimization of n-VNS delivery in unsupervised settings. NTS: nucleus tractus solitarius.

VNS observed and quantified in preclinical studies due to the skin-electrode impedance, the filtering effects of the skin as a barrier between the stimulation site and the vagus nerve, and the time it takes to adjust the stimulation amplitude per subjective tolerance[^31]. For instance, implantable VNS has sub-second effects in anesthetized animals[^32],[^33] and has been modeled for electrodes that are in direct contact with the nerve[^34],[^35]. Latency for the physiological effects of n-VNS would likely be greater than implantable stimulation due to the mentioned differences regarding the electrode-skin-tissue barrier. Determining the onset of action for n-VNS provides pertinent information on n-VNS kinetics in continuous physiological signals germane to design specifications for wearable sensing systems; this, in turn, advances us one step further toward closing the loop for improved n-VNS treatment quality.

Prior work introduced and evaluated downstream cardiovascular and peripheral biomarkers of cervical n-VNS that quantify the physiological response to acute treatment using noninvasively obtained signals; the effects of n-VNS when applied after laboratory-induced psychological stress were also explored[^36]-[^38]. Statistics involving said biomarkers were presented as static outcomes based on average changes from a baseline state upon acute stress application. These biomarkers included heart rate (HR) as a measure of both sympathetic and parasympathetic influences, the pre-ejection period (PEP) of the heart as a measure of cardiac contractility and sympathetic activity, and the amplitude of peripherally measured photoplethysmogram (PPG) signals as a peripheral sympathetic measure. In this work, we extend the state-of-the-art by making the following contributions: (i) We analyze when these biomarkers change during stimulation on 24 human participants in a double-blind study, half undergoing active n-VNS and half undergoing sham stimulation; (ii) We propose a method to identify the latency between n-VNS initiation and the onset of n-VNS related physiological changes determined by the outset of expected changes in the instantaneous biomarkers; and (iii) To differentiate the physiological effects of n-VNS from possible placebo effects or other means of modulation, we applied the same latency identification method on the data obtained from the half who received sham stimulus at the same treatment area on the neck; we then compared both groups’ results. Our findings from 233 administrations suggest pertinent timing considerations germane to the design of effective clinical studies involving physiological effects of n-VNS.

Methods

Human Subjects Experiments

Figure 2. Protocol diagram. The protocol included three days: the first day included six traumatic stress prompts followed by immediate n-VNS or sham stimulation and two stimulation administrations without stress. Each of the second and third days included one stimulation administration without stress.
The study examines the physiological effects of n-VNS following acute traumatic stress. Investigating acute traumatic stress has clinical importance, as exposure to traumatic events can cause strongly encoded intrusive memories, or in contrast, impairments in memory function. These intrusive thoughts may persist in vulnerable individuals, possibly leading to posttraumatic stress disorder (PTSD). As traumatic stress is a trigger for PTSD symptoms, the protocol was designed around laboratory-induced traumatic stress exposure followed by stimulation. Note that stimulation also occurred on its own to understand possible physiological differences. The study was approved by the Institutional Review Boards of Georgia Institute of Technology, Emory University School of Medicine, SPAWAR Systems Center Pacific, and the Department of Navy Human Research Protection Program. A total of 24 adults who have experienced prior psychological trauma (ages mean ± SD: 31 ± 9 years, 12 females) were recruited, and written, informed consent was obtained. Each participant was asked to write his / her personal traumatic memories; later, voice recordings based on these memories were prepared for delivery as acute traumatic stress during the protocol. The traumatic stressors (each lasting for approximately one minute) were delivered audibly through headphones. Upon randomization for double-blind protocol, each participant was assigned to an active n-VNS or sham device having identical appearance, placement, and operation (GammaCore, ElectroCore). Participants, clinical staff, and researchers were blinded to the devices. Active n-VNS devices produce a 25 Hz voltage signal with 5kHz sine wave bursts. Sham devices produce a slow AC biphasic voltage signal with 0.2 Hz square pulses. The stimulation intensity ranges from 0 to 5 arbitrary units (AU), with a corresponding peak output ranging from 0 to 30V for active n-VNS, and from 0 to 14 V for the sham device. During each application, intensity was increased to a tolerable level determined by the participant. The amplitude levels participants received were 3 AU (± 0.8 SD) for active n-VNS and 4.5 AU (± 1 SD) for sham stimulus.

The protocol spanned three days for each participant (see Figure 2 for the protocol summary). On the first day, participants listened to their traumatic stress scripts as acute traumatic stressors (a total of six scripts per participant), and stimulation was applied immediately after each script. To understand the physiological changes for the stress-free (baseline) condition, this day also included two separate n-VNS/sham applications without traumatic stress scripts read immediately prior to stimulation. On both the second and third days, participants received one stimulation without a preceding stress script. Overall, the participants received six stimulations following six traumatic stress prompts and four stimulations without stress. Five participants did not complete all the traumatic stress prompts in the protocol. Excluding the missing data from these participants, there was a total of 137 traumatic stress prompts, followed by 137 stimulation administrations (72 active, 65 sham), and 96 administrations without stress (48 active, 48 sham). Each participant received approximately 10 administrations over the protocol days (233 administrations in total, 120 active, 113 sham).

**Physiological Sensing**

Noninvasive cardiovascular and peripheral signals were concurrently collected during the protocol. To measure the electrical activity of the heart, three-lead electrocardiography (ECG) signals were collected. As a blood volume pulse measure, finger-based transmissive photoplethysmography (PPG) signals were collected. Chest-wall vibrations (indicative of the mechanical activity of the heart) were measured using seismocardiogram (SCG). ECG and PPG signals were acquired using wireless amplifiers (Bionomadix RSPEC-R and PPGED-R, Biopac Systems). SCG signals were collected using a low-noise accelerometer placed on the mid-sternum (345A32, PCB Electronics, Depew, NY). All data were transmitted to a 16-bit data acquisition system (MP150, Biopac Systems) at a 2kHz sampling rate.

**Signal Processing and Feature Extraction**

Figure 3 summarizes the signal processing and feature extraction steps completed in MATLAB (R2017b, Natick, MA), also detailed in 36. All signals were first bandpass filtered with finite impulse response filters for noise reduction
using 0.6-25Hz, 0.6-40Hz, and 0.4-8Hz frequency ranges for SCG, ECG, and PPG signals, respectively, to maintain consistency with prior literature. The continuous physiological features extracted were HR, PEP, and PPG amplitude. First, R-peaks of ECG signals were located using thresholding. The R-R intervals were then calculated and converted to instantaneous HR in beats per minute (bpm). Second, SCG and PPG signals were segmented (ensemble averaged) referenced to the R-peaks of ECG signals. Third, SCG beats were exponentially moving averaged with a time constant of three beats to reduce the effect of motion artifacts. After segmentation, fiducial points of the beats were located by i) labeling the second peak of SCG beats as aortic opening (AO) point and ii) by finding the global maximum and minimum of PPG beats to extract PPG amplitude. The time interval from ECG R-peak to SCG AO point was extracted as instantaneous PEP (in milliseconds, ms), and the amplitude difference between global maximum and global minimum of each PPG beat was extracted as instantaneous PPG amplitude (in AU).

As the instantaneous variables are prone to corruption by motion artifacts, arrhythmias, and other complex mechanisms, they should not directly be used, as suggested in multiple works examining closed-loop physiological control. Therefore, we smoothed the instantaneous signals using local regression, assigning lower weight to the outliers and using a span of 5% of the total number of data points in a 25-minute interval. Smoothing provides new variables that reflect the transient changes associated with n-VNS.

Figure 4. Annotation diagram. The smoothed instantaneous biomarkers (HR, PEP, PPG amplitude) were plotted from pre-stimulus to post-stimulus. If at least two of the three mentioned changes in the biomarkers occurred, the onset time was marked at the onset of the second change. If no eligible change was observed, the annotation was marked as “absent.”

**Onset of Action Annotation**

The onsets of action following device initiation were annotated manually using the smoothed variables. Manual annotation was completed by three researchers. The researchers were instructed to peruse all participants' data prior to manual labeling. Based on our previous investigations and related implantable VNS literature, the anticipated changes following stimulation compared to the period before stimulation were: i) decrease in HR (i.e., decrease in sympathetic tone or increase in parasympathetic tone), ii) increase in PEP (i.e., decrease in cardiac contractility and cardiac sympathetic activity), and iii) increase in PPG amplitude (i.e., decrease in peripheral sympathetic activity). As multiple sensing modalities were used, occasional noisy measurements existed. Therefore, observing the occurrence of all three of these changes following each n-VNS administration was not expected. Thus, as indicated in in Figure 4, we located the first datapoint that satisfied two of the three aforementioned criteria and marked this time point as the onset time. These criteria were established and agreed upon prior to any manual labeling to ensure guidelines were not contorted to match desired results *a posteriori*. To find the corresponding onset of action, we subtracted the n-VNS start time from the labeled onset time. If only one of the three signals experienced noticeable change, the onset of action was marked as “absent.” Likewise, if no changes at all were observed or if all changes were relatively insignificant compared to noise and normal variation, the corresponding onset of action was marked as “absent.” To allow for independent sampling, we averaged the counts of absent onsets for each participant. Additionally, all annotations were independently performed by the three researchers to later assess the inter-annotator agreements for validation purposes. These were calculated as follows: pairwise agreements between the annotators were calculated in seconds (absolute difference between each onset time annotation) and in counts (agreement percentage for absent
onsets). The final agreement results reported are the overall average absolute difference in annotated onset times and the average percent agreement in absent onsets.

Statistical Analysis
To understand whether baseline characteristics and baseline biomarker measures were comparable between the active n-VNS and sham groups, demographic characteristics (age, gender, weight, height, body mass index) and baseline measures of the biomarkers (HR, PEP, PPG amplitude) were compared using two-sample t-tests for normally distributed continuous variables, Wilcoxon rank-sum tests for non-normal continuous variables, and chi-squared tests for categorical variables. The Shapiro-Wilk test was used to assess normality. Next, the Wilcoxon rank-sum test was used for absent onset count comparison between the groups. A two-sided threshold of p<0.05 was used to indicate statistical significance. All statistical analyses were performed using MATLAB Statistics and Machine Learning Toolbox.

Findings
Table 1 lists the baseline characteristics of the device groups and associated p-values, proving there are no statistical differences in either demographics or baseline biomarkers. The continuous physiological parameters from two representative participants in the presence of traumatic stress are shown in Figure 5, one participant undergoing sham and the other undergoing active n-VNS. The pre-stimulus values for each of the biomarkers are shown with dashed lines to provide a reference for the predicted deviations.

Table 2 lists the onset of action for active n-VNS for both with and without traumatic stress, as well as the absent onset counts comparing the active and sham device groups. Based on the physiological biomarkers used, the effects of n-VNS were observed 18 ± 7 seconds from the start of n-VNS without stress. When n-VNS was applied after traumatic stress (six traumatic stress scripts followed by six n-VNS per participant, n=12 participants), effects were observed on the biomarkers in a similar latency, resulting in 16 ± 9 seconds. As for the absent onset counts (n-VNS administrations that had not met the criteria), a significant difference exists between the device groups: there were 5 ± 2 absent onsets per participant for the sham group, significantly higher than the active group’s 2 ± 2 absent onset counts (p=0.006). There were 24 and 65 absent onset counts for 120 active n-VNS and 113 sham administrations, respectively. The overall average of inter-annotator agreements resulted in a 4 ± 1 seconds difference between the labeled onset times and a 90 ± 5.5% agreement in absent onset counts.
Figure 5. Continuous physiological parameters showing n-VNS without traumatic stress, for one participant undergoing sham (left) and one participant undergoing active n-VNS stimulus (right). Markers represent the extracted data, lines represent the smoothed data. Shaded regions represent stimulus delivery. Dashed lines show the pre-stimulus averages of the measures. The onset time is marked as soon as two of the three annotation criteria mentioned in Figure 4 are detected.

Discussion

This work investigated the onset of action for n-VNS as observed by noninvasive physiological signals. The time durations reported herein serve to estimate the onset of action for n-VNS, which can be used for clinical study design and to provide engineering considerations of closed-loop n-VNS therapy. The continuous signals from representative subjects in Figure 5 show the broad expected changes in the entire sample. The participant undergoing sham stimulus did not experience notable change in HR, PEP, and PPG amplitude during the stimulus, compared to the period before the stimulus. In contrast to the sham participant, the active participant experienced notable physiological modulation during the stimulus: a sudden drop in HR, keeping it below the pre-stimulus range during the stimulation. Additionally, PEP first recovered to the pre-stimulus range during the stimulation, then it exceeded this range by the end of the stimulation, indicating decrease in cardiac contractility and cardiac sympathetic activity. A latent increase in PPG amplitude compared to pre-stimulus was also observed, indicating decrease in peripheral sympathetic activity. These transient changes (decrease in HR, increase in PEP and PPG amplitude) could be interpreted as decreased sympathetic tone during the stimulation. Note that in this active participant, the PPG amplitude remained at a relatively increased level after the stimulus was removed, indicating a sustained decrease in peripheral sympathetic activity even after application. This finding was quite typical in active participants, supporting post-stimulus findings from our previous static analysis study. Another noteworthy set of differences between the active and sham responses deals with changes in these biomarkers prior to stimulus delivery, which can be seen in Figure 5. In particular, we observe a pre-stimulus spike in HR and decrease in PEP. These momentary increases in sympathetic tone prior to stimulus delivery
for active n-VNS could be related to anxiety and was quite typical in the overall sample set. During application, stimulation intensity is increased to as high a level as the subject can tolerate without pain. The active device delivers higher power than the sham device for the same intensity level, which might be perceived as a higher perturbation to the physiology.

As the vagus nerve is a complex structure that affects both sympathetic and parasympathetic activity, the timing of n-VNS effects will vary depending on the type of autonomic response. We observe that the effects in sympathetic measures, PEP and PPG amplitude, for the representative active subject are more latent than HR, another typical occurrence in the overall sample. Also notice that the peak effects in these biomarkers are observed towards the end of the stimulus period. In contrast, the physiologic response due to parasympathetic activation as seen in HR would occur sooner, as it is influenced by both sympathetic and parasympathetic changes. Sympatho-inhibitory phenomena (as observed in PEP and PPG amplitude in the context of this study) are regarded as slower than parasympathetic activation (seen in HR), which goes along with our observations.

**Timing Considerations for n-VNS Studies**

Mental stress studies are particularly important for psychiatry and the cardiovascular disease domain. Physiological responsivity to mental stress has been shown to carry cues on the identity and severity of several conditions such as PTSD, depression, anxiety, and coronary artery disease. Therefore, various types of stressors serve as clinical tools that could be induced in the laboratory under controlled conditions for diagnosis and prognosis purposes. Pairing stressors with vagal stimulation in attempts to improve mood, performance, or plasticity has been complementary to mental stress research and extensively studied in vagal stimulation studies with implants and recently with noninvasive vagal stimulation tools. Due to differences in stressors, their duration, or the application time of stimulation, the physiological outcomes have been variable, specifically in noninvasive studies. The onset time analysis from this randomized, double-blind trial could be instrumental to the design of clinical studies.

The findings of this study are also salient in the design of next-generation engineering tools to improve quality of life based on n-VNS. Recent advances in noninvasive technologies pave the way towards closed-loop systems that combine wearable sensing and stimulation. Real-time decision making through noninvasively measured parameters stands as the key mechanism for such technologies. This study lays the groundwork for closed-loop n-VNS systems that could provide “dosage” recommendations, personalized optimal delivery, or determination of response time.

**Limitations**

The sample size was relatively low; however, the two groups had comparable baseline characteristics. The onsets of action were manually annotated, as the sample size was low. To ensure reproducibility of results, multiple annotators independently annotated, and the inter-annotator agreement was quantified. The current study is also limited by left vagus stimulation per the study design. The findings should be re-evaluated for trials that include right vagus stimulation, as it is predicted to have different effects on cardiovascular and peripheral function.

**Conclusion and Future Work**

Wearable cardiovascular and peripheral biomarkers—HR, PEP, and PPG amplitude—were modulated in 18 ± 7 seconds for n-VNS without stress and in 16 ± 9 seconds for n-VNS following traumatic stress with a significant difference in the absent onset counts between active and sham groups. The utility of this work is to eliminate ambiguity of the physiological outcomes for n-VNS studies. The findings of this study have applications in clinical studies that use n-VNS in tandem with or without stress, as well as in the design of wearable systems that combine sensing and stimulation. For instance, stimulation timing appears to be important in the outcomes of multiple studies that test the differences in cognitive functioning, memory functioning, psychomotor functioning, or executive functioning with VNS application. The outcomes of this study could be used to design effective clinical studies for n-VNS devices. From the wearable sensing standpoint, the results could be instrumental for decision making algorithms, such as the determination of stimulation timing or the effectiveness of the stimulation. The inclusion of the sham group and multi-day protocol presented in this study provides unique, continuous wearable sensing data to consider for physiological outcomes of similar studies.

Future work should assess approaches to automate this process as more patients are recruited who have been diagnosed with psychiatric conditions. Further investigation into translating these findings from laboratory settings to wearable devices will help generalize this work, and confirming the reproducibility of these results in larger sample sizes is also pertinent. Of particular importance is the sexually dimorphic nature of cardiac and neurological responses in men and women; as the recruitment process continues, we will leverage larger sample sizes in future work to separate based
on sex and quantify any gender differences. The multiparametric determination presented herein may answer questions related to identifying physiological changes during n-VNS and the optimal time of delivery in response to a detected event.

Abstract

Self-management techniques that assist patients with chronic conditions, such as epilepsy, diabetes, and arthritis, play an important role in managing and caring for their conditions. The US Center for Disease Control and Prevention (CDC)-funded Managing Epilepsy Well (MEW) Network consists of 11 study sites across the US that aims to develop and disseminate self-management techniques for epilepsy patients. Epilepsy affects more than 65 million patients worldwide with serious negative impact on their own as well as their family member’s quality of life. Taking advantage of advances in biomedical informatics, the MEW Network has created an integrated database (MEW DB) using a common data model and two tiers of study variables. The MEW DB consists of 1680 patient data records covering a wide range of patient population nationwide. Therefore, there is growing interest in the use of the MEW DB for different cohort query analysis. To address the challenges in: (1) selecting appropriate MEW research studies based on inclusion/exclusion criteria; (2) creating a patient cohort for given research hypothesis; and (3) performing appropriate statistical tests; we have developed an integrated data query and statistical analysis informatics tool called Insight. The Insight platform features an intuitive user interface to support the three phases of study selection, patient cohort creation, and statistical testing with the use of an epilepsy domain ontology to support ontology-driven query expansion. We evaluate the Insight platform using four user evaluation methods of “first click testing” and “user satisfaction survey”. In addition, we performed a time performance test of the Insight platform using four patient datasets and three statistical test. The results of the user evaluation show that Insight platform is strongly approved by the users and the results of the time performance show that there is marginal difference in performance as the volume of patient data increases in the MEW DB.

Introduction

Epilepsy is a serious neurological disorder and it severely affects the quality of life of both the patients as well their family members (1, 2). Epilepsy affects more than 65 million persons worldwide with more than 2.8 million persons in the United States who experience seizures, which lead to disabilities, decreased ability for daily functioning, and common comorbidities including depression as well as cognitive impairment (1, 3). The cost of care for epilepsy is high with total cost burden estimated to be more than $36 billion per year, which disproportionately affects the elderly and minority populations who are economically vulnerable (1). The challenges in managing patients with epilepsy are significant with a growing population of older persons (estimated to increase to approximately 80 million by 2060) (4), high utilization of healthcare services often due to non-adherence to medication, and stress on patients as well their family members.

Self-management techniques have been successfully developed for many chronic conditions, including heart diseases, asthma, and depression, which enable patients to address disease symptoms, stress, and improve their quality of life (5). Epilepsy self-management techniques aim to address the limitations of existing approaches for providing care, for example difficulty in monitoring of daily medication adherence, and lack of availability of time or clinical resources to common comorbidities of depression or other psychosocial conditions (6). Self-management techniques for epilepsy patients involves improving their medication adherence, memory, and quality of life (7). Therefore, in 2007, the US Center for Disease Control and Prevention (CDC) created a network of multiple institutions to develop “self-management” techniques for epilepsy called Prevention Research Centers’ Managing Epilepsy Well (MEW) and disseminate the best practices to patient population (8).

The MEW Network institutions have developed multiple epilepsy self-management programs that use multi-modal communication and dissemination techniques to advance the adoption of self-management techniques in the patient population (7). These programs include the Epilepsy Awareness Support and Education (WebEase) project (9), the...
As part of the MEW Network initiative, we have harmonized the data from different MEW Network sites using a traditional Extract Transform Load (ETL) approach to create the MEW database (MEW DB) consisting of 1680 patients from 11 study sites. The MEW DB is being used to analyze different aspects of epilepsy treatment, including self-management techniques. For example, a study by Friedman et al. examined depressive symptoms and suicidality in epilepsy patients who were enrolled in self-management studies (12). The study found that depression and suicidal thoughts are common in epilepsy patients who were enrolled in self-management studies. Similarly, a study by Begley et al. evaluated the demographic and clinical correlated in epilepsy patients to characterize their self-management skills (13). This study used data from 436 patients involving five MEW Network studies and found that there was significant variation in the self-management competencies of patients. These studies highlight the need for well-defined data integration techniques as well as statistical analysis methods that can be used to both create a national-level patient population resource as well analyze it to derive insightful results for potential interventions.

There has been significant amount of work in the informatics community related to data integration for patient cohort query using ontology-driven techniques (14-16). However, to the best of our knowledge, many of these existing data integration platforms have limited or no support for the statistical analysis methods that need to be performed on a patient cohort data after it has been extracted from the integrated database. Users often have to download and perform tedious data transformation as well as curation steps over the patient cohort data before it can be analyzed using appropriate statistical methods such as t-test, Chi-Square, Mann-Whitney U test, ANOVA test, Fisher's exact text and Kruskal-Wallis test. In addition, users often have to rely on external, third-party tools that support these statistical methods for analysis. The lack of support for statistical data analysis in informatics tools for patient cohort query becomes a significant rate limiting step as the number of research studies using the data rapidly increase, for example the governing body for the MEW DB receives multiple requests for new research studies using this unique resource. In addition, the lack of integrated statistical data analysis tools in a data integration platform makes it difficult for users to perform exploratory data analysis by modifying study parameters based on results of statistical analysis.

In our previous work, we developed an epilepsy-focused, ontology-driven data integration and patient cohort query platform called Insight (17). The Insight tool uses the Epilepsy and Seizure Ontology (EpSO) to support data processing, integration, and query to allow users to create research study cohorts via an intuitive visual interface. The results of the cohort queries can be exported as comma separated value (CSV) files for subsequent processing and analysis using statistical tools. In this paper, we describe the development and application of a dedicated statistical analysis component in the Insight platform that can support a variety of statistical methods. This integrated statistical analysis feature of Insight significantly reduces the challenges for patient cohort analysis in the MEW network and we believe it can be easily extended to other domains given the widespread use of statistical data analysis tools in the biomedical research domain. To validate the integrated statistical feature of the Insight platform, we replicate three research studies using MEW-DB data.

Materials and Method

Setting

The goal of the MEW Network is to develop self-management intervention techniques that can be adopted by persons with epilepsy in their home and work environments using a community-based approach (7). At present, the MEW Network consists of centers at eight institutions across the US, including the University of Arizona, Morehouse School of Medicine, New York University, the University of Washington, the University of Minnesota, the University of Illinois at Chicago, and Case Western Reserve University. The MEW Network as developed and tested a wide range of intervention techniques for self-management techniques with a special focus on underserved and minority populations (10, 18-21). The MEW Network works closely with national organizations focused on epilepsy, including the American Epilepsy Society and the Epilepsy Foundation to disseminate evidence-based self-management interventions. This paper integrates and analyzes data in the MEW-DB from 11 studies with a total of 1680 patients and this study was approved by the University Hospital Cleveland Medical Center Institutional Review Board (IRB).

Data Collection
The data in the MEW-DB were obtained as part of the 11 research studies and included a variety of details that based on a set of common data elements (CDE) that are approved by the MEW DB steering committee for inclusion in the integrated dataset. The current set of MEW CDEs are categorized into Tier-1 and Tier-2 variables with Tier-1 variables consisting of 16 CDEs and Tier-2 variables consisting of 15 CDEs. These variables include description of patient demography and clinical outcomes (more details about the variables is presented in our earlier work (17). Table 1 describes the details of the patient data in the MEW DB with a higher percent of female patients (45%) as compared to male patients (28%). The patient data table shows that the MEW DB studies focus on low income group (18% earn less than $25,000 per year).

Reference Studies

The three reference studies used in this paper were conducted using the MEW-DB data. We briefly describe these three studies. The first study (Study 1) used the integrated data to evaluate the mood symptoms in 770 patients who are enrolled in self-management interventions using the 9-item Patient Health Questionnaire (PHQ-9) scores (12). The study found that 43.4% of the patients in the study have moderate to severe depression and about 20.1% of the patients had suicidal ideation. The study used multiple statistical methods to evaluate the correlation between depression variables and PHQ-9 total scores, for example Spearman’s correlation was used to characterize the relation between age and PHQ-9 scores. Similarly, multiple logistic regression was used to characterize the independent association between demographic and clinical variables to PHQ-9 total scores. This study showed that depression and suicidal ideation are common in the patients enrolled in the various self-management studies.

The second study (Study 2) analyzed data from 459 patients that were collected across four research centers to identify correlates of quality of life (QOL) (7). In particular, the study used various demography data, such as age, gender, race, education and employment, together with quality of life QOLIE-10 scale and PHQ-9 scale for depression. The study found that association between the severity of depression and lower QOL scores. The study used Kruskal-Wallis nonparametric methods for analysis of the data. Finally, the third study (Study 3) assessed the outcome of 5 randomized control trials (RCTs) with respect to symptoms of depression in epilepsy patients (13). The study used data from 453 patients with 232 in self-management intervention and 221 patients in usual or wait-list control. Using a series of t-test, the study characterized the changes in PHQ-9 scores over a period of time and a mixed model analysis was done to evaluate the association between baseline variables and changes in PHQ-9 scores over time.

Insight Epilepsy Informatics Platform

The Insight architecture consists of a set of modules that support three primary functions: (1) study selection based on inclusion/exclusion criteria, (2) cohort query formulation using a domain ontology-driven visual query interface, and (3) integrated statistical analysis. The current version of Insight has been developed using the Django web application framework (the previous version of Insight used the Ruby on Rails (17)). The use of Django web framework uses the

Python programming language, which has a large number of libraries and modules that support variety of data processing and analysis tasks, including statistical methods. The architecture of Insight allows it to integrate and manage data from multiple studies with the use of either software modules for data pre-processing and conversion to a common data model following the well-known Extract Transform Load (ETL) approach. We note that as part of the data processing step, multiple terms in the study data are annotated using an epilepsy domain ontology, which enables Insight to support ontology-driven query execution.

Figure 1 shows the current architecture of Insight that uses the Model View Template (MVT) approach with data accessed via an object relational data Model, the Insight user interface supported by the View component, and the user interaction with various features of the software mediated by the Template [Django]. The Insight platform is accessed via a Web browser with role based access control (RBAC) with users assigned to different user groups. The access privileges of a user are based on the specific study protocol that is approved by the MEW DB steering committee, which reviews and accepts or declines a proposed study to access the integrated datasets. Users follow a three-step process to identify specific research studies based on their inclusion-exclusion criteria, followed by creation of a study cohort using an intuitive query formulation process, and the study cohort data in finally analyzed using appropriate statistical methods in the data analysis module.

During the first step for study selection, users can select appropriate inclusion and exclusion criteria from a drop-down menu and the specific research studies that conform to the selected inclusion/exclusion criteria are listed for users to review. Users can also choose to select all studies in the MEW-DB for the second phase of cohort query. During the second phase, users can compose a patient cohort query using any of the Tier-1 and Tier-2 variables (described in the previous section above) using a drop-down menu and assign specific values to query variables, for example age between 20-40 years or Patient Health Questionnaire-9 (PHQ-9) score of -5. The selected variables, which are mapped to the Epilepsy and Seizure Ontology (EpSO) (22), are used to compose the patient cohort query followed by “query unfolding”. The query unfolding uses ontology reasoning to include all the subclasses of a term in the user-defined query, which ensures that the query results are exhaustive. EpSO is a domain ontology that has been developed to model multiple aspects of epilepsy, including seizure semiology, medication, and etiology (for detailed description of EpSO we refer to (22)). Users can view the results of the cohort query in the Insight visual interface or download it for statistical data analysis.

However, there are many challenges associated with use of statistical data analysis after downloading the patient cohort data, including re-formatting the data into a format that is required by a given statistical tool (e.g., Mann-Whitney U test and chi-squared test). In addition, downloading and transferring the patient cohort data between different computing platforms that have relevant statistical data analysis tools is cumbersome and significantly increases the time required for statistical analysis. An intuitive approach to address this challenge is to enable users to perform various statistical analysis in the Insight platform itself, which would eliminate the need to download and process the patient cohort data. Therefore, we implemented a new integrated statistical data analytics module in Insight to streamline and effectively reduce the time required to analyze patient cohort data.
Figure 2: The three components of the Insight platform, namely: (1) Study Selection; (2) Patient Cohort Selection; and (3) Statistical Analysis component.
Statistical Data Analytics Module Development

The Insight platform supports multiple statistical methods that can be applied to the patient cohort data. To apply statistical methods on the patient cohort data, a new statistical data analysis module was developed and implemented. Using the patient cohort data after execution of the two phases of Study Selection and Cohort Query, which have been described in details earlier (17), the statistical analysis module uses a similar user-friendly approach for invoking the a set of statistical methods on the results of the cohort query.

The implementation of the statistical methods involves three aspects: (1) storage and modification of data in a common model; (2) user interface features for invocation of statistical methods; (3) visualization of results of statistical data analysis. In the first phase, the results of the patient cohort query are stored as a “view” in the Insight database, which allows fast access to the data during subsequent statistical data analysis. In addition, the database view is also used to support download functions for users. In the second phase, the Insight statistical data analysis module interface is used to conduct the statistical analysis. The statistical functions in Insight are implemented using a modular approach, which allows new statistical modules to easily added. At present, Insight supports multiple statistical analysis methods, including variance, t-test, chi-squared test, and Mann-Whitney U test. As discussed earlier, these statistical methods are used in all the three research studies involving use of the MEW-DB integrated data.

Figure 2 shows the creation of the patient cohort using the first two components of the Insight platform (Study Selection and Cohort Query). Figure 2 shows the application of statistical methods on the patient cohort data using the Insight interface features, where a user can select specific statistical method to be applied to the data. For a given statistical method, the Insight interface automatically populates the subcategories of the drop-down menu with appropriate variables selected from the patient cohort data (output of the second component of Insight described earlier). This adaptive population of drop-down menu allows users to quickly select cohort-specific variables to be analyzed using a statistical method, which is both efficient as well as user-friendly. Once the statistical method and appropriate study variables are selected and applied, the output results are listed for viewing by the user. The results of the analysis can also be downloaded also by the user.

Evaluation of Data Analytics in Insight

The objectives of our evaluation are two-fold: (1) the first goal is to evaluate the usability of the Insight platform using two approaches, namely a “user satisfaction survey” and “first click testing”; and (2) the second goal is to evaluate the time performance of the statistical modules with respect to different datasets. The usability evaluation of the Insight platform was conducted with two team members of the MEW project who have performed several tasks on the MEW DB, including data processing and statistical analysis. We propose to perform a comprehensive user evaluation study of the Insight platform with a focus group consisting of participating MEW network members in the future. The details of two methods used for usability evaluation are:

1. **First click testing**: This method is used to evaluate the effectiveness and efficiency of the user interface in terms of enabling users to accomplish their tasks. We defined four tasks for users to complete by using the Insight user interface for the statistical data analysis, namely: (a) computation of t-test over a select cohort; (b) computation of Mann-Whitney U test over specific study variable; (c) computation of mean; and (d) computation of variance of study variables in a given cohort. This testing measures the number of clicks performed by the users in completing a given task, which may involve selecting the correct or incorrect set of options in the user interface. Intuitively, users who select the correct sequence of options in the user interface complete their tasks with a minimal number clicks and on time.

2. **User satisfaction survey**: In addition to the first click test, we also performed a broader user satisfaction survey with the objective of evaluating: (a) whether users can locate relevant information easily; (b) whether the results of their queries are easily accessible as well as visualized; (c) a comparative evaluation of the Insight interface with respect to existing tool; and (d) the likelihood of users recommending the Insight platform to other users for cohort data analysis.

The response of the users was recorded on a graded scale of 1-10 points with 1 corresponding to lowest value and 10 corresponding to highest value. The performance evaluation test used data from all the three studies that used the MEW DB data (described earlier), which demonstrate the scalability of the Insight platform with different size of datasets.

**Results**

The results are shown in Figure 3 show the results of the two user evaluation surveys for the Insight platform.
First click testing. The results for the first click testing (Figure 3(A)) show that both the users performed extremely well in terms of selecting the correct options in the interface to complete the four tasks (described in the previous section above). The first question asked the users whether they were able to complete the four tasks in the first attempt and both the evaluation results show that both the users completed the tasks in their first attempt. The second question validated the design principle of the user interface that users should be able to reach a final selection option with minimal number of clicks. Both the users agreed strongly (user rating score of 10) in the third question that the drop-down menu showed only the relevant study variables for a give statistical data analysis method. The two users gave a rating of 10 and 9 (corresponding to user 1 and user 2) in the fourth question for the difficulty level associated with locating a specific statistical data analysis method in the user interface. Finally, both the users agreed that the Insight platform was very easy to use to perform statistical analysis as compared to existing statistical packages such as SAS. However, one of the users noted that at present the Insight platform did not support a large number of statistical data analysis methods, which we aim to address in the future with implementation of additional statistical data analysis methods.

<table>
<thead>

<td><img src="image2" alt="User Satisfaction Survey Graph" /></td>
</tr>
</tbody>
</table>

**Figure 3:** The results of the user evaluation of the Insight platform are shown using two approaches: (A) First Click user evaluation; and (B) User satisfaction survey with two users who are familiar with the MEW DB

User Satisfaction Survey. Figure 3(B) shows the results of the user satisfaction survey consisting of 5 questions covering the navigation, visualization, effort required to complete tasks, and whether they would recommend the Insight platform to other MEW DB users. One of the users noted that the Insight platform was “fairly easy (to use) after demonstration” and it would have been more difficult to use without a demonstration. We agree with this assessment and we aim to create comprehensive user manual for the Insight platform that will allow first time users to quickly learn the different components of the platform. Both the users agreed that it was relatively easy to select specific statistical analysis method the associated study variable in the second question. Similarly, both the users strongly agreed that results of the three Insight platform

| ![Performance Graph](image3) |

**Figure 4:** A comparative evaluation of the time performance of the Insight platform using four different sizes of patient data and three statistical test.
components (Study Selection, Cohort Selection, and Statistical Analysis) were clearly visualized in the third question. Although both the users strongly agreed that the Insight platform reduces the time and effort required to conduct statistical data analysis as compared to existing methods in the fourth question, one of the users noted that at present the Insight platform does not allow for more in-depth data analysis. We aim to work with the users to address this concern. Both the users strongly agreed in the fifth question that will recommend the Insight platform to other MEW DB users.

Performance evaluation for statistical analysis. To demonstrate the practical usability and scalability of the Insight platform, we used four datasets consisting 100, 200, 400, and 450 patients from Study 3 to compute three statistical tests, namely t-test, Chi-Squared test, and Mann-Whitney U test. Figure 4 shows the time performance of the Insight platform statistical analysis module in milliseconds for the four datasets and three statistical tests. The results show that performance difference between the four datasets is marginal for all the three statistical tests. For example, there is a difference of 0.2 milliseconds and 0.1 milliseconds between the 100 patient datasets and the 200 as well as 400 patient datasets respectively. Similarly, there is a difference of 0.1 to 0.4 milliseconds for the t-test. These results show that there is no significant impact on the time performance of the Insight platform in the MEW-DB as the number of patients increases. It is also interesting to note that the difference between the time performance of the three statistical tests is also marginal with difference in values ranging from 0.1 milliseconds (for 100 patients) to 0.7 milliseconds (for 200 as well as 450 patient datasets).

Discussion and Conclusion

This study demonstrated the significant utility of a focused ontology-driven informatics tool for epilepsy clinical research that offers functionalities spanning study selection, cohort identification, and integrated statistical analysis in the context of a multi-center national study on epilepsy self-management. We are not aware of other existing tools that offer a similar level of granularity and functionality that can be readily used in the MEW Network project. The utility of the Insight platform and in particular the statistical data analysis module lies in its potential to significantly improve the efficiency and effectiveness of data analysis procedure for users as the size of the MEW DB continues to increase in terms of the volume of data and the number of studies proposed to be conducted on the integrated data. Although there are multiple data integration and ontology-driven informatics tools that are available in the biomedical research domain, there are significant challenges associated with their adoption in highly specialized, specific disciplines of medicine. Therefore, we decided to develop the Insight platform as an epilepsy-focused informatics tool that meets the requirements of this domain with the use of a domain-specific ontology (EpSO) and specialized data processing, querying, and analysis features.

The availability of integrated functionalities, in particular the statistical analysis module in the Insight platform has several advantages as compared to the use of offline statistical analysis tools. For example, users do not need to download and transfer data across one or more computers that increases the risk to safe management of research study data, including de-identified study data as used in the MEW-DB. Therefore, the integrated functionalities for statistical testing in the Insight platform offers significant advantages in terms of ease of use as well as maintaining data access restrictions for users as compared to existing approaches of manual data transfer and analysis.

The primary objective of the Insight platform is to serve as an informatics tool that facilitates greater use of the MEW DB for analysis and evaluation of self-management techniques in epilepsy. To achieve this goal, we are implementing new features in the Insight platform, including the development of a Docker-based version, which will allow the Insight platform to be easily shared and installed by the MEW Network community. The Docker-based version will allow individual MEW researchers

The work reported in this paper has some limitation. For example, as highlighted by a user during the user evaluation the current version of the Insight platform does not support in-depth statistical analysis. In addition, the number of statistical tests currently available in the Insight platform are limited. Therefore, we plan to significantly increase the number of statistical tests available in the next version of the Insight platform. In addition, we propose to add extensive result visualization features in the next version of the Insight platform.

In conclusion, in this paper we presented an integrated data processing and analysis platform called Insight that can significantly facilitate epilepsy patient cohort studies in the MEW Network in the context of epilepsy self-management studies.

Abstract

Objectives: To evaluate the data breaches incidents in the U.S. between 2010 and 2018, identify the characteristics of breaches involving more than a million records, and compare the changes before and after wide adoption of EHR in 2015. Materials and methods: Incidents of data breaches between 2010 to 2018 were retrieved from the Office of Civil Rights portal. Descriptive statistical analyses were performed to assess the trends and characteristics, and changes between states from 2015 to 2018 were assessed and mapped. Results: From 2010 to 2018, a total of 2,529 breaches affected 194.74 million individual records. Overall, 72.08% incidents involved healthcare providers; theft (32.94%) and hacking (22.7%) were major types of breaches. Large cases affecting more than a million records happened due to compromised internal structures and systems. After 2015, the magnitude of the data breaches has changed at varying levels in the U.S. states necessitating further research and actions.

Introduction

Use of electronic health records (EHR) offers several benefits including enhanced communication and decision-making in the points of care,2 improve adherence to advised preventive or therapeutic measures by providing timely reminders to the patients or caregivers,4 reduce unnecessary laboratory tests by coordinating previous and prospective diagnostic plans,5 improve quality of care,6 and manage payments and reimbursements.7 The adoption of EHR across different health systems followed diverse pathways.8 Critical challenges like technological complexities, legal issues, economic costs, concerns for safety and security of the records influenced the development of EHR.9 In the United States, two major acts were introduced to address the legal and security-related challenges regarding protected health information.10 Firstly, the Health Insurance Portability and Accountability Act (HIPAA) was passed in 1996 which emphasized physical, administrative, and technical safeguards.10 Secondly, the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 enforced the implementation and utilization of EHR.11 This act mandated the Centers for Medicare and Medicaid Services (CMS) recipients to adopt EHR by the beginning of 2015 to continue receiving full reimbursements and preventing penalties due to inability to adopt EHR.12 In addition, the HITECH Act also stresses the importance of reporting incidents of data breaches involving protected health information.11 Since 2009, the number of providers adopting EHR increased alongside the number of data breach incidents.13 Such incidents erode the trust of individuals on digital health technologies and jeopardize the potential benefits of technological advancements.7,14 In addition, the direct economic burden of data breaches can be as high as $6.2 billion with other legal and administrative consequences.15,16

Several studies have reported the characteristics of those breaches,13,17 types and media locations of breach events,18 geographic locations and types of covered entities,19 and causes behind those incidents in different time periods.20 However, there is a lack of evidence that illustrates the changes in the trends and characteristics of the data breach for all the complete years since the HITECH Act was passed. Moreover, several incidents involved more than a million records per breach,17 but the detailed causes and characteristics of those large cases are not explored yet. Furthermore, the number of breach incidents or affected records might not provide the actual picture of data breach in the U.S. at the state level due to varying population size from state to state. It is critical to examine the population adjusted individual records affected due to data breaches after the mandatory adoption of EHR across the nation since 2015. The objectives of this study are 1) identify all the reported incidents of data breaches in the U.S. between 2010 and 2018, 2) list the key characteristics of incidents which involved more than a million individual records, and 3) describe
the changes in population adjusted records affected in different U.S. states following the mandatory adoption of EHR in 2015.

Materials and methods

In this study, we used the data of all the reported breach incidents between 2010 to 2018 from the breach portal of the Office of Civil Rights at the U.S. Department of Health and Human Services. According to section 13402(e)(4) of the HITECH Act, the incidents of the data breaches involving protected health information of more than 500 individuals are reported to OCR. We retrieved these publicly available data which provide the name and type of covered entity, the presence of business associates, location, time, and the number of affected individual records for the incidents. Moreover, specific types of the breaches including hacking, improper disposal, theft, loss, and unknown types are reported. We grouped the entries with more than one type of breach as multiple types of breaches in this analysis. Further, the data informs the media location of the data breaches including a network server, paper, desktop, laptop computer, portable devices, email, electronic medical record, and others. In this category, we grouped the entries with more than one media location as multiple locations. Using the above-mentioned data in Microsoft Excel and Stata 15.0 (College Station, TX), we performed descriptive statistics and two-way measures of association using chi-squared tests.

Furthermore, to examine the changes in data breaches following the adoption of EHR across the nation, we calculated the total number of affected individual records at the state level for 2015 to 2018. We adjusted this annual breach data for each thousand population using the annual population estimates for each state derived from the U.S. Census Bureau. We used the population adjusted affected individual records per state to create maps for each year illustrating the changes in the data breach incidents from 2015 to 2018 using ArcGIS software. Moreover, the breach data includes web description of the cases which include qualitative information about the characteristics and consequences of the incidents. We used the description corresponding to the cases that involved more than a million individual records in assessing the characteristics of those large data breach incidents.

Results

Characteristics of data breaches from 2010 to 2018

Total 194.74 million individual records were affected due to 2,529 incidents of the data breaches over a period of nine years from 2010 to 2018 as shown in Table 1. The number of breaches increased every year compared to the previous years except in 2015.

the highest number of individual records were breached (n=113.28 million) in 2015 (Figure 1). Moreover, data breaches varied with the types of covered entities which was statistically significant. Most incidents (72.08%, n=1,832) happened in covered entities which were healthcare providers followed by the business associate (14.23%, n=360) and health plan (13.4%, n=339). Further, different types of breaches were significantly associated with the number of breaches each year. Overall, theft (32.94%) and hacking or IT incident (22.7%) were major types involved in breach incidents whereas a significant proportion (31.87%) of breaches involved more than one type. However, hacking or IT incidents were much lower (4.02%) in 2010 which had increased in 2018 (43.44%).

Figure 1: Number of incidents and individual records affected due to data breaches in the U.S. between 2010 and 2018.
Similarly, the number of multiple types of breaches were reported much lower in 2010 (8.54%) compared to 2018 (39.07%). In addition, the breaches happened through different media; papers or films (21.59%) and multiple media locations (21.43%) were reported alongside the breach incidents. Also, the rate of incidents happened through laptop had declined from 24.12% in 2010 to 4.64% in 2018. In contrast, incidents through network server had increased from 9.05% in 2010 to 16.39% in 2018. Similarly, breach incidents happened through email was only 2.01% in 2010 which increased up to 29.78% of annual incidents in 2018.

**Breaches affecting more than a million records at a time**

Among 194.74 million total breached records, only 23 incidents involved more than a million records each, resulting in a total 151.81 million records which are about 78% of all records breached between 2010 and 2018 (Table 2). More than 105 million breached records were associated with health plans representing 69% of all large incidents of breached data. At the state level (Appendix-1), Florida, New York, and Tennessee had a higher number of such large incidents (n=3 for each of these states).

Most of the breaches (n=13 out of 23) occurred through hacking or IT incident resulting in 128.24 million breached individual records. In addition, most of the incidents (n=10) occurred using network servers whereas 4 incidents involved multiple media locations. Among all 23 breaches affecting millions, only 9 had web descriptions reported in the OCR data breach portal. Five out of 9 such incidents involved hacking or IT incidents as the type of breaches and network server as the medium of the breach. The largest incident affecting the highest number of individual records (n=78.8 million) occurred in 2015 through a series of cyber-attacks to the IT system of the covered entity. Other cases affecting millions of individuals involved unauthorized access (n=3.47 million), breaching SQL database (n=2.21 million), hacking computer records (n=4.5 million), misuse of information systems through hacking (n=1.1 million), displaced locked cabinet (n=1.05 million), theft of unencrypted tapes (n=1.7 million), stolen laptops (n=1.22 million), and multiple breaches due to unprotected systems and processes (n=4.02 million). Three cases reported settlements ranging from $2.3 to $16 million paid to OCR as penalties whereas all cases reported that the covered entities implemented varying protective measures to prevent data breach incidents.
Changes in health data breaches at the state level from 2015 to 2018

Population-adjusted rate of affected individual records illustrated varying severity of data breaches across the U.S. states (Figure 2). The overall adjusted rates show a decline in data breaches from 2015 to 2018 with different rates of individual records affected in different states in different times.

In 2015, Indiana had the highest rate of individual records breached (1.26 million affected records per 100,000 population) followed by Washington, New York, Maryland, and California. In the subsequent years, Arizona (65,140 affected records per 100,000 population), Kentucky (16,438 affected records per 100,000 population), and Arkansas (7,129 affected records per 100,000 population) had the highest population-adjusted data breaches in 2016, 2017, and 2018 respectively. Moreover, Washington, New York, California, and Georgia had a higher population adjusted affected records in all four years. In contrast, Idaho, Hawaii, North and South Dakota had lower population adjusted affected records throughout the study period.

Figure 2: Changes in the population-adjusted breached records from 2015 to 2018 in the United States except Hawaii, Alaska, and Puerto Rico.
Discussion

In this study, we evaluated all reported incidents of data breaches in the U.S. covering all the completed years after 2009 when the data breach registry was introduced under the HITECH Act. Our analysis shows a high burden of the data breach from 2010 to 2018 with a varying number of incidents and individual records affected. In addition, the changes in the covered entity, types of breaches, and media location of data breaches provide a broader picture of data breaches in the U.S. Moreover, the population-adjusted data breaches in 2015 after mandatory adoption of EHR illustrates the severity of data breaches in most of the states, which had decreased in subsequent years. However, many states continue to suffer from a high rate of the data breach, which is a major public health concern. Furthermore, the large data breaches affecting more than a million records per incident offer several critical insights. First, more than 72% breach incidents involved healthcare providers; in contrast, 8 large incidents involved health plans resulting in more than 105 million individual records, which is attributable to 69% of large breaches and 54% of all breaches. Therefore, careful attention should be given to the types of entities covered under HIPAA for securing the protected health information. Second, the increased rate of data breaches through hacking or IT incidents affecting 84% of the major breaches highlights the necessity of safeguarding the EHR systems. In addition, more than 123 million records were breached through the network servers, which revalidates the high number of IT-related incidents. Third, among the 23 major incidents, 11 resolved cases involving more than 46 million cases did not have any description on the OCR portal. A substantial lack of such information can hinder scientific, administrative, economic, and legal analyses about the respective cases.

To mitigate the burden of data breaches in the U.S., it is critical to examine the reasons for such events and explore intervention strategies to address the same. First, at the institutional level, a lack of effective resources is a major challenge to prevent breaches. Such resources include physical infrastructure that can store and manage health records efficiently, electronic systems protected with adequate authorization processes, and human capital that can effectively utilize the health data management systems without compromising the safety and security of data. For the physical and electronic components, standardizing the inputs and processes may improve the safety outcomes of the health information systems. Second, it is essential to incorporate the data security competencies in the health education and training programs, highlight such competencies in the hiring process, promote the work culture ensuring data safety, and unauthorize the credentials from the information systems while replacing the human resources. Third, patients and their informal caregivers are increasingly using EHR and other digital health platforms. They should be empowered with adequate knowledge, safety practices, and access to secured patient data management systems. This can improve their EHR usage and engage them in preventive measures adopted by the providers and institutions. Fourth, at the systems level, exploring the challenges and opportunities to secure health information is central to bring changes for broader impact. One such critical challenge is the scope of HIPAA which was introduced earlier than the adoption of EHR. In that time, the instruments and technologies were not that complex as they are today. Therefore, revisiting and updating the legal and regulatory measures can strengthen the digital health systems against potential breaches. Fifth, data breaches affecting protected health information can involve federal agencies other than HHS. Recent investigations and settlements conducted by FBI and FTC, assessment of health information products and services by FDA are a few examples of how many agencies can engage during health data breaches. It is essential to define the roles and scopes of these institutions and develop a meaningful partnership to address health data breaches. Lastly, the institutional and systems-level approaches to secure protected health information would require sustained financing. The HITECH Act provides up to $27 billion over 10 years as incentives encouraging the adoption of EHR systems. Leveraging such options and bridging other health systems financing strategies would be vital to the successful prevention of health data breaches in the United States.

This study has several limitations. First, we could not assess the unique individual records out of all the breached records. Without such precision, it cannot be concluded that 194.74 million of breached records belong to the equal number of people. Second, the reported cases contain 500 or more individual records. This implies that all those breaches that had less than 500 records were not reported to OCR and therefore, those incidents are not included in this study. This systematic exclusion of unknown events jeopardizes the actual estimation of data breaches in the U.S. Third, we grouped the types and media locations of data breaches if there were more than one entry. An itemized number of affected records from multiple components could provide a more accurate characterization of the types and media locations of breach incidents. Fourth, we could not find what were the contents of breached protected health
information, which could show the magnitude of how much importance the contents would have carried and how they can potentially be abused against the individuals and other stakeholders. Fifth, it is possible that there were other administrative, financial, or institutional data that were breached alongside the reported cases, which were not primarily covered under HIPAA as protected health information. Such information is not reported to OCR, but implicit data about covered entities serving a specific population in a specific geographic location can be used to derive inferences about health behavior, access, utilization, billing, and a wide range of outcomes. We could not find such data in the OCR portal and examine the same, which is another limitation of this study. Sixth, we could not evaluate if the reported incidents of data breaches, particularly those involving hacking or IT incidents, did make any changes within the data stored in those affected databases. Such manipulations of sensitive data might have more severe and long-term consequences. Lastly, we evaluated only the OCR-reported measures under the HITECH Act. We did not evaluate additional legislative and regulatory measures in the state-level which might have influenced the trends and characteristics of data breaches. Future research should explore these avenues, address the limitations of this study, and inform the development of multi-level interventions to address health data breaches in the U.S.

Conclusion
Advancements in health information technologies have improved the access to health services, however, the raising security concerns of adopting advanced technologies may affect the individuals and providers enormously instead of increasing the efficiency of the existing systems. The characteristics of data breaches and trend over the past nine years inform the high magnitude of this serious public health problem in the United States. Also, repeated breaches in different location and time using diverse strategies and media types indicate the overall weakness of the health system to ensure the safety of protected health information. To address such a massive problem which has been affecting millions of people, rigorous research is essential to explore nature and reasons for the data breaches. The findings of empirical research studies can facilitate the development of evidence-based policies and programs aiming the prevention of future breaches. Last but not the least, strong economic and political commitment is required to implement the multipronged preventive measures at the institutional and systems levels, where the key stakeholders can collaborate protecting the health data safety of the U.S. population.

Health Cards to Assist Decision Making in Consumer Health Search

Jimmy, MIS.\textsuperscript{1,2}, Guido Zuccon, PhD.\textsuperscript{1}, Gianluca Demartini, PhD.\textsuperscript{1}, Bevan Koopman, PhD.\textsuperscript{3}  
\textsuperscript{1}University of Queensland, Brisbane, Australia; \textsuperscript{2}University of Surabaya, Surabaya, Indonesia; \textsuperscript{3}Australian E-Health Research Center, CSIRO, Brisbane, Australia.

Abstract

We investigate the effectiveness of health cards to assist decision making in Consumer Health Search (CHS). A health card is a concise presentation of a health concept shown alongside search results to specific queries. We specifically focus on the decision making tasks of determining the health condition presented by a person and determining which action should be taken next with respect to the health condition. We explore two avenues for presenting health cards: a traditional single health card interface, and a novel multiple health cards interface. To validate the utility of health cards and their presentation interfaces, we conduct a laboratory user study where users are asked to solve the two decision making tasks for eight simulated scenarios. Our study makes the following contributions: (1) it proposes the novel multiple health card interface, which allows users to perform differential diagnoses, (2) it quantifies the impact of using health cards for assisting decision making in CHS, and (3) it determines the health card appraisal accuracy in the context of multiple health cards.

Introduction

It is common practice for people to search the Web for health advice and information about conditions, treatments, experiences and health services – we refer to these search activities as Consumer Health Search (CHS). CHS is a challenging domain where effective search is hindered by vocabulary mismatch and the users’ lack of domain expertise. These issues affect both query formulation and result appraisal\textsuperscript{1}. A study by Zeng et al\textsuperscript{2} showed that, while the general public believes that they were effective in searching for medical advice online, 70% of the study’s participants were relying on incorrect advice. Furthermore, Fox & Duggan\textsuperscript{3} found that 38% of CHS users did not seek professional attention once they found medical advice online. This is problematic as in some cases incorrect medical diagnosis and treatment could lead to a fatal outcomes.

This study investigates the effectiveness of health cards to assist decision making in CHS (e.g., Figure\textsuperscript{1}). Health cards are a specific type of entity card that have recently been introduced by major web search engines to provide quicker access to trusted information relating to a specific health concept\textsuperscript{4}. In general Web search, entity cards are effective in supporting user search activities by presenting heterogeneous information in a coherent way\textsuperscript{5}. Yet, no previous work has thoroughly investigated the effectiveness of health cards to assist decision making in CHS.

We specifically focus on the health decision making tasks of (A) determining the health condition presented by a person (self-diagnosis) and (B) determining which action should be taken next with respect to the health condition (e.g., consult a doctor, self-treat, etc.). To support users in making these decisions, we propose a novel interface that shows multiple health cards within a search engine result page (Figure\textsuperscript{1} right) – we call this multi-cards – in place of traditional single health card interfaces (Figure\textsuperscript{1} left). The multi-cards are inspired by interfaces for product comparison used within shopping websites\textsuperscript{6} (e.g., to compare laptops, shoes, etc.) where features of the compared products are summarised and presented side-by-side to assist the user in their purchase decisions. We believe that the multi-cards would allow CHS users to perform differential diagnoses by quickly, and with less effort, comparing their health observations with several probable conditions at once. In this context, we aim to address the following questions:

RQ1: How do single and multiple cards influence CHS users when making health decisions? The impact of health cards on CHS decisions is measured by: (1) the use of health cards as a source of information; (2) the correctness of decisions made on their basis; (3) the time needed to make decisions; (4) the number of web pages opened; (5) the rate of good abandonment\textsuperscript{7}; and (6) the level of confidence in the decisions.

The multi-cards solution shows a set of health cards rather than a single card. This is useful in contexts where the search systems is unsure about which single relevant card should be shown to the user. The ability of showing multiple health cards increases the chance that the relevant (correct) health card is shown for the user’s condition. However, it
is unclear whether users would be capable of identifying the correct card for their condition. We investigate this in our second question:

**RQ2: How accurate are CHS users in appraising the correctness of health cards?** Search results appraisal is challenging in CHS, and is affected by medical terminology, lack of prior knowledge, and cognitive biases, among others. We investigate if this holds for the use of health cards by measuring how well CHS users identify the correct health cards for their health situation, in the context of a multi-cards interface.

To answer these questions, we conduct a study where 64 participants are presented with eight health scenarios and pre-formulated queries, and are asked to consider a search engine result page (SERP) containing health cards and search result snippets. Participants are then left to interact with the SERP and are asked to make two decisions: (A) What is the most likely health condition for the scenario? (B) What would you do next? Participants are rotated across two interfaces: one with a single health card, and one with the multi-cards.

**Methods**

A within-subjects user study was set up to answer the research questions presented above. Figure 2 depicts the activity flow of the user study. Participants were requested to complete eight health scenarios using two search interfaces and two correctness settings: (SC) with a correct single-card, (SN) with an incorrect single-card, (MC) with multi-cards, including a correct card, and (MN) with multi-cards, where none of the cards are correct. A health card is correct when it matches the known diagnosis of the scenario (see Table 2).

The user study was performed in a usability laboratory with a PC equipped with eye tracking technology. To minimise fatigue bias, we rotated the eight scenarios and the four search interfaces using a Graeco-Latin square rotation, resulting in 32 scenario–search interface combinations. Participants were principally university students. The study

received Human Research Ethics Committee clearance (#2018002115). Next, we discuss each part of the user study.

Informed consent and demographic questionnaire

After consenting to participate, each participant was given a set of instructions presenting the elements of the interface and rules for the collection of evidence to answer the scenarios. Next, a demographic questionnaire collected information on the participant’s age group, highest level of education, education background, English proficiency\(\ast\) and the frequency of use of Web search engines. We used the responses to determine the participant’s eligibility.

Pre-task questionnaire

After completing the demographic questionnaire, participants completed pre-task questionnaires shown in Table 1 for all eight scenarios. We used the first three items to understand participants’ background knowledge for each health scenario and items 4 to 6 (adapted from Kelly et al.\(\ast\)) to understand the participant’s interest and background knowledge for each health scenario.

Search scenarios

We selected eight scenarios of the 45 standardised patient vignettes used in a survey of symptoms checkers.\(\ast\) The vignettes were compiled from various clinical sources such as education material for health professionals and a medical resource website. Each vignette contained age, gender, symptoms, correct diagnosis and correct category of triage urgency for a given condition. They include both common and uncommon diagnoses (based on prevalence) from three categories of triage urgency: requiring emergency care, requiring non-emergency care, and self-care appropriate. We ensured that each diagnosis in the eight selected scenarios had a matching Google health card.

Then, we created a topic description based on each vignette. A topic description contains all symptoms as reported by the patient in the vignette, excluding clinical observations (since in a real setting, the user would not have such information). We also replaced medical terms with layman terms, where appropriate (e.g., “rhinorrhea” was replaced with “runny nose” and “acetaminophen” was replaced with “paracetamol” as “paracetamol” is a more commonly known term in Australia than “acetaminophen”). Finally, we asked research students in our team lab (who have no medical background and had English as first language) to formulate a search query for each topic description. Table 2 reports the topic description, diagnosis, urgency category, and search query for each health scenario.

To complete each scenario, we asked participants to first make a diagnosis then copy and paste the condition mention — either from the snippets, linked documents, or from the health cards. This protocol allowed us to track where participants found the relevant diagnosis mention and evidence for making their health decision (i.e., they could have found it across different information objects, but they made their final decision based on the copied one). Second, we asked participants to select the urgency condition for the scenario: requires emergency care (e.g., calling 911 or immediately going to hospital), requires non-emergency care (e.g., contacting GP or nurse help line), or self-care appropriate (e.g., taking over the counter drug or home-remedy, resting, performing activities to mitigate the condition). Finally, we asked participants to rate their confidence of the responses (1=Very not confident to 5=Very confident), and the quality of the presented health card(s) with respect to three dimensions: relevancy, understandability and trustworthiness (1=[neg], 2=Partially [pos] 3=[pos]; where [neg], [pos] labels were contextualised to the items; the partial option was only shown when multi-cards were shown).

\(\ast\) We verified participants English proficiency by checking whether they: (1) spoke English as first language, or (2) achieved IELTS overall test score of at least 5.0 with a score of at least 4.5 in each of the four test components. These are the minimum English proficiency to work in Australia.
We ranked the identified health concepts (i.e., disease or syndrome) based on how many of the top 50 search results for extracting Unified Medical Language System (UMLS, version 2018AA) medical thesaurus entities from free-text. We identified disease or syndrome concepts in the title and the snippets of each search result using QuickUMLS in the interface (either from the results or from a health card), we presented them with the archived web page. We then noted by Jimmy et al.

To obtain the search results for each health scenario, we submitted the query to the Bing Web Search API thus, participants would be accustomed to the interface. The search interfaces contained three panes: left (not shown in Figure 1), middle, and right. The left pane displayed the topic, instructions, and tasks to be completed by participants. For the search interface with a single-card (Figure 1 left), the middle pane displayed the query string (disabled so a new query could not be entered) and the top ten search results (title, url, and snippet). The right pane of a single-card interface showed the health card. For the search interface with multi-cards (Figure 1 right), we merged the middle and the right panes to display the query string, the four health cards, and the top 10 search results. We designed the snippet list and the health cards following the Google search interface as it was the most popular search engine in Australia, i.e., where this study took place; however, we added multi-cards to accommodate the MultiSearch study participants. Since the MultiSearch study participants reported their overall experience in completing the tasks and their previous experiences in searching online for health information, with specific attention to the use of health cards. Due to space constraints, the analysis of the user experience questionnaire and exit questionnaire are out of the scope of this paper, and are left to future work.

**Search Interfaces**

The search interfaces (Figure 1) contained three panes: left (not shown in Figure 1), middle, and right. The left pane displayed the topic, instructions, and tasks to be completed by participants. For the search interface with a single-card (Figure 1 left), the middle pane displayed the query string (disabled so a new query could not be entered) and the top ten search results (title, url, and snippet). The right pane of a single-card interface showed the health card. For the search interface with multi-cards (Figure 1 right), we merged the middle and the right panes to display the query string, the four health cards, and the top 10 search results. We designed the snippet list and the health cards following the Google search interface as it was the most popular search engine in Australia, i.e., where this study took place; thus, participants would be accustomed to the interface.

**Search Results**

To obtain the search results for each health scenario, we submitted the query to the Bing Web Search API on February 2nd, 2019 and acquired the top 50 search results. To avoid problems with possible web pages and SERP updates, as noted by Jimmy et al., we archived all search results and source web pages. When a participant clicked on any link in the interface (either from the results or from a health card), we presented them with the archived web page. We then identified disease or syndrome concepts in the title and the snippets of each search result using QuickUMLS, a tool for extracting Unified Medical Language System (UMLS, version 2018AA) medical thesaurus entities from free-text. We ranked the identified health concepts (i.e., disease or syndrome) based on how many of the top 50 search results...

contained each concept and we kept the five most frequent health concepts. We ensured the selected five concepts contained four incorrect health concepts and one correct health concept (there could not be more than one correct health concept for a scenario). If the top five concepts were all incorrect, we exchanged the lowest ranked with the correct concept. This was so that in the multi-cards interface we could display either four incorrect or three incorrect and one correct health cards. We only considered health concepts that matched a Google health card. Table 3 lists the five cards for each health scenario. Finally, we selected the two search results with the highest rank for each health concept, to make up in total 10 search results for each health scenario, to display in the SERP. The 10 search results were ordered based on ranks from Bing.

Health Cards
Health cards were acquired from the Google search engine based on Table 3. Each health card contained a title, aliases (i.e., “also called”), if any, an image, a summary tab (i.e., about), a symptoms tab, and a treatments tab. Each tab contained a URL that links to the source information for the health card. In the acquired Google health cards, the word “critical” in bold would appear in the bottom part of the card if the associated condition requires emergency medical attention (e.g., “Appendicitis”); we maintained this feature. For health cards that had no image from the Google health cards, we obtained an image from other medical web pages that discuss the same condition. We fixed the health cards height to 600px and summarised the health cards content to ensure that all information fit the height setting. This was done to provide a similar look & feel for all search interfaces in the study.

Capturing Interaction Data
Throughout the user study, we captured participants interactions with the search interfaces using the Big Brother logging service. Big Brother records mouse movements (including anchored to <div> containers, e.g., enter and leave the container), clicks, scroll, page loading (start and end), cut/copy/paste, and window’s scroll position (mainly to align and validate eye-tracking data).

We used the Tobii Pro Spectrum eye tracker to acquire eye gaze data, set to operate at the frequency of 300Hz. The eye tracker was connected to a monitor with a resolution of 1920 x 1080 pixels. The eye tracker was calibrated for each participant at the start of the study using the method described by Blignaut. We implemented the velocity-threshold identification algorithm to identify fixation points. We set the velocity radius threshold to 70 pixels following the size of the eye gazing point visualisation from the Tobii Pro Eye Tracker Manager. We set the minimum fixation duration threshold to 100ms as suggested by Blignau. Then, we mapped the fixation points to three areas-of-Interest (AOIs): scenario description (left pane), list of snippets, and health cards.

The eye gaze data was used to determine whether participants noticed the health cards, and how much time they spent on the health card, compared to the rest of the SERP or actual result web pages. Other analyses of the collected eye

‡https://github.com/hscells/bigbro
tracking data was regarded as being out of scope of this paper, and left to future work.

**Participants**
The study was advertised widely through The University of Queensland, a large public university in Australia, as well as through Facebook groups mainly tailored to students and alumni of this university. We did not enforce participants to be university students or affiliates (but we excluded research staff), and we allowed any member of the public to take part in the study. Nevertheless, the majority of the participants were university students. The following eligibility criteria for participation in the study were set and enforced: aged 18 years or above, no specific prior medical studies, experienced with using a web search engine on a daily basis, and proficient English readers and writers. Participants were told that the study would last approximately one hour and were given a AUD$15 gift card for their participation.

**Experiment Results**
From 64 participants, each performing eight scenarios, we collected 512 interaction data points. This gave us enough power for statistical analysis (power > 0.90), statistical tests using unpaired t-test adjusted with Bonferroni correction due to multiple comparisons in an analysis. Each of the 16 sequences of scenarios-search interface pairs was performed by three participants. Participants comprised 38 females and 26 males: 31 between 18-24 y.o., 23 between 25-34 y.o., 9 between 35-44 y.o. and 1 between 45-54. Their education background was: 20 Engineering/IT, 13 Business/Economics, 13 Science, 5 Psychology, 6 peripherally health related majors with no medical or diagnostic experience (e.g., personal trainer), 7 Humanities/Social Science. We confirmed that no participant had experience in the medical field and specifically in diagnosing health conditions. The highest level of completed education was: 13 high school, 13 diploma, 18 bachelor degree, 5 graduate diploma, and 15 postgraduate degree.

Participants considered the eight scenarios as interesting and unfamiliar. Overall, the participants’ average level of interest in the scenarios was moderately high (3.9 with, 1=very not interesting to 5=very interesting). Further, participants had no to little knowledge of the scenarios (M = 1.88) and never or rarely searched for information related to the scenarios (M = 1.42). We found very weak to no correlation between the participants’ level of interest, prior knowledge and prior search for the scenario on all six measurements; thus these had no systematic effect on results.

Then, we investigated whether fatigue may have had a systematic effect on results. We did this by correlating the sequence of scenarios and the results from the six measurements used in RQ1. We found that there was a weak negative correlation between the scenario sequence and duration taken to complete a scenario (corr=-0.21): this may have been due to fatigue or acquired familiarity with the search tasks and interface. Further, we found very weak to no correlation between the scenario sequence and the other five measurements: health card usage rate (corr=0.02), correct diagnosis rate (corr=-0.05), correct urgency score (corr=0.06), number of page read (corr=0.04), good abandonment rate (corr=0.00), and confidence rate (corr=-0.13). This indicates that the results are comparable across scenario sequences. Next, we investigated the impact of presenting single and multi-cards on decision making behaviour.

The multi-cards interface was found to drive users’ attention toward the health cards (as opposed to the search results). When the multi-cards were shown, most participants spent more time on health cards (M = 82%) than on snippets (M = 18%). However, when only a single-card was shown, participants spent equal amounts of time on snippets and on health cards (M = 51% vs. M = 49%). These findings were observed by measuring which AOI (i.e., snippets vs. health cards) participants paid attention to when health cards were displayed. (We removed eye tracker data associated to other display areas, e.g., the instructions pane.) Since the time taken by each session varied, we normalised durations, and present results with respect to the progress in the session. Figure 2 reports the percentage of participants that paid attention to each AOI throughout the session. These findings are understandable since when the single-card is shown, there is more information to process in snippets and the display area containing the snippets is larger. On the other hand, the multi-cards occupy most of the initial display and only the top three snippets are visible without scrolling. Participants may have also found most of the information they required among the multi-cards.

Participants often considered health cards earlier in their session: There is a moderate to strong negative correlation between attention on health cards (according to eye tracking) and time point in the session when both single-card (corr=-0.50) and multi-cards (corr=-0.90) were shown. Interestingly, regardless of the declining attention overtime, we found that the attention on health cards increased at the end of the session for both interfaces. We speculate that...
although health cards were prioritised at the beginning of the session, participants may have felt the health cards did not contain enough information to make the final decision, and went on examining snippets throughout the SERP. Participants may have felt that information from the snippets was still not sufficient to complete the scenario, hence, they re-considered the health cards at the end of the session.

Results for RQ1: How do single and multiple health cards influence CHS users when making health decisions?

Regardless of the search interfaces, participants perceived health cards as relevant ($M = 0.8203$), trustworthy ($M = 2.5762$) and easy to understand ($M = 2.703$). We measured health cards’ relevance as binary where 0=not relevant and 1=relevant (Note that a health card that was considered as relevant, was not necessarily considered as correct). We speculate that participants may have considered an incorrect health card as relevant since it helped participants to rule out a condition. Trustworthiness and understandability were measured on a 1 to 3 scale (3 being most trustworthy/understandable). Next, we contrast the influence of single and multiple health cards on CHS decision making based on results on the key metrics reported in Table 4.

Multi-cards were preferred as a source of information. This is evident from the probability that the information in health cards was selected for making the health decisions. When multi-cards were presented, in fact, most participants preferred to select information from one of the health cards to complete the scenario (68.75% of 256 scenarios), while when the traditional single-card was presented, the organic search results were preferred more than the health card (only 37.11% of 256 scenario show information selected from the health card). This was regardless of the correctness of the health cards, and differences are strongly statistically significant.

In terms of diagnosis correctness, the single-card was more effective than the multi-cards in leading participants to identify the correct diagnosis (37.89% vs. 24.61%): these differences are strongly statistically significant. Similarly, for the level of urgency correctness, we also found that the average correctness score of the submitted urgency was

</table>
significantly higher when a single-card was shown (0.543) than when multi-cards were shown (0.4453). To determine the correctness score of the submitted urgency, we computed \( \text{score} = 1 - (|\Delta \text{urgency}| \cdot p) \) where \( \Delta \text{urgency} = \text{correct urgency} - \text{submitted urgency} \) and the possible level of urgency are: 1= self-treat, 2= contact a health professional, and 3= use an emergency service. Lastly, \( p \) models the penalty for an incorrect urgency decision. We set the penalty for incorrect decisions so as to greatly penalise urgency decisions that put the well-being of the person at risk (e.g., decided to self-treat when the correct urgency was to use an emergency service). For this study, we set \( p = 1 \) when \( \Delta \text{urgency} \geq 0 \) and \( p = 0.5 \) when \( \Delta \text{urgency} < 0 \).

The multi-cards interface, on average, lead participants to identify lower levels of urgency (not the correctness score). In fact, a significantly higher level of urgency was recorded when a single-card was shown (\( M = 1.9258 \)) than when multi-cards were shown (\( M = 1.7813 \)). Yet, the mean of the submitted level of urgency from both settings were lower than the mean of the correct level of urgency (2.125). This suggests that participants were more likely to make incorrect “what to do” decisions that could have put the person in the scenario at risk.

The interface type did not influence the session duration (no significant difference, \( M = 158 \text{seconds} \)); however the multi-cards required less efforts (clicking and browsing web pages) from participants than the single-card interface (this difference is statistically significant). In fact, regardless of the presence of a correct card, users opened significantly less result pages when provided with multi-cards. Furthermore, results also show that multi-cards were more likely to lead participants to good abandonment\( ^2 \) compared to the single-card (difference is statistically significant). Note that good abandonment occurs when a scenario is completed without clicking on links from the SERP. Interestingly, although not statistically significant, we found that the likelihood of participants submitting a correct diagnosis was higher when good abandonment occurred (35.36% of 181 scenarios) than when clicking on links (29%). Of the 181 good abandonment occurrences, 83.43% of the decisions were made by selecting information from health cards.

Finally, we found that there were no significance differences in the level of confidence in the decisions made across all search interfaces. Interestingly, in line with Zeng et al.'s findings\( ^1 \), we found no correlation between the level of confidence in the user decisions and the user decisions’ correctness (both diagnosis correctness and urgency score). The majority of the diagnosis decisions (66%) submitted with (very) confidence were incorrect.

Of the six measurements, only the diagnosis decisions’ correctness suggests that the multi-cards are significantly less useful than the single-cards for assisting decision making in CHS. In fact, the highest probability of making a correct diagnosis (57.81%) and the highest average urgency correctness score (0.5977) were found when single correct cards were shown. Nevertheless, determining the single-card that is relevant to a user’s query is not trivial for a search system. A search system may identify the single-card to show by relying on the top search result; alternatively it could rely on ranking cards according to the popularity of the underlying concept within the search results. However, if a system based on a single card interface was to follow any of these two methods, then it would display the correct card for only 1 of the 8 queries in Table\( ^3 \) (thus, probability of single correct card shown: \( P(SC) = 0.125 \)). This is unlike for a multi-cards interface, for which the probability of correct card shown: \( P(MC) = 0.5 \). Overall, the probabilities that a correct diagnosis is made depending on the two interfaces can be compared:

\[
P(\text{correct}|S) \geq P(\text{correct}|M) \Rightarrow \\
P(SC) \cdot P(\text{correct}|SC) + P(SN) \cdot P(\text{correct}|SN) \leq P(MC) \cdot P(\text{correct}|MC) + P(MN) \cdot P(\text{correct}|MN) \Rightarrow \\
0.125 \cdot 0.5781 + 0.875 \cdot 0.1797 \leq 0.5 \cdot 0.4062 + 0.5 \cdot 0.0859 \Rightarrow 0.2295 \leq 0.2461 \tag{1}
\]

The result above suggests that, if the probability of the system showing a correct health card was accounted for, then the multi-cards interface is more likely to lead to correct diagnoses.

**Results for RQ2: How accurate are CHS users in appraising the correctness of health cards?**

Next, we only focus on the MC interface to investigate the users’ ability in identifying the correct health card. We tied the correctness of the appraisal of an information object (cards, snippets) to the diagnosis decision that participants made based on the information object, which is identified by the source of information measurement. That is, a correct appraisal of a health card, for example, occurs when a correct decision is made and information from that health card is selected in their answer.

We found that the majority of participants were not able to assess the correctness of a health card within the MC interface. In fact, of all decisions taken using this interface, 39.1% were taken based on incorrect health cards (and
which lead to incorrect diagnoses), while 33.6% were taken based on correct health cards. This situation is however better than when users attempted to assess snippets. In this case, in fact, the majority of decisions taken using snippets lead to incorrect diagnoses (20.3%), while only 7.0% were correct. Remember that in every SERP, a minimum of two out of 10 snippets contained the correct diagnosis.

In summary, the appraisal of health cards by users is still a challenge, but health cards are more likely to be correctly appraised than search results snippets.

Discussion

Diagnosis correctness was found to be dependent on the correctness of the presented health cards, in line with findings of Pogacar et al. 

Regardless of the interface (single vs. multi-cards), the correctness of the diagnosis was statistically significantly higher when a correct card was presented (0.4922) than when no correct card was presented (0.1328). The highest level of correctness was found when only the correct health card was presented.

Participants consistently underestimated the necessary level of urgency (e.g., decide to self-treat when they should have gone to the Emergency); this finding is independent of the correctness of the diagnosis. Figure 4 shows that, before searching, 51% of 512 tasks have been assigned the wrong level of urgency. Of these, 57% (43%) were underestimated (overestimated). In fact, search activities lead to a strongly significantly increase in number of correct diagnoses (4% correct diagnoses prior to search VS. 38% (single-card) and 25% (multi-cards) post search). However, the number of correctly estimated urgency levels are comparable prior (49%) and post search (50% for single-card; 44% for multi-cards). Of the incorrectly estimated levels of urgency post search, 67% (single-card) and 76% (multi-card) of the times these were underestimated. When considering decisions for which a correct diagnosis was identified, 43% of these had an incorrect urgency level (73% of which were underestimated).

Conclusions

We investigated the influence of health cards to assist decision making in consumer health search. Specifically, we presented eight health scenarios and asked 64 participants to make two decisions: determining the portrait health condition and determining the follow up action that should be taken (level of urgency). The experiment was conducted in a laboratory using two search interfaces: one with a traditional single card and one with a novel multi-cards design. Regardless of the search interfaces, health cards were perceived as relevant, trustworthy and easy to understand.

We found that showing a correct single card leads to the highest probability of identifying a correct diagnosis and level of urgency. However, determining the correct single card that is relevant to a user’s query is not trivial for a search system, and errors are made when an incorrect card is presented instead. If the probability of the system showing a correct health card is accounted for, then the multi-cards interface (which is more likely to show a correct card) leads to a higher number of correct diagnosis decisions than the single-card interface. We also found that participants consistently underestimated urgency across settings: this is of particular concerns because, while an incorrect diagnosis can be rectified by a clinician, this would not happen if users do not seek medical attention.

Furthermore, we found that the multi-cards interface enables users to make health decisions with significantly less effort than the the single card interface. When multi-cards were shown, in fact, participants clicked significantly less links, and completed significantly more scenarios without clicking on links from the SERP (i.e., good abandonment), than when they were presented with a single-card.

The multi-cards were the most preferred source of information, compared to the traditional single cards and the search results snippets. From the eye-gazing data, in fact, we found that when a single-card was shown, participants spent a
comparable amount of time considering the health cards and the snippets. On the other hand, when multi-cards were shown, participants spent significantly more time considering the health cards, compared to the snippets.

Finally, we found that the appraisal of search results is still an issue, even within the multi-cards interface (MC). In fact, only 33.6% of decisions taken in this context and using the health cards lead to a correct diagnosis. However, this was better than when using snippets only (7.0%).

Our findings suggest that, from a search engine designer’s perspective, the provision of health cards (in addition to organic search results) should generally be preferred to the display of search results only. However, care should be taken in selecting the health cards to display, as their correctness influences the correctness of health decisions (both in terms of diagnosis and urgency). To address this aspect, in future work we plan to investigate and advance the effectiveness of current entity-oriented retrieval methods to identify and rank health cards.

A limitation of our study is that participants were recruited from a university campus and this may not be representative of the real diversity of users (e.g., our sample of users was biased towards young people). In future work we plan to overcome this limitation by considering other means of participant recruitment and by increasing the sample size.

Assessing the Validity of a *priori* Patient-Trial Generalizability Score using Real-world Data from a Large Clinical Data Research Network: A Colorectal Cancer Clinical Trial Case Study

Qian Li, MS¹, Zhe He, PhD²#, Yi Guo, PhD¹#, Hansi Zhang, MS¹, Thomas J George Jr, MD, FACP¹, William Hogan, MD, MS¹, Neil Charness, PhD², Jiang Bian, PhD¹*

¹University of Florida, Gainesville, FL, USA; ²Florida State University, Tallahassee, FL, USA;

Abstract

Existing trials had not taken enough consideration of their population representativeness, which can lower the effectiveness when the treatment is applied in real-world clinical practice. We analyzed the eligibility criteria of Bevacizumab colorectal cancer treatment trials, assessed their *a priori* generalizability, and examined how it affects patient outcomes when applied in real-world clinical settings. To do so, we extracted patient-level data from a large collection of electronic health records (EHRs) from the OneFlorida consortium. We built a zero-inflated negative binomial model using a composite patient-trial generalizability (cPTG) score to predict patients’ clinical outcomes (i.e., number of serious adverse events, [SAEs]). Our study results provide a body of evidence that 1) the cPTG scores can predict patient outcomes; and 2) patients who are more similar to the study population in the trials that were used to develop the treatment will have a significantly lower possibility to experience serious adverse events.

Introduction

Clinical studies (trials) are essential in evidence-based medicine.¹ Clinical trials, however, are often conducted under idealized and rigorously controlled conditions to improve their internal validity and success rates; but such conditions, paradoxically, may compromise their external validity (i.e., trial results’ generalizability to the real-world target populations).² These idealized conditions are sometimes exaggerated and reflected as overly restrictive eligibility criteria. The generalizability and study population representativeness have long been major concerns.²,³ Certain population subgroups, such as older adults,⁴,⁵ are often underrepresented due to unjustified exclusion criteria, especially in cancer studies.⁶⁻¹⁰ The underrepresentation of these population subgroups can lead to low trial generalizability, and subsequently, reduce treatment effectiveness and increase the likelihood of adverse outcomes in these population subgroups when the treatments are moved into real-world clinical practice. As a consequence, some approved drugs have been withdrawn from the market after serious adverse drug reactions were observed on population subgroups excluded from the original trials.¹¹

In clinical trials, the target population represents the patients to whom the results of the clinical trials are intended to be applied. The study population represents the patients being sought as defined in the clinical trial eligibility criteria (Figure 1). To ensure patient safety and demonstrate treatment efficacy, eligibility criteria are often restrictive, thus representing a constrained subset of the target population. Further, study samples are the enrolled participants of a trial. Even though study participants are screened based on eligibility criteria, due to real-world constraints such as trial awareness, the study sample may not adequately represent the study population defined by the eligibility criteria. Further, it is worth noting that the notions of generalizability and population representativeness are related but distinct. Population representativeness measures the study population’s coverage of real-world patients, with respect to study traits (e.g., age, vitals, and labs), often defined by eligibility criteria. On the other hand, generalizability is the portability of the causal effects of an intervention to real-world settings. Besides population representativeness, other factors also affect studies’ generalizability, such as variation in patients across different clinical settings, discrepancies in conditions under which a trial was conducted, and incomplete reporting.¹²,¹³ Nevertheless, population representativeness of the study population is one of the determining factors for its generalizability.

Figure 1. Populations in clinical trials.
There are two major types of approaches to assessing a study’s population representativeness: 1) the \textit{a priori} generalizability is the representativeness of eligible participants (study population) to the target population; 2) the \textit{a posteriori} generalizability is the representativeness of enrolled participants (study sample) to the target population. The \textit{a priori} generalizability can also be called as the eligibility-driven generalizability, whereas the \textit{a posteriori} generalizability can be called as the sample-driven generalizability.\textsuperscript{14} However, the \textit{a posteriori} generalizability is an artifact after the fact (i.e., can only be done when a trial is concluded and complete trial data are collected), while the \textit{a priori} generalizability is affected by the trial’s eligibility criteria that are modifiable during the study design phase.

In 2014, an \textit{a priori} generalizability score “Generalizability Index for Study Traits” (GIST 1.0; we use 1.0 to differentiate these from the GIST 2.0 metrics introduced below) was introduced to quantify the population representativeness using eligibility criteria one at a time and real-world patient data.\textsuperscript{15} The GIST 1.0 score characterizes the proportion of patients that would be potentially eligible across trials with the same trait over the target population. GIST 1.0 was validated using a simulated target population.\textsuperscript{16} As some criteria are correlated, GIST was extended to mGIST 1.0 with joint use of multiple eligibility criteria.\textsuperscript{17} Later, GIST 2.0\textsuperscript{18} was developed to consider both 1) the dependencies across multiple criteria in a study, and 2) the significance of individual traits across different diseases (e.g., HbA1C is more important in type 2 diabetes than it is in chronic kidney disease). GIST 2.0 has two components: sGIST (w.r.t. one criterion) and mGIST (w.r.t. multiple criteria) corresponding to the original GIST 1.0 and mGIST 1.0, respectively. GIST scores are between 0 and 1, where a higher score indicates a greater population representativeness. From now on, we will use sGIST and mGIST to refer to the GIST 2.0 metrics.

Nevertheless, to be able to rationalize adjustments of eligibility criteria towards ultimately better generalizability early on, it is important to identify the relationships among the \textit{a priori} generalizability and the actual outcomes of the interventions/treatments in real-world settings. Treatment outcomes can be measured in several different ways: 1) improvement in clinical outcomes (e.g., better lab results), 2) less adverse events (AEs); and ultimately 3) longer survival and better quality-of-life (QoL). Adverse event is an important measure of treatment safety during clinical trials. Previously, Sen et al. found that GIST 2.0 score was significantly correlated with the number of AEs (i.e., the lower the GIST 2.0 score the higher the number of AEs) based on data from 16 sepsis trial results sections in ClinicalTrials.gov.\textsuperscript{14} Nevertheless, their study is limited as it does not provide any evidence on whether the \textit{a priori} generalizability of the trials had any impact on the clinical outcomes (i.e., the number of AEs) when the treatment is applied to the target patients in real-world clinical practices.

On the other hand, the wide adoption of electronic health record (EHR) systems and the proliferation of clinical data warehouses with rich real-world patient datasets offer unique opportunities to address these studies. The U.S. Food and Drug Administration (FDA) recently coined the terms real-world evidence (RWE) and real-world data (RWD) as “data regarding the usage, or the potential benefits or risks, of a drug derived from sources other than traditional clinical trials.”\textsuperscript{19,20} RWD can come from various sources including EHRs, claims and billing activities as well as patient-generated data. These data will play an increasingly important role in health care and regulatory decisions.

In this study, we aim to fill this important knowledge gap exploring the hypotheses that 1) the \textit{a priori} generalizability of treatment trials is correlated with the clinical outcomes of the treatment (i.e., the number of AEs) and 2) patients who are eligible (i.e., based on the trials’ eligibility criteria and patient characteristics in their EHRs) for the original trials used to develop the treatment will have better clinical outcomes than those who are not, when the treatment is applied on both eligible/ineligible patients in real-world clinical settings, using RWD—a large collection of linked EHRs and claims—from a large clinical data research network. Our current study focuses on Bevacizumab (under the trade name Avastin)—a first of its kind of monoclonal antibody as a tumor-starving (anti-angiogenic) therapy—approved by the FDA in 2006 for the treatment of metastatic colorectal cancer.\textsuperscript{21}

\section*{Methods}

\subsubsection*{Data sources}

\textbf{Bevacizumab (Avastin) clinical trials and trial eligibility criteria.} We obtained free-text eligibility criteria from ClinicalTrials.gov—a registry maintained by the National Library of Medicine (NLM) in the United States. As of March 2019, over 299,335 studies across all 50 states in the US as well as in 208 countries are registered on ClinicalTrials.gov. Study information in ClinicalTrials.gov is semi-structured: study descriptors such as study phase, intervention type, and locations are stored in structured fields while eligibility criteria are largely free-text. Through ClinicalTrials.gov, we found 57 Bevacizumab trials that met our inclusion criteria: 1) the trial was conducted in the US; 2) the primary purpose of the trial is the development of the treatment agent; and 3) excluding post-market observational studies (e.g., comparative effectiveness studies, and essentially all Phase IV studies).
Real-world patient data from the OneFlorida. We obtained individual-level patient data from the OneFlorida Clinical Research Consortium (OneFlorida CRC), one of the 13 Clinical Data Research Networks (CDRNs) contributing to the national Patient-Centered Clinical Research Network (PCORnet) previously funded by the Patient-Centered Outcomes Research Institute (PCORI). PCORnet is now supported by the newly incorporated People Centered Research Foundation (PCRF), a nonprofit formed by PCORnet investigators with significant additional infrastructure-building funds from PCORI. The OneFlorida data repository integrated various data sources from contributing organizations in the OneFlorida CRC currently including 10 healthcare organizations: 1) two academic health centers (i.e., University of Florida Health, UFHealth and University of Miami Health System, UHealth), 2) seven healthcare systems including Tallahassee Memorial Healthcare (TMH affiliated with Florida State University), Orlando Health (ORH), Adventist Health (AH, formerly known as Florida Hospital), Nicklaus Children’s Hospital (NCH, formerly known as Miami Children’s Hospital), Bond Community Health (BCH), Capital Health Plan (CHP), and Health Choice Network, (HCN), and 3) CommunityHealth IT—a rural health network in Florida. In addition, OneFlorida also obtained claims data from the Florida Medicaid (FLM) program. As a network, the OneFlorida CRC provides care for approximately 48% of Floridians through 4,100 physicians, 914 clinical practices, and 22 hospitals with a catchment area covering all 67 Florida counties. Most HCOs in OneFlorida contributed EHRs, while CHP and FLM contributed claims data. We linked patients across the different EHRs and claims data sources using a validated privacy-preserving record linkage method. OneFlorida contains only a limited data set under the Health Insurance Portability and Accountability Act (HIPAA) and follows the PCORnet Common Data Model (CDM) v4.1 including patient demographics, enrollment status, vital signs, conditions, encounters, diagnoses, procedures, prescribing (i.e., provider orders for medications), dispensing (i.e., outpatient pharmacy dispensing), and lab results. The scale of the data is ever growing with a collection of longitudinal and robust patient-level records of ~15 million Floridians and over 463 million encounters, 917.6 million diagnoses, 1 billion prescribing records, and 1.17 billion procedures as of December 2018. Since our goal is to evaluate the generalizability of Bevacizumab trials as a colorectal cancer treatment, we extracted colorectal patients from OneFlorida as the target population using ICD-9/10-CM codes (i.e., ICD-9: 153.*, 154.*, 159.0; ICD-10: C18.*, C19.*, C20.*, C26.0). We identified 39,776 unique colorectal patients and extracted their data from OneFlorida.

Figure 2. Overall study design and selection of study populations.

**Overall study design**

There are 3 different populations in our study: 1) population A: OneFlorida colorectal cancer patients who were treated with Bevacizumab; 2) population B: patients who were treated with Bevacizumab and eligible for the original trials
Our hypothesis is that population A and population B will have better outcomes (i.e., less AEs) compared with population C. To do so, we devised a composite patient-trial generalizability (cPTG) score based on GIST that considers both trial generalizability and patient eligibility of the individual trials.

Our analysis consists of 7 steps: 1) analyzing Bevacizumab colorectal cancer treatment trials extracted from ClinicalTrials.gov to determine the computability of each eligibility criterion and constructing queries to extract study traits corresponding to each trial eligibility criterion based on the OneFlorida data; 2) identifying the different populations of interest (i.e., populations B and C as described above); 3) calculating each trial’s GIST score based on the computable eligibility criteria of each trial; 4) determining the eligibility (i.e., a binary variable) of each patient for each Bevacizumab trial of interest; 5) calculating the composite patient-trial generalizability score for each patient; 6) identifying each patient’s clinical outcome (i.e., the number of serious AEs) of being treated with Bevacizumab; and 7) comparing the difference in the numbers of serious AEs between population B and population C and examining the relationships between the cPTG score and the number of serious AEs.

### Defining populations of interest and serious adverse events (SAEs) related to using Bevacizumab

We used International Classification of Diseases, Ninth Revision/Tenth Revision, Clinical Modification (ICD-9/10-CM) codes to identify patients who were diagnosed with colorectal cancer in the OneFlorida data. Within the colorectal cancer patients, we then used the Healthcare Common Procedure Coding System (HCPCS) codes (e.g., C9257, J9035) combined with Bevacizumab’s RxNORM (e.g., 337521) codes to identify the administration of Bevacizumab. To identify SAEs in patients treated with Bevacizumab, we first reviewed the FDA approved drug label of Bevacizumab using the DailyMed database maintained by NLM. Then for each SAE, we identify the corresponding ICD-9/10-CM codes, as shown in Table 1.

### Table 1. ICD-9/10 codes to define serious adverse events for Bevacizumab based on its drug label.

As shown in Figure 3, to count as a SAE related to Bevacizumab, the SAE diagnosis code has to occur 1) after the first Bevacizumab procedure, but 2) within 180 days after the last Bevacizumab procedure. Note that the first Bevacizumab procedure has to occur after the diagnosis of colorectal cancer. Using these criteria, we counted the total number of SAEs for each patient.

### A new composite patient-trial generalizability (cPTG) score based on GIST

Figure 3. Selection window for serious adverse events related to treating colorectal cancer with Bevacizumab.
The original GIST metric quantifies the \textit{a priori} generalizability of clinical trials with respect to selected quantitative eligibility criteria that specify a permissible value range (e.g., HbA1c $> 7\%$), one at a time.\textsuperscript{15} The GIST score ranges from 0 to 1, with 0 being not generalizable and 1 being perfectly generalizable. In essence, it characterizes the proportion of patients potentially eligible across trials. The extension of GIST, mGIST,\textsuperscript{17} can quantify the population representativeness with joint use of multiple criteria of interest. Both GIST and mGIST focus on the generalizability assessment at the disease domain level (i.e., assessing the generalizability of trials targeting the same disease). GIST 2.0 was then introduced as a scalable multivariate metric for quantifying the population representativeness of individual clinical trials by explicitly modeling the dependencies among all eligibility criteria.\textsuperscript{18} The original implementation of GIST 2.0 was in Matlab. We implemented GIST 2.0 in Python and made it available in a public Github repository (i.e., \url{https://github.com/Andeeli/GIST.git}). The calculation of sGIST and mGIST is trivial and details can be found in the original GIST 2.0 publication.\textsuperscript{18} One key input is to define the target population (i.e., the real-world patient population that the treatment is intended to be applied on). For our study, we defined patients with colorectal cancer and treated with Bevacizumab (i.e., population A) as our target population. The outputs of GIST 2.0 are single-trait GIST score (sGIST) for each trait and one multiple-trait GIST score (mGIST) for the trial.

As the mGIST score is a trial-level variable, we also need to determine whether a patient is thought to be eligible of a trial based on its eligibility criteria and corresponding patient traits as defined in their EHRs (i.e., based on OneFlorida data in our case). The process is straightforward. For example, “Platelet count at least 1,500/mm$^3$” is an inclusion criterion in trial NCT00025337. The lab results for platelet tests are coded using Logical Observation Identifiers Names and Codes (LOINC) (i.e., 26515-7, 777-3, and 778-1) in OneFlorida. Based on these LOINC codes, we queried patients’ platelet test results and transformed the measurement unit to mm$/^3$ if needed. If a patient’s platelet lab result is larger or equal to 1,500/mm$^3$, we will consider the patient as met this particular inclusion criterion. We then determined the patient’s eligibility (i.e., a binary variable) of the trial, when the patient met all the inclusion criteria while did not meet any of the exclusion criteria. Note that not all eligibility criteria are computable as the needed data elements may not exist in their EHRs (e.g., “Fertile patients must use effective contraception”). We did not use these non-computable criteria when determining a patient’s eligibility.

In order to consider both the patient-level eligibility and trial-level \textit{a priori} generalizability, we propose a composite patient-trial generalizability (cPTG) score. To calculate cPTG score, we first calculated the mGIST score (ranging from 0 to 1) for each trial. Then, we used patients’ traits data (from OneFlorida) to create an index (i.e., 0 as not eligible or 1 as eligible) to indicate whether a patient is eligible for the specific trial or not. We then took the average of the dot product of the vector of mGIST and the vector of patient’s eligibility as follows:

$$cPTG_{i} = \frac{1}{K} \sum_{j=1}^{K} e_{ij} g_{j}$$

where $e_{ij}$ is the eligibility (0 or 1) for patient $i$ of trial $j$, and $g_{j}$ is the generalizability score (i.e., mGIST) of trial $j$, for each patient $i$ (i.e., $i=1,2,...,N$) and each trial $j$ (i.e., $j=1,2,...,K$). The cPTG score ranges from 0 to 1. Intuitively, a higher cPTG score for a patient means the patient is eligible for more trials in the set of trials of interest and those trials have higher \textit{a priori} generalizability.

\textbf{Statistical analysis}

Mean and standard deviation were calculated for continuous variables. For categorical variables, frequency and percentage was calculated. As more than 80\% of the patients in our data have zero adverse events. We fit a zero-inflated model to consider the number of SAEs as the outcome and the cPTG score as a predictor. We also considered the following variables as controlling covariates in the model: the number of Bevacizumab procedure, days of follow up from latest Bevacizumab procedure, and patient demographics including age, gender, race, and ethnicity. Since the variance of the outcome is much larger than the mean, the data is over-dispersed. So, we preferred the zero-inflated negative binomial model to a zero-inflated Poisson regression model.\textsuperscript{26}

\textbf{Results}

\textbf{Cohort characteristics}

We identified 2,531 unique patients who had been diagnosed with colorectal cancer and treated with Bevacizumab (out of a total of 39,776 colorectal cancer patients). Among these patients, 2,034 (80.4\%) had no SAE while 497 (19.6\%) had at least one SAE. The average age of the patient at her/his last Bevacizumab procedure is 59 years old. Although male patients are slightly more than female patients, there are more female patients with SAEs. Table 2 shows the characteristics of our target population.
Table 2. Demographic characteristics and outcomes of the target population in OneFlorida.

**Analysis of Bevacizumab colorectal cancer trial eligibility criteria**

From the collection of 57 Bevacizumab colorectal trials, we extracted 1,674 eligibility criteria (i.e., 951 inclusion criteria and 723 exclusion criteria) from ClinicalTrials.gov. 124 of the 951 (13.04%) inclusion criteria contained negations; and 19 of the 723 (2.63%) exclusion criteria contained negations. On average, each colorectal trial has 26 (4 to 65) inclusion criteria and 27 (0 to 39) exclusion criteria. Comparing to our previous study on Hepatitis C Virus (HCV) trials, colorectal cancer trials have significantly more inclusion and exclusion criteria (5.56 inclusion criteria and 7.98 exclusion criteria in HCV trials). We then extracted the core elements of each inclusion/exclusion criterion and summarized these 1,674 eligibility criteria into 678 unique criterion patterns. Many of the inclusion and exclusion criterion patterns were fundamentally similar (i.e., querying the same core data elements). Note that some criteria can be decomposed into multiple sub-criteria; we thus considered the smallest units as individual study traits (e.g., “history of primary CNS (central nerve system) tumor, or stroke” can be decomposed into “history of primary CNS tumor” and “history of stroke”). Table 3 shows the top 10 most frequent criterion patterns, separated by inclusion vs. exclusion.

**Table 3. Top 10 frequent criterion patterns used by the 57 trials, separated by inclusion vs. exclusion.**

</table>

However, not all eligibility criteria were computable against our OneFlorida patient database. We found that 194 (28.61%) of the 678 unique patterns were not computable. The main reasons are: (1) the criterion asked for subjective information (e.g., patient’s consent or investigator’s judgement of patient’s health status); and (2) the data elements needed for the criterion were not presented in the OneFlorida data (e.g., “performance status ecog 0-1” is not captured).

The composite patient-trial generalizability (cPTG) score
Out of the 57 trials, there are 10 Phase I, 6 Phase I/II, 31 Phase II, and 7 Phase III trials (the other 2 have no phase information). We randomly selected 4 trials out of the 7 Phase III trials to model patient eligibility and trial generalizability. We selected Phase III trials as they are conducted to expand on the safety and effectiveness results from Phase I and II trials, to compare the drug to standard therapies, and to evaluate the overall risks and benefits of the treatment, right before the treatment can be approved by the FDA and be put on the market. A Phase III trial typically recruits larger groups of people with more relaxed eligibility criteria comparing to Phase I and II trials.

To calculate cPTG scores, we first calculated the mGIST scores of the 4 trials using population A as the target population (i.e., patients who were treated with Bevacizumab for colorectal cancer). Table 4 lists the total number of study traits based on the eligibility criteria (regardless of inclusion or exclusion), the number of computable traits, and the mGIST score for each of the 4 trials. There are 219 unique study traits across the 4 trials, and the top 5 common traits are: age, aspartate aminotransferase (AST), bone fracture, pregnancy test, and skin ulcers.

*SAE: serious adverse event; SD: standard deviation; mGIST: multi-trait Generalizability Index on Study Traits (GIST 2.0).

We first used Wilcoxon rank sums test to test the difference of the number of SAEs between eligible vs. no eligible patients and found the differences are statically significant for all 4 trials (Table 4).

The relationship between the patient-trial generalizability and clinical outcomes

The zero-inflated negative binomial model results have two parts, as shown in Table 5.

Table 5. Zero-inflated negative binomial model for the relationships between cPTG and clinical outcomes.

</tbody>
</table>
The first part is a logistic model, estimating the probability of being an excessive zero (i.e., having no SAE). Two variables—gender and the number of Bevacizumab procedures—are statistically significant at 0.05 level in this part of the model. The odds ratio for female verse male of being an excessive zero is exp(-0.78) = 0.458. This indicates that female has a higher possibility of having SAEs than male while holding other predictors constant. Further, with the number of Bevacizumab procedures increasing by 1, the odds of having no SAE decreases by 0.049 (i.e., 1 - exp(-0.05)=0.049). This indicates that having more Bevacizumab procedures increases the possibility of having SAEs, holding other predictors constant. Although the cPTG score is not statistically significant in the logistic model, the estimate equals to 1.30, meaning the odds of having no SAE increase by exp(1.30*0.1) - 1 = 0.139 for a 0.1 increase in the patient-trial generalizability score, holding other variables constant.

The second part is a negative binomial regression model, estimating the expected number of SAEs. Two variables—the number of Bevacizumab procedures and cPTG score—are statistically significant at 0.05 level. The expected number of SAEs increases by exp(0.024) – 1 = 0.0243 for 1 increases in the number of Bevacizumab procedures, indicating more Bevacizumab procedures would have more SAEs. Further, the expected change in the number of SAEs decreases by 1 – exp(-1.079*0.1) = 0.102 for 0.1 increase in cPTG. This indicates that a higher cPTG would lead to a smaller number of SAEs, while holding other variables constant. The dispersion is 5.421 (>1); thus, using a binomial model is more appropriate than a Poisson model.26

Discussion and conclusion

Our results successfully connect the generalizability to clinical outcomes using RWD. First, we showed that the patients who are eligible for the original trials (that were used to develop the treatment, population B in our case) have better treatment outcomes compared with those who are not eligible (i.e., population C) in real-world clinical practice. This indicates reduced generalizability of the original trials because of the differences between the characteristics of the trial (or trial-eligible) population and ineligible population. Because of these differences, the original trials may have failed to gather sufficient safety and efficacy data on the entire target population, resulting in poorer outcomes when the treatment is applied in real-world clinical settings. Second, we devised a new patient-trial generalizability score considering both patient-level eligibility and trial-level a priori generalizability. A higher cPTG score of a patient indicates that the patient can be eligible for more (original) trials (i.e., the patient’s characteristics are more similar to those in the trial population) and these trails have a higher a priori generalizability.

These results have multiple implications. First, it shows the feasibility of using RWD, especially EHRs, to assess patients’ clinical outcomes (e.g., adverse events) and examine various patient characteristics associated with these outcomes. Being able to capture AEs using data collected through routine the standard of care provides us the opportunity to create informatics surveillance systems for post-market drug safety monitoring. Comparing to the existing AE reporting systems (e.g., the FDA Adverse Event Reporting System, [FAERS]), EHRs is a much richer data source (e.g., lab results and diagnoses of other diseases) that provides a more complete picture of patients’ characteristics. Further, being able to work with data from a large data research network not only gives us a large sample size and sufficient power to make robust conclusions but also makes our approaches adaptable to other similar networks. Because of the use of a common data model (CDM), our study can be readily replicated in other sites of the PCORnet, which covers more than 100 million patients across the United State.28 Moreover, it is also possible to extend our study to other clinical research network initiatives such as the National Center for Advancing Translational Sciences (NCATS)’s Clinical and Translational Science Awards Accrual to Clinical Trials (CTSA ACT) network and the Observational Health Data Sciences and Informatics (OHDSI) consortium. Even though they are using different CDMs, adapting our approach to a new CDM is rather straightforward.

Further, our study builds a body of evidence to support the development of an eligibility criteria design tool for optimizing study generalizability at the study design phase. Such an eligibility criteria design tool is much needed and will benefit stakeholders of the clinical trial communities. To the extent that trial participants share the same characteristics as the majority of patients, trials should be developed to fit patient profiles seen in real-world clinical practice, and thus, facilitate the application of trial results to real-world clinical settings.29 This could be achieved if trials had few restrictions on eligibility, allowing more representative patients to participate. A significant proportion of real world patients are unable to participate in clinical trials due to stringent exclusion criteria, but many still received treatment outside of clinical trials and benefited from therapy.30 A recent special issue on eligibility criteria in the Journal of Clinical Oncology—a leading clinical oncology research journal—calls for “broadening eligibility criteria to make clinical trials more representative.”31 As a response, the National Cancer Institute (NCI) has revised its clinical trial protocols to expand access for previously excluded patients in an effort to ensure that study participants are more reflective of real-world populations.32 Our study provides initial data evidence that 1) a priori
generalizability is qualifiable and 2) combined with patient eligibility, the cPTG score can predict clinical outcomes in real-world patients. This eventually could lead to metrics that rationalize the design (or relaxation) of eligibility criteria.

Last, our study also leads to opportunities to develop a computable eligibility criteria framework for EHR-based cohort identification to facilitate trial recruitment. One can imagine a tool that a trial investigator could not only identify patients who are eligible to the trial of interest based on their EHRs, but also be able to estimate the impact of recruiting a particular patient on the trial’s generalizability and possible clinical outcomes on similar patients.

Our study is not without limitations. The process of analyzing and decomposing existing eligibility criteria into computable eligibility criteria against EHRs is both time- and labor-intensive. Exploring advanced natural language processing tools tailored for analyzing eligibility criteria might be beneficial. Nevertheless, to tease out the subtle ambiguities in free-text eligibility criteria, human judgments are always needed. Moreover, many eligibility criteria cannot be accurately translated into database queries (e.g., “At least 10 days since prior aspirin dose of more than 325 mg/day”). We took a simplistic approach and did not consider these temporal constraints, which may lead to a small number of inaccurate identifications of patient eligibility. Further, some criteria (e.g., lab results) may be matched to multiple observations (e.g., blood pressure) that vary from time to time. We made an assumption that the patient will meet the criterion as long as if any one of the observations fell into the permissible value range.

In sum, our results are significant. Our ultimate goal is to provide an easy-to-use and more efficient computable eligibility criteria construction platform for investigators to identify eligible patients based on their existing EHRs while maximizing the trial’s a priori generalizability.

Abstract

Approximately 60 million people worldwide suffer from epileptic seizures. A key challenge in machine learning approaches for epilepsy research is the lack of a data resource of analysis-ready (no additional preprocessing is needed when using the data for developing computational methods) seizure signal datasets with associated tools for seizure data management and visualization. We introduce SeizureBank, a web-based data management and visualization system for epileptic seizures. SeizureBank comes with a built-in seizure data preparation pipeline and web-based interfaces for querying, exporting and visualizing seizure-related signal data. In this pilot study, 224 seizures from 115 patients were extracted from over one terabyte of signal data and deposited in SeizureBank. To demonstrate the value of this approach, we develop a feature-based seizure identification approach and evaluate the performance on a variety of data sources. The results can serve as a cross-dataset evaluation benchmark for future seizure identification studies.

1 Introduction

Epilepsy is one of the most common neurological disorders, and an estimated 60 million people suffer from this condition worldwide. An epileptic seizure (hereafter referred to as seizure) is a brief episode of signs or symptoms due to transient and undesired, excessive and synchronous electrical discharge, involving large numbers of neurons within the brain. When a seizure occurs, it may change patient behavior, movements or feelings, and level of consciousness. It may produce temporary confusion, uncontrollable jerking movements of the arms and legs, inability to speak, and loss of consciousness or awareness. In a worst-case scenario, frequent seizures may predispose a person to sudden unexpected death of epilepsy (SUDEP). The more frequent the seizures, the higher the risk of SUDEP.

The identification and diagnosis of specific types of epileptic seizures require long-duration monitoring of patients’ electrophysiological status including electroencephalogram (EEG) and electrocardiogram (ECG) in Epilepsy Monitoring Units. However, manual processing of long-duration electrophysiological signals after their acquisition can be a tedious, labor-intensive, time-consuming, and error-prone task. Therefore, it is desirable to develop robust and reliable automated techniques for epileptic event identification based on electrophysiological signals, in order to facilitate real-time seizure monitoring. However, most existing approaches for seizure analysis face the following challenges.

Data preparation. Data preparation, including data extraction, cleaning, reorganization, and reformattting, is an important step in seizure-related studies and applications. In general, an estimated 80% of the work conducted by data scientists is focused on data preprocessing. Cleaning and organizing data take 60% of their time. It is time-consuming and labor-intensive to create a clean, high-quality, and large dataset.

During the data preparation step for the Center for SUDEP Research (CSR), we have encountered several challenges. (1) Data corruption: Sometimes the clinical data may be corrupted during the transaction or conversion process. Certain Zip archives may not be unzipped using the existing software or tools. (2) Inefficiently use of computing resources: A plenty of time and memory were expended on retrieving and extracting irrelevant data from the dataset. (3) Lack of standardized annotation labels: In the CSR data repository, there are three types of labels in an annotation file: official annotation label (OAL), machine label, and free-text label. OALs are from the CSR official and curated annotation label library. Machine labels are created by different machine learning algorithms. Free-text labels are generated by different annotators or experts, which may contain typical manual errors, such as: (i) spelling mistake, e.g., “clinical eventend” should be “clinical event end”; (ii) many-to-one correspondence, i.e., different labels represent the identical meaning for an annotation, e.g., both “clinical end” and “clinical seizure end” represent the end time of a
seizure; and (iii) annotation incompleteness, e.g., some annotations only have the label of the event start time without the label of the event end time.

**Lack of integrated data management, visualization, and analytic system.** The need for data integration and management systems arises with the increasing volume of data. Researchers need query and data exploration tools to find and extract subset of signal data meeting their specific requirements from a large dataset. The lack of an effective and efficient solution to capture, integrate, manage and query seizure-related data becomes one of the main challenges in epilepsy research. Beyond epilepsy research, supporting high-quality data management, analytics, and visualization is one of the goals in National Institutes of Health (NIH) strategic plan for data science.

**Lack of a cross-dataset evaluation benchmark for seizure analysis.** Most previous approaches for seizure analysis were performed and evaluated on a single public seizure dataset, as there is a lack of cross-dataset evaluation benchmark for testing the performance of an approach applied on different datasets. Such cross-dataset evaluation benchmark may empower the development of reliable and robust analytical methods for real-world applications.

In this paper, we introduce SeizureBank, a web-based signal data management and visualization system for epileptic seizure research, to address the above-mentioned challenges. SeizureBank has several key features as follows.

**A scalable seizure data preparation pipeline.** We develop a data preparation pipeline with a novel data model. We address the issues of data corruption and lack of standardized annotation labels with three steps in the pipeline: data extraction, data validation, and data correction. We improve computational performance for data preparation with scalable algorithms, making it more suitable for rapid changes in the growth of data. The input of this pipeline is the raw data from the CSR data repository, including the signal data in European Data Format (EDF) and associated annotation files. The output is the processed data stored in a database with our new data model (Section 3.2.B).

**An analysis-ready electrophysiological signal dataset.** We extract seizure-related signal data according to annotation files in the CSR using our data preparation pipeline, and then import the analysis-ready data into the database. It provides a set of epileptic seizure-related data. The signal fragments (i.e., signal data during a time period) use less storage space in a simple and common file format, such as JavaScript Object Notation (JSON) and Comma Separated Values (CSV). They can be individually or group exported instead of using entire large signal file with complex data structures such as EDF. With such analysis-ready dataset, researchers may obtain the preprocessed data directly and spend less time on data preparation and cleaning.

**A feature-rich, web-based seizure data management and visualization system.** The main idea of this system is to provide a set of functions that enable users to perform a clinical event-specific query and exploration at precise time-points. With such capabilities, researchers can compose complex queries over a number of patients and signal files according to their research requirements, quickly visualize physiological signal fragments of interest, assess the feasibility of research studies, and make appropriate full data access requests for further analysis.

To validate the utility of SeizureBank, we implemented our new data preparation pipeline on a subset of electrophysiological signal data (1.15 TB) from the CSR repository and performed a preliminary performance evaluation to demonstrate the feasibility and advantages of our data preparation process. Based on the analysis-ready seizure signal dataset, we developed a feature-based seizure identification technique. We extracted 134 new features and applied four classifiers to three different datasets: a dataset in SeizureBank and two widely used public datasets. Our experiment results on two public datasets compared favorably to previous work. All the results of the three datasets can serve as a cross-dataset benchmark for future seizure identification research and applications.

**2 Background**

**2.1 The Center for SUDEP Research (CSR)**

CSR is a Center Without Walls Initiative of the National Institute for Neurological Disorders and Stroke (NINDS) for collaborative research in the epilepsies. CSR is comprised of researchers from 14 institutions, bringing together diverse expertise for SUDEP research. CSR provides a comprehensive, curated prospectively constructed repository of epilepsy-related data consisting of electrophysiological signals linked to risk factors and outcome data for about 3,000 epilepsy patients (with a broad spectrum of age, social, racial, and ethnic) with thousands of 24-hours recordings.
2.2 Public epileptic seizure datasets

Two popular seizure datasets are publicly available. The first one is the University of Bonn seizure dataset (UBSD), which is considered a benchmark dataset of testing classification techniques. This dataset contains five subsets (A, B, C, D, and E) of EEG data from both normal and epileptic subjects. Set A and B consist of normal EEG data during an awake state with eyes open and eyes closed respectively from 5 subjects. Sets C, D, and E contain recorded signal data using implanted intracranial electrodes from 5 epileptic patients. However, set C and D contain only activities measured during seizure-free intervals, and only set E carries seizure activities. Each subset contains 100 text files of segmented EEG signals fragments (in 23.6 seconds) and a total of 4,097 samples at a 173.61 Hz sampling rate. There is no available information about the age and gender associated with this dataset.

The second public dataset is the CHB-MIT scalp EEG database. EEG records at a sampling rate of 256 Hz were obtained from 23 pediatric patients (5 male patients in the age group of 3 to 22 years, and 18 female patients in the age group of 1.5 to 19 years). The basic statistics of the two datasets are summarized in Table 1.

3 Methods

We introduce a seizure analysis workflow with SeizureBank, including a new data preparation pipeline and a data management and visualization system (Figure 1). With this workflow, we create an analysis-ready seizure-related signal dataset and apply different seizure identification approaches to a variety of data resources. First, we obtain raw data from the CSR data repository (Figure 1.A). Then, with our data preparation approach (Figure 1.B, details are described in Section 3.1), the analysis-ready and well-formatted (in CSV or JSON) seizure-related electrophysiological signal data are imported into the database. With a web-based system dedicated for SeizureBank, researchers can query, visualize, and download each seizure signal fragment of interest with built-in signal visualization and analytic functions (Figure 1.C, as described in Section 3.2). With our new signal dataset, we further introduce and evaluate different seizure identification approaches in Section 3.3 to demonstrate a pathway for constructing a cross-dataset evaluation benchmark based on three datasets, including the UBSD, CHB-MIT, and SeizureBank, for future research.

3.1 Data preparation pipeline in SeizureBank

A. Data extraction. In the CSR data repository, about 10% of raw data had data corruption or unzipping issue. It is a serious problem during the data preparation since data parsing may be interrupted due to "uncompress file error" or "unknown file exception." It is difficult to manually fix the corrupted data. We develop three functions to recover uncorrupted files from a corrupted zip archive. There is no need to read and uncompress the entire archive, especially for signal files, to obtain the required information. We extract the metadata and annotation data, which is only a small part (< 0.1%) of the entire file, from the archive. Based on the extracted metadata and annotation data, we filter the irrelevant files and focus on the signal files with seizure annotations. This way, the memory usage and the running time for data extraction can be improved. It becomes more efficient to retrieve and extract a piece of the signal containing useful data. For label matching, we use Levenshtein distance to handle the misspelling of labels. Informally, the Levenshtein distance between two words is defined as the minimum required number of single-character edits, such as insertions, deletions or substitutions, to change one word into another one. Thus, our program can recognize the majority of labels with few exceptions. We create two mapping files, named OAL mapping and OAL alias mapping, for label pairing and pattern matching to address many-to-one label issue. Using the two mapping files, the program
can find the correct corresponding labels based on the mapping files.

B. Data validation. All the extracted seizure-related label-pairs from step A, containing the start time and end time of a seizure event, are stored in an annotation database. It is necessary to verify the correctness of extracted label-pairs by domain experts due to the issue of inconsistent annotation labels. There are three potential cases as follows. (1) In the case of correct label-pairs, we extract and reformat the corresponding signal data to an efficient data format and import the reformatted data into the database (Figure 1.B.4). (2) In the case of incomplete label-pairs caused by missing labels, we record all these incomplete label-pairs, which can not find the corresponding start time label or end time label, and related annotation files. Experts manually verify the annotation labels with the signal and annotation files and recover the missing labels. Then we add recovered annotation labels into the mapping file to re-extract label-pairs (Figure 1.B.5). (3) In the case of anomalous label-pairs caused by annotation incompleteness issue, we correct seizure data in the step of data correction (Figure 1.B.6) described next.

C. Data correction. There may exist two types of anomalous seizure label-pairs. (1) Caused by incorrect start or end timestamp. For example, if the duration of a label-pair is more than 60 minutes, which rarely occurs in an epileptic seizure, the label-pair will be recorded and sent to domain experts for further verification. After verification, we correct the timestamp of the label-pair based on experts’ feedback. (2) Caused by overlap. For extracted label-pairs, a label-pair with long duration may contain several label-pairs with short durations. We divide the long one into several separate short-duration label-pairs. Overlapping portions between extracted label-pairs are removed afterwards.

The signal fragments are extracted based on curated label-pairs and reformatted with new data format (Figure 1.B.7). All the signal fragments are imported into the database for further querying, visualization, and analysis (Figure 1.B.8).

3.2 Data management and visualization system

SeizureBank provides an integrated data management and visualization system (Figure 1.C) with feature-rich web interfaces for clinicians and researchers, including (1) cloud storage (the storage in the server) for seizure-related data, to address the storage limitations of the local machine; thus, researchers no longer need to store the entire signal dataset and only keep the relevant seizure data for further analysis; (2) standardized, metadata-based search and query of seizure-related signal data for accessing precise signal fragments of a specific patient; (3) interfaces for querying, seizure-specific extraction, and repackaging of electrophysiological signal data; (4) online visualization of single, multiple, or cross-sectional seizure waveforms; (5) signal analytic functions; and (6) customized seizure-fragments exporting function.

A. System architecture. The system architecture of SeizureBank (Figure 2) consists of (1) a back-end database to store signal fragments with its metadata, (2) a query engine based on the Rails framework for processing user requests, such as event-based searching and exporting and signal fragments, and (3) user interfaces and information display. Overall, SeizureBank system uses the Model View Controller (MVC) architecture pattern. It is implemented using Ruby on Rails and Data-Driven Documents (D3) which is an open source JavaScript library for data visualization. We describe different components of SeizureBank in following subsections.

B. Data model. We select MongoDB as the backend database in the server (serving as the cloud) for data storage and management. MongoDB is a NoSQL database system based on JSON-like documents with schemas. MongoDB provides more flexible data modeling, considerable scalability (for large dataset), and better data management performance (high queries per second (QPS) for both reading and writing) compared with SQL databases.

We design and develop three different data models to store patient metadata, signal metadata, and signal fragments. As shown in Figure 2, patient metadata model consists of the information of each patient, such as age and gender. Signal metadata model is designed for storing metadata of each signal fragment, such as the sampling frequency and
seizure duration. Signal fragment model contains the raw physiologic signal data of each clinical event, for example, the epileptic seizure event. The main idea of our new data schema is to break large sequential data files into minimal fragments. Such fragments can be assembled, retrieved, rendered, or repackaged according to users’ requests. Based on these models, seizure-related data can be searched, viewed, and exported in various ways for different purposes.

C. Interface. The interface of SeizureBank incorporates a set of query and visualization functionalities.

Query and exporting interface. SeizureBank query interface is designed as a feature-tag based item search engine. It provides several attributes and features for the user to choose, such as age range, gender, different types of signal channels, events types, and seizure duration. These choice options are implemented as several simple drop-down lists for users to construct queries. Based on user-selected features, the query results include all the metadata of corresponding patients and are shown in the results table. Furthermore, users can view detailed information about each patient. For data exporting, based on the query, users can customize specific clinical and signal data in the downloaded file using CSV format instead of downloading entire large signal files in EDF.

Visualization interface. SeizureBank provides a new interactive visualization interface based on a similar idea in our previous work17. It not only supports all the features in the previous work, such as fragment navigator, functional time-scale scrollbar, signal color configuration, and amplitude-scale scrollbar, but also integrates several new signal visualization and analytic functions, such as graphical montage configuration, signal Fourier analysis and spectrogram analysis18.

3.3 Feature-based seizure identification/classification approach

Leveraging the analysis-ready seizure-related signal dataset in SeizureBank, we develop a feature-based seizure identification technique for epileptic seizure research and evaluate the performance on a variety of datasets.

A. Feature extraction. We extract 134 features including time-domain, frequency-domain, non-linear, and wavelet-based features: (1) five time-domain features19,20 consisting of kurtosis, skewness, and Hjorth parameters; (2) 24 frequency-domain features including spectral power and spectral amplitude of 12 frequency bands (slow-oscillations: 0.5-2.0Hz, slow-wave activity: 0.5-5.5Hz, delta: 1-4Hz, theta: 4-8Hz, alpha: 8-10.5Hz, spindle: 10.5-14.5Hz, sigma: 12-15Hz, slow sigma: 12-13.5Hz, fast sigma: 13.5-15Hz, beta1: 15-20Hz, beta2: 20-30Hz, gamma: 30-60Hz); (3) three non-linear dynamics features were extracted, namely, C0 Complexity21, Shannon Entropy22, and Spectral Entropy23; and (4) 102 wavelet-based features: wavelets are a comparatively recent approach for signal processing, and the main advantage is that wavelets allow multi-resolution analysis in time and frequency, simultaneously24. EEG signals are subjected to 5-level decomposition using Daubechies-4 wavelet. From the decomposition process, a total of 6 coefficient sets were generated, and we calculated 17 measurements (Table 2) as wavelet-based features for each coefficient set.

B. Classifier description. Four different classifiers are applied to the extracted features: K-Nearest Neighbor (KNN), Artificial Neural Network (ANN), Support Vector Machine (SVM), and Random Forest (RF). KNN is an instance-based learning approach for classifying objects based on the closest training examples, and it is among the simplest of all machine learning models25. ANN contains a set of interconnected processing nodes, called artificial neurons, and connections between artificial neurons; such neurons and connections have weights to adjust learning process and work in unison to solve specific problems25,26. SVM is a supervised learning model and performs classification by maximizing the margin among the classes25. It has been used in various classification problems and regarded as the benchmark classifier in the performance evaluation. RF is an ensemble learning method for classification by constructing a group of decision trees, and its overall output is determined by selecting the classification with the most weighted votes26. The detailed comparison of these classifiers can be found in our previous work26.

C. Evaluation measurements. We evaluate the seizure identification performance of the four classifiers using the

recall ($R$), precision ($P$), F1-score ($F1$), and accuracy ($ACC$)$^{27}$. In addition, Cohen’s kappa coefficient$^{28}$ is an important and more robust measure compared with simple percent agreement calculation to evaluate the performance of a classifier. The interpretation of kappa coefficient has six levels of agreement: poor (less than 0), slight (0.00-0.20), fair (0.21-0.40), moderate (0.41-0.60), substantial (0.6-0.80), and excellent (>0.8)$^{28}$.

4 Results

SeizureBank was used to process electrophysiological data collected from consented subjects enrolled in the University Hospitals Cleveland Medical Center (UH) dataset in the CSR. In the following, we introduce the dataset in SeizureBank; present the interface results of SeizureBank system, including query, exporting and visualization interface; and then describe the comparison of seizure identification performance of each approach tested on different datasets.

4.1 Data preparation and dataset description

Using our data preparation pipeline, we extracted 224 seizure fragments of 115 patients (41 males, 68 females, and 6 patients with unknown gender) in the age group of 2 to 75 years. A new dataset containing about 28.02 GB of clean and well-structured seizure-related data were extracted from 1.15 TB of EDF files in the UH dataset. The new dataset includes two different types of data: seizure signal fragments, and 2) non-seizure signal fragments which is randomly selected from patients’ recordings. All the detailed characteristics of the new dataset are described in Table 3. Figure 3 shows a summary of basic demographic and clinical data of the patients in SeizureBank: (a) age distribution, (b) gender distribution, (c) distribution of the number of seizures per patient, and (d) distribution of seizure duration. We compared the performance of our previous data preprocessing method and new data preparation pipeline in Figure 4. The execution time of data preparation with new strategy is significantly improved, and the new pipeline shows higher scalability than the previous method when increasing the dataset size. For memory usage, the previous method extracted all signal files in an archive and cost 30% more memory compared with the new method. For other limitations, the previous method can not address the issues of data corruption and annotation label inconsistency.

4.2 System interfaces

A. Query and exporting interface. The features of the query and exporting interface are as follows. (1) Clinical feature selection: users can select appropriate clinical features, such as age and gender, to obtain the data of expected patients; (2) Signal feature selection: users can retrieve specific signal recordings according to selected signal features, such as event type, signal channel, and fragment durations, to better navigate through the data; and (3) Customized signal fragments downloading function. Figure 5 shows the components in query and exporting interface, including (A) feature selection, (B) feature management, (C) query results table, and (D) subject details table. In the feature selection component, users can select specific clinical and signal features. Selected features are editable in feature management. The query are executed based on selected features, and the results are shown in query results table. Clicking the “show” button (marked with a circle) of each patient will display the details in the subject details table. These two functional tables provide a simple way for users to navigate through the data, such as table size control, page-turning, and sorting function. Clicking “download” button enables the user to download corresponding files of

Figure 3: Summary of SeizureBank dataset

Figure 4: The performance of previous method and new pipeline with different size of dataset.
selected patients.

**Figure 5:** The query and exporting interface of SeizureBank system.

**B. Visualization interface.** The components of the visualization interface are shown in Figure 6. Signal data with selected channels were visualized in the *interactive visualization interface*. Some of the basic functions, such as functional time-scale scrollbar and amplitude-scale scrollbar, were described in details in our previous work\(^{17}\). The system provides a new function of graphical channel/montage configuration and management in the *channel selection* component. Montage is the voltage difference between two different channels, and the *channel selection* component provides the functionalities for editing customized channels/montages. For frequency analysis, the system provides two approaches: Fourier analysis (as shown in Figure 6.C.1) and time-frequency analysis (i.e. spectrogram, as shown in Figure 6.C.2). To measure the length and amplitude of the interesting part of the signal, we designed and implemented a ruler function, as shown in Figure 6.D. The ruler can be triggered by clicking on the signal rendering panel and following the mouse pointer as users moving it around the signal; the X-axis means the signal length with the unit of seconds and the Y-axis means the signal amplitude with the unit associated with each channel.

**C. Usability evaluation.** In order to evaluate the usability of the user interface, we performed a simple questionnaire-based usability test according to existing criteria\(^{29,30}\) to measure users’ satisfaction with the system. We invited four non-technical users to complete several tasks, such as query by clinical features, query by signal features, and visualize
signal fragments with different montage settings. Then the users answered 7 questions in the questionnaire with a rating score. The rating is on a ten-point scale from “Strongly Disagree” (1) to “Strongly Agree”(10). The questions and evaluation results are shown in Table 4. The preliminary results indicate that SeizureBank provides an easy-to-use query and visualization tool, and it is straightforward for users to learn how to use the functionalities in SeizureBank.

4.3 Comparative evaluation of seizure identification approaches

For each of the three datasets (UBSD, CHB-MIT, and SeizureBank), we processed, filtered, and extracted 134 features in the time domain, frequency domain, wavelet fields, and non-linear fields of single EEG C3 channel. We randomly separated all seizure and non-seizure data into two parts: training set (70%) and testing set (30%), and for both sets, the number of seizure fragments was equal to the number of non-seizure fragments. We performed the whole identification procedure 10 times. The average identification evaluation results of three different datasets are shown in Table 5. All the classifiers were implemented with built-in functions in Matlab 2018a, and the parameter settings of each classifier are as follows. (1) For KNN, number of neighbors was 20; (2) For SVM, logical scalar setting was “true” and other settings used default values; (3) For RF, the number of trees was 500 and other settings used default values; and (4) For ANN, the number of hidden layer neurons was 500 and other settings used default values.

The highest value of each measurement among different classifiers is highlighted. The UBSD provided three categories of data: healthy (set A and B), seizure-free (set C and D), and seizure (set E) data. Therefore, there are four distinct data combinations: [seizure, seizure-free], [seizure, healthy], [seizure, seizure-free, healthy], and [seizure, the combination of seizure-free and healthy]. In total, there were 9 test cases in UBSD: (1) A and E; (2) B and E; (3) C and E; (4) D and E; (5) A, C, and E; (6) A, D, and E; (7) B, C, and E; (8) B, D, and E; and (9) A, B, C, D as non-seizure and E as seizure. For all the tests, both SVM and RF had similar excellent performance. RF provided the best performance on the classification of seizure, seizure-free, and healthy data (in the most of tests), and all the kappa coefficients were in the excellent agreement level (>0.8). For the CHB-MIT and SeizureBank, there were two types of signal data: seizure and non-seizure data. Similarly, RF provided the best performance on both CHB-MIT (with 86.20% F1-score and 0.7357 Kappa) and SeizureBank (with 87.35% F1-score and 0.7547 Kappa) dataset. The evaluation results of our approach tested on the UBSD and CHB-MIT datasets were compared favorably to previous approaches; therefore, the identification results applied to SeizureBank could be considered as a benchmark for further seizure identification/classification research using SeizureBank dataset.

All the experiments were executed on a machine with Intel Core i7 2.93 GHz processor, 16 GB main memory, and operating system of macOS Sierra 10.12.6.

5 Discussion

With the growing trend of multi-center collaborative studies, there is a need to adopt emerging data repositories with integrated system to meet research requirements. The results of our data preparation pipeline and system interface demonstrate advantages of SeizureBank for obtaining signal data for epileptic seizure research. Features of SeizureBank can lead to reduced time (less data preparation execution time), space (lower storage requirements), and labor costs (easy to search and query) for analysis-ready seizure-related signal data. The majority of data scientists regard cleaning and organizing data as the least enjoyable work. With SeizureBank, researchers may obtain analysis-ready data directly and spend less time on data preparation and cleaning. SeizureBank is already used in several seizure-related studies in our group, including seizure detection and seizure prediction. The framework including data model, data preparation pipeline, and system architecture of SeizureBank can be extended to other medical and clinical studies using electrophysiological signal data. With the dataset in SeizureBank, we introduced a cross-dataset benchmark for
seizure identification, which can serve as a reference for developing and testing robust and reliable epileptic seizure identification approaches and applications in the future.

Limitations. In this paper, we only extracted seizure-related data from a part of one dataset in the CSR repository. In future work, we will expand more data from additional datasets in the CSR repository. To increase the data diversity of SeizureBank, we plan to extract and import seizure subtype data into our data repository. For data preparation, reading a large signal file (e.g., more than 20 GB) may require more RAM, and we plan to develop a parallel approach for reading and processing large-scale EDF files. For data visualization, we plan to design and implement additional functionalities in our system such as the functionality of user-contributed annotation visualization, where users can store and visualize their identification results.

6 Conclusion

Electrophysiological signal data, such as EEG and ECG, are often used in monitoring, identification, prediction, and therapy of the epileptic seizures. However, a key challenge in epilepsy research is the lack of analysis-ready seizure-specific signal data of large patient cohort repository as well as a system for managing, visualizing, and exporting seizure events. To address this challenge, we developed SeizureBank, an analysis-ready data repository along with web-based data management and visualization interfaces for epileptic seizure research. Our preliminary evaluation demonstrated the feasibility of SeizureBank. With SeizureBank, we also introduced a feature-based seizure identification approach that was tested on multiple datasets. The evaluation results compared favorably to previous seizure identification approaches. Results obtained on the UBSD, CHB-MIT, and SeizureBank datasets can be considered as a cross-dataset evaluation benchmark of seizure identification for future research.

Abstract

Patient perceptions of wait time during outpatient office visits can affect patient satisfaction. Providing accurate information about wait times could improve patients’ satisfaction by reducing uncertainty. However, these are rarely known about efficient ways to predict wait time in the clinic. Supervised machine learning algorithms is a powerful tool for predictive modeling with large and complicated data sets. In this study, we tested machine learning models to predict wait times based on secondary EHR data in pediatric ophthalmology outpatient clinic. We compared several machine-learning algorithms, including random forest, elastic net, gradient boosting machine, support vector machine, and multiple linear regressions to find the most accurate model for prediction. The importance of the predictors was also identified via machine learning models. In the future, these models have the potential to combine with real-time EHR data to provide real time accurate estimates of patient wait time outpatient clinics.

Introduction

In recent years, hospital systems have increasingly emphasized quality of care, which includes patient satisfaction.\(^{1,2}\) Patients’ perception of wait time in a primary care or specialty care outpatient clinic contributes to patient satisfaction.\(^{3-5}\) In fact, the literature suggests that the time a patient spends waiting for their scheduled appointment is the largest source of patient dissatisfaction.\(^5\) Longer wait time negatively impacts the patient’s satisfaction and distorts the patient’s perception of the quality of care and the physician’s abilities.\(^1\) Although waiting may be unavoidable in outpatient clinics, it is important to note that providing accurate information about wait times could improve patients’ satisfaction by reducing uncertainty.\(^4,7\) However, there are limited studies of proposed models to predict outpatient clinic wait time by using statistical methods.

The complexity of clinic workflows can make predicting patients’ wait time challenging. For example, in an ophthalmology clinic, ophthalmologists typically utilize multiple exam rooms simultaneously, examine patients at different stages in the visit, and integrate ancillary staffs and trainees into the clinical workflow.\(^8\) Thus, it is difficult to provide accurate estimates of wait times in clinical settings. To bridge this gap, secondary use of electronic health records (EHRs) with machine learning algorithms can be a reasonable choice. Supervised machine learning algorithms are an effective tool for predictive modeling with large and sophisticated data sets. These algorithms resist abnormal outliers, rank the relative importance of variables, and self-modify without human supervision.

Our study was performed in an academic ophthalmology department because it is a high volume, fast-paced specialty where estimating patient wait time is paramount. The purpose of this work was to develop analytical models that provide an accurate prediction of patients’ wait time in ophthalmology outpatient clinics using advanced machine learning methods. In addition, we wanted to determine the features that are most important for these predictive models.

Methods

This study was approved by the Institutional Review Board at Oregon Health and Science University (OHSU). OHSU is a large academic medical center in Portland, Oregon. This study was conducted at Casey Eye Institute, OHSU’s ophthalmology department serving all major ophthalmology subspecialties. The department performs over 130,000 outpatient examinations annually and is a major referral center in the Pacific Northwest and nationally. In 2006, OHSU implemented an institution-wide EHR (EpicCare; Epic Systems, Verona, WI) to handle all ambulatory practice management, clinical documentation, order entry, medication prescribing, and billing.
Data Preparation
We used 6 years (January 1, 2012 to March 31, 2018) of office visit data from seven pediatric ophthalmology faculty providers at OHSU Casey Eye Institute. Time-stamp and related data from office visits were extracted from the enterprise-wide clinical warehouse and audit log timestamp data were used to calculate time-related variables. The appointment length is determined by the difference between the office visit check-in and check-out times recorded in the EHR. The provider-patient interaction times were determined by audit log values using previously validated methods. The wait time was defined as total wait time during the clinic appointment (total appointment length – provider-patient interaction time).

Data Preprocessing

Data cleaning – we removed all encounters with missing data and excluded abnormal time variables. Clinic visits were excluded if (1) wait time was longer than 180 minutes, less than 0 minutes, or missing; (2) provider-patient interaction time was longer than 120 minutes or less than 1 minute; (3) appointment length was longer than 300 minutes or less than 10 minutes; (4) arrival interval was longer than 240 minutes or less than 240 minutes.

Data transformation and dimensionality reduction – several variables were re-categorized and all categorical variables were converted to dummy variables. Some potential predictors were removed on the basis of our experience and observation.

Outcome Variables and Analytical Models
The primary outcome variable of regression models was patient wait time, which is a continuous variable. Four machine learning algorithms – random forest, elastic net, gradient boosting machine (GBM), and support vector machine (SVM) and multiple linear regression were developed to predict patient wait time. We chose these models to represent a broad approach to machine learning. Random forest and gradient boosting machine are ensemble decision trees algorithms, elastic net is a regularized method of linear regression, and support vector machine constructs hyperplanes to classify the data.

In addition, patient wait time was transformed into a categorical variable value as “Long” or “Normal”. “Long” indicated the upper half (> 58 minutes) wait time and “normal” indicated bottom half (≤ 58 minutes) wait time. We used the median of the patient wait time as cut-point. Four classification models, including random forest, elastic net with logistic regression, GBM, and SVM, were developed to determine “long wait time” or “normal wait time”. The categorical variable can be used in scheduling templates.

Random forest is an ensemble decision trees algorithm, which grows with a bootstrap sample from the training data. Randomly selected subsets of predictor variables are implemented into each decision tree. The prediction for new observation is made by averaging the output of the ensemble of trees. We used R package randomForest to perform the prediction model.

Elastic net is a regularized regression method that combines penalties of the lasso and ridge methods. We used R package glmnet to build the prediction model.

Gradient-boosting machines is an ensemble learning method for improving predictive performance. Unlike random forest, which builds an ensemble of deep independent trees, GBM makes an ensemble of weak successive trees with each tree learning and improving on the previous one. We used R package gbm, assuming the Gaussian distribution for minimizing squared-error loss.

Support vector machines are supervised learning models used for both classification and regression analysis. The algorithm outputs optimal hyperplanes, which categorizes new examples. We used R package e1071 with a linear kernel to build the prediction model.
Predictor Variables
Twenty-four predictor variables were selected from the original data set and were grouped as below:

(1) Predictors related to date and time: Year, month, day of the month, day of the week, clinic session (AM or PM), clinic hour, which was the hour of the patient’s check-in time relative to the scheduled half-day clinic session.

(2) Patients’ demographic and clinical features: Age, which was grouped as six categories, visit name, patient financial class, whether the patient was a new patient, whether the patient was scheduled or walked in, and International Classification of Diseases, tenth revision (ICD-10) diagnosis code. We grouped the ICD-10 codes into categories based on diagnosis frequency. The 20 most common ICD-10 diagnoses were selected, and all the remaining diagnoses were categorized as “Other” (21 total categories).

(3) Predictors related to clinical examination: Boolean values representing if the patient exam included a pupil dilation, a visual acuity test, a visual field test, a tonometry test, a refraction test, or a fundoscopic exam.

(4) Predictors related to prior visit length: The wait time of patient’s previous office visit and the provider-patient interaction time of patient’s previous office visit.

(5) Predictor for the arrival interval for the current appointment: The arrival interval is defined as the duration between patient check-in time and the scheduled visit time. An arrival interval can either be positive (late arrival) or negative (early arrival).

(6) Predictors related to number of patients: The total number of patients seen by all providers on the day of the appointment and the clinic volume, which indicates the number of patients in the half-day provider’s clinic in which the appointment was scheduled.

Validation and Evaluation of Performance
The data set was randomly assigned to a training set (75%) and testing set (25%) to avoid over-fitting. K-fold cross-validation was used to validate the models. A larger number of folds makes less bias towards overestimating the truly expected error but may have higher variance. In this study, we used 5 fold cross-validation, which shows the flat slope of the learning curve and the size of each validation partition in 5 fold cross-validation being large enough to provide a fair estimate of the model's performance. Each prediction models was developed with the training data set. Root mean square error (RMSE) and R² were used to determine the predictive accuracy of each regression model. We developed five regression models in this study, including random forest, elastic net, GBM, SVM, and multiple linear regressions. Moreover, receiver operating characteristic (ROC) curves and the area under ROC curve (AUC) were used to evaluate the accuracy of the classification models for predicting “long wait time” or “normal wait time”. There are four classification models in the study, including random forest, elastic net with logistic regression, GBM, and SVM. We also ranked the importance of features based on the increase in mean square error of prediction as a result of a certain variable being permuted (%IncMSE) in the random forest regression model. All data processing and analyses were conducted using R programming language version 3.5.2.

Results

Descriptive Data

Table 1 shows the characteristics of the patient visits including patient’s age, visit name, financial class, whether the patient was a new patient, and information about visit length. There were 37,787 (98.8%) patients visits that met inclusion criteria and 445 office visits were excluded (1.2%). Most patients were school age (32%) and pre-school age (26%). Amblyopia, Esotropia, and Exotropia are the most common diagnoses. Most patients used Medicaid and commercial insurance. Besides, 63% of patients came to follow-up visits, 23% of patients were new patients, and approximately half of patients (53%) were scheduled for pupil dilation.

Evaluation Performance of Models

The performance of the five models is presented with $R^2$ and RMSE in Table 2. We found that the random forest model had the highest $R^2$ (0.3822), which means the random forest model can explain about 38 percent of the variability of the patient wait time. Also, the random forest model showed the best RMSE (24.24). Thus, we selected the random forest as the best predictive model in this study. The ten most important features of random forest
regression model and their %IncMSE are shown in Figure 1. We found that patients scheduled for pupil dilation, patients’ primary ophthalmologist, and arrival interval have the strongest impact on the predictive model.

Figure 1: The 10 most important features in the random forest model as determined by %IncMSE.

Figure 2 shows the ROC curves of four machine-learning models in the testing dataset for predicting when patient wait times will be long. Area Under the Curve, (AUC) was measured in all models. The random forest model presented the best performance (AUC=81.55% [95% CI 80.69%-82.41%]) followed by the support vector machine (AUC=81.14% [95% CI 80.28%-81.99%]), gradient boosted machine (AUC=80.05% [95% CI 79.17%-80.92%]) and elastic net (AUC=79.88% [95% CI 79%-80.76%]).

Figure 2: ROC curves of machine learning models
Discussion
In this study, we evaluated the applicability of machine learning models to predict patient wait time in pediatric ophthalmology clinics. The key findings from our study were (1) Machine learning models (such as random forest) can accurately predict patient wait time in pediatric ophthalmology outpatient clinic; (2) Machine learning models can provide insight into the factors associated with patient wait time; (3) Patient wait time predictive model can be a useful tool in managing clinical practices.

In our study, the random forest model provided the most accurate prediction (R² 0.38 and RMSE 24.22), which is higher than the prediction accuracy of the linear model (R² 0.36 and RMSE 25.02). Machine learning algorithms are a great choice for predicting sophisticated and noisy phenomena like patient wait time in a pediatric ophthalmology outpatient clinic. Moreover, random forest and GBM models were able to identify patient factors that are associated with patient wait time. The feature importance of random forest regression model and GBM regression model are similar to each other. The top three important predictor variables identified in both models were pupil dilation, then primary ophthalmologist, and arrival interval. The importance of pupil dilation may be because it takes about 25 minutes for pupils to fully dilate, and patients must wait during this period. In this study, the average wait time for patients with pupil dilation was 68.39 minutes (SD=27.09) and for patients without pupil dilation, the average wait time was 44.54 minutes (SD=30.13). The importance of the physician is because the clinic volume of each physician is different and each physician has their own pace when seeing patients. The range of the average wait time of seven faculty providers was 47.36 minutes to 75.01 minutes. The importance of arrival interval is due to patients arriving at the clinic early, which results in wait times. In our study, patients arrived at the clinic about 10 minutes earlier than their scheduled time on average and the Pearson correlation coefficient between patient wait time and arrival interval is -0.22.

Moreover, in Figure 1, we noticed that the year is the 4th important predictor variable in random forest regression model. The importance of year may be because the clinic policies/procedures changed over time. More investigation is needed to determine why this is important since it probably isn’t relevant for future predictive analyses. Exploring the important predictors can be useful for improving the predictive model in the future; for example, building models for each provider, eliminating dilation time from wait time and adjusting wait time calculations to eliminate bias from early arrivals may improve the accuracy of the wait time predictions. For elastic net, multiple linear regression and SVM regression models, we calculated the regression coefficients, which describes the relationship between each feature and the outcome variable. However, the units vary between the different types of variables and cannot be used as the feature importance directly.

Providing accurate information about wait times could improve patients’ satisfaction by reducing uncertainty. In future, the predictive models could be incorporated with real-time data to provide accurate information about wait times for patients in clinical settings. Even with perfect scheduling, it is difficult to completely eliminate patient wait time, so communicating potential delays to patients is important for maintaining patient satisfaction. In the future, the predictions in this study might be used in real-time to help inform patients of expected wait times while in clinic.

There are several limitations in our study. First, the EHR timestamps do not always accurately capture the provider-patient interaction time, which in turn can produce incorrect wait times. That said, we have previously validated that these provider interaction time timestamps were accurate across a wide range of ophthalmology providers at a single institution. Second, the models might improve with a larger data set and our study was limited at a single institution. Finally, the patterns observed in our study might not be generalizable to other subspecialties within ophthalmology or other healthcare systems. Our intention is to extend and replicate these study methods to different patient and provider populations at different institutions in order to increase the generalizability of our findings.
Conclusion
Patient perceptions of wait times in pediatric ophthalmology outpatient clinics can affect patient satisfaction and quality of care. However, there are not many studies about the efficient ways to predict wait time in the clinic. In this study, we found that supervised machine learning models can provide accurate patient wait time prediction and we were able to identify the factors with the largest contribution to patient wait times. It is important to note that patient satisfaction increases when patients are told about their expected wait time. In the future, we may be able to incorporate real-time scheduling data from the EHR to improve estimates of patient wait-time and scheduling efficiency in a clinic setting.

Transfer Learning from BERT to Support Insertion of New Concepts into SNOMED CT

Hao Liu, MS, Yehoshua Perl, PhD, James Geller, PhD
Dept of Computer Science, NJIT, Newark, NJ, USA

Abstract

With advances in Machine Learning (ML), neural network-based methods, such as Convolutional/Recurrent Neural Networks, have been proposed to assist terminology curators in the development and maintenance of terminologies. Bidirectional Encoder Representations from Transformers (BERT), a new language representation model, obtains state-of-the-art results on a wide array of general English NLP tasks. We explore BERT’s applicability to medical terminology-related tasks. Utilizing the “next sentence prediction” capability of BERT, we show that the Fine-tuning strategy of Transfer Learning (TL) from the BERT\textsubscript{BASE} model can address a challenging problem in automatic terminology enrichment – insertion of new concepts. Adding a pre-training strategy enhances the results. We apply our strategies to the two largest hierarchies of SNOMED CT, with one release as training data and the following release as test data. The performance of the combined two proposed TL models achieves an average F1 score of 0.85 and 0.86 for the two hierarchies, respectively.

Introduction

Insertion of new concepts into their proper positions in a terminology is a challenging problem in automatic enrichment of terminologies. Traditionally, for terminologies based on a Description Logic, curators tend to use a reasoner such as Snorocket [1] or HermiT [2] to insert a new concept into a terminology’s hierarchy. Recently, researchers have proposed to use Deep Learning models such as Convolutional/Recurrent Neural Network models [3] to verify an IS-A relationship between a new concept and an existing concept, which will recommend the location of the new concept in the hierarchy. In such an approach, concepts are represented by various language embeddings from Natural Language Processing (NLP) [4-6].

However, training such an ML model from scratch is expensive and time-consuming, as it requires large data sets and extensive computing resources. Instead, it is common and efficient to conduct Transfer Learning from pre-trained language representation models to the task of interest. In this paper, we utilize a new general language representation model called Bidirectional Encoder Representations from Transformers (BERT) [7]. BERT is a pre-trained model which obtains state-of-the-art results on a wide range of NLP tasks. It has been integrated into applications [8, 9] for clinical tasks in biomedical domain. We experiment with two Transfer Learning (TL) strategies, Fine-tuning and Pre-training, from the pre-trained BERT\textsubscript{BASE} model to address the terminology enrichment problem. In Fine-tuning, we train a classifier on top of a BERT\textsubscript{BASE} network with IS-A relationships as training data. This training fine-tunes the weights of the pre-trained BERT\textsubscript{BASE} network to enable it to classify relationships between new concepts and existing concepts. The fine-tuning strategy innovatively utilizes the “next sentence prediction” of BERT, to train BERT to distinguish which pairs of concepts should be connected by IS-A relationships. In Pre-training, we accommodate BERT to medical data, by training it from scratch using terminology data from SNOMED CT.

To measure the performance of the two proposed strategies, we use the two largest hierarchies of the SNOMED CT [10] terminology, the Clinical Finding and the Procedure hierarchies, as our testbed. The SNOMED CT release of July 2017 is used as training data. For testing, we use 911 and 2005 new concepts from the Procedure and Clinical Finding hierarchies of the January 2018 release, respectively. The results of this experiment for the Fine-tuning strategy and for the combined strategy starting with Pre-training and continuing with Fine-tuning are reported.

Background

SNOMED CT is an internationally leading clinical terminology, managed by SNOMED International. The Clinical Finding and the Procedure hierarchy of the January 2018 release of SNOMED CT consist of 111,081 and 57,806 active concepts, respectively. SNOMED CT is released twice every year on January and July. All the content for a given release of SNOMED CT terminology is defined in a “snapshot” file. In addition, a “delta” file identifies the individual changes that occurred between the previous release and the current release. A full history of concepts and relationships that are added, changed, or removed is also provided. By comparing the Procedure and Clinical Finding hierarchies of January 2018 with the previous July 2017 release, we found that 911 new concepts were added into the Procedure hierarchy and 2005 new concepts were added into the Clinical Finding hierarchy and placed in the proper
positions in the hierarchy by SNOMED CT’s curators, based on their structural and semantic definitions stated in Description Logic. Liu et al. [11] proposed a methodology to automatically determine the placement of a new concept in the ontology’s hierarchy if a new concept’s name and one of the concept’s parents is given. The solution is based on training a Convolutional Neural Network (CNN) model to distinguish between those pairs of concepts that are connected by IS-A links and those pairs that are not.

For the language representation model, there are two main research streams: Context-free and Contextual representations. Traditional word embeddings such as word2vec [12], GloVe [13], or fastText [14], are Context-free embeddings, which generate a single "word embedding" representation for each token in the vocabulary. Therefore, they are not likely to capture any word meaning changes caused by surrounding context changes. Contextual models, instead, generate a representation of each word that is based on the other words in the context. Contextual representations can further be categorized into unidirectional or bidirectional.

BERT is the first unsupervised, deeply bidirectional system that outperforms previous methods. BERT is a general-purpose "language understanding" model trained on a large text corpus (like Wikipedia), which can be used for various downstream NLP tasks without heavy task-specific engineering. BERT’s model architecture is a multi-layer bidirectional transformer encoder, based on the original implementation proposed by Vaswani et al. [15]. BERT has advanced the state-of-the-art for several major NLP benchmarks, including named entity recognition on CoNLL-2003 [16], question answering on SQuAD [17], and sentiment analysis on SST-2 [18].

Methods

The main contribution of this paper is suggesting a way to harness the high performance of BERT for a critical task in medical terminology enrichment, in spite of the fact that BERT was not trained with medical literature. One approach is to add medical knowledge to the general knowledge learning of BERT. For this we use the SNOMED CT knowledge, providing a “document” for each concept of SNOMED CT. The second approach is to train BERT to be able to distinguish between concept pairs which should be connected by IS-A relationships and pairs that shouldn’t. This kind of learning utilizes the “next sentence prediction” feature of BERT. In the following we describe the technical issues and the details involved in implementing these ideas.

We experimented with two strategies of using BERT. 1) Fine-tuning BERT\textsubscript{BASE} by supervised training a relationship classifier on top of BERT with concept pairs connected by IS-A relationships and pairs not connected (non-IS-A pairs) taken from SNOMED CT. 2) Pre-training BERT\textsubscript{BASE} with unsupervised concept-based “documents” from SNOMED CT, and then fine-tuning it as an IS-A relationship classifier. We implemented the experiments with Tensorflow [19] and ran the testcases on a computer with two Intel Xeon E5-2630-v4 CPUs with processor speed 2.2 GHz; 128 GB memory per CPU and two Nvidia Tesla P100 “Pascal” video cards with 16 GB RAM per GPU.

BERT\textsubscript{BASE} (12 Transformer layers) and BERT\textsubscript{LARGE} (24 Transformer layers) are two models trained on English Wikipedia (2,500M words) and BooksCorpus [20] (800M words) for one million update steps. Due to limited GPU resources, we only used BERT\textsubscript{BASE} in this experiment, since BERT\textsubscript{LARGE} requires resources currently beyond our high-performance hardware. The configuration parameters of the pre-trained BERT\textsubscript{BASE} model are L=12, H=768, A=12, total Parameters=110M, where L is the number of layers (i.e., Transformer blocks), H is the hidden size, and A is the number of self-attention heads. The feed-forward/filter size is set to 4H, i.e., 3072 for H = 768.

The two strategies of our research are as follows:

Strategy 1

Step 1. Fine-tuning the BERT\textsubscript{BASE} model (Figure 1): We extracted IS-A linked and not linked concept pairs as supervised fine-tuning data from the SNOMED CT July 2017 release. We will refer to these pairs as IS-A and non-IS-A pairs. Then we trained a relationship classifier on top of BERT\textsubscript{BASE} with the IS-A and non-IS-A pairs to obtain the BERT\textsubscript{BASE+CLF} model.

Step 2. Prediction on new release data (illustrated in the rightmost process of Figure 1): We tested the trained BERT\textsubscript{BASE+CLF} model to verify IS-A links and the absence of IS-A links for newly added concepts in the SNOMED CT January 2018 release.

Strategy 2

Step 1. Pre-training the BERT\textsubscript{BASE} model (Figure 2): We preprocessed concept-related information from the July 2017 release to generate documents that were used as unsupervised pre-training data. Then we trained BERT\textsubscript{BASE} with unsupervised concept level data so that the trained BERT\textsubscript{BASE+SNO} model integrated terminology information. Then
we applied the fine-tuning process (of Strategy 1) to train a classifier on top of BERT_BASE+SNO to derive the BERT_BASE+SNO+CLF model.

Step 2. Prediction on new release data (illustrated in the rightmost process of Figure 2): We tested the trained BERT_BASE+SNO+CLF model to verify IS-A links and non-IS-A pairs for newly added concepts in the SNOMED CT 2018 January release.

**Figure 1:** The pipeline for Strategy 1 Fine-tuning. CLF is short for Classifier.

**Figure 2:** The pipeline for Strategy 2 combining Fine-tuning with Pre-training. SNO is short for SNOMED CT.

Details of the specific stages of the two strategies are discussed in the following:

**Fine-tuning strategy**

**Data preparation:** The training samples passed to the Fine-tuning process are a set of IS-A and non-IS-A concept pairs. In SNOMED CT, the IS-A concept pairs are given. Thus, we can use them as a positive sample. On the other hand, the negative sample could be all the non-IS-A pairs of concepts. This creates an imbalance between the positive and negative samples, because there are many more pairs not connected by IS-A links. Thus, we pick non-IS-A pairs for the negative sample as follows. For each IS-A pair (A, B) we look for the siblings C₁, C₂, … Cₖ of B. Then we choose non-IS-A pairs (A, Cᵢ) with i=1, 2, … k. The advantage of such pairs is that they are closely related to the corresponding IS-A pair. This will sharpen the distinction between IS-A and non-IS-A pairs in training. For example, (Crushing injury of back, Crushing Injury) defines an IS-A link, while (Crushing injury of back, Shear injury) is a similar pair that should not be connected by an IS-A link. The reason is that Shear injury is a sibling of Crushing Injury, with the same parent Injury by mechanism.
In the data preparation for Fine-tuning, we first extracted the positive and negative samples, and randomly downsampled the negative sample to the size of the positive sample, at the beginning of each training round. We shuffled our dataset and then used 90% of it for training and kept 10% as the test set. The samples went through three preprocessing steps: Text normalization (E.g., Excision of Reinke’s edema, → excision of reinke’s edema), Punctuation splitting (E.g., excision of reinke’s edema, → excision of reinke’s edema), and WordPiece tokenization (excision of reinke’s edema, → ex #cision of rein #ke’s ed #ema). Then the samples were processed by BERT\textsubscript{BASE}, which performed its own preprocessing, including input embeddings, segment masking, labeling, etc [7]. The input embeddings are the sum of the token embeddings, the segmentation embeddings and the position embeddings. Due to space limitations, we concentrate on the operations that are essential for Fine-tuning.

For example, Urine xanthine level is the child of Evaluation of urine specimen in the SNOMED CT Procedure hierarchy. The input sequence will be “1 Evaluation of urine specimen (t) Urine xanthine level (t)” This input will be converted as one training instance to “[CLS] evaluation of urine specimen [SEP] urine x ##ant ##hine level [SEP]” as shown in Figure 3(a). The first token of the sequence is the classification embedding ([CLS]), representing a classification label. A special token ([SEP]) is used to separate sentences. Out-of-vocabulary words are split into word pieces and denoted with ##. For example, “xanthine” is denoted as three items “x”, “##ant”, and “##hine.” Similarly, Rubella screening is not a child of Down’s screening – blood test. The input sequence “0 Rubella screening (t) Down’s screening – blood test (t)” will be converted to “[CLS] rub ##ella screening [SEP] down ’ s screening - blood test [SEP]” in Figure 3(b).

**Figure 3:** Fine-tuning data: Preprocessing (a) IS-A and (b) non-IS-A concept pairs

**Fine-tuning the BERT\textsubscript{BASE} model:** We fine-tuned the BERT\textsubscript{BASE} model to predict the IS-A and non-IS-A linking for the concept pairs in the test data. This is similar to a binary sentence-pair classification task. We used the sentence prediction capability of BERT\textsubscript{BASE}, trained as BERT\textsubscript{BASE+CLF}, to predict IS-A links between concept pairs of a

**Figure 4:** Fine-tuning the BERT\textsubscript{BASE} model with concept pairs to obtain BERT\textsubscript{BASE+CLF} model.
We randomly masked out two tokens “##mon” and “##tis” over other tokens in the vocabulary. The BERT Base model computed the probabilities for Class 0 and Class 1, and recorded the result as a 2 x 1 vector. The classifier reported the class label with the higher probability. The error between the true label and the label predicted by the model was back-propagated through the model to improve the network’s parameters. The obtained model is denoted as BERT Base-CLF (CLF = classifier), the model after Fine-tuning. For this we used the default model hyperparameters in pre-trained BERT Base, with the exception of the sequence length (=128), batch size (=64), learning rate (=2e-5), and number of training epochs (=3).

Pre-training and fine-tuning strategy

Data Preparation: In our setup of unsupervised Pre-training, BERT Base is not trained for a specific task, but the purpose is integrating medical knowledge into its representation. This is done by training with non-task related samples taken from SNOMED CT. BERT was originally trained with millions of documents that are composed of sentences. Similarly, we generated a list of terminology-oriented documents by creating one “document” per focus concept F (Figure 5), with related concept(s) as “sentences” of such documents. The ID for a document is the corresponding SNOMED CT concept ID. The content of this document consists of the concepts that are hierarchically related to F (Figure 5(a)). Specifically, we chose F’s parents (targets of IS-A links from F), F itself, and its children (sources of IS-A links to F). Thus, the whole document text is: Parent(s) – Focus concept – Child(ren) (Figure 5(b)). The concept groups are separated into lines, e.g., “(Parents) finding of abnormal level of heavy metals in blood, finding of trace element level – NEW LINE– (Focus concept) blood copper abnormal –NEW LINE– (Children) raised blood copper level, serum copper level abnormal” is the document for the focus concept blood copper abnormal. This construction is based on the idea that a concept is the topic of a document and that the closely related concepts are descriptions of the meaning of this concept in the terminology hierarchy. To feed sentences into the BERT Base model, all the documents are concatenated in one text file, separated by empty lines.

Pre-training the BERT Base model: To utilize BERT’s powerful language representation, we started with BERT Base and embedded terminology knowledge with new training data. BERT was originally trained for two unsupervised prediction tasks: Masked Language Modeling (MLM) and Next Sentence Prediction (NSP) on an arbitrary text corpus. We adopted the same two training tasks and objective with concept-based documents from SNOMED CT. In the MLM phase, the training objective is to predict only the masked words. We randomly masked out 15% of the words across all the concept-based documents, and then trained the complete BERT Base model to output the masked words. In the NSP phase, the objective is to learn relationships between concepts: Given two concepts A and B, is B a child of A, or not (Figure 6). We extracted two “sentences” Colitis and Phlegmonous colitis from the document for the focus concept Colitis. After preprocessing these two concepts (treated as two “sentences”) as shown in the middle level, we masked out two tokens – “##mon” and “##tis”. The BERT Base model was trained to raise the probabilities of two correct tokens “##mon” and “##tis” over other tokens in the vocabulary. In addition, as Phlegmonous colitis IS-A Colitis, the BERT Base model was also trained to output the correct classification label “IsNext.” The obtained model
is denoted as $\text{BERT}_{\text{BASE+SNO}}$ (SNO=SNOMED CT). Then we applied the Fine-tuning process (see above) to the $\text{BERT}_{\text{BASE+SNO}}$ model to get the $\text{BERT}_{\text{BASE+SNO+CLF}}$ model.

The training parameters used for Pre-training are as follows: batch size = 64, sequence length =128, training steps = 15,000 for Procedure and 200,000 for Clinical Finding, learning rate = $2 \times 10^{-5}$, dropout rate = 0.1, and activation function = gelu (Gaussian error linear unit).

**Figure 6:** Pre-training the $\text{BERT}_{\text{BASE}}$ model with concept-based documents to obtain $\text{BERT}_{\text{BASE+SNO}}$ model. FFNN is short for Feedforward neural network.

**Figure 7:** Data flow for testing the trained $\text{BERT}_{\text{BASE+CLF}}$ or $\text{BERT}_{\text{BASE+SNO+CLF}}$ models with unseen data.
Testing the prediction on new release data

To evaluate the BERT\textsuperscript{BASE+CLF} and the BERT\textsuperscript{BASE+SNO+CLF} models on previously unseen data, we created separate test tasks, using new concepts from the Procedure and the Clinical finding hierarchy of the January 2018 release (Figure 7). This description will focus on the Procedure hierarchy. For each new concept that was added to the Procedure hierarchy in this release, we extracted it and its parents as positive sample pairs. For example, Local excision of lesion of kidney has two parents Local excision and Excision of lesion of kidney. The corresponding positive testing samples are “Local excision (t) Local excision of lesion of kidney” and “Excision of lesion of kidney (t) Local excision of lesion of kidney” with the true Class label = 1. For the negative sample, we paired each new concept with a randomly chosen concept from the other new concepts’ parents. For example, we randomly select Ultrasonography of left lower limb, which is the parent of Ultrasonography of left knee region, and paired it with Local excision of lesion of kidney to form the instance “Ultrasonography of left lower limb (t) Local excision of lesion of kidney” with the label = 0.

The concept pairs were randomly arranged into a sequence and sent to the trained BERT\textsuperscript{BASE+CLF} and BERT\textsuperscript{BASE+SNO+CLF} models. The tested model processed each input pair, using the weights that it had learned before, returning a class label (0 or 1) as prediction result. For negative samples, label 0 is correct, indicating that there is no IS-A link between these two concepts in the new SNOMED CT release. Label 1 is correct for positive samples, indicating the existence of an IS-A link. The predicted result labels were compared with the true labels to calculate prediction accuracy in terms of Precision, Recall, and F1 score.

Results

We first report the prediction results of the Fine-tuning model and Pre-training & Fine-tuning model with samples extracted from the Procedure hierarchy of the SNOMED CT 2018 January release, with 15,000 training steps. The Precision, Recall, and F1 scores for ten tests are presented in Table 1. For the Procedure hierarchy, the model was tested against 3,908 pairs (1,954 positives and 1,954 negatives). For example, in Test 7 for IS-A classification, the Precision is 0.69, Recall is 0.98, and F1 score is 0.81 for Fine-tuning. When adding Pre-training, Precision is 0.73, Recall is 0.98, and F1 score is 0.84. The F1 score improved by about 3.7%. Similarly, for Non-IS-A tests, the F1 score increased from 0.71 to 0.77, an 8.5% improvement. On average, by adding Pre-training, there are 6.3% (from 0.80 to 0.85) and 14.5% (from 0.69 to 0.79) improvements of F1 for IS-A and Non-IS-A classifications, respectively.

Due to space limitations, we only report the summary of the Precision, Recall, and F1 scores from ten tests for the Procedure hierarchy with 10,000 training steps (Table 2). In each test, the model was tested against 3,908 pairs (1,954 positives and 1,954 negatives). On average, by adding Pre-training to Fine-tuning, the improvements are 3.75% (from 0.80 to 0.83) and 10.1% (from 0.69 to 0.76) for IS-A and Non-IS-A classifications, respectively.

For the Clinical finding hierarchy, the summary of ten tests results with training steps = 200,000 is reported in Table 3. In each test, the model was tested against 8,574 pairs (4,287 positives and 4,287 negatives). On average, by adding Pre-training, the improvements are 7.5% (from 0.80 to 0.86) and 15.3% (from 0.72 to 0.83) for IS-A and Non-IS-A classifications, respectively.

Regarding the prediction of IS-A links for new concepts, we show ten examples of our two models’ prediction results (Table 4) for ten pairs for which the second concept was newly added to SNOMED CT’s Clinical finding hierarchy in the 2018 January release. For each test, we paired one Test Concept with one New Concept as one test instance,
then we let the model predict IS-A links between them. For instance, for Example 2, we chose Arthropathy of knee joint as the first concept and paired it with Aseptic necrosis of right lateral femoral condyle. Then the task became to predict whether there is an IS-A link between the two concepts. Both the Fine-tuning and Pre-training & Fine-tuning models returned the correct label (=1). For Example 4, the Fine-tuning model is wrong, and the combined model is correct that Chronic pain following radiotherapy IS-A Persistent pain following procedure. Both models are wrong about Injury of bilateral optic tracts, because it is not a Soft tissue injury (Example 9).

**Discussion**

In this paper we set out to investigate whether the “next sentence prediction” capability of BERT can be fine-tuned to verify the parent(s) of new concepts added to a terminology. Such a capability can be utilized in automatic enrichment of terminologies. The results for the Procedure and Clinical finding hierarchy confirm that our technique, which utilizes this capability of BERT, is indeed able to verify the IS-A relationships from new concepts to their parents with a 0.80 F1 average value. When enhancing Fine-tuning of BERT with Pre-training the average F1 score grows to 0.85 (0.86).

However, looking at the details we see that the recall to identify IS-A relationships is very high (0.98) while the precision is only 0.74. The outcome for identifying the Non-IS-A pairs of concepts is the opposite, with high (0.97) precision and low (0.66) recall, yielding an F1 value of 0.79. These results indicate that our technique verifies almost all the IS-A relationships, but wrongly identifies some Non-IS-A pairs as having IS-A relationships.

Thus, the challenge for future research is to improve the precision. In previous research [11, 21], we have shown that using summarization techniques of terminologies [22] can improve the training of ML techniques to better distinguish between IS-A relationships and pairs that are not connected by IS-A relationships. In future research, we will investigate whether utilizing summarization techniques can improve the precision and thus the F1 value.

Another issue is the number of training steps required for Pre-training. For the Procedure hierarchy 15,000 training steps provided the best results for enhancing the process by Pre-training. The enhancement was about double than for 10,000 training steps. Experiments with 20,000 and 25,000 training steps showed a leveling off of F1 at 20,000 and a lower F1 value at 25,000. However more research is needed to confirm this behavior beyond 15,000 training steps. For the Clinical finding hierarchy, which is about twice the size of the Procedure hierarchy, 200,000 training steps were required to obtain the same enhancement as for the Procedure hierarchy, which had required just 15,000 training steps. Hence, much more pre-training steps are required when the hierarchy is larger. The two transfer learning models using BERT are superior to our previously proposed CNN model [11], which was trained with the whole SNOMED CT consisting of 473,756 concepts. That CNN model achieved an average F1 score of 0.70, and could only verify IS-A links for new concepts with multiple parents. As a consequence of this observation, it is preferable to perform automatic enrichment for each hierarchy of SNOMED CT separately, rather than for the whole SNOMED CT. Another reason for enriching each hierarchy separately is that the content of each hierarchy is different, and ML is likely more effective by modularizing the learning into uniform hierarchies than learning a large, non-uniform body of knowledge in one process.

In the BERT\textsubscript{BASE} model, features are more generic/linguistic in the early network layers and more dataset-specific in the later layers. Thus, fine-tuning is normally inexpensive, because one only needs to modify the later layers or train one or two task-specific layers on top. All of the results in the paper can be replicated in at most 3 to 5 hours on a single GPU, starting from the same pre-trained BERT\textsubscript{BASE} model. Pre-training is more expensive than Fine-tuning. For example, it took about four days to run 200,000 steps to pre-train the model with the Clinical finding hierarchy data on a single GPU. However, this is a one-time procedure for each hierarchy. We plan to release the two pre-trained models of this paper for future research work, to save other researchers the effort and time to pre-train their own models from scratch.

**Limitations:** The BERT\textsubscript{BASE} model was trained with the concatenation of the BooksCorpus (800M words) [20] and English Wikipedia (2,500M words). It employs the WordPiece embeddings [23] with a 30,522 tokens vocabulary, which does not include most medical terms. Thus, medical terms that are not in the WordPiece vocabulary are split into word pieces denoted by ##. For example, “adenoid” is split into “aden” and “##oid.” The lack of medical terms in BERT’s vocabulary limited its applicability to support insertion of new concepts into a medical terminology such as SNOMED CT, and would probably impair other NLP tasks within the medical domain. In future work, we will expand the vocabulary to include common medical terms selected from terminologies such as SNOMED CT. We will investigate whether pre-training BERT with medical terms can help improve its performance in some common NLP tasks in the medical domain, such as tagging and named entity recognition in EHRs.
Conclusion
We have shown that one can fine-tune the BERT model and obtain an effective technique for correctly placing new concepts in the right positions of a terminology. Furthermore, by pre-training BERT with SNOMED CT content, we improved the precision while preserving the high recall and thus we improved the F1 value.

Abstract
When assessing the characteristics and performance of telemedicine interventions, most studies followed a patient-centric approach, leaving the telemedicine providers’ role out of consideration. As a result, little was known about the demographics and prescription pattern of telemedicine physicians, the knowledge of which is integral to a holistic evaluation of the virtual delivery of accountable care. To fill this gap, our study explored how physicians’ traits and encounter-specific characteristics correlate with prescription outcomes, using multivariate analyses. Significant inter-physician variation in prescription behaviors was observed and analyzed in sub-groups. The average Virtual Urgent Care physician’s prescription likelihood was 69% with a mean prescription count of 0.98; male physicians and primary care providers tended to prescribe both more often and with a greater number of medications. This study called attention to the quality and reproducibility of telemedicine providers’ prescription decision and warned the likely absence of well-defined practice guidelines for delivering virtual care.

Introduction
Telemedicine facilitates patient-provider interaction and the delivery of clinical consultation via information technology1. While most telemedicine research focuses primarily on patient’s characteristics, clinical effectiveness, and technical outcomes3,4, limited number of studies investigated the physicians’ prescribing behaviors in a virtual setting.

Telemedicine Providers’ Prescribing Patterns
In the past, researchers were primarily concerned with telemedicine providers’ performance in terms of diagnostic accuracy, obtained by analyzing medical images in certain specialties such as radiology, dermatology, ultrasound, and pathology6. However, this approach was not applicable to common acute illnesses, which made up the majority of current commercial virtual visits7. Only a handful of studies shed light on the demographics and practicing behaviors of telemedicine providers. Previously, researchers studied the difference between in-person and telemedicine providers’ prescribing patterns, concluding that provider type was a significant influence in determining the count of medication prescribed per consultation8. Another study investigated the prescription behaviors of General Practitioners in a Danish out-of-hours primary care telephone consultation practice. The authors further explored the association between various patients and physicians’ characteristics and prescription frequency, concluding that one in five phone consultations ended with a prescription; the prescription likelihood was the highest from 4 to 8 p.m. on weekdays and during the early morning on weekends9.

These findings, to some extent, complemented the previous research on inter-physician variation in prescribing practice in the traditional, face-to-face setting, which generally suggested a positive correlation between the providers’ personal characteristics and prescription outcomes10,11. However, the presence of a significant knowledge gap in telemedicine physicians precluded a systematic, direct comparison between the in-person and virtual physician populations. Therefore, the knowledge of telemedicine providers will offer valuable insights on the patient-physician relationship in the virtual environment, which has become an urgent matter as telemedicine gained more acceptance in recent years.

Virtual Urgent Care
This study is uniquely important in a sense that it investigated a rarely-studied type of telemedicine service—a Virtual Urgent Clinic (VUC) telemedicine platform, providing virtual medical consultation to the general population in North Carolina 24-hours a day, 7-day a week. More importantly, the VUC physicians come from four areas of specialties, which enabled between-provider-type comparison. Encounters characteristics, such as time of day, day of the week,
modality, and encounter duration were analyzed to provide a comprehensive understanding of telemedicine providers’ prescribing behaviors.

**Objective**
The goals of this paper were to further understand the characteristics of VUC physicians and to identify pattern and variation in their prescribing behaviors, using a combined method of descriptive and multivariate analysis. In addition, we discussed the implications of the providers’ behaviors in improving the delivery of accessible and accountable virtual care.

**Methods and Materials**

**Program Description**
We investigated the first 11-month operation data from the 24/7 virtual urgent care service in 2018. The VUC provides patient care across North Carolina with synchronous, virtual consultation for illnesses of acute nature—around-the-clock and 7 days a week—enabled by a third-party telemedicine platform.

Registration is mandatory for all patients in order to access the VUC service. Upon registration, the users are required to provide both demographic data (including age, gender, zip codes of residence, and status of dependency) and detailed accounts of medical history such as allergies, drug sensitivities, and family health history. At the point of scheduling a consultation, the patients are presented with a comprehensive list of conditions which could not be treated via the platform. The patients specify the reason for the visit from a pre-identified list of conditions and choose a provider per one’s preferences and availability. Moreover, the patient will choose either a phone call or video conference as their preferred encounter medium. Additional instructions are provided in case where the required software has not been appropriately installed. During the consultation, the VUC provider evaluates the patient symptoms and document the diagnosis in the standard ICD-9-CM Diagnosis Code; in situations which result in a prescription of any medications, the physician will send an electronic prescription to the patient’s pre-assigned pharmacy. The VUC service cost is a flat fee regardless of consultation types or duration. The study was approved by the Institutional Review Board at the University of North Carolina-Chapel Hill.

**Study Population**
VUC delivers urgent medical care to residents of North Carolina above the age of two-year-old. In addition, the patients will need access to a smartphone or a computer with the required software installed. VUC serves patients regardless of their demographic traits, insurance coverage, or other status.

All VUC third-party providers were board-certified physicians. We collected data of 26 VUC providers, including 9 Family Medicine, 8 Internal Medicine, 6 Emergency Medicine, 2 Pediatrics, and 1 General Practice physician. The sole General Practice provider was excluded from the analysis due to its inability to represent the General Practice physician population, which is likely to compromise the overall quality of the study. We decided to focus on two main types of providers: Primary Care—which encompassed Family Medicine, Internal Medicine, and Pediatrics providers—and Emergency Medicine.

**Dataset and Variables**
For analysis purpose, 141 incomplete and test-user encounters were excluded. Eight independent variables from two categories, the physicians’ characteristics and the encounter-specific features, were extracted and coded.

The provider’s gender, enunciation date, and medical specialty were identified through looking up their National Provider Identifiers(NPI), which was included in the original dataset, on the NPPES NPI Registry website. The procedure was aided by applying generic web-scraping algorithm in Python. The variable Year of Practice was constructed by calculating the difference between the physician’s year of enunciation and the current year (2019) and was subsequently categorized into over 10 years and under 10 years. Additionally, we counted the number of encounters completed by each provider and constructed Practice Frequency, indicating an individual’s degree of involvement in practicing telemedicine; likewise, the variable was divided into three categories—over 100 times, 51-100 times, and 11-50 times. Encounter-specific features were also recorded in the original VUC dataset, including Time of Day, Day of Week, Encounter Modality, and Encounter Duration. The features were classified into subgroups for the purpose of evaluation, as shown in Table 1. For additional inter-physician prescription variation analysis, we divided the dataset by the top five popular diagnosis codes: Sinusitis, Urinary Tract Infection, Pharyngitis, and Bronchitis).
Outcome Variables

The primary outcomes of interest were prescription likelihood and prescription count. Prescription Likelihood denoted the possibility of whether an encounter ended with medication prescribed; it was calculated by averaging the binary prescription outcome of encounters under a certain criterion, where 0 indicated no prescription and 1 indicated at least one count of medication. The variable Prescription Count recorded the exact number of medications prescribed per session on a range of 0 to 6.

Statistical Analysis

Descriptive analysis was conducted on the test population, giving the mean prescription likelihood and count by physicians and encounter characteristics. For the count variable Prescription Count, we applied the Kruskal-Wallis test to determine if the means in a group were significantly different from one another. The non-parametric Kruskal-Wallis test was chosen over the One-way ANOVA since the former does not assume the normality condition\textsuperscript{13}. For the nominal variable Prescription Likelihood, Pearson Chi-squared test was used for assessing the in-group difference. In addition, the top five most popular diagnoses were extracted and tested individually for the presence of inter-physician difference in prescribing outcome using Chi-squared test.

Variable Selection and Modeling

To remove the unnecessary predictors, a Stepwise Regression was run with all eight independent variables. Five predictors were kept for the final modelling while four were excluded. Doing so help reducing the noise which may arise from the collinearity among the redundant predictors.

Subsequently, a Multivariate Logistic Regression model was constructed to investigate the association between Prescription Likelihood and the five independent variables; log ratios and p-values were calculated. In addition, a Poisson Regression was built for estimating the impact of the independent variables on Prescription Count. Based on Cameron and Trivedi’s recommendation in their 2009 study, we calculated the robust standard errors for the parameter estimates in order to compensate for mild violation of the equal variance assumption\textsuperscript{14}.

Data Collection and Cleaning

Encounter data was automatically scrapped from the service’s website and stored in a secure SAP© Business Objects (BO) enterprise system. The dataset included physicians’ unique identifier, diagnosis code, prescription count, and encounters characteristics such as time of day, day of the week, duration, and modality information. The dataset was cleaned and preprocessed with Excel and OpenRefine. The statistical analyses and models were generated using R (R Foundation for Statistical Computing, 2014). The data visualization was made with Tableau Desktop 2019.

Results

This study analyzed a total of 1,217 encounters completed by 25 physicians, collected during the 11-month period between February 8\textsuperscript{th} and November 29\textsuperscript{th}, 2018. On average, 69\% of VUC encounters ended with at least one medication prescribed, with a mean prescription count of 0.98 per encounter.

Inter-physician Variation in Prescribing Behavior

To evaluate the presence of inter-physician variation in prescribing behavior, we assigned each provider a unique identifier, Provider ID (ranging from 1 to 25), which was subsequently tested as a predictor of prescription outcome. A Pearson Chi-squared test of Provider ID and Prescription Likelihood yielded a p-value of 0, indicating an extremely strong correlation between the individual provider’s accumulated characteristics and prescription likelihood. In other words, the 25 physicians prescribed in significantly different manners. Figure 1. visualized the frequency of prescribing a certain number of medications (0, 1, 2, and 3+) as a percentage of a provider’s total encounters.

In encounters resulting in prescription, one count of medication was the most common case. However, some physicians showed a tendency of prescribing multiple medications per encounter; for instance, provider 6 prescribed more than one medication per session about 90\% of the time and frequently prescribed greater than three counts. On the other hand, some providers showed reluctance towards prescribing at all (Provider 4, 12, 23), Figure 1.
Figure 1. Individual Difference among VUC Physicians’ Prescription Counts.

Descriptive Analysis

Providers Characteristics

Among the 1,217 encounters, 71.5% were completed by male physicians, who, on average, prescribed 24% more frequent than the female counterpart, Table 1. Of all consultations, 84.72% were completed by providers with over ten years of experience. Physicians with less than ten years of practice tended to prescribe a significantly greater number of drugs per encounter; however, they were not more likely to prescribe than their counterpart. Furthermore, Primary Care providers completed the most number of consultations (68.45%), while Emergency Medicine contributed the remaining 31.55%. The Chi-squared test results of both outcome metrics indicated significant difference between provider types. Lastly, 40.76% of the consultations were conducted by physicians who practiced less often (11-50 times), while physicians who had completed over 100 sessions contributed 37.14%. The between-group differences were significant in both outcome measures.

Encounters Characteristics

Of all encounters, 39.77% took place in the morning (6 a.m. - 12 p.m.); afternoon (12 p.m. - 5 p.m.) and evening sessions (5 p.m. - 10 p.m. and 10 p.m. - 6 a.m. combined) composited around 30% of total encounters respectively. Physicians were more likely to prescribe during morning hours, where 73% of sessions ended with drugs prescribed; sessions happened after 10 p.m. had the lowest prescription likelihood of 61%. Likewise, morning sessions had the highest prescription count (1.04), which is 73.56% higher than the average count of late night sessions (0.84). Additionally, approximately 7 out of 10 encounters lasted between 1 and 5 minutes. Durations of less than 1 minute and over 10 minutes were rare, with less than 2% and 6% rates of occurrence respectively. Furthermore, about 3 out of 10 encounters happened during the weekend, the prescription likelihood and count of which were both significantly lower than those of the Weekday encounters. In terms of telemedicine modality, Phone (88%) was predominantly more popular than Video (12%); the difference in prescription outcomes between the two, however, was not significant.

**β** denotes Chi-squared test p-value <0.05 for characteristics—prescription likelihood.
**Prescription Outcomes Analysis**

**Prescription Rate**

To further understand whether a certain physician or encounter characteristic could potentially affect the likelihood of prescription at a given consultation encounter, a Multivariate Logistic Regression was run to determine both the significance and magnitude of each independent variable’s predictive power, as shown in Table 2.

The resulting test statistics indicated that Provider Gender and Specialty was the most significant predictors, with p values of less than 0.05; Time of Day and Day of Week were less strong but still marginally significant, with p-values of less than 0.1. Odds ratio were subsequently calculated. For instance, all else held equal, male providers were 2.1 times more likely to prescribe than their female counterpart. Primary Care providers were 42% more likely to prescribe than the EM specialists. On the other hand, a Weekend encounter, completed by a physician with the same set of characteristics and shared the identical encounter features as its Weekday counterpart, was 78% less likely to end with medication prescribed. In addition, consultations happened in the morning hours were about twice more likely to get prescription as compared to the sessions taken place after 10 p.m..

**Prescription Count**

A Poisson Regression with Prescription Count and the set of 5 variables was performed. To ease the interpretation, we transformed the resulting log-odds estimate into incidence rate ratio, Table 2.

Provider Gender and Specialty turned out to be significant predictors, with p-values of less than 0.01 and 0.1 respectively. All else features held equal, male physicians prescribe 48% unit more than the female. Under the same encounter settings, Primary Care providers prescribe 15% more than the EM specialists of their own gender and practice frequency.

Prescription Outcome Analysis for the Top 5 Diagnosis

The five most popular diagnosis (accumulated n=463, 38.04% of total encounters) were individually tested for inter-physician variation in prescribing outcome. The statistics were obtained using Chi-squared test, as shown in Table 3.

Different physicians prescribed in significantly different manner when treating Sinusitis, Urinary Tract Infection, Pharyngitis, and Upper Respiratory Infection (p value<0.05). However, the inter-physician variation was not observed in treating Bronchitis. Bronchitis patients were also the most likely to get prescription (prescription likelihood =85.7%). In case of Upper Respiratory Infection, only 63.8% encounters ended with any drug prescribed.

Discussion

Main Findings

We found that virtual care providers were predominantly male primary care physicians with over ten years of experience. Male providers displayed a tendency toward prescribing a greater number of medications at any given consultation. In addition, the difference between Primary Care and Emergency Medicine physicians were evident in both outcome measures, with the latter being more reluctant toward prescribing and suggesting a higher count of drugs. A marginally significant correlation existed between temporal factors (Time of Day, Day of the Week) and prescription outcomes. On the other hand, the impact of telemedicine modality and duration of encounter were not evident in affecting the physician’s prescribing behaviors. Inter-physician variation in prescription outcome was the most present in treating diseases of the respiratory system (ICD-10-CM Diagnosis Code J00-J99), which were also the most popular VUC diagnoses.

Previous Study

Telemedicine Interventions

In terms of prescription outcomes, the variations were considerable: The average prescription likelihood of VUC encounters was 0.69, which was significantly higher than the rate of 0.19 in a similar study of a telephone consultation intervention in Denmark. On the other hand, VUC’s mean prescription count was 0.98, which was 29.6% lower than the 1.27 average in another e-visits intervention. However, the scarcity of comparable literature prevented us from understanding the underlying pattern of such pronounced differences among individual telemedicine interventions. These great variances alarmed the potential absence of common practice guidelines in the virtual setting, raising questions on the fairness and quality of telemedicine delivery.

In-Person Urgent Care Visit

According to a national survey conducted with 436 in-person Urgent Care Centers in the United States, primary care providers managed 72% of total encounters, while emergency medicine physicians and non-primary care specialists contributed 28% and 20% respectively. Our study indicated a similar composition of physician’s specialty, with a 2:1 ratio between primary care and emergency medicine physicians. However, there was an absence of non-primary care specialists among the telemedicine providers. We suspected that the VUC protocol, designed specifically for the
assessment of common acute illnesses via voice or video conferencing, prohibited advanced patient-physician interaction that might be required in the specialists’ consultation.

Time and day of urgent care visit were significantly different between in-person and virtual settings. One study sampled 387,746 records of acute care visit in the U.S., collected between 1997 and 2010, suggesting that 95 percent of visits to office-based primary care providers happened on weekdays. On the other hand, three out of ten VUC encounters took place on weekends. The virtual urgent care demonstrated potential in providing more timely and accessible medical service due to the around-the-clock availability of telemedicine physicians. In other words, telemedicine service could complement the office-based delivery of primary care, ameliorating the staffing problem faced by many healthcare organizations nowadays.

**In-person Physician**

Our study agreed with a number of researches on that male physicians tend to be high-prescribers. One study concluded that physicians who had more practice days and saw more patients per day would also prescribe greater number of drugs. While our findings indicated significant between-group differences among telemedicine physicians with varied frequency of practice, the variable itself was not an effective predictor of both prescribing outcomes in a virtual setting.

**Strengths and Limitations**

This study was the first to investigate the characteristics and prescription behaviors of virtual urgent care telemedicine providers, with first-hand data collected from a Southeastern commercial telemedicine platform. In addition, we searched for literature on office-based urgent care centers in the United States and compared the operational statistics with the VUC dataset. However, the inter-physician variation in prescribing styles suggested that one’s prescribing decision might be prone to personal biases, which we were not able to validate in this paper.

In addition, this paper did not directly compare telemedicine physicians with in-person physician due to the lack of access to comparable data collected from in-person urgent care settings. We were only able to compare our findings with similar telemedicine evaluation studies. The implications of this paper could be further strengthened if comparison was made between virtual and traditional urgent care providers.

On the other hand, we only studied the five most popular diagnostic groups, which made up 38.04% of total encounters, instead of analyzing all diagnoses. The reason for this is that the original dataset came with 124 types of diagnoses, which we were unable to categorized into meaningful groups without expert knowledge in disease classification. Therefore, further studies may focus on analyzing a selective group of diagnoses, which would yield more disease-specific findings.

Last but not least, the quality and reproducibility of telemedicine consultation remained in question. To our knowledge, only one study evaluated the reproducibility of telemedicine diagnosis of common acute problem, suggesting a strong trend for telemedicine physicians to disagree on primary diagnosis made by office-based physicians. Future work could test the inter-physician agreement on prescription outcome of a certain type of acute illness. Additional test could be designed to assess the unbiasedness of telemedicine provider, measured by the consistency of prescription outcome generated by an individual provider.

**Future Direction**

Previous studies highlighted the pivotal role of an extensive examination of both the quantitative and the qualitative determinants in order to understand the motivation and preference behind the physician’s prescribing behavior. Therefore, future research could incorporate qualitative metrics that measure personal, organizational, and sociotechnical qualities: the physicians’ attitudes toward telemedicine, work ethics, and organizational culture, etc. Such measures could be obtained through survey questions or contextual interview.

On the other hand, traditional urgent care and ambulatory care had been known for antibiotics overuse. According to one study, about 1 in 3 antibiotics prescribed at ambulatory care visits was unnecessary. Researchers could analyze the antibiotics prescription pattern in the telemedicine interventions, which will add to the current knowledge of antibiotic abuse.

Moreover, it was unknown whether the virtual care providers had received telemedicine-specific training prior to practicing online. We highly recommend telemedicine developers and healthcare organization leadership to consider developing training and educational programs in order to standardize and regulate prescription appropriateness in the virtual setting.
Conclusion

In conclusion, this study investigated physicians prescribing behaviors in a telemedicine urgent care platform. We identified that male primary care physicians made up the majority of the telemedicine provider population; this subgroup was also the most likely to prescribe a greater number of drugs at a given consultation. Primary Care providers and EM physicians showed different prescribing styles, with the latter appeared to be more reluctant toward prescribing online. However, this study alone could not explain the inter-physician variation in prescribing behavior due to the lack of access to qualitative measures such as the physician’s attitude toward practicing online.

Nevertheless, this study highlighted the difference in prescribing pattern among telemedicine providers, which could potentially compromise the quality of virtual care delivery. We urge future researchers to focus on the appropriateness and reproducibility of telemedicine physician’s prescribing outcomes.

While telemedicine has been increasingly perceived as a timely, cost-effective alternative to traditional office-based medical care delivery, it is crucial to ensure that the quality of care is not compromised. We believe that an enhanced understanding of telemedicine providers’ behaviors would help improving the delivery of around-the-clock, appropriate, and accountable medical care to the population.

Improving the Odds of Success for Precision Medicine Using the Social Ecological Model.

Scott P. McGrath, PhD
University of Nebraska at Omaha, Omaha, NE

Abstract
The concept of precision medicine aims to provide additional context to patient data for healthcare providers. A decade after the HITECH act of 2009, the state of EHRs can be considered a mixed bag. Increased levels of physician burnout have been attributed to the impact EHRs have had on traditional patient and provider interactions. In order for precision medicine to be allowed to establish a foothold, it must demonstrate the ability to improve clinical outcomes. One path to achieving this is by improving health behavior, which is a difficult task. In this paper, the case is presented for using the social ecological model to help shift health behaviors with precision medicine.

Introduction
In this era of start-ups, over-night success stories, and Internet billionaires, there is a tendency to oversell and overhype ideas and concepts; a condition the healthcare industry is not immune to. Take for example the company Theranos, a Silicon Valley health technology company which promised to revolutionize blood testing with its microfluidics, and earned its founder, Elizabeth Holmes, the title of the youngest female self-made billionaire. The company had been valued at $9 billion, but in October of 2015, an expose in the Wall Street Journal indicated the company wasn’t using its technology on the blood tests it was conducting for customers. A year later the company was embroiled in a lawsuit for $140 million from Walgreens. The FDA has banned Ms. Holmes from the blood testing business for two years, and as of August 31st 2018, Theranos has ceased operation. This provides a clear warning to those who are looking for miracle “silver bullets” or chasing after the next “killer app” in the medical domain: expediency may work for developing social media platforms and ride sharing apps, however efforts to find a one-size fits all solution for healthcare is often short sighted.

The concept of precision medicine (Fig.1) aims to provide additional context to patient data for healthcare providers. Precision medicine overlays three additional layers of patient data on top of standard patient information: environmental exposure, personal lifestyle and behavior patterns, and information gleaned from their genome. While precision medicine promises to provide physicians and their patients with increased levels of customization for preventative and primary care, there is evidence that preparation relating to the genomic pillar of precision medicine is not yet adequate to ensure successful deployment.

Genomics is not a panacea for all our ills, so to focus on how the genomic aspect of precision medicine can advance our knowledge and ability to prevent and care for disease, it needs to be viewed in the proper context. Studies have clearly demonstrated that simple awareness of increased risk of disease due to genetics has no significant impact on improving health behavior (1-3). So to herald the genetic component of precision medicine as a ‘miracle elixir’ may be disingenuous at best. We often discuss “curing” cancer, but this frames the question in an improper mindset, as many people equate cure as returning to a state where the individual is as good as new. It is possible that offering a “cure” removes the individual’s overall share as a stakeholder in his or her own health. If a patient falls ill, they can get treated, and they return to a normal state. Patient investment in this scenario is more indirect through cost of time and money to the patient. Contrary to this, improving a patient’s health behavior increases their percentage of ownership in their health. Diet and exercise require far more investment in time and energy than adding a few pills to their morning routine. In the long term, it has been postulated that that adjusting health behavior will pay more dividends than simply being the recipient of a treatment or “cure” for a disease. It is simply stated, but it has been quite the enigma for physicians, how to engage patients to shift this perspective. I think it is imperative to frame precision medicine as a method to ultimately improve health behaviors instead as path to delivering new treatments and improving outcomes. To be sure, both are beneficial aspects of precision medicine, however there is a unique opportunity to transfer emphasis of care to preventative over reactive care through precision medicine.
Figure 1: Pillars of precision medicine: Traditional medical records will be supported by supplementing medical data with information that can be curated into the following categories: 1) environmental 2) lifestyle, and 3) genomic. The environmental pillar will be collected based on environmental exposure an individual encounters in both work and life. Lifestyle pillar will be comprised of data from personal activity, exercise, and diet. The genomic pillar will be built using an individual’s genetic and genomic data. In combination, all three will help build a fuller picture of an individual’s health in the precision medicine model.

To support this perspective, I propose we aim to implement the model of precision medicine using the social ecological model and social determinants of health. The advantage of using an ecological model is that they contain a heuristic value by forcing the researcher to consider multiple levels of influence on the subject of their study. Rimer and Viswanath (4) outlined five principles for ecological models rooted in studying health behavior (Figure 1):

1. There are multiple levels of influence on health behavior
2. Environmental contexts are significant determinants of health behaviors
3. Influences on behaviors interact across levels
4. Ecological models should be behavior specific
5. Multilevel interventions should be most effective in changing behaviors

Figure 2: The social ecological model and social determinants of health. (5) Reprinted with permission from the National Academies Press, Copyright 2003, National Academy of Sciences.
Social Ecological Model

Rimer and Viswanath point to the advances made in tobacco control as evidence of success with ecological models in changing health behavior. The Surgeon General began to highlight the dangers of cigarettes back in 1964, which initiated the process of encouraging Americans to quit smoking (6). Economic factors, mass media education efforts, clinical smoking cessation programs, and multi-level programs have had an aggregative effect on lowering smoking prevalence (7). This is a good example of viewing the social ecological model working at the public health level. When addressing such a large population, 42.4% of all adults in America were smoking in 1965 (8), smoking cessation approaches needed to be launched on multiple layers identified in the social ecological model.

An additional example of the application of social ecological model to help address the health and behavior associated with a disease can also be seen in the control efforts to combat the spread of HIV infection. Efforts to address HIV-spread have been most successful when multi-level approaches were taken to address societal and structural HIV behavior change, in addition to preventing the further spread of virus (9-11). Effective interventions were identified as methods that “contained attitudinal arguments, educational information, behavioral skills arguments, and behavioral skills training” and the least effective methods centered on using fear. Target audience gender, ethnicity, risk levels, and other variables influenced strategy success (11). The complexity of the number of variables that can be leveraged to help shift health behavior can be difficult to track, which is where the socio-ecological model can help. Kaufman et al. used the ecological model to help categorize some of these variables.

Alignment of Precision Medicine and the Social Ecological Model

The proposed model of precision medicine highlights lifestyle, environmental, and genetic data. There are two primary influencers in the ecological model: external factors and internal factors. When you look at environmental and lifestyle data, these largely align to the outer layers of the ecological model. Environmental impacts are associated with where an individual lives, works, and travels. In order to impact or change the exposures encountered in various environments, it is often too large a task for just a single individual, therefore it is better suited for large organizations or governmental bureaucracies to engage as well. Later in this paper we will examine how the Learning Health System may be an effective tool for these outer layers of the ecological model. Individuals have a lot more influence on their lifestyle, based off what they elect to eat and their activity levels. However, just like smoking, social and economic pressures can help influence health behaviors. Implementing soda or sugar taxes have shown to be an effective method of helping people improve their dietary consumption patterns associated with chronic disease and obesity (12).

Genetic data fits squarely into the intrapersonal layer. Intrapersonal is an internal influence on behavior, which can impact the perceived environment. By keeping the focus on improving health behavior, the intention is to help keep resisting the impulse to have precision medicine emphasize treatment over prevention. The ecological model should help with this challenge by keeping the environmental and lifestyle framed in the picture. Research has shown that simple notification of genetic risk of disease has no significant effect on smoking cessation, diet, physical activity, or even preventative actions like alcohol use, or applying sunscreen (13). Meaning, simple disclosure of the risks does not lead to changes in health behaviors.

If coupled with other layers of the ecological model, odds of behavior change will likely be improved. These changes were demonstrated in a recent study inspecting the impact of biomarker, genetic testing, and lifestyle factors on health behavior for individuals who were first-degree relatives of patients suffering from rheumatoid arthritis (RA), but who were not suffering from RA themselves (14). Researchers found that participants who were provided with access to a web based Personalized Risk Estimator for Rheumatoid Arthritis (PRE-RA), which included discussion over genotype, autoantibody results, and behavior changes that could improve RA-risk (smoking, diet, exercise, or dental hygiene) showed positive behavioral changes. The control group for this study was provided with standard RA education. The intervention helped to improve health behaviors at six months with 63.9% of the PRE-RA group following the recommended changes in comparison to the 50% of the control group who had not received the non-personalized standard RA education. Taking guidance from studies like this can help keep our focus on developing precision medicine in a way that will help to improve clinical outcomes.
The social ecological model's emphasize that health behavior is not simply influenced in a binary fashion is what makes it an appealing approach to consider when trying to deploy precision medicine. Take the simple action of prescribing medication to treat a disease. The action is fairly linear in design, a diagnosis is reached, and a treatment plan is developed with the inclusion of a selected drug. However, a variety of elements contribute to the ultimate efficacy of the drug. Medication regimen adherence is one a major hurdle care providers are faced with, and adherence is influenced by multiple factors itself: cost of the drugs, how “forgetful” the patient is, side effects from the drug, etc. This is why precision medicine needs to be developed in a way that was considered as the diversity of influenced on health behavior and to also accommodate people’s lifestyles as well. Not all layers of the ecological model have the same level of weight that influences the individual. Social, family and community networks will help shape individual behavior more than broad national campaigns occurring at outer layer of the ecological model. As demonstrated with the campaign against smoking, approaching the problem from several different levels (interpersonal, social, living and working environments, and societal) put up clear boundaries that collectively helped changed health behaviors. We cannot claim precision medicine as a successful model if “wins” are only described in individual cases. The financial costs and work investments required to launch and sustain precision medicine requires sustained shifts in clinical outcomes at the population level to help justify its expense.

**Individual behavior impact**

In order to explore this framework as a model to help implement precision medicine, I have conducted a few studies working within the living and working layer of the ecological model as part of my dissertation. The focus of my dissertation was examining how to help a growing patient population understand genetic results as we see more genomic data being introduced to health records. The first project explored the knowledge gap between primary care physicians and genetic experts (clinical geneticist and genetic counselors) via a validated survey instrument. A national survey was conducted, and participants (n=264) were sorted into two categories, genetic specialists (genetic counselors and clinical geneticists) and medical providers (primary care, internists, physicians’ assistants, advanced nurse practitioners, etc.). The survey presented three genetic test report scenarios for interpretation: a genetic risk for diabetes, genomic sequencing for symptoms report implicating a potential HMN7B: distal hereditary motor neuropathy VIIIB diagnosis, and a statin-induced myopathy risk. Participants were also asked about their opinions on Direct-to-Consumer-Genetic Test results and rank their own perceived level of preparedness to review genetic test results with patients. The rates of correctly interpreting results were relatively high (74.4% for the providers compared to the specialist’s 83.4%) and age, prior genetic test consultation experience, and level of trust assigned to the reports were associated with higher correct interpretation rates. The self-selected efficacy and the level of preparedness to consult on a patient’s genetic results were higher for the specialists than the provider group. This study lends support that the genetic specialist still remains the best candidates to educate patients about genetic test results, however primary care healthcare providers can provide accurate interpretations when specialists are not available. Initial findings were shared at the 2019 AMIA Informatics Summit in San Francisco as a podium abstract, and a full manuscript is currently under editorial review for publication.

The second project was a scoping review to map out the ideal educational techniques for physicians to help increase patient comprehension of genetic testing results. Twenty-six manuscripts were selected for inclusion in the scoping. The papers were categorized into three themes that emerged: papers focused on education interventions between patients and providers, professional and curriculum development to enhance adoption and comprehension of medical genetics, and review papers, which were found to have overlap with the intended aim of this paper. There are a few clear areas where emphasis should be placed for further work on this topic: continuing to develop web-based educational tools designed with active learning methodologies, conducting more randomized controlled trials to develop more robust evidence, and linking clinical outcomes with educational interventions, which will in turn assist in developing new medical curriculum with a renewed emphasis on genomics. The full manuscript for this study is also under editorial review for publication with an available preprint publication online (15).

The final project documented the process of developing a mHealth app designed to aid health care professionals (certified athletic trainers) in detecting and managing concussions in patients under their care (16). Telehealth and mHealth are attractive technologies to help extend the reach of health professionals with genetic expertise. By exploring these various components, the goals of proposed my dissertation research was (a) to identify barriers facing healthcare providers in regards to educating patients about their own genes/genomes (b), to outline the best pedagogical approaches for patient education, and (c) highlight how existing health technology can assist with said communication. These three studies focused on how to assist healthcare providers in their efforts to increase patient
understanding when dealing with data generated from the genomic pillar of precision medicine. Additional efforts will be needed at different layers of the ecological model in order to help shape health behaviors. In the following section, and the learning health system will be explored as example of how to impact the social economic and cultural level of the model. Precision medicine has moved from theoretical and planning stages into real world initiatives. There are a large amount of resources already being invested to usher it into practice. It is critical to identify future roadblocks while they still remain manageable and investigate solutions; this work aspires to target a few of these roadblocks and present some countermeasures to help facilitate the deployment of precision medicine.

**Learning Health System**

Addressing ways to work within the broad social economic and cultural level of the social ecological model is challenging, however the Learning Health System is one potential candidate to work in this space. One of the biggest impediments to advancing medical care in the United States is the extremely protracted length of time it can take to innovate medical procedures and to align the best medical practices with the most current corpus of clinical knowledge. It takes, on average, 17 years for research findings to be translated into products, policy, or clinical practice (17). How can we accelerate this pipeline to improve clinical care in the near future, and not in the next decade or two, what strides have been made to reach this goal? The answer is we have not significantly moved the needle on the “time lag” for biomedical research into clinical practice. The period of time remains between 10 to 25 year depending on which medical research domain is being evaluated (18), which is still too long. One proposed solution is the learning health system (19-21). Under the Learning Health System (LHS) model, a federated system of health data derived from EHRs would be established at the national level (19). This would allow members of the LHS to pose queries, to which others can supply relevant responses from their own collected data. This could occur in a variety of ways. For example, in drug trials, participants could be recruited by asking within the LHS “How many patients who meet these specific eligibility criteria does your institution have?” subsequently, if the drug reaches the market, the LHS can help monitor the drug’s safety by cataloguing and adverse health events. Real-time national surveillance can be enhanced through tracking of infectious disease. In fact, the entire aim of a LHS is to deliver “a health system that learns as quickly as possible about the best treatment options appropriate for each patient—and delivers it.” (22). The implications of the LHS is also recognized by the Health and Medicine Division, formerly the Institute of Medicine (IOM), which state “the nation’s health and economic futures—best care at lower cost—depend on the ability to steward the evolution of a continuously learning health care system” (23). This belief was also adopted by the Office of the National Coordinator for Health Information Technology (ONC) as they set it as a part of their 10-year strategic goal where a LHS would help to reduce health care costs, improve public health, empower patients, and help usher in new innovation (24). The need for this is urgent, with as much as 25% of medical expenditures, an approximate $750 billion per year, is lost due to administrative inefficiencies, abuse, fraud, and treatments which failed to improve clinical outcomes (20). Even with an expenditure of 18% of the US gross domestic product on healthcare (25) we still see patients who fail to receive 45% of recommended care, and overall healthcare quality improvements remains anemic (20). LHS is being recognized as a major plank in reducing the ‘GDP footprint’ healthcare currently occupies (26).

LHS is strong candidate to help drive precision medicine forward, it can also serve as an element that helps to extend beyond the individual level of the social ecological model. This partnership has been recognize by others, as outlined by Dr. Chambers in his 2016 article (27). Precision medicine is positioned to generate a sizable amount of data to help with clinical decision-making, but ultimately the means to measure the level of clinical effectiveness of the data in a cost efficient manner is lacking. This is where the LHS can assist, by refocusing on organization’s goals to ongoing system improvement in an incremental process, much like the agile software development model. The pairing of LHS and precision medicine is a natural fit, but the addition of implementation science is needed to bridge the two components. Implementation science is defined as “the scientific study of methods to promote the systematic uptake of research findings and other evidence-based practices into routine practice” (28). Discoveries and breakthroughs identified by precision medicine can be plugged into the LHS via a framework provided by implementation science (Fig. 2).
Health care services are housed within the living and working strata of the ecological model (5), a LHS could serve as a conduit for precision medicine have an impact at that layer. A nationalized LHS could also eventually reach the outer layer of the model by helping advance public health with enhanced surveillance and improved clinical treatment plans and outcomes.

The LHS concept was initially proposed back in 2007 (29), so how is the model coming along? The answer is we have seen several organization making progress toward a LHS (Geisinger (30), Kaiser Permanente (31), and the VA (32)) and we are reaching a point where impact can start to be measurable/quantitated, but there appears to be a lack of research on evaluating the impact (33). Efforts appear to still be largely in arguing the feasibility of the LHS. In a recent publication, Embi et al presented some policy recommendations to help LHS move past this argument by establishing the “evidence-generating medicine” phase (EGM) (34). As defined, EGM is the “systematic incorporation of research and quality improvement considerations into the organization and practice of healthcare in order to advance biomedical science and thereby improve the health of individuals and populations.” (35). Three principal recommendations were put forth by Embi: evidence needs to be generated at the local level (point-of-care), research needs to be conducted across organizations, and this ecosystem of local data generation and nationalized research needs to be supported and allowed to grow. To accomplish increased data generation, research should be incentivized at the local level, and regulations adapted to foster this aim, which require additional investment in health IT. Networking research between organizations requires a skilled workforce that is trained in informatics, and standards need to be set in addition to establishing governance protocols. Sustaining progress achieved through the first two aims will require strategic adjustments of federal funding guidelines and there should be an effort to improve the use of the research data, allowing for multiple parties to extract value.

Conclusions

The social ecological model helps us to understand that health behavior can be impacted by multiple factors, and is often not a single variable that leads people to make the decisions they make. It is possible to influence health behavior in part by focused efforts that only engage the individual at a single layer of the ecological model, but evidence points to efforts that try to engage individuals on multiple layers are more effective. Simple notification of genetic risks does not lead to lasting change, which is why precision medicine really needs to be viewed as an enhancement to current medical care instead of a re-inventing of care. The lifestyle, environmental, and genetic data accumulated into patient records should be treated like a spice or seasoning that is present to enhance the quality of the meal, but not to replace or overwhelm the meal itself. Treatment and patient engagement with the goal of
changing health behavior can be enhanced with blending in some of this information to find the correct balance for subgroups of patients. Some of the data we generate through precision medicine will have universal application, much like salt and pepper, others will have more nuanced applications where it will only need to be used sparingly, like saffron, in order to make the desired impact. Therefore, genetic risk assessment scores are expected to develop into the type of ‘seasoning’ that will have limited use cases. It isn’t something that you want to roll out for every patient, but when properly identified, it can lead to very positive results. Pharmacogenomics and expanding our treatment options will be more like the general ‘seasoning’, where large number of individuals will benefit from increased choices. The social ecological model helps us to frame precision medicine in the scope and scale suitable for our effort to improve health behaviors. Efforts require attention to the details, knowing when to pursue what proves to actually be effective, and avoid chasing after silver bullets or overhyped claims.

A Qualitative Study to Examine Approaches used to Manage Data about Health Facilities and their Challenges: A Case of Uganda

Jonathan Mpango, MS¹, Josephine Nabukenya, PhD²

Abstract

Availability of an accurate and complete health facility list is fundamental in producing quality and timely data that is sufficient to aid evidence-based decision, resource allocation and planning within the healthcare ecosystem. This study aimed at examining the approaches used in Uganda to manage data about health facilities and the challenges they are facing. We conducted a qualitative study involving 32 interviews with participants from Ministry of Health, government regulatory organizations, district local government, general public, academia, implementing partners and healthcare providers. Our analysis identified four divergent approaches that had five common challenges, namely: lack of a health facility unique identifier, non-standardized, incomplete, inaccurate data, difficulty accessing and using data. Establishing a national central health facility registry to manage the national health facility list would improve patient referrals, facility look-ups, health information exchange, data curation and access and health information system integration.

Keywords: Health Facilities, Health Information Exchange, Master Facility List, eHealth, Uganda

Introduction

Availability of accurate and timely information on the quality and supply of healthcare services is essential for monitoring and evaluating health systems (1). Having quality and complete information enables countries to track the progress and performance of their health information systems (HIS). However, few countries have accurate and up-to-date information on the state of their health facilities (HFs), covering the public, private-for-profit and private-not-for-profit sectors. This poses a challenge in producing quality and timely data that is sufficient to aid evidence-based decisions and resource allocation (2). One innovative approach that low and middle-income countries (LMICs) have undertaken is embracing Information and Communication Technology (ICT) to develop and implement electronic HIS (eHIS) within the healthcare system to manage data about HFs (3).

Despite the huge investment in implementing eHIS in Uganda, it is still challenged by divergent levels of data standards that hinder data exchange, poor coordination and communication, limited skilled human resource, fragmented data collection processes, inadequate infrastructure and isolated HIS (4–6). According to World Health Organization (WHO), most of the LMICs have multiple sets of HF lists which may contain contradicting data on HFs and they lack a common HF unique identification number (7). Maintaining such multiple HF lists is costly and in case they contradict each other, it may be difficult to identify the correct one. To address this challenge, WHO recommends that countries should establish one comprehensive Master Facility List (MFL) that should house complete, accurate and up-to-date data on all HFs that exist in a given geographical location (7,8). This recommendation is also mentioned in the Uganda eHealth Policy (9).

In recent years, progress has been made globally by different countries to develop tools that support them to collect and manage data about HFs (7,8,10–12). Several studies have mentioned the benefits that have been attained by countries that have established a comprehensive and up-to-date MFL including; supporting emergency response operations, efficient allocation and distribution of resources related to HFs, improved disease surveillance and improved HF identification (7,8,10–12). The government of Uganda through its in-line Ministry of Health (MoH) in collaboration with its stakeholders has made progress in establishing a national MFL, which was yet to be officially launched by the time this study was conducted. Over time, the status of HFs in a given location change due to establishment of new ones, others get upgraded or downgraded whilst some are closed. This requires the MFL to be continuously updated whenever such changes occur, which are not an easy task.

In order to address this challenge, WHO recommends that countries can establish a national Health Facility Registry (HFR) to manage its MFL (8). The HFR is a software application that acts as the central authority to collect, store and distribute accurate, complete and standardized data on HFs (7,8,11). There are numerous benefits that are attained by countries that have established a national HFR that are documented in the existing literature. Implementing an HFR fosters better monitoring and evaluation by supporting the harmonization of facility linked datasets, improves referrals and facility look-ups, facilitates health information exchange (HIE), and facilitates data curation (7,13–15). Notwithstanding such benefits, there is no national HFR yet developed to manage Uganda’s MFL although some steps have been taken through the national eHealth strategy.
At the time this study was conducted, there was no evidence published in existing literature about the approaches used within the healthcare sector to manage and/or access data about HFs. Thus, we aimed to use the study findings to improve on the current approaches by establishing optimal requirements and features a HFR should have to better manage data about HFs in Uganda’s healthcare system.

Methods

Study settings: The study was conducted in Uganda, a landlocked country in the eastern region of Africa. Its estimated population is 42.86 million by the end of 2017, with an annual growth of three percent (16). Uganda healthcare system is decentralized composed of public and private sectors (17,18). The public sector is decentralized at district and sub-district levels ranging from national referral hospitals (NRHs), regional referral hospitals, general hospitals, health centers, to village health teams whilst the private is divided into private not for profit organizations (PHFPs) and private for profit organizations (PFPs).

Study design: A qualitative exploration approach was used in this study. An exploration approach is research approach used to investigate a problem that has not been studied more clearly which is the case with this study (19). The purpose was to examine the approaches that were being used to manage and/or access data about HFs within the Uganda healthcare sector.

Participant selection: Purposive sampling was used to identify the study participants from organizations that utilize data about HFs during their decision making process. This method of sampling helps to create a homogenous sample of participants that have experience with the phenomenon (20). Participants selected from the sampled organizations were required to at least have used data about HFs in their day-to-day operations. The category of participants selected included policy makers, monitoring and evaluation officers, technical officers, program officers, district health officers, district biostatisticians, academic researchers, healthcare providers, data officers and patients. In this study, participants were no longer recruited once saturation had been reached, in which no new information was provided to aid the understanding of the phenomenon (21). Participants were contacted face to face on appointment with a cover letter and consent form explaining their rights as participants.

Data collection: The first author, who completed data collection, bracketed biases before beginning data collection to assure data accuracy. A semi-structured interview protocol was developed and reviewed by both authors, and edited based on feedback. The interview questions were generated from the literature review around the phenomenon under study. These questions were reviewed and modified by consensus between the authors who have vast knowledge on HIS and the healthcare system of Uganda. Each interview was treated as an individual case, and all interviews were audio-recorded and de-identified. Throughout the process of the interviews, probes and follow-up questions were added as needed to encourage amplification and elucidate responses. Specific questions were added as the interview process proceeded. Data collection was completed over a period of 2 months and ended upon saturation.

Table 1. Semi-structured interview protocol

| What approach do you use to manage data about health facilities at your organization or national level? |
| Probe: What other approaches are you aware of in the sector?; Currently, how do you access data about health facilities in the approaches you have mentioned? |
| What issues affect the mentioned approaches for managing data about health facilities? |
| What are your recommendations to address the mentioned challenges? |

Data analysis: At the end of the interview process, the audio recordings were transcribed verbatim by the first author and validated independently by the co-authors who re-listened to the audio recordings to ensure they were accurately transcribed. Observations from the co-authors were shared with the first author who incorporated them into the final interview script. We engaged in a reflexive dialogue to conduct an open inductive analysis (22,23). After familiarization with the raw data a coding scheme was developed in a multi-level process. Statements that mentioned approaches, challenges and recommendations were identified and categorized into codes. Any discrepancies were discussed and new codes or code definitions were created. Trustworthiness of findings was enhanced through frequent discussion between the authors to ensure that the codes, sub-themes and themes adequately described and encompassed data collected.
Study period: Data collection was done in August and September 2018 and analysis was done in October and November 2018.

Ethical considerations: The Higher Degrees, Research and Ethical Committee (HDREC) of Makerere University School of Public Health approved this study. All participants gave written consent and their privacy and confidentiality was ensured during the study.

Results
A total of 32 individuals involved in using data on health facilities consented to participate in our qualitative study, where 32 one-on-one key informant interviews were conducted with participants. Participants included 2 policy makers, 5 monitoring and evaluation officers, 7 technical officers, 3 program officers, 2 district health officers, 3 district biostatisticians, 1 academic researcher, 2 healthcare providers, 2 data officers, and 5 patients (Table 2).

The study examined the approaches used to manage and/or access data on HFs and their challenges in Uganda. We present our findings grouped in two major themes that were identified during data analysis. These include: (i) approaches used to manage and/or access data about HFs, and (ii) the challenges faced by the identified approaches.

Theme 1: Approaches used to manage and/or access data about health facilities

Based on the data analysis, four approaches for managing and/or accessing data about HFs in Uganda healthcare sector were identified, namely; the draft 2018 Ministry of Health Master facility list, the national electronic health information system, the institutional-based facility list and the paper-based approach.

The 2018 Draft Ministry of Health Master Facility List: About 9% (3/32) of the study participants alluded to the 2018 draft MoH MFL as an approach used to manage data about HFs in the country. The 2018 draft MoH MFL is a Microsoft excel-based file that houses data about HFs (public and private) that has been compiled and managed by MoH in collaboration with its stakeholders. By the time this study was conducted, the MFL was yet to be released for public use. Some of the study respondents view it as the primary source of truth for data on HFs in the healthcare sector. The data attributes captured about a HF in this approach include, HF name, level, type, administrative location, ownership, operating status, contact address, geographic coordinates and services offered.

One of the comment from a study participant:
“The MoH has just compiled a national MFL that contains information on all health facilities in the country. The list has been validated and I look at it as the primary source of accurate and complete data on health facilities in our healthcare sector.” -- Participant 07, Monitoring and evaluation officer

The National Electronic Health Information System: The national eHis is a web-based application based on the open source District Health Information System (DHIS2) which is used to collect, store, and disseminate aggregated healthcare data to support data-driven decision making (4). HF's that are expected to report on the aggregated healthcare data are registered into the eHis. Thus, the eHis was mentioned as an approach used to manage and/or access data about HF's within the healthcare sector by 53% (17/32) of the study participants. The data attributes captured about a HF in the eHis include: HF name, level, ownership and geographic coordinates.

Some of the comments from the study participants:

“All health facilities are expected to report data into the national eHis, we consider the health facility list in the eHis when planning for activities that involve health facilities ...” -- Participant 04, Program officer

“... we often use the facility list we downloaded from the national DHIS2 when seeking for information about any specific health facility. We trust the information in the system because it is managed by the Ministry of Health...” -- Participant 08, Technical officer

The Institutional-based Facility List: The results show that 12% (4/32) of the study participants referenced to their own institutional-based facility lists for data about HF's. Several non-government and faith-based organization exist in Uganda healthcare sector and these support the MoH in strengthening healthcare service delivery especially at HF level. These organizations have established and maintained their own HF lists that they reference to during planning for activities that involve HF's. These institutional-based facility lists are managed using Microsoft office applications and access to them requires authorization from the managing institution. Majority of the institutional-based facility list observed during this study had varying data attributes collected to define a HF.

Some of the comments from the study participants:

“We have our own facility list that we routinely update with data on health facilities based on information we get when we physically visit these health facilities for on-site supervision and training activities.” -- Participant 02, Monitoring and evaluation officer

“... at the district, we have our own health facility list with all health facilities in our district that we manage.” – Participant 10, District biostatistician

The paper-based approach: Some of the study respondents especially the patients in the general public mentioned referencing to data about a given HF that they manually wrote on a piece of paper. The piece of paper was alluded to by 6% (2/32) of the study participants as an approach they use to manage and access data about HF's within the healthcare sector.

To quote a representation of these sentiments:

“I don’t have a system I refer to for information about a health facility. After getting a recommendation from a friend who received a service from a particular facility, I always write down the facility name, address and doctor’s name on a piece of paper which I refer to later before seeking healthcare.” -- Participant 13, Patient

Theme 2: Challenges faced by the identified approaches

Based on the results obtained, each of the identified approach used to manage and/or access data about HF's in the country had notable challenges that were mentioned by the study participants. These included: (i) lack of standardized HF unique identification number, (ii) non-standardized data attributes, (iii) incomplete HF listing, (iv) inaccurate data about HF's, (v) lack of policies and legislation that govern the facility listing, (vi) difficulty in accessing and using data about HF's.

Lack of standardized health facility identification number: 94% (30/32) of the study participants were of the general view that there was no standardized and approved HF unique identification number (UIN) that uniquely identified a HF from the rest within the healthcare sector. The 2018 MoH MFL had two UINs that were assigned to a HF (Table 3). The MoH did not yet approve both UINs by the time this study was conducted. 15% (17/32) of the study participants who mentioned the HF listing in the national eHis were not sure if it had a HF UIN. Although one of the study respondent mentioned that the eHis automatically generated and assigned a 128-bit system based globally unique identification number (GUID) whenever a new HF record is added into the system. The GUID is neither recognized nationally as an approved HF UIN. None of the study participants that mentioned the institutional-based facility list and the paper-based acknowledged that they had a HF UIN.
Some of the comments from the study participants:

“... the National Health Provider Identification (NHPI) code is an 8-digit code that is permanently assigned to a health facility and the code didn’t have any meaning attached to the health facility whilst the Health Service Taxonomy Code (HSDTC) was generated and assigned to a health facility based on its geographic location ... when a health facility location changes, a new HSDTC is generated and reassigned to that health facility.” -- Participant 10, Technical officer

“... the task of generating an d updating the two codes was complex ... and the codes that were assigned to the health facilities were too long to be remembered and used. We cannot use them at the district ...” Participant 14, District Health Officer

“The facility list does not have a unique identification code for the health facilities” -- Participant 02, Monitoring and evaluation officer

“No, I don’t include a unique identifier for a health facility... the health facility name and level is all I need to identify a health facility” -- Participant 13, Patient

Non-standardized HF data attributes: According to the data analyzed each approach had different set of data attributes that were collected to define a HF. The draft 2018 MoH MFL captured the HF name, unique identification number, level, type, ownership, administrative location (national, region, district, health sub district, county, sub county and parish), geographic coordinates, list of services offered, contact address, operational status and date when the data was collected as the HF data attributes. In the paper-based mechanism, patients mainly capture the facility name, physical address, contact of the healthcare doctor whilst the institutional-based facility lists had varying data attributes. The eHIS captured the HF name, level, ownership and geographic coordinates.

Some of the comments from the study participants:

“The MFL has data on health facility UIN, facility name, level, ownership, type, location, geographic coordinates, services offered, contact address, operation status and record date.” -- Participant 07, Monitoring and evaluation officer

“The list contains the facility name, level, ownership, type, administrative location and in-charge contact address” -- Participant 10, District biostatistician

“The national eHIS contains the health facility name, type, level, ownership and geographic coordinates as attributes collected on a health facility...” -- Participant 04, Program officer

Incomplete HF listing: The completeness of the HF listing in the identified approaches varied across the study participants. Some felt that the national eHIS lacked data on majority of the private HFs in the healthcare sector. The institutional-based facility list mostly contained information about HFs that exist in the locality where that particular institution/organization operate leaving out the rest of the HFs. According to some of the study participants, the 2018 draft MoH MFL had complete listing of all HFs (private and public) that existed in the
healthcare sector since the list underwent several validations with different stakeholders. The paper-based approach contained only data about HFs that are of concern to a particular individual/patient.

To quote a representation of these sentiments:

“the eHIS facility listing does not include all health facilities in the health sector; most of the private health facilities are not included since they are not obligated to report through the reporting system” -- Participant 17, Healthcare provider

Inaccurate data about HFs: Respondents reported that some of the attributes captured on a HF in the national eHIS were not accurate whilst those who use the institution-based facility list mentioned that they routinely update the data about HFs based on information they receive from the district health officer and the information they get when they physically visit the HFs during on-site supervision and training activities. The respondents didn’t not mention about the accuracy of data in the individual paper-based approach, however, majority of data about HFs is obtained through recommendations from a friend, workmates or relative.

For example, some of the study participants mentioned:

“...the geographic coordinates in the national eHIS for some of the health facilities are not accurate and we cannot rely on them during visualization of health facilities using the system GIS application” -- Participant 11, Monitoring and evaluation officer

“...after getting a recommendation from a friend...”-- Participant 13, Patient

Lack of policies and legislation that govern the facility listing: Majority of the respondents interviewed were very categorical on the need to establish some form of policy and legislation to guide on the process of managing and maintaining the data on HFs because they were missing.

To quote a representation of these sentiments:

“... district health team should be legally bound to maintain the national health facility list up-to-date with accurate information ...” -- Participant 14, District health officer

“...financing of districts by MoH should be based on the total number of health facilities in a particular district that are accurately maintained in the national health facility list. ...” -- Participant 05, Academic researcher

Difficulty in accessing and using data about HFs: With a few exceptions, the general consensus among the respondents was that accessing data about HFs across the different identified approaches was difficult. To access data about HFs in the eHIS and the institutional-based approaches require authorization and authentication from MoH and the institution managing the facility list and MoH respectively. The 2018 draft MoH MFL was yet to be launched, therefore the data was not yet available for public use at the time this study was conducted.

To quote a representation of these sentiments:

“I lost my cousin because we were in a location that we weren’t familiar with and we couldn’t tell which health facility was nearby with a particular specialization to save life. If the country had a comprehensive health facility list with all details on facility location, facility contact and services offered at a particular health facility that we can freely access, then a life could have been saved.” -- Participant 05, Academic researcher

“...before implementing any activity regarding health facilities in a specific district, we first inquire from the district health team who then share with us their district specific health facility list stored in Microsoft excel ...” -- Participant 09, Monitoring and evaluation officer

Discussion

This study provided an insight into the current approaches used in Uganda to manage and/or access data about HFs and the challenges they are facing from the perspective of the study participants. The key findings revealed that multiple approaches for managing and/or accessing data about HFs existed and they had notable challenges. A country having multiple approaches for managing data about HF is not new in existing literature (12,24); The approaches established by this study included the 2018 draft MoH MFL, the national eHIS, institutional-based facility list and the paper-based mechanism. The national eHealth policy mentions of a need to merge all data from all the existing approaches and establish one national MFL that is centrally managed by MoH and accessed by all stakeholders in Uganda healthcare sector (9). This recommendation is in line with the desired recommendation given by the study participants.

This study also revealed that all the identified approaches had notable challenges. These included, lack of standardized HF unique identification number, non-standardized HF attributes, incomplete HF listing, inaccurate data about HFs, lack of policies and legislation that govern the facility listing, and difficulty in accessing and
using data about HFs. In the next sections of the paper, we discuss the challenges identified with the approaches currently used to manage and/or access data about HFs. We further present the electronic Health Facility Registry (HFR) for managing the MFL as a potential intervention for addressing the challenges observed and improving the efficiency of the HF listing efforts in the country.

All the identified approaches lacked a standardized and approved UIN that uniquely identified a HF in the healthcare sector. This is attributed to the fact that the central governing body (MoH) has not yet established a standard one to uniquely identify HFs within the healthcare sector. This has led to the establishment of an enterprise-wide system of non-standardized identification numbers that are generated and assigned to HFs by different entities. Establishing a common standard UIN for HFs has numerous benefits as observed in literature. These include: improved efficiency in HF identification, management and resource distribution (8,10,25); creates opportunities for HIS interoperability (25); improves healthcare referrals (26–28); and facilitates exchange of data on health facilities (29,30). Nigeria has implemented a HFR and the HF UIN has meaning associated with the current government area and state of location of the HF (25). When a HF moves to a new government area or state, the existing UIN is nullified and a new one is generated. As a result, the HF UN becomes burdensome to use for various stakeholders (doctors, district planners, program officers, among others) when identifying a HF. Our recommendation from the study participants is a HF UIN that is short, clear, precise and not associated its current geographical location.

The data attributes collected on each health facility record were different across the identified approaches. This hinders achieving data exchange and system integration (8,10,25). According to WHO guidelines for establishing a national MFL, a MFL should contain the HF unique identifier, facility name, facility type, ownership, administrative location, geographic coordinates, operational status, facility contact address, data collection, services offered, available human resource and available inpatient and maternity beds as the minimum dataset collected on a HF record (7,8). According to Rose-wood et al., having an accurate and complete MFL within a healthcare sector is fundamental for effective planning, coordination and delivery of health services (12). By the time this study was conducted, none of the identified approaches was nationally recognized to house accurate and complete data about HFs within the healthcare sector. The situation of having multiple HIS in LMICs and none serves as a national repository for accurate, up-to-date and complete listing of health facilities is not new in literature (8,12,31). There is need to establish a national MFL that has accurate, up-to-date, complete, and standardized data about HFs that exist within the healthcare sector.

Existing literature reveals that unavailability of standard policies and legislations to govern access and usage of data about HFs, deficiencies in skilled human resource to manage the data about HFs, and inadequate implementation of the recommended practices for data management are some of the reasons that can be attributed to the discrepancies in data about HFs (25,32). This study has revealed that there were no policies that defined how data about HFs should be established, updated, deleted and archived. To maintain the data about HFs accurate, up-to-date and complete, there is a need to establish and enforce proper legislation aimed at ensuring that data is regularly updated (8,25). Additionally, a data governance framework is needed to manage data issues such as security, sharing and access associated with the MFL (10,12).

Accessibility and availability of data about HFs housed in the MFL is a fundamental factor to improved health service delivery and effective distribution and planning of resources within a healthcare sector (4,33,34). The study finding revealed that majority of the approaches required authorization to access and use the data about HFs. This could have led to the establishment of multiple approaches for managing and/or accessing data about HFs in the sector. WHO recommends that the data about HFs should be easily accessible to all stakeholders at any given period of time to aid data use for data-driven decision making, monitoring of HF distribution and resource allocation, HF identification and patient referrals (8).

To address the challenge of maintaining and managing the MFL with accurate, complete and up-to-date data, a HFR has to be implemented (25,35,36). The HFR can be used to manage and/or access data about HFs in Uganda to aid evidence-based decision making at all strategic levels within the healthcare sector. With the HFR established, other information systems and/or stakeholders can easily access its data. Future research could focus on establishing requirements for establishing a functional HFR in Uganda.

**Conclusion**

Our study has provided evidence on existence of various approaches used for managing and accessing data on health facilities in Uganda. The study has also revealed some important challenges that hinder effective use of these approaches including lack of a health facility unique identification number, management of data on health facilities, health information exchange and interoperability because each mechanism had different data elements captured, and data access and use to aid evidence-based decision making. As such, we suggest that in order to improve the task of managing and maintaining data on health facilities accurate, complete and up-to-date, there is need to establish a national HFR as it was alluded to by the national eHealth policy (9). The government of Uganda
through its line Ministry of Health should improve on its in-house coordination and governance including establishment and implementation of policies that should focus on eliminating duplicated approaches established by various health institutions and promote the establishment of a central HFR that can be accessed and used by all stakeholders in the healthcare system.

Acknowledgment
The authors would like to thank the respondents who generously extended their time for the interview and openly shared their opinions on the subject under study. Without them it would have been impossible to accomplish this work. In addition, we acknowledge the moral support from Makerere University School of Public Health and Monitoring and Evaluation Technical Support (METS) Project and the financial support from the HI-TRAIN program, a Norwegian funded project for higher education in Uganda for conducting this research.

Statement on conflicts of interest
There is no conflict of interest that the authors need to declare.

Abstract
We studied the medication reconciliation (MedRec) task through analysis of computer logs and ethnographic data. Time spent by healthcare providers performing MedRec was compared between two different EHR systems used at four different regional perioperative settings. Only one of the EHRs used at two settings generated computer logs that supported automatic discovery of the MedRec task. At those two settings, 53 providers generated 383 MedRec instances. Findings from the computer logs were validated with ethnographic data, leading to the identification and removal of 47 outliers. Without outliers, one of the settings had slightly smaller mean (SD) time in seconds 67.3 (40.2) compared with the other, 92.1 (25). The difference in time metrics was statistically significant (p<.001). Reusability of an existing task-based analytic method allowed for rapid study of EHR-based workflow and task.

Introduction
Medication errors are a leading cause of patient harm. In over half of the patients, discrepancies were found between the medication patients were taking at home and the list of medications known to the hospital caregivers after intake.(1–3) Many of these errors result from an incomplete overview of medication either at a patient’s referral to or at discharge from the hospital. Medication Reconciliation (MedRec) is the process of creating the most accurate and complete list of medications a patient is taking—including drug name, dosage, frequency, and route—and comparing that list against the physician’s admission, transfer, and/or discharge orders, with the goal of providing correct medications to the patient at all transition points within the hospital.(4)

MedRec plays an important role in reducing adverse drug events (ADEs). A common approach to estimate the impact and effectiveness of MedRec on ADEs has been to use database entries and EHR data, which were then evaluated independently by experienced physicians.(5,6) Several studies used observational data to assess the processes required to carry out MedRec and estimate severity of ADE’s in-order to develop ADE prevention strategies and ascertain those related to medication errors.(7,8) Interviews have also been used to assess providers’ perspectives on the use of technology for MedRec to improve ambulatory medication safety and identify barriers of the implementation process.(9,10)

Medication safety could be affected by the amount of time a professional spends on MedRec. Tamblyn et. al developed a prototype e-medical reconciliation software in the surgical wards to measure the time spent on MedRec when discharging patients per professional.(11) The
overall Mean (SD) time in minutes during each of the RightRx session was 5.8 (7.8) for physicians and 10.9 (10.9) for pharmacists. Meguerditchian et. al used a time-and-motion study to observe and time health professionals in three hospital units: geriatrics, medicine and surgery.(12) Only one major task, preparing the discharge prescription, was selected for timing during MedRec at discharge. The results showed that the difference in time spent on MedRec varied greatly between units, ranging from an average of 10 minutes (general surgery) to 92 minutes (geriatrics).

Mayo Clinic has undergone an enterprise-wide, large-scale EHR conversion. Before the conversion, the ROOT (Registry Of Operations and Tasks) project was launched in 2016 to document and harmonize EHR-mediated workflows and Health Information Technologies (HIT) interactions. ROOT focusses on understanding variations across different systems and sites by using broad range of methods including video ethnography, computer logs analysis and interviews.

ROOT’s approach consists on triangulating ethnographic methods and automatic analysis (mining) of computer logs to understand different dimensions of EHR-mediated workflows.(13–16) This novel method was used to analyze and compare time metrics for the vital signs charting task before conversion to the new EHR. Vital signs charting was documented with two different EHRs used at four different preoperative (PreOp) regional clinic settings at the Mayo Clinic: Arizona (Phoenix, AZ), Jacksonville (Jacksonville, FL), Methodist and Saint Marys (Rochester, MN). Time metrics for vital sign charting were automatically quantified using computer log analysis. Outcomes were validated with ethnographic data and outliers could be identified, explained and removed. Without outliers, similar mean (SD) times in minutes (1.3 (1.1), 1.2 (1.3) and 1.2 (1.2)) were found between sites when performing vital sign charting.(17)

Here, we reused the same methodological approach applied to the study of vital sign charting to the analysis of a different task, MedRec. This study also occurred at the same settings where the vital sign charting task was studied.

**Objective**

The aim of this work is to demonstrate rapid reusability of an existing task-based analytic method for the comparison of the EHR-mediated MedRec task between two different EHR systems used at four different regional perioperative settings.

**Methods**

1. **Clinical Settings**

   This study took place before the enterprise wide conversion to the new EHR. This research involved the following Mayo Clinic settings: Arizona (Phoenix, AZ), Florida (Jacksonville, FL), Methodist and Saint Marys (Rochester, MN). Both Arizona and Florida settings used EHR system 1 (SurgiNet). While both settings at Rochester used EHR system 2 (MICS LastWord) for MedRec.

2. **Data Collection**

   Three investigators collected observational data at the settings across the entire surgical setting (PreOp, IntraOp, PostOp). Data collection and curation was based on the clinical workflow capture and analysis methodology adopted as a standard approach in the Applied Clinical Informatics program at Mayo Clinic.(18)

   As a method of data collection, ethnography entails examining the behavior of the participants in a certain specific social situation and also understanding their interpretation of such behavior.(19) Ethnographic techniques used for this research included interviewing, shadowing, video ethnography, artifact collection, and contextual inquiry. Leadership and key provider
activity interviews were recorded and transcribed. Activity interviews were used to characterize “walk throughs” of key workflows. Shadowing was captured using handheld audio recorders and artifacts were captured using a digital camera. Video ethnography involved capturing HIT interactions with a handheld video camera and with the Morae™ software. Via the use of a webcam, Morae™ was also able to video record participants’ hands, desk space and paper-based artifacts that were used during interactions with the EHR. Morae™ was also used to record audio of participants verbalizing their thoughts and conversations in the immediate vicinity.

One computer scientist specialized in workflow analysis and a computer science graduate student collected the computer logs generated by the EHR at the settings during the same days when the ethnographic study took place. A computer log is a file that records events taking place for a clinical activity during execution of a particular process instance. Computer logs include information about what activity is being performed by whom, when and for which patients. Computer logs in a healthcare setting can be used to discover and study clinical workflows.

3. Data Analysis

Ethnographic videos were analyzed to quantify the duration of the MedRec task and to provide insights on the task.

Programs in Java version 8 were written to automatically detect MedRec activities from computer logs generated by the EHR systems. The discovered computer logs corresponding to MedRec tasks were then imported to Disco™, a licensed tool, for automatic time metric analysis. Descriptive statistics (means and SD) and a time-based histogram, where the bins represent ranges of time duration, were computed in order to identify and eliminate MedRec outliers. Outcomes were validated through triangulation with ethnographic data. A t-test analysis was performed to assess differences in time metrics between sites, with alpha level of 0.5.

Results

1. Data Collection

For all the perioperative sites, a total of 4,400 minutes of video recordings were captured for 99 providers during 16 days. For EHR system 1: at Arizona, 76,000 event logs for 15 providers for a 5–day period were collected; at Florida, 116,706 event logs for 31 providers for a 4–day period were collected. For EHR system 2: across the two Rochester sites, 81,886 event logs for 53 providers for a 7-day period were collected.

2. Data Analysis

2.a. Analysis of video recordings of EHR interactions

Figure 1 presents a schematic representation of the interface used for MedRec at Arizona and Florida. First, the provider navigates to the “Order-Charges” section located on the left side of the interface and clicks on a button labeled as “Document Medication by Hx”. The next screen displays the current medication list and at the bottom a compliance section serves to add the last doses taken. There is no saving option to store changes made.

Figure 2 presents a schematic representation of the interface used for MedRec at Rochester. The process for MedRec involves three steps. First, in the “Outpatient Order-Medication List” page the provider opens a command window and enters a shorthand code “medlist” which directs her to the medications home page. Then the provider selects the “Message” button from the medications home page which takes her to the “Order view” page. There the
provider can leave a message about a medication, reconcile the last dose taken and remove changes to doses. Performing the task of entering medication compliance involves the provider accessing the “Order view” page. The “Add Dose Last Taken” button is clicked which opens the “Dose Last Taken” window for adding the date and time. The “Continue” button is clicked to populate the compliance section with the new date and time. This works as a saving function.

Figure 1: Schematic representations of the MedRec interfaces from EHR system 1 used at Florida and Arizona: A) “Document Medication by Hx” button can be clicked in the “Order-Charges” section, B) the last dose taken of a medication can be added through the “Compliance” section.

Figure 2: Schematic representations of the MedRec interfaces from EHR system 2 used at Rochester: A) the “Message” button can be clicked in the “Outpatient Order - Medication List” page, B) the buttons “Adm/Outpt Verify Message”, “Add Dose Last Taken” and “Clear Dose Last Taken” can be clicked to leave a message about a medication, reconcile the last dose taken or remove changes to doses, C) when the “Add Dose Last Taken” button is clicked it opens the “Dose Last Taken” window for adding the date and time; changes are saved by clicking “Continue”.

2.b. Analysis of computer logs that capture EHR interactions
We manually compared seven video recordings of MedRec tasks performed using the EHR with the corresponding computer logs. This process was used to facilitate the interpretation of the computer logs.

We learned that the computer logs did not have the granularity needed to automatically differentiate between MedRec and other medication-related tasks. We previously discussed how MedRec charting was performed in Arizona and Florida by the providers by accessing the “Order” section. As the Morae™ videos revealed, MedRec was not the only task that could be performed in the “Order” section. Other tasks, like deactivate orders, create a medication list and document medications could be also activated following a similar procedure. Unfortunately, the computer logs did not provide detailed information to differentiate between all those possible tasks and automatically detect time metrics related to the MedRec task.

Table 1 is an example of the sequences of computer logs that represent tasks completed by a provider, Provider1, for a patient, Patient1, at Arizona. The first row shows that Provider1 accessed the “Order” section at 05/04/2016 12:11:23 PM to perform MedRec charting for Patient1, as denoted by Subtimer= ORDERS/PVORDER. At 05/04/2016 12:11:25, Provider1 accessed the “Order” section again, as denoted by Subtimer= ORDERS/PVORDER. While the event logs do not provide information on the specific tasks that were performed, the videos revealed that in the first case Provider1 was performing a MedRec task, while in the second case Provider1 was deactivating orders.

While we provide here one example, we analyzed with the help of video recordings 11 (13.1%) out of the 84 computer log cases available. It was found that it was not possible to automatically differentiate with event logs alone when providers were performing MedRec tasks.

With the help of five video recordings we could determine that computer logs from Rochester contained information to automatically detect MedRec tasks. Table 2 is an example of the sequence of computer logs recorded when Provider2 completed MedRec tasks for Patient2. The first row indicates that Provider2 accessed the screen “RXLIST” at 12/05/2016 02:51:23 PM to perform MedRec for Patient2. The task was completed at 12/05/2016 02:56:45 PM when value of the module column changed from “OCX” to “FLW”. While we can quantify how much time the provider spent during the MedRec task, event logs are not detailed enough to quantify how many medications or to describe the type of medications that were reconciled.

For computer log analysis, 53 perioperative providers at the two Rochester were analyzed. The providers included registered nurses (RN), health unit coordinators (HUC) and certified registered nurse anesthetists (CRNA). A written computer program automatically discovered 383 instances of the MedRec tasks from the collected computer logs. Table 3 summarizes the time metrics calculated by Disco™ from the discovered MedRec instances.

The discovery of MedRec tasks for both Rochester sites through process mining revealed the presence of MedRec instances significantly longer than the mean duration. To automatically remove outliers, we considered all the 383 instances of MedRec tasks and found the Median + 2 standard deviations = 89.25 + 206.2 was approximately equal to 295 seconds.

We use the performance filter of Disco to automatically filter out MedRec tasks that took more than 295 seconds. To further validate the method used to detect outliers, a time-based histogram was created using all the MedRec instances (Figure 3). It was found that 89% of instances had a duration of 300 seconds or less. Time metrics after removing the outliers are also presented in Table 3. Statistically significant differences (p<.001) were founded in MedRec time metrics between sites.

Figure 3: Histogram showing frequency of MedRec tasks at two Rochester sites

3. Data Validation
To validate the findings from the analysis of Rochester computer logs (Table 3), first we considered five MedRec instances for which we had both ethnographic videos and computer logs. When we compared their time metrics, we found full agreement.

Second, we used interview data to identify provider’s involvement in the process of MedRec. In Rochester, the RN and HUC roles preformed MedRec while PCA, CRNA roles were not usually in charge of MedRec. Those findings were consistent with the finding from the application of process mining methods, as depicted in Table 3.

Third, we used ethnographic videos and observation outcomes to understand the reasons for the outliers that were automatically discovered and removed. We found in the video’s explanations for the discovered outliers, including:
   a. Interruptions: the provider interacts with the patient, providers, takes phone calls, etc. during MedRec charting.
   b. Use of paper artifacts: the provider writes down certain information regarding the patient.
   c. Multi-tasking: the provider accesses other applications, like medication administration, vital signs charting, etc.

Discussion
A generalizable and reusable mixed method approach was applied to the study of two different EHR-mediated tasks. The proposed analytic approach supports automatic calculation of time metrics from computer logs and removal of outliers using time-based histograms. The method developed for the analysis of the vital sign task was easily reused for the analysis of the MedRec task. Reusability required changing the program so it would automatically identify the computer log signals specific to the beginning and the end of the MedRec task. The rest of the computer-based analytic methods were fully reusable. This led to a significant reduction in the time spent analyzing data, from approximately two months to two weeks.

The method includes validation of findings using ethnographic data and proposes potential explanations for detected outliers. Through data triangulation, this methodology helps to increase the confidence on results and improve the interpretation of the resulting outcomes.

Important lessons were learned from reusing the same mixed-method approach to the study two different clinical tasks. First, the types of research questions that can be answered with automatic methods depend on the quantity and quality of the computer logs used. As it was shown in the case of the prior EHR system used at Arizona and Florida, the EHR did not encode in the event logs the information needed to automatically quantify the start and end of the MedRec task. In contrast, the EHR used at Rochester recorded event logs that could be used to accurately
determine the duration of the MedRec task. However, the event logs collected at Rochester lacked the level of detail needed to identify number and type of medications reconciled in each MedRec session. These findings could be used to guide future decisions on the level of granularity and the type of information encoded in the event logs generated by the new EHR.

Second, there is no standard definition of what constitutes a MedRec task. In its simplest form, MedRec encompasses the creation of a complete and accurate patient medication list, and the comparison of that gold standard list to other available sources. (4) In contrast, the MedRec task could be considered to include the revision of patient’s demographic information, assessment of patient’s medication knowledge, external research on the medication history (e.g. asking the patient’s caregiver), and recommendations for in-hospital prescriptions.(12) These differences in interpretation of what the MedRec task encompasses make it challenging to compare and contrast time outcomes from this study with previous findings.

Mixed method approaches as the one we used here can be time and resource intensive. It requires access to health care environments to support in-situ collection of ethnographic data and collaboration of an interdisciplinary research team with expertise in both computational and ethnographic methods to analyze, triangulate and validate collected data. On the other hand, mixed methods can help build on the strengths of video ethnographic and temporal data mining techniques by integrating the two to overcome the biases inherent in either type of method alone. In the case of ethnography, how generalizable are the findings drawn from small samples? For temporal data mining analysis, how accurate are the discoveries drawn from automatic analysis of big data, when compared with observable data?

An interesting future direction of research will be incorporating into the analysis findings from an automated review of a patient’s EHRs. Similar to computer logs, EHR patient data is already collected by health care facilities. Compared with ethnographic data, the access to EHR data tends to be less resource intensive and intrusive, and more scalable. By accessing a patient’s EHR some of the limitations of the event log analysis could be overcome. For example, in the case of MedRec, EHR data could be used to identify the number of and type of medications that were reconciled for each patient prior to surgery. For another future direction, there are ongoing plans to reuse the task-based mixed method analytic approach explained here, to compare time metrics for key EHR-mediated task’s between pre and post EHR conversion with the goal of informing clinical optimization initiatives at the Mayo Clinic.

Conclusions
This paper demonstrated the rapid reusability of a mixed method analytic approach that combines the use of computer logs and ethnographic data for the study of EHR-based tasks.
These findings offer promising new directions of research. As future work, we plan to further test the applicability of the proposed method to the comparative study of other clinical tasks before and after Mayo Clinic’s conversion to a new EHR. Outcomes of that analysis will be used to inform optimization efforts.

Acknowledgments
Mayo Clinic (BMS0148), for the financial support provided to Arizona State University and Mayo Clinic authors. We also thank the clinicians for allowing us to observe and record their activity. We would also appreciate the help received from Dr. Matthew Burton, Sarah Hirn, Robert Sunday, Sheryl Castaneda and Joanne Bouchereau with ethnographic data collection.

Abstract

Human-centered design (HCD) can be used to communicate research study findings to designers of health information technologies (HIT). We used the HCD approach to develop personas, scenarios, and design guidelines for designers with the aim that it would lead to new HIT designs that support the autonomy and health of older adults. The foundation of the personas, scenarios, and design guidelines was a study that focused on understanding how older adults manage their health information and the role that stakeholders play in that process. In this paper, we describe how we carried out a HCD approach and how it led us to expand the persona process to create a network of connected personas. The connected personas allowed us to show the complexities of personal health information management for older adults and emphasize the importance of relationships with family, friends, and providers.

Introduction

Personal health information management (PHIM) is a process that includes creating, seeking, organizing, and sharing health information⁵. PHIM for older adults often also includes activities that are supported by family and friends⁶. Health information technologies (HIT), such as patient portals and fitness trackers, have been designed to help people manage their health and health information. However, use and adoption of health technologies by older adults has been slow in comparison to the use of general technologies like email and the Internet⁷,⁸. Human-centered design (HCD) and its methods have been embraced within the field of health informatics and used to develop technologies for patients⁹,¹⁰,¹¹. However, there has been less work addressing the implementation of this approach, especially in regard to translating research study findings into artifacts for designers to use when designing HIT. In this paper, we will describe how we used an HCD approach to develop personas, scenarios, and design guidelines for designers creating HIT for older adults.

Background

HCD, also referred to as user-centered design, is an iterative approach that places impacted people at the center of the design process to ensure that the design and development of a product that is usable, meets people’s needs and goals, and addresses people’s challenges or pain points⁶. In health informatics, HCD has been advocated as an approach that can manage the complexity of health activities, such as the often invisible work of PHIM performed by older adults and their family members and friends¹⁰,¹¹. HCD methods have been used to develop and evaluate health technologies for managing diabetes¹, tracking health indicators¹, and managing personal health records¹².

A crucial goal of an HCD approach is gaining an understanding of people who are impacted by the designs, including end users and other stakeholders. Although this process is generally nonlinear, learning about the people involved—including their context, needs, and goals—is typically placed at the beginning of the process so that this knowledge can play a role in the design ideas and solutions⁶. There are a variety of artifacts that can result from HCD methods. For our project we chose to create personas, scenarios and design guidelines. Personas represent different people and their needs, and provide a sense of their behaviors, attitudes, needs, and goals in specific contexts¹³,¹⁴,¹⁵. Personas are developed from user research, using methods such as interviews, observations, and surveys¹³.

Personas aim to create a common language for designers, to encourage empathy for stakeholders, and to help designers understand stakeholder goals¹³,¹⁴. Personas include elements such as the name of the individual they are describing, a photo of the individual, demographic information, personal goals, pain points (e.g., challenges), and a description of the individual’s use and comfort with technology. Personas often include a scenario or narrative, that illustrates the context surrounding the individual and features their goals, challenges, and experiences with a technology⁴.
Personas have been used and studied in a variety of contexts. In the field of health informatics, personas have been used to raise awareness of a particular population\(^4\) and to translate study findings to inform the design process of health information systems\(^6\). Studies seeking to understand how designers use personas in practice found that personas were often used in the initial stages of the design process as a communication tool within a team, to introduce new team members to their stakeholder groups and to help the team avoid making assumptions about their stakeholders\(^{17,18}\). Personas have also been used to communicate with broader stakeholders, like others within the organization but outside of the project team, about the people using a system\(^{16,19,20}\).

Although the persona method is popular, it has not been without criticism. Some of the main critiques have been that it is difficult to trace persona details to specific data and validate personas using scientific methods\(^{16,21,22}\). In addition, some have argued that the persona method is limited in addressing the complexity of managing health and health information\(^23\). Our study addresses these limitations with a modification of the persona method to accommodate the complexity of PHIM in the context of older adults. As described in this paper, we used findings from an extended study of older adults and their supportive networks to develop an expanded and connected set of personas, demonstrating the web of supportive relationships surrounding a central person’s PHIM processes. This set of connected personas provides a fuller picture of the older adult’s needs and experiences, providing information about the role that family, friends, and providers play in that process. Its overall aim is to improve HIT for older adults to support their health and autonomy. To address these goals, the SOARING study design was based on the Balance Model, an ecological model which takes into consideration the role of social, organizational, technological influences in carrying out specific activities, in this case older adult PHIM\(^24\). As a part of SOARING, we conducted a qualitative study to investigate the health information management practices and needs of adults 60 years and older who lived in a variety of living situations (i.e., independent living, retirement communities, and assisted living). We conducted in-depth interviews with 88 older adults, 52 of their family and friends, and 27 health care providers\(^{25,26}\). Results from this research served as the foundation for the development of the personas, scenarios, and design guidelines.

Methods

This work is a part of a larger project called SOARING (Studying Older Adults & Researching Information Needs and Goals)\(^27\). It is a 5-year project at the University of Washington, funded by the Agency for Healthcare Research and Quality (AHRQ). SOARING seeks to deepen understanding of how older adults manage their health information and the role that family, friends, and providers play in that process. Its overall aim is to improve HIT for older adults to support their health and autonomy. To address these goals, the SOARING study design was based on the Balance Model, an ecological model which takes into consideration the role of social, organizational, technological influences in carrying out specific activities, in this case older adult PHIM\(^24\). As a part of SOARING, we conducted a qualitative study to investigate the health information management practices and needs of adults 60 years and older who lived in a variety of living situations (i.e., independent living, retirement communities, and assisted living). We conducted in-depth interviews with 88 older adults, 52 of their family and friends, and 27 health care providers\(^{25,26}\). Results from this research served as the foundation for the development of the personas, scenarios, and design guidelines.

The persona, scenario, and design guideline development effort was led by a small group of researchers from the SOARING team. We implemented a HCD approach to create these design resources. We refined the personas, scenarios and design guidelines through an iterative process with older adults and designers, as well as through feedback from subject matter experts. Subject matter experts included members of our SOARING team who have expertise in geriatrics, health informatics, nursing, medicine, biostatistics, and human-computer interaction. Figure 1 provides an overview of our HCD approach.

HCD 1.1 Persona Process

We used SOARING study data from the interviews conducted with older adults, family and friends, and providers to draft each set (i.e., older adults, family and friends, providers) of personas. Once we drafted each set of personas (i.e., older adults, family and friends, providers) we sought feedback from our subject matter experts on the accuracy and completeness of the content and the design of the persona. After each feedback session, we incorporated the feedback in an iterative fashion into modifications of the personas. We held at least five feedback cycles for each set of personas - this included in-person meetings with the individual team members and a group of subject matter experts, as well as individual reviews where the personas were sent to the subject matter experts who provided in-document comments. As a result, we created six sets of connected personas.
**Figure 1.** Overview of our human centered design approach

**HCD 1.2 Design Guideline Process**

The aim of the design guidelines was to provide a list of design considerations that would apply specifically to health information technology for older adults and complement the connected personas. To develop the guidelines we drew from the diverse perspectives of HCD designers, older adults, and subject matter experts. We first invited undergraduate and graduate students from the Human Centered Design and Engineering (HCDE) department at the University of Washington to participate in an applied class of developing the design guidelines. We introduced the students to the SOARING project and its findings, as well as to the connected personas. Throughout the quarter, we asked students to brainstorm a list of preliminary design requirements using the personas and through sketching design ideas of health information technologies. Based on this work, students helped to prepare video scenarios of the design requirements to show to older adults in focus groups (Figure 2).

**Figure 2.** Video Scenario. This set of slides illustrates the video scenario of two design requirements that allows older adults with the opportunity to choose who they share their health information with.

We next conducted three focus groups with older adults living in senior living communities and facilities to gain their feedback on the preliminary design requirements. Prior to the start of the session, participants completed a demographic questionnaire. Each session was facilitated by a SOARING researcher and observed by a student or a member of the SOARING team. Three students observed the first focus group, a SOARING researcher observed the second focus group, and one student observed the third focus group. All focus group sessions were recorded. Participants received a handout for each video scenario so they could follow along and take notes. Scenarios were used as discussion prompts to discuss and obtain feedback on preliminary design requirements. After each video,
participants were asked whether the scenario resonated with their experience and their perspectives on concepts such as sharing and privacy.

At study completion, the field notes were coded by a two researchers (DST, MX) using thematic analysis. We used the videos to support our analysis and to verify the themes. We shared the design guidelines draft with the subject matter experts, and modified them based on their feedback. We had at least four feedback cycles.

**HCD 1.3 Study with designers**

We conducted a two-part study with designers to understand their perceptions of the connected personas in comparison to individual personas. We also wanted to understand how designers would use the connected personas in their design process. We conducted two sessions with designers. In the first session, designers worked in groups of 3-5 people and were asked to brainstorm ideas for a design challenge. The design challenge asked designers to design for this question: “How might we help older adults balance receiving support in managing their information related to their health and maintaining independence?”

To compare the designers’ experience between an individual persona and connected personas we used a three phased approach where the groups worked first with just the older adult persona and then were given the connected personas. The designers were then given all six sets of personas consisting of the primary older adult personas and their connected personas. The designers from the first session were invited to the second session. In the second session, designers worked in groups to prototype ideas for the same design challenge from the first session. In addition to the family of connected personas, the designers were provided with the design guidelines to inform their ideas.

All of the sessions were video- and audio-recorded. We also observed the groups and took notes. The groups reported their experiences throughout the design session through feedback forms with open-ended questions. The designers also produced sketches of their ideas and prototypes. Each designer completed an exit survey at the end of every session.

After the sessions, four researchers (DST, KK, AT, YW) conducted a thematic analysis by reviewing the first session video recording. As a group, we reviewed the emerging themes and identified themes code in the rest of the video data. Each researcher reviewed a set of video recordings coded for the themes and transcribed those parts of the video. Then, three researchers used affinity diagramming to organize the themes. One researcher (DST) triangulated the themes with the data from the group discussion feedback forms and individual exit surveys, while being open to additional themes that emerged.

**Results**

The HCD methods we used guided us through an iterative process that was based on study data, informed by feedback from subject matter experts, evaluated by older adults and designers, and supported by academic literature and published information from organizations. This process provided the space for discussions about the complexity of older adults’ PHIM and led to influential decisions about the personas and design guidelines. We discuss below some of the decisions and evaluations that occurred through using a HCD approach, including the emergence of connected personas, outcomes from focus groups that evaluated the design guidelines, and designers’ experiences with both the personas and design guidelines.

**HCD 1.1 Drafting personas and emergence of connected personas**

We started by following the typical persona development process. Our goal was to develop a set of “stand-alone” personas that represented the different experiences of older adults and their family members, friends, and providers. We segmented the older adult personas based upon their living situation because we learned that it had a significant impact on the ways that older adults practiced PHIM. For example, older adults who live in an assisted living facility manage their personal health information differently than older adults who live in a private residence. Older adults who live in an assisted living facility may rely on a variety of staff to gather and store their health information documents (e.g., after-visit summaries), while older adults who live in private residences may keep and file their documents on their own. Other parameters that distinguish the older adult personas from each other included health conditions, their organizational style, and the people in their lives that support their PHIM.

For our first feedback session of the family and friends personas with subject matter experts, the family and friends personas were each drafted as individual personas. Since they were stand-alone personas, the format was similar to the older adult personas. However, as the subject matter experts reviewed these personas and reflected on their
knowledge of older adults and related PHIM research, conversations emerged acknowledging that although the personas were representative of individuals, they did not illustrate the connective nature of the network of people who support the older adults in PHIM. We had gained a deep appreciation of this important aspect of older adult PHIM through embedding the SOARING interviews with family and friends into the ecological framework of The Balance Model\(^4\). This model led us to take an integrated approach to consider older adults’ tasks, tools/technologies, social/organization systems, and the physical environment. Family, friends, and providers played a significant role in the ways that older adults organized, managed and shared their personal health information. Representing the older adults and friends and family in a traditional stand-alone fashion could not adequately capture the rich interconnected nature of these relationships, and the design needs that arose from these connections. As a result, we decided to break from the typical persona method of individual persona groups, and to instead create connected personas.

In order to effectively describe the supportive role of connected personas, we changed the persona layout. The connected persona became one page, with the content focusing on the ways in which each stakeholder supported the PHIM of the older adult they were connected to. Each set of personas features an older adult in a different living situation (i.e., independent residence, retirement community, assisted living, etc.) and connected personas of family and friends and/or providers. Each persona within a set contains a scenario. The older adult scenario describes their current situation in terms of their health, their relationships with the people they are connected to, and with health information technologies, specifically patient portals. Similarly, the scenarios for connected personas (family and friends, and providers) illustrate a viewpoint on their relationship with the older adult and the ways they want to, or do, support the older adult. It also illustrates the goals and challenges they face related to their role in the older adult’s PHIM.

The final result of HCD 1.1 was six sets of personas, with each set featuring an older adult persona as the primary persona and connected personas of family and friends as well as providers who play a role in the older adult’s PHIM (See Figure 3).
The design guidelines were informed by the SOARING interviews, by the personas, and by feedback from older adults and subject matter experts. Below we present themes from the focus groups and feedback from subject matter experts that influenced and shaped the design guidelines. The guidelines encourage designers to consider PHIM-related needs (i.e. issues that might arise as an older adult is managing health information) and user experience needs (i.e. considerations for the use of the health information technology itself). For example, a PHIM-related guideline for family members of an older adult is, Escalate support: Specifically consider tools that will allow older adults to plan for situations in which they may need extra help or full support from family and friends to manage their health and health information. An example of a user experience need is, Design for diversity: Consider approaches like inclusive design to reach people across a wide range situations and with differing abilities. All of the design guidelines were based upon the SOARING findings, academic literature and national organization websites.

To investigate whether our design guidelines resonated with older adults and explore additional design considerations, we conducted three focus groups with older adult participants. In total, 21 older adults participated in the focus groups. The average age among participants was 79 years old. Most participants were female (76%) and a majority identified as white (95%), with a college degree or higher (71%). Most older adult participants reported using a computer on a daily basis (71%) and about half (52%) described their computer experience as being at an intermediate level, meaning between some experience and very experienced. In addition, about half (52%) of participants said that they were using patient portals.

Several themes emerged from these focus groups: keep it simple, support autonomy, balance between maintaining privacy and ease of use, and recognize the diversity among older adults in their use of, and attitudes toward, information technologies. These are described in more depth in the following paragraphs.

Some participants said that they expect that it should be easy to find information and complete tasks using health information technologies. One participant plainly stated, “keep it simple”. This theme also included the ability to understand information, and the suggestion that technologies should avoid using jargon and unfamiliar medical terms. During our sessions, we showed a video that demonstrated features like adjusting size of the text by using icons and buttons. Some participants noted that they were unfamiliar with some of the icons and with some of the terms.

“When I go to my patient portal, it is very simple. That’s what I want. I don’t have to hit all these buttons.” (Participant A, Focus group 2)

“The buttons should be labeled.” (Participant B, Focus group 2)

Another theme expressed was that technology should support autonomy. Several participants resonated with the scenario which described family members requesting access to the older adult’s health information. However, they also expressed that older adults should be able to choose who can have access to their health information. One participant acknowledged the challenge between maintaining autonomy and being safe.
“It’s difficult to maintain autonomy and control privacy and get the help you need. Some people are more willing to give that up than others.” (Participant, Focus group 1)

A third theme centered on the balance between maintaining privacy and ease of use. Ease of use arose as an issue in discussions about logging into a system. Participants expressed their frustrations with remembering passwords. Some participants offered ideas for password solutions, such as using a fingerprint, facial recognition, and voice assistant. However, the importance of privacy also came up in these discussions.

“I object to the idea of using the SSN (social security number), I’m not convinced that it’s safe.” (Participant, Focus group 3)

Although our primary discussions in the focus groups were about the guidelines for HIT, some participants voiced the need to recognize the diversity among older adults in their use of, and attitudes toward, information technologies. Four participants from two focus groups expressed a concern about technology taking away existing services or making those services difficult to use.

“My big concern is that I know a lot of people are like me. They don’t want to use a computer. They don’t want to use a smartphone. They just want to talk to someone. What do we do with those people who cannot get a hold of anybody? There has to be a way.” (Participant, Focus group 2)

In addition to guidelines generated from our own studies, where appropriate we incorporated existing guidelines and best practices for designing for this population and supporting the design of health information technologies. Resources used in the guideline development process include information from published reports, and organization websites like the Pew Research Center, Bureau of Labor Statistics Occupational Outlook Handbook, Center for Disease Control and Prevention (CDC), Alzheimer’s Association, Web Accessibility Initiative guidelines and plainlanguage.gov. We were thus able to address the diversity and range of technology experience among older adults and the importance of involving older adults in the design process. We also used academic literature for creation of the development of the design guidelines. The final result of HCD 1.2 was a set of 37 design guidelines.

HCD 1.3 Assessment: Designers’ experiences with the personas and design guidelines

Our final stage was to provide both the connected personas and design guidelines to a group of designers. There were several themes that came from our two-session study with designers about their experiences with the connected personas and design guidelines. One of the themes was that the connected personas provided designers with a holistic perspective of the older adult and of the problem space. Another was that designers refined their designs to include family, friends, and providers. Although the connected personas were positively received, there were also room for improvement. For example, designers were overwhelmed by the amount of information they had to digest and organize across the six sets of connected personas.

A total of 16 designers participated in the study. In general, the connected personas were well received by designers. A primary benefit of the connected personas expressed by designers was that it provided them with a broader perspective on the older adults’ situation and problem space. It also cultivated empathy for the older adult. They suggested that providing an overview summary of each set of personas with key information, or a video summary about each persona set, would be helpful. They also expressed that the design guidelines were useful and helped them to prioritize their design ideas.

Discussion

This paper outlines our use of a HCD approach to translate and synthesize study findings into design materials in the context of designing HIT for older adult PHIM. We described our development and evaluation of connected personas and design guidelines for designers. Our approach involved close collaboration with SOARING researchers, feedback from subject matter experts, and insights from both older adults and designers. This work supports prior research in health informatics that has translated study data into personas. It also acknowledges the limitations of traditional personas to convey the complexity of health information by challenging the persona method to accommodate the complexity of PHIM for older adults. This work builds on prior work the expands the persona method to accurately describe user groups, their needs and behaviors. Connected personas incorporate the insights we have gained from
taking a holistic approach to investigating older adult PHIM through application of the Balance Model, which considers the individual in the context of their tasks, tools and technologies, environment and organizational structures. Through utilizing this holistic framework, we observed crucial PHIM needs within the connections between older adults and their family, friends, and providers that would not easily be communicated with stand-alone personas. Our personas needed to reflect this complexity because it was essential to the practice of PHIM for older adults. If we had developed traditional personas of individual older adults, we would lose valuable information that only rises out of the relationships between older adults and their social networks.

In using a HCD approach, we found it to be flexible and robust, allowing us to help designers navigate and appreciate the complexities of older adult PHIM. HCD methods have been advocated in health informatics as a way to design and evaluate health information systems that are informed by users, as well as their needs and behaviors. Using a HCD approach provides researchers with a method to translate and communicate complex processes that are critical to the work people do and are necessary for HIT design.

We found that designers appreciated the connected personas and found them to be useful to their design process. We also learned that the connected personas led designers to broaden their perspectives on the users of HIT beyond older adults, to include considerations for the older adults’ family, friends and providers. This finding indicates that the connected personas were successful in communicating the complexity of older adults’ PHIM. Overall, this study demonstrated that using connected personas has the potential to stretch the boundaries of the typical persona method to more accurately represent users and their context. This method may be useful on other complex areas of healthcare in which a variety of roles influence activities, such as care management for children with disabilities and patients undergoing cancer treatment.

Limitations
Our personas and design guidelines are meant to provide information about older adult PHIM that should be considered in the design process of HIT. We did not focus on a particular HIT or explore other activities beyond PHIM. Our results may not be generalizable to other technologies, activities or contexts. We created our connected personas and design guidelines independently from a team of designers. Prior studies have found that designers who are not involved in the development of personas may not use them to make design decisions. Research into the use of these personas in actual practice is needed.

Conclusion
In this paper, we described how using a HCD approach lead to the development of connected personas and design guidelines for designers of HIT to better meet the needs of older adults. This approach allowed us to synthesize study findings about the complexity involved in the ways that older adults manage their health information. In particular, we were able to illustrate the importance of relationships to supporting older adults with their PHIM. Through feedback from designers, we learned that the connected personas were useful in communicating the complexity of PHIM for older adults, and led designers to consider the connections between older adults, their family, friends and providers related to PHIM in their design ideas. Overall, the connected personas and design guidelines helped designers to dive into a greater understanding about older adults and their PHIM. Having this knowledge will lead to HIT that meets the needs of older adults and as a result is used and adopted by older adults.

Abstract

Documentation burden has become an increasing concern as the prevalence of electronic health records (EHRs) has grown. The implementation of a new EHR is an opportunity to measure and improve documentation burden, as well as assess the role of the EHR in clinician workflow. Time-motion observation is the preferred method for evaluating workflow. In this study, we developed and tested the reliability of an interprofessional taxonomy for use in time-motion observation of nursing and physician workflow before and after a new EHR is implemented at a large academic medical center. Inter-observer reliability assessment sessions were conducted while observing both nurses and physicians. Four out of five observers achieved reliability in an average of 5.75 sessions. Our developed taxonomy demonstrated to be reliable for conducting workflow evaluation of both nurses and physicians, with a focus on time and tasks in the EHR.

Introduction

With the integral role that electronic health records (EHRs) play in healthcare today, the implementation of a new system promises to bring numerous changes to both the institution and the workflow of its clinical providers. Quality and clinical outcomes such as preventive screening rates and length of stay are commonly measured before and after an implementation of a new EHR. In addition to potential fluctuations in quality and clinical outcomes, changes in clinician workflow are likely to occur and should be analyzed to address issues and realize potential gains in productivity and/or efficiency. As part of a larger study evaluating the implementation of a new commercial EHR at a large northeastern medical center, we are collecting time-motion data of both nurses and physicians before and after implementation to measure the impact on clinician workflow and documentation burden. Documentation burden can be understood as a combination of many factors, including time, low usability, low satisfaction, and high cognitive spending. Time-motion observations can be used to understand the time component of documentation burden. Collecting time-motion data involves observing a person as they conduct tasks to measure how much time is spent on each task and the sequence of task performance that makes up a workflow. Currently, most time-motion studies that have evaluated clinician workflow in the era of the EHR observed either physician or nursing workflow, but not both. Because one of the overall aims of implementing a new EHR is to reduce documentation burden and increase efficiency for all clinician types, we developed an interprofessional task taxonomy to capture nursing and physician workflow. This taxonomy allows for accurate description of different workflows while obtaining a picture of pooled documentation burden among the patient care team.

While the prevalence of EHRs has grown, documentation burden among clinicians has become a challenge, with time spent on data entry of particular concern. The Office of the National Coordinator (ONC) on Health Information Technology recently released a draft strategy for reducing clinician documentation burden and the first overarching goal is to “reduce the effort and time required to record health information in EHRs for clinicians.” EHR data entry requires that the clinician record clinical findings in the patient’s electronic record, while data viewing is the consumption of entered data. Evidence suggests that both nurses and physicians spend more time documenting after the implementation of an EHR. Increased documentation times are associated with clinician burnout and low satisfaction. In addition to time spent documenting, poor alignment of the EHR with optimal care delivery workflows is a known challenge. The ONC names “better alignment of EHRs with clinical workflow” as the first strategy to improve EHR usability. As we work to support healthcare’s Quadruple Aim – improving the care
experience, improving population health, reducing cost, and improving the well-being of providers – it is important to understand the role that EHRs play in either hindering or aiding in providers’ care delivery\textsuperscript{19,20}.

Much research has been conducted to measure documentation burden and the role of EHRs in clinician workflow\textsuperscript{4,6–14}. While many investigators are utilizing EHR log file data to measure documentation times, a limitation to this methodology is lack of validation by direct observation\textsuperscript{14}. For example, while the log files may indicate that a user spent thirty minutes of uninterrupted time viewing a note, it is possible that the user walked away while remaining logged in and delivered direct patient care or was interviewing the patient while reading the note. This patient-care time would be inaccurately reported as note-viewing time only, without the utilization of direct observation. Time-motion observation serves as a method for corroborating findings from EHR log data and for incorporating tasks that occur outside of the EHR.

Much of the current literature surrounding EHR documentation burden is centered on physician documentation burden and has offered strategies involving redistribution of workload from physicians\textsuperscript{2,10,21,22}, including adding order entry to the responsibility of “clinical staff”\textsuperscript{10}. Such efforts should include consideration of existing documentation burden among other clinical roles, such as nursing. Studies have shown that nurses are also dissatisfied with the current state of EHRs and cite EHR inefficiencies as barriers to delivering best-practice patient care\textsuperscript{3,23}. A potential unintended consequence of restricting EHR burden analysis to one clinical role is that low-satisfaction tasks like data entry will be passed from one role to another and improvement will not occur across the care team. By utilizing the same tasks while observing both nurses and physicians, we seek to understand the documentation burden of both clinical roles within the care team, as well as how they are both impacted after a new EHR is implemented.

**Methods**

In July and August of 2018, the primary author conducted a review of the literature on time-motion evaluations of clinician workflow, specifically surrounding the use of electronic health records (EHRs). We did find that Ballerman and colleagues utilized a shared taxonomy to conduct time-motion observation of both nurses, physicians, and respiratory therapists, though their study was conducted before an EHR was implemented, thus did not have EHR-specific task names\textsuperscript{24}. Therefore, we could not utilize their taxonomy for our purposes. Task names were extracted from relevant articles and brought to an interprofessional team of clinical researchers (RNs and MDs)\textsuperscript{4,6–9,25,26}. Each task was evaluated for its relevance to nursing and physician workflow and then re-worded and re-defined in order to accurately describe the work executed by each profession. For example, in a previous study conducted by Yen and colleagues, evaluating nursing multi-tasking on a medical surgical unit, a task named “Direct – Procedure” was defined as “RN performs treatment or procedure that cannot be delegated (top of license task)”\textsuperscript{24}. We redefined this task so that procedures performed by both nurses and physicians could be captured under “Direct Care – Procedure”. Our task definition is, “Performs direct procedure (e.g. wound care, blood draw, CVC placement)”. Therefore, when a nurse performs wound care or phlebotomy, or a physician places a central venous catheter, our observers capture this action as a “Direct Care – Procedure” task. (Note: we are not observing clinicians in the operating room, therefore operating procedures are out of scope). With this approach, we can capture a pooled measurement of time spent performing procedures by both nurses and physicians before and after implementation, with respect to the differing types of procedures they are each licensed to carry out. EHR tasks such as data entry also often differ between nurses and physicians. Physicians typically enter their clinical findings into a note, while nurses may spend more time entering findings into flowsheets or care plans and synthesize in shorter “end of shift” notes. Instead of employing multiple tasks, we capture each activity in our definition of “Data – Entering.” This allows for measurement of data entry across the two roles, as well as increases the likelihood that observers will be able to reliably capture each of these tasks because they have fewer tasks to choose from.

The task list evolved over a period of four months through team discussion, lab training, and clinical-setting training. After task alterations were made to accommodate nursing and physician workflow, any further alterations were made to reach a level of granularity that allowed us to reliably capture tasks in real time. The taxonomy was pared down from 43 to 38 final tasks, including “tasks” that capture the clinician's location and communication activities (Table 1). Efforts were made to prioritize capture of data entry tasks, data consumption tasks, and patient care tasks, because much of the current sentiment around EHRs reflects frustration at their functional role as time-consuming data repositories, detracting from patient care, rather than as sources of clinical information delivery\textsuperscript{3,10,15,16}. The taxonomy is organized into the three overarching categories – location (where the clinician is, physically), task (what the clinician is doing), and communication (conversations the clinician is having or listening to). These categories were developed and validated for time-motion evaluations by investigators at The Ohio State University Department of Biomedical Informatics in their creation of a web-based time-motion observation platform, TimeCat\textsuperscript{27}. TimeCat allows the
observer to document up to one active task in each category at any time during the observation so that the clinician’s location, what they are doing, and any conversations they may be having, simultaneously, are recorded. TimeCat version 3.9 was used in this study.

**Table 1.** Final taxonomy

*Viewing historical patient data will happen in this application after go-live of new EHR

After obtaining IRB approval, we evaluated the interprofessional taxonomy by conducting inter-observer reliability assessments (reliability sessions) on an acute care/step-down unit. The five observers in our study include two licensed and experienced registered nurses, two licensed and experienced medical doctors, and one medical student. Reliability sessions involved two observers following the same clinician, either a nurse or a physician, simultaneously documenting tasks conducted for one and a half to two hours. All activities, clinical and non-clinical, were observed throughout the session and observers entered patient rooms unless the patient was on isolation precautions or the patient or clinician requested otherwise. Each clinician consented to being observed before the session began. Observers did not converse with each other or the clinician during the observations and the data were compared for similarity afterward.

TimeCat includes a sophisticated module for conducting reliability sessions which displays similarity scores in domains called Proportion, Naming, Duration, and Sequence\textsuperscript{4,29}. It also displays a side-by-side visualization of the tasks captured by each observer throughout the observation (Figure 1). Each of the domains were developed and validated by Lopetegui and colleagues and are described in a publication pending review\textsuperscript{29}. The Proportion domain assesses the proportion of time that the two observers document that a specific task is occurring\textsuperscript{29}. For example, if in 10 seconds, Observer 1 documents that the clinician is entering orders, and during 8 of those seconds Observer 2 documents that the clinician is entering orders, the Proportion agreement would be 0.8. This data is then used to calculate Cohen’s kappa agreement score. The Naming domain evaluates each task and compares its name to the task name with which it has the most time overlap\textsuperscript{29}. By measuring the proportion of tasks that share the most time overlap...
that also share the same name, this score reflects observer agreement on the task that is occurring at any given moment. This domain is also measured with a Kappa agreement score. The Duration domain builds off the Naming domain by calculating a concordance correlation coefficient from tasks with the most time overlap, to reflect the agreement between observers on the length of the task. The Sequence domain reflects agreement between observers on the sequence of tasks, no matter their duration. This is measured with a Needleman-Wunsch algorithm score which was developed using informatics approaches to sequence amino acids. Each domain and its score definition is outlined in Table 2 and an example of the output in TimeCat is shown in Figure 1. Domain scores are calculated for each of the three categories – Task, Location, and Communication.

Table 2. Inter-observer reliability domains, measures, and definitions from Lopetegui et al.

<table>

</tbody>
</table>

Our criteria for achieving reliability is that within a minimum of three observations, the observer must obtain at least two with a score of at least 0.8 in the Proportion and Duration domains, a score of at least 0.7 in the Sequence domain, a recent observation scoring at least over 0.65 in each, and with demonstration of improvement over time. This definition is consistent with previous work delineating substantial reliability between observers. Once an observer achieves reliability, they become a “gold standard” for training future observers and can begin conducting observations on their own. Because many time-motion studies measure and report inter-observer reliability inconsistently, Lopetegui and colleagues outlined suggestions for setting inter-observer reliability goals according to the research question being asked, rather than aiming to achieve high scores in each domain. Following these guidelines, we determined that the Proportion, Duration, and Sequence domains are most important for our reliability sessions. Our aims are two-fold; first, to understand how much time nurses and physicians spend entering data, viewing data, and caring for patients, and second, to capture a picture of their workflows. The
Proportion and Duration assessments test our ability to reliably meet the first aim by measuring agreement on task occurrence and duration. In addition to these assessments, the Sequence domain tests our ability to reliably meet the second aim by measuring agreement on the order of tasks. These scores, therefore, take priority over the Naming domain, which is of more importance for studies interested in answering the question, “What do clinicians do at any given time?”29, which is not a target of our study.

Results

Twenty reliability sessions were completed. All sessions were conducted between 7am and 7pm, at varying times during this window. Three sessions were conducted on Monday, five on Tuesday, one on Wednesday, five on Thursday, and six on Friday. Four out of five of our observers achieved reliability in as few as four reliability sessions and as many as eight (average 5.75 sessions/observer). One of our sessions included perfect agreement on Communication Proportion, Communication Duration, and Communication Sequence. Three included perfect agreement on Location Duration and one included perfect agreement on Location Sequence.

Additionally, inter-observer reliability scores trended positively, regardless of whether the observer was following a nurse or a physician. For example, two of our observers achieved one reliable observation while observing a nurse, and then their second reliable observation while observing a physician. It might be hypothesized that the nurse observers would be biased toward a nursing interpretation of each task and vice versa for the physicians/medical student. However, our taxonomy demonstrated to be reliably executable by nurses, physicians, and a medical student while observing both nurses and physicians on an acute care hospital unit. Table 3 displays the results of our reliability sessions.

*Number of inter-observer reliability sessions the observer needed to conduct before meeting reliability criteria.
PK¹=Proportion Kappa, CCC²=Duration Concordance Correlation Coefficient, NW³=Sequence Needleman-Wunsch Score

Figure 2 shows a task time agreement matrix for a reliable session. In the agreement matrix, tasks captured during the session are listed across the top of the grid and along the left of the grid. The number of seconds that both observers agreed on the task occurring is plotted across the grid in green. The numbers in red display the seconds that the observers disagreed on the occurring tasks and they are plotted at the intersection of the tasks documented by each observer.

Figure 3 shows a plot of task duration correlation for a reliable session. In this plot, each task, designated by a colored dot, is plotted with an x-value denoting the number of seconds Observer 1 documented that the task occurred, and a y-value denoting the number of seconds Observer 2 documented that the task occurred. A 45-degree line is plotted as
a reference point of perfect duration agreement. TimeCat generates these plots and labels observers as either “Gold standard” or “Trainee” to reflect the inter-observer reliability process of validating new observers.

**Figure 2.** Example task time agreement matrix (generated by TimeCat)

**Figure 3.** Example task duration correlation (generated by TimeCat)

**Discussion**

The outcomes of our reliability sessions are significant because they demonstrate that with careful consideration of task taxonomy and adequate training, observers from differing backgrounds can reliably capture tasks performed by a nurse using the same taxonomy as tasks performed by a physician, and vice versa. Additionally, our specific taxonomy has demonstrated to reliably encompass workflow among nurses and physicians using an EHR. Also, by conducting our inter-observer reliability sessions over varying times and days of the week, we can be confident that we tested reliability during the work hours in which we will collect real observation data. Future studies looking to evaluate shared documentation load and to capture a picture of clinician workflow may model this approach and utilize this taxonomy.

All care team members should be considered when looking to reduce EHR burden and improve alignment of the EHR with clinicians’ workflow. The interprofessional taxonomy developed here was shown to be reliable in our settings for conducting workflow observations of both nurses and physicians to answer research questions surrounding EHR tasks and their duration time. Further, our taxonomy proved to be reliably executable by observers with both nursing and medical backgrounds. Though one of our observers has not yet achieved reliability, that observer is receiving further training to help meet criteria.

The level of detail in our taxonomy allows us to reliably answer questions surrounding changes to time spent on patient care, data entry, and data viewing, as well as changes to general workflow. Using this data to accompany more granular detail of user behavior from EHR audit log data will help us identify areas where efficiency and/or workflow alignment is gained from the new EHR, as well as areas for improvement, for both nurses and physicians. We will be employing this taxonomy to conduct time-motion observations in both the hospital and ambulatory settings. Future work may expand the use of this taxonomy to study additional clinical roles such as social workers, care coordinators, and therapists. Incorporating even more members of the care team will further strengthen our understanding of shared documentation burden and the role of the EHR in clinicians’ workflow. Additionally, this time-motion and EHR audit log data could be used to quantify the care team documentation time required per patient.
Limitations

Though time-motion study of workflow is an ideal accompaniment to EHR audit log analysis, we acknowledge that it can be prohibitively resource intensive, and thus feasibility in all settings is limited. In consideration of resources and scope, we are only focused on day shift hours Monday through Friday, though we acknowledge that night shift and weekend workflow should be considered in future work. We also acknowledge that our task taxonomy might not be useful for answering questions such as, “How much time do clinicians spend multitasking during note documentation?” As stated previously, we found it prudent to sacrifice capturing this level of detail in our time-motion analysis in favor of reliably capturing the broader workflow. We plan to utilize the audit log data to analyze time and click navigation patterns surrounding EHR tasks such as note documentation. However, more granular time-motion studies may be conducted to focus on specific EHR tasks with taxonomy modification. Additionally, this study is primarily focused on evaluating the workflows of nurses and physicians, though, as mentioned previously, there are certainly other care team members integral to patient care who could benefit from a similar inclusive approach to workflow analysis using and extending this taxonomy, as needed.

Conclusion

In summary, we were able to validate an interprofessional taxonomy that is useful for reliable EHR-focused time-motion observation of nursing and physician workflow. Our work is significant because it demonstrates the potential to utilize one method to quantify burden and analyze workflow across different clinical roles, at a time when reducing EHR burden and improving EHR congruence with clinical workflow is a national priority. If the lens isn’t widened to examine more than one member of the care team when looking to improve the role of the EHR in clinicians’ care, then myopic strategies may be implemented that do not ultimately improve care delivery because some clinicians will continue to be inefficient and overburdened. By capturing the influence of EHRs among multiple care team members’ workflows and burden, we can focus on visionary re-design strategies of EHR tasks to promote care efficiencies that ultimately aid patient-centered care. This taxonomy can be used in future work looking to evaluate the role of the EHR in clinical workflow and documentation burden so that improvements can be made for all members of the care team.

Effects of a Virtual Pointer on Trainees’ Cognitive Load and Communication Efficiency in Surgical Training

Azin Semsar, MS¹, Hannah McGowan¹, Yuanyuan Feng, MS¹, Hamid R. Zahiri, DO ², Ivan M. George ², Timothy Turner, PhD ², Adrian Park, MD², Helena M. Mentis, PhD¹, Andrea Kleinsmith, PhD¹

Abstract

We investigated the cognitive load effect of a trainer providing surgical instruction by pointing/drawing over laparoscopic video to a trainee. Results showed that while cognitive load is higher overall with the use of the instructional system, there is a decrease by the second experience of being instructed by the Virtual Pointer. Further analysis showed that trainees were more likely to perform the surgical task and watch/listen to the trainer’s instruction at the same time when the instructional system was used. This is thought to be an indication of more efficient communication when using the instructional system. Thus, although there is a small cognitive overload with the instructional system initially, the more efficient communication allows trainees to better integrate the knowledge and instructions being conveyed into the actions they must perform - indicating a better learning environment.

Introduction

Evidence demonstrates that both cognitive underload and overload leads to decreased performance ¹,² and learning ³,⁴. Greater learning outcomes are predicted when training tasks and technologies that reduce cognitive load are employed. The reasoning is simple – more working memory resources will be available for learning ⁵,⁶. Understanding the effects of cognitive load in medical training is especially important given that many of the necessary activities require the learner to integrate different skills, knowledge and behaviors concurrently ⁷. Studies have shown that trainees have fewer cognitive resources, i.e., less working memory, available for decision making when comprehension of the instruction is more demanding ⁸.

To evaluate the effects of instructional technologies on cognitive load, the multimedia dual-processing theory ⁹ may be a consideration. This theory posits that there are two systems for processing information, one for visual information and another for audio/verbal information ¹⁰,¹¹. Both systems have a finite amount of processing capacity, thus the presentation of two forms of visual information require the visual processing system to be divided in two, leaving the audio processing resources untouched. The claim is that new technologies that can make use of both processing systems allow for more availability of the total cognitive resources ¹²,¹³. Studies investigating this theory have demonstrated greater knowledge acquisition is achieved, and cognitive resources are not overloaded when both processing systems are used, i.e., the audio/verbal channel and the visual channel ¹⁴,¹⁵,¹⁶.

We employed both subjective and objective measures of cognitive load of surgical trainees while performing tasks and being instructed by a trainer using an instructional technology called The Virtual Pointer. The Virtual Pointer enables a trainer to point or draw a free hand sketch over live laparoscopic video; adding the visual instruction channel to the existing traditional verbal instruction. Adding an additional channel of communication in a dyadic interaction can have positive implications for communication efficiency ¹⁷. Cognitive load can be influenced by communication efficiency in a training interaction ¹⁸. The more efficient the communication, the less cognitive processing is required for understanding the communicated content. Therefore, more cognitive resources are available for learning the content. Our hypothesis was that a Virtual Pointer can enhance communication efficiency, and consequently allow for further cognitive processing.

Cognitive Load And Information Processing Channels

Cognitive load theory ¹⁹,²⁰,²¹,²² describes working memory as having a limited capacity in processing information. When the number of informational units exceed the limited capacity of working memory, new information cannot be processed and thus learning will be hindered. In a learning environment, cognitive load may arise from the instructional tools and techniques rather than the complexity of the task itself. Learning, as an outcome of a training process, will be hindered if instructional materials and methods overwhelm a trainee’s cognitive resources ²⁰. In
multimedia learning (i.e., learning from words and pictures), cognitive load arising from instructional techniques is a central challenge faced by designers of multimedia instructions. Mayer and Moreno (2003) suggest nine ways to reduce cognitive load in multimedia learning including a cognitive process involved in integrating verbal and visual cues. One other recommendation they make is to off-load one information receiving channel (e.g. verbal and visual) by splitting the information among multiple channels. This solution reduces the processing demand of one channel so the learner has further capacity for processing within other channels. They demonstrated that students understood a multimedia explanation better when the words were narrated rather than shown as an on-screen text.

Brunken et al.’s study confirms the guideline of splitting the information among multiple channels using a dual-task methodology. In their study, participants were asked to perform two tasks at the same time: the primary task involved learning from a multimedia program on how the human cardiovascular system works, and the secondary task involved needing to press a button as soon as a letter color changed. Analyzing the reaction time for the secondary task as a cognitive load measure, they found that reaction times were lower for the audiovisual presentation compared to the visual only presentation. This showed that a combination of audio and visual presentation induced less cognitive load than a single modality presentation, i.e visual-only. The dual-task methodology is based on the assumption that cognitive capacity is limited, but can be flexibly allocated. In the case of processing two tasks at the same time, the cognitive resources have to be split between the two. Therefore, when a person is able to better perform a second task simultaneously with the first task, the less cognitively loaded the person is on either task, thus allowing for better integration of cognitive processing.

To conclude, the way instructional techniques and tools are constructed may affect cognitive load differently. While it is suggested that designing an instructional method in a way that splits the information between auditory and visual channels reduces the cognitive load, a Virtual Pointer has not been studied in terms of how it affects the cognitive load even though it uses the same principle of splitting information between two channels. Because it has been reported that multiple modalities of processing channels allows for more cognitive processing space, we are interested in examining if the Virtual Pointer may affect cognitive load for this reason.

**Cognitive Load and Communication**

Analyzing cognitive load in communication settings is additionally important to allow for effective group collaboration. For example in Computer Support for Collaborative Learning (CSCL), it has been discussed that the interaction among subjects in a learning environment may generate communication activities (e.g. explanation, disagreement, and mutual regulation), which may trigger extra cognitive mechanisms (e.g. knowledge elicitation, and internalisation). The primary reason for the importance of cognitive load in CSCL environments is that CSCL environments force learners to coordinate one or more external, instructional representations. In such environments, the need for learners to integrate the textual, verbal, and visual information sources presented to them creates an additional cognitive load on top of the task itself. The balance between the reduction of individual computing due to division of labor and the increase of individual computing necessary for interaction is the key to avoid detrimental cognitive overload in CSCL environments.

Effective instructional methods can enhance the communication efficiency between the learner and the trainer. Once the communication becomes more efficient, the cognitive resources will be directed toward activities that are relevant to learning. Communication is a joint activity, which is coordinated based on common ground – shared knowledge, beliefs, and suppositions. And in turn, common ground is incrementally built on the previous joint activities within a group. Thus, as common ground accumulates, communication becomes more efficient and efficient communication reduces the costs for the development of common ground.

In conversation, one major coordination task is turn taking, i.e., all people conversing coordinate the time of entry and exit in the conversation. The changes in the coordination of turn taking on one hand indicates the efficiency of communication, and on the other, relates to the grounding costs, such as the costs in language processes, i.e., the construal of meaning, and the costs in signaling and accepting. For example, more turns, fewer words and more synchronicity manifest in teams with an increased amount of shared understanding, and thus more efficient communication. The increased common ground and improved communication efficiency facilitates the construal of what would be presented, manifested by more quick and short turns. For instance, Fussell et al. studied the effects of shared visual context in a collaborative repair task on communication efficiency through turn taking analysis. The greater number of turns in the audio-video instruction compared to audio-only instruction shows that audio-video instruction enhances the communication efficiency between the trainee and trainer in performing a repair task. Because of this, we decided to not only investigate cognitive load, but communication efficiency elicited by the Virtual Pointing system because of its integrated audio-visual instruction basis.
Cognitive Load in Surgical Training

An investigation of the effect of haptic feedback on surgical residents’ cognitive load when performing a laparoscopic task in a virtual reality setting while they were imposed by a secondary mental arithmetic task showed that residents performed 36% faster with haptics compared to without. This suggests that the addition of haptic technologies allowed for a reduction in cognitive load and thus increased performance efficiency. In comparison, Andersen, et al. found that adding technology to a surgical training condition neither increased or decreased cognitive load nor did it affect performance. Here, they compared trainees’ cognitive load with and without a simulator-integrated tutor function in a virtual reality surgical setting by analyzing the reaction time of secondary observational task. They found the integrated tutoring did not influence reaction times and did not have an effect on cognitive load. They did, however, observe that novices gain proficiency in the Virtual Reality surgical simulation after relatively few practice sessions. This effect of experience, i.e., increase in proficiency after additional exposure to using a new technology, has been observed in other studies and could play a critical role when examining a technology’s effect on cognitive load. For example, Theodoraki et al. assessed surgeons’ cognitive load of using an image-guided navigation system - a system that combines the information captured from cameras, ultrasonic, electromagnetic sensors and relay the patient’s body view and the surgeon’s movements in relation to the patient, to the surgeon’s screen. Non-significant difference in heart rate and heart rate variability between the two conditions showed that cognitive load did not differ between use with and without the navigation system. Nevertheless, the heart rate variability was slightly higher in the navigation-supported condition. Moreover, they observed that residents who had more practice in performing the procedures showed a slight decrease in mental workload while using the navigation system. This suggests that with more experience, there may be more cognitive processing space open to allow for the addition of new technology to be beneficial.

Material and Method

System Design and Setup

The Park Trainer (Stryker Corporation, USA) was used for the simulated laparoscopic tasks (Figure 1.c). It consists of a housing unit for physical anatomical models, a flexible shield with openings for the laparoscopic camera and instruments to be inserted, a standard laparoscopic camera with light source using the Stryker computer system, and a standard laparoscopic monitor on an adjustable arm at the top. The Virtual Pointer was designed to facilitate the conveyance of knowledge during surgery by enabling attending surgeons to point or draw on the laparoscopic video for a surgical resident to see (Figure 1). To this end, the Microsoft Kinect sensor version 2 (Microsoft Corporation, USA) was used as a mechanism of touchless interaction – enabling the system to be used in the sterile operating field. Refer to Feng et al. for a detailed description of the system and how it works.

Experiment Design and Procedure

The experimental design is a counterbalanced, within-subject design, with two mentoring approaches: the control is Standard condition, and the intervention is Virtual Pointer condition. In the Standard condition, trainer instruction was conducted as it would be normally, through verbal or hand gestures. In the Virtual Pointer condition, the Virtual Pointer application was used by the trainers as an addition to standard guidance to facilitate instruction.

The trainees worked on four simulated laparoscopic tasks under trainer guidance. The tasks were selected based on a hierarchical task analysis of the laparoscopic cholecystectomy procedure and confirmed by an attending surgeon that they were of similar difficulty levels and required both skills of anatomical structure identification and instrument manipulation. The tasks were performed on a validated laparoscopic training physical model, including (1) mobilizing the cystic duct and the cystic artery, (2) clipping the cystic duct, (3) clipping the cystic artery, and (4) cutting the cystic artery and the cystic duct. Task order and condition were counterbalanced for each trainee yielding a total of 14 runs in the Virtual Pointer condition and 14 runs performed in the Standard condition.

The study was approved by the University of Maryland, Baltimore County institutional review board (IRB) and informed consent was obtained from all participants before their participation. After consent, the trainees and trainers completed a demographics questionnaire, which included information on their surgical experience and familiarity with the Kinect system. After each task, the trainees and trainers completed a cognitive load questionnaire. The study was video recorded and the operative field was screen recorded.
Participants

Participants were recruited from the Department of General Surgery, Anne Arundel Medical Center, Annapolis, Maryland - 7 surgical trainees (all male), including 1 surgical fellow, 1 research fellow, and 4 surgical residents (2 PGY-1 and 2 PGY-2) were recruited. One attending surgeon and one surgical fellow were recruited as the trainers. The attending surgeon guided the surgical fellow in performing the tasks and the surgical fellow guided the rest of the trainees. None of the participants had any previous interactions with the Virtual Pointer before the experiment.

Data Collection

Subjective Measure of Cognitive Load. Subjective measures are considered an unobtrusive, and inexpensive method of assessing workload and are commonly employed to assess surgeons' cognitive load in training scenarios. Commonly employed cognitive load questionnaires for training are the Paas scale, a short, single 9-point Likert scale; and the NASA-TLX, a considerably longer, multidimensional scale. Given that the NASA-TLX requires more time to complete and the fact that it aims to assess overall workload, i.e., not only cognitive load, we chose the Paas scale for our study. The trainees completed it with reference to the mental effort they invested in understanding the instructions, from 1 – very, very low mental effort was invested; to 9 – very, very high mental effort was invested. The trainee completed the questionnaire after performing each task. The Paas scale was also used by the trainers to examine their cognitive load with reference to the mental effort they invested in giving the instructions.

Objective Measure of Cognitive Load. We also included an objective, continuous physiological measure of cognitive load – EDA (electrodermal activity). This continuous measure allows us to assess temporal, dynamic aspects of cognitive load. Physiological measures have a high degree of sensitivity; allowing them to be used for measuring changes in cognitive load. The Empatica E4 wristband was used to record the trainees’ EDA used as the objective measure of cognitive load. The Empatica E4 wristband (Empatica Inc., US) was worn on the trainees’ non-dominant wrist. According to the E4 user manual, the nondominant wrist is recommended to minimize motion artifacts. At the start and end of each task, an event was tagged on the wristband through its physical button. These tagged events were to be used in the data analysis process for time synchronization. The data was recorded directly onto the E4’s flash memory, i.e., wirelessly. After recording each trainee, the E4 was connected via USB to a PC, and Empatica Manager was used to transfer the data to Empatica’s secure cloud platform, Empatica Connect. Each trainee’s data was then downloaded and renamed with her/his anonymized participant ID. The start and end time of each task was tagged directly on the data using the physical button on the wristband.

Objective Measure of Trainee’s Response to Trainer’s Instruction. Video recordings were annotated to determine how often the trainee stopped performing the task to listen to instruction (i.e., single-task instances) and how often they continued performing the task while also listening to instruction (i.e., dual-task instances). All non-study-related events that occurred between tasks, such as waiting for equipment or fixing of the model were not considered in the analysis. In both mentoring conditions, only the trainees’ responses for each instruction given by the trainer were considered. In the Virtual Pointer condition, instructions using the Virtual Pointer, such as moving it to indicate a structure or using it to facilitate verbal instruction were annotated. In the Standard condition, verbal instructions such as “over here” and “move up higher” were also annotated.
**Objective Measure of Number of Turns and Turns Length.** To examine communication efficiency between the trainer and trainee, we analyzed the turn taking structure of communication. As communication becomes more efficient, turn-taking increases and turns become shorter \(^27\). The video recordings were annotated to count the number of turns the trainee and trainer took throughout each task. Both verbalizing and taking an action (e.g. the trainer giving an instruction and the trainee performing a laparoscopic action) were counted as turns. The length (i.e. amount of time) of each turn was also measured. As the number of turns throughout each task is associated with the length of the task, the fraction of number of turns to the sum of all turns’ length was computed as a normalized measure for each task. The analysis was performed on the normalized number of turns and length of turns.

**Data Analysis**

**EDA Data Preprocessing.** Observer XT version 14.1 (Noldus, Netherland) was used to synchronize the EDA data with the video recordings. Each trainee’s EDA data was normalized to a range between 0 and 1 as is standard practice \(^45\). For each specific comparison, normalization was performed across tasks which enabled us to compare subsequent experiences of each mentoring condition for each trainee. We focused our analysis of the EDA data around the points of instruction provided by the trainer in both mentoring conditions. We identified the times that the trainer used the pointing and drawing mode to show a location on the laparoscopic display and the corresponding points of instruction in the Standard condition. A verbal instruction in the Standard condition was considered corresponding to a Virtual Pointer instruction if it was given to show the trainee a location (e.g. “right in the middle”). The instructions were considered as stimuli in the EDA signal. The EDA signal has two components: the slowly changing skin conductance level (SCL) component, and the rapidly changing skin conductance response (SCR) component. The SCR occurs as a peak in the signal, generally as a response to stimulus between 1 to 4 seconds after stimulus presentation \(^46\). Therefore, we extracted the EDA data for the first 5 seconds after the start of each instruction, Peak amplitude of the SCR has been used as an indicator of cognitive load \(^47\). The EDA signal was decomposed into SCL and SCR by performing continuous decomposition analysis using the Matlab-based software, Ledalab \(^48\). The amplitudes of the SCRs for the five-second intervals were computed and used in the statistical analysis.

**Statistical Analysis.** Statistical analysis was performed using a linear mixed model to compare the trainees’ cognitive load between the two conditions for both subjective and objective measures. Because our intention was to focus on the effect of the Virtual Pointer on cognitive load over time, we modeled the mentoring conditions (Virtual Pointer or Standard) and the task order as fixed factors. Due to the similar level of difficulty of the tasks, we considered the task as a random factor. The trainees were also considered a random factor. All statistical analysis was performed using R version 3.2.0 (R foundation for Statistical Computing, Austria). The results are shown as mean and standard error of the mean. A p-value of less than 0.05 was considered statistically significant.

**Results**

**Trainees’ subjective cognitive load scores**

The trainees’ average self-reported cognitive load scores were a bit higher in the Virtual Pointer condition (M=4.28, SD=1.72) compared to the Standard condition (M=3.78, SD=1.67) indicating that the trainees did not experience a significant increase of cognitive load when instructed using the Virtual Pointer (p=0.224) (Figure 2.a). We then investigated whether the trainees’ self-reported cognitive load scores decreased over time, meaning the second experience of using the Virtual Pointer perceived as less cognitively demanding in comparison to a second experience with the Standard method. We analyzed the differences in cognitive load scores between the first and second experience of each condition (Figure 2.b). Although the average cognitive load scores decreased by the second experience of each condition, the decrease within each condition was not significant. However, because the scores did decrease, we also analyzed the decrease between the second experience of each condition. Somewhat surprisingly, these results were not significant either; suggesting that the trainees’ perception of cognitive demand while using a Virtual Pointer is not significantly different from the Standard instruction.

Given that the trainers’ cognitive load is also likely to be impacted by using the Virtual Pointer as an instruction mechanism, it was important to assess whether different levels of cognitive effort are required to provide the instruction. We compared the trainers’ average self-reported cognitive load scores across all tasks using the Virtual Pointer with all tasks in the Standard condition (refer to Figure 2.c). The results indicate that the trainers’ cognitive load actually decreased significantly with the Virtual Pointer (M=3.42, SD=1.45) in comparison to the Standard condition (M=5.64, SD=2.06) (p<0.001). This result suggests that the Virtual Pointer is more beneficial to use as an instructional aid than the traditional instruction method.
EDA Data and SCR Amplitudes

We also examined the trainees’ EDA as it is an involuntary, continuous objective measure of cognitive load. Statistical analysis was conducted using the SCR amplitudes for the first 5 seconds after the start of an instruction with the Virtual Pointer and equal instructions in the Standard condition. A total of 62 Virtual Pointer instructions and 35 equal instructions in the Standard condition were identified. Overall, no significant difference was found in SCR amplitudes between the Virtual Pointer (M=0.031, SD=0.057) and the Standard condition (M=0.025, SD=0.033) (p=0.576) (Figure 3.a). This result confirms the finding of the subjective cognitive load measure.

To have a better understanding of how additional familiarity with the system may impact cognitive load, we also looked at the SCR amplitudes between the first and second experience of each condition as illustrated in Figure 3.b For the Standard condition, similar to the subjective results, the decrease in SCR amplitude was not significant (first experience: M=0.030, SD=0.059; second experience: M=0.026, SD=0.021) (p=0.606). However, for the Virtual Pointer condition, there was a slightly significant decrease in SCR amplitudes from the first experience (M=0.037, SD=0.071) to the second experience (M=0.024, SD=0.034) (p=0.047). These results suggest that although there is an initial slight cognitive load on the trainees with the first experience with the Virtual Pointer system, this load appears to diminish by the second experience as the trainees become accustomed to the system. In fact, after the second experience of instruction with the Virtual Pointer, cognitive load in the Virtual Pointer condition is not significantly different from the traditional mentoring method of instruction.

Single- and Dual-task Instances

To investigate whether cognitive load may be attributed to how the trainees attended to the tasks at a fine-grained, instruction-by-instruction level, the occurrence of single- and dual-task instances was analyzed for each condition. Overall the percentage of single-task instances was higher than dual-task instances in both the Virtual Pointer condition (60.65%) and Standard condition (77.8%). To compare the two mentoring conditions, the percentage of single- and dual-task instances in each of the four laparoscopic tasks was normalized to a range between 0 and 1. Overall, there was no significant difference in the percentage of dual-task instances between the two mentoring conditions (p=0.146) even though the mean was higher in the Virtual Pointer condition (Virtual Pointer M=0.392, SD=0.152; Standard M=0.238, SD=0.373). To further examine the dual-task instances, the percentage of dual-task instances within and between the first and second experience of both conditions was analyzed (refer to Figure 4.a). The results show not only that the increase in dual-task instances within the Virtual Pointer condition was significantly higher in the second experience (p=0.01), but also that dual-task instances completely disappeared in the second experience of the Standard condition (p=0.004). Thus, the differences between the second experience of each condition are also significant (p<0.001) (Virtual Pointer: M=0.476, SD=0.115; Standard M=0, SD=0). These overwhelming differences in dual-task instances in the second experience of the Virtual Pointer suggest that as the trainees became more accustomed to the system, they were able to perform more of the laparoscopic task while watching and listening to the trainer’s instructions without negatively impacting their cognitive load.

Turn Taking Results - Number of Turns and Turns Length Mean

To investigate whether the higher number of instances of dual-tasks while experiencing the same level of cognitive load in the Virtual Pointer condition is due to more efficient communication, the turn-taking structure, specifically the normalized number of turns (Figure 4.c) and turns length (Figure 4.b), was analyzed. Overall, there was a significant difference ($p=0.01$) in the turns’ length between the Virtual Pointer condition ($M=1.975, SD=0.507$) and Standard condition ($M=2.535, SD=0.889$). In addition, significantly higher normalized number of turns ($p=0.01$) were found in the Virtual Pointer condition ($M=0.623, SD=0.142$) compared to the Standard condition ($M=0.487, SD=0.138$). The shorter turns’ lengths and higher number of turns in the Virtual Pointer condition supports our assumption that the Virtual Pointer improves the communication efficiency, thus allowing for further cognitive processing. Consequently, trainees are able to perform dual-tasks while experiencing no additive cognitive load.

Discussion and Conclusion
